Title: Contextual changes in cortico-striatal transmission during time production in monkeys

Authors: *T. W. SUZUKI[1], M. TANAKA[2]
[1]Hokkaido Univ. Sch. of Med., Sapporo, Japan; [2]Hokkaido Univ. Sch. Med., Sapporo, Japan

Abstract: Cortico-basal ganglia loop is involved in temporal information processing. Recent studies have revealed the scalable nature of timing-related neuronal activity, which exhibits expansion or shrinkage of entire temporal profile in proportion to the length of measured interval. However, the underlying mechanism for the generation of such neuronal activity remains largely unknown. To explore this, we recorded local field potentials (LFPs) at sites in the caudate nucleus where the timing-related neuronal activity was previously found. Three monkeys performed the oculomotor version of time production task, in which they generated a memory-guided saccade after the prescribed interval (400, 1000, or 2200 ms, instructed by color of the fixation point) following the visual cue (100 ms). We found that the magnitude of

visually-evoked potentials for the cue altered depending on the conditions, showing larger response for shorter interval (one-way ANOVA, $p < 10^{-3}$). When we assessed the spectral power, the low frequency components (< 25 Hz) clearly exhibited time-dependent modifications during the monitoring of elapsed time, but the power at higher frequency (30–40 Hz) did not. Furthermore, the power of low-frequency components before the cue presentation differed across interval conditions, showing greater spectral power for longer intervals ($p < 10^{-3}$). These results suggest that the network-level alteration in the state of the cortico-basal ganglia pathways before and during temporal monitoring might be important for the flexible adjustment of neuronal activity. Specifically, the power of low frequency components might be relevant to the gain of cortico-striatal transmission. To test this hypothesis, we applied single pulse electrical stimulation to the supplementary eye field before the cue onset and examined the short-latency response recorded from the caudate nucleus. We found that the magnitude of evoked response was indeed modulated depending on the interval conditions (one-way ANOVA, $p < 0.05$). Thus, the network state and the gain of cortico-striatal transmission appear to be adjusted before the monitoring of elapsed time, which might lead to the scalable nature of neuronal activity within the cortico-basal ganglia pathways for proper behavioral timing.

Title: Contribution of the thalamic pulvinar to saccade and reach behavior in humans and monkeys

Authors: *M. WILKE[1], C. SCHMIDT-SAMOA[3], P. DECHENT[3], K. MILOSERDOV[2], S. MAHDAVI[2], J. LIMAN[4], M. HOLZGRAEFE[4], A. U. DOMINGUEZ-VARGAS[5], K. WILLIAMS[3], I. KAGAN[5], M. BAEHR[4]

Abstract: Expansion of the pulvinar in primates and its anatomical connectivity to fronto-parietal cortices suggests its involvement in higher-order cognitive and visuomotor functions. While recent studies in non-human primates suggest a contribution of dorsal pulvinar portions to visuomotor functions, its causal involvement to behavior and cortical activity in humans remains poorly understood. Here we studied eight patients with pulvinar lesions (4 left, 2 right and 2 bilateral) with saccade and reach tasks involving different levels of spatial choices. Patient data in each task was compared to 9-20 healthy subjects. In the patients with a pulvinar lesion, saccade amplitudes to the contralesional visual field were significantly smaller than in controls and saccade latencies towards the contralesional hemifield were prolonged in free choice, but not in instructed, trials. Patients with a right, but not with left or bilateral pulvinar lesions exhibited an ipsilesional bias in the saccade free choice condition. Reach errors were most pronounced for the contralesional hand and hemifield, and when the target position was dissociated from the gaze position, thus resembling optic ataxia observed following parietal lesions. The main functional effect of the pulvinar lesions on remote brain regions consisted of a bilateral increase of fMRI BOLD activity in frontal cortices accompanied by a bilateral reduction of activity in the intraparietal sulcus during spatial cue presentation. Our previous findings in monkeys and new preliminary data show stronger impairments for contralesional hand and hemifield, and for dissociated reaches, after dorsal pulvinar inactivation. Taken together, these results suggest that visuospatial pulvinar function is partly lateralized in humans. The hand-specific deficits in both species imply that pulvinar function goes well beyond its subscribed role in visual cognition. Instead its role might be more appropriately conceived as an integrator of motor and sensory activity for the programming of voluntary eye and hand movements.

Title: Role of superior colliculus neurons in value-based decisions

Authors: *A. GOPAL P A[1], O. HIKOSAKA[2]
[1]Bethesda, MD; [2]Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: There is a circuit in basal ganglia involving caudate tail and cdl SNr that can reliably distinguish the stable value of objects presented in the contralateral visual field (Hikosaka et al.2014). This network is responsible for the fast detection of valued objects among distractors and the reduction in reaction time (RT) when a saccade is directed to highly rewarded object compared to a low reward object. This behaviour may be achieved by sending the value sensitive information from the SNr to the SC neurons. In line with this hypothesis, a recent study from our lab showed that superficial neurons in SC fire strongly for objects consistently associated with greater juice reward compared to low-reward when presented in the contralateral visual field. For an animal to choose a valued object in it visual field, it is essential for the neurons in value network of BG and SC to be sensitive about the objects present in the ipsilateral visual field as well. To test this, we trained a monkey to perform a value based two alternate choice task in which the objects were presented, one in each hemifield. A set containing 8 fractal objects- 4 good (large juice reward) and 4 bad (small reward)- was used and presented in pairs of good-good, bad-bad, or good-bad combinations. After 10 days of training, multi-unit visual and visuomotor neurons from the SC was recorded while the objects were presented in the neuron's receptive field (RF) and in the diametrically opposite position (anti-RF). We found that SC neurons are sensitive not only to the value of objects present in the RF but also to the value of objects present in the anti-RF. Firing rates were higher when a good object in the RF was opposed by a bad object in anti-RF, compared to a good object in the RF opposed by good objects in the anti-RF. Since good objects were present in the RF in both conditions, the initial responses were identical but later diverged due to different valued objects in the anti-RF. When we compared conditions in which both RF and anti RF contained good or bad objects the neurons initially responded to the value of the object in the RF. Later the activity between the two conditions became indistinguishable due to the object of same value present in the anti-RF. Consistent with the neural response, the fastest RT was on good-bad trials while there was no difference between RTs on good-good vs. bad-bad trials that presented no objectively correct choice. We hypothesize that modulation of neuronal activity based on the object present in anti RF maybe mediated by mutual inhibition from the opposite hemisphere of the colliculus through the inter collicular connection.

Title: Influence of reward on superior colliculus activity during spatial- and feature-based visual search

Authors: *H. LIAO, M. YANG, M. C. DORRIS
Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai City, China

Abstract: Choosing a particular saccade from multiple visual targets engages both prior knowledge of our environment and immediate sensory information. To examine the mechanism by which prior information and sensory information may be combined in midbrain superior colliculus (SC), we had monkeys perform visual search tasks in which higher liquid reward was associated with a particular spatial location (Spatial Bias Task) or stimulus color (Feature Bias Task) while recording single SC neurons. Both tasks had the same basic structure in which four stimuli (1 target and 3 distractors) were simultaneously presented equidistant from central fixation and separated by 90 degrees. Monkeys received liquid reward for directing a saccade to the 'oddball' target that differed from distractors in brightness or color, respectively. One stimulus was always presented in the response field of the recorded SC neuron. *Spatial bias task* –Monkeys were required to saccade to the brighter target among isoluminant distractors. Monkeys performed 5 blocks of trials in which reward for the response field location ranged from ¼, ½, 1, 2, to 4 times the reward at other stimulus locations. There was an interaction between spatial reward and sensory information; choice was dominated by sensory information when discrimination was easy but predominantly directed towards highly rewarded locations when discrimination was difficult. Pre-stimulus baseline activity and stimulus-aligned sensory activity were concomitantly influenced by the spatial distribution of rewards. *Feature Bias Task* – Monkeys were required to look to the oddball color (either red or green) among isoluminant yellow distractors that were an equal mix of red and green. The same reward differences were used but, in this case, linked to color. Choices became progressively biased towards a stimulus color as its reward value increased. There was no effect on early baseline or initial visual SC activity. Only later, as the time of saccade initiation approached, did SC activity discriminate the colored target from distractor. Together our results suggest that the SC plays distinct roles when prior information is related to spatial or feature attributes. When prior spatial information is available, early baseline activity and immediate visual activity are strongly affected across the SC spatial map to influence target selection. However, the SC is largely "blind" when prior information is based on stimulus features. This suggests that prior feature information is largely processed upstream of the SC and, afterwards, the pre-selected target is simply relayed to the SC for execution.

Title: Tuned persistent activity in prefrontal cortex reliably follows every saccade

Authors: *I. CALANGIU, V. MANTE
Inst. of Neuroinformatics, Zuerich, Switzerland

Abstract: Our understanding about prefrontal cortex (PFC) computations has been heavily shaped by the existence of pre-saccadic, memory-related activity, a form of persistent activity that is modulated by the direction of the *upcoming* saccade. Large-scale recordings (Utah arrays) from the dorso-lateral PFC (dlPFC) of awake primates engaged in a classic center-out saccade task however reveal a more prevalent form of persistent activity—overall, dlPFC responses were dominated by post-saccadic activity, which peaks after the onset of the saccade and is modulated by the direction of the *preceding* saccade. Critically, we analysed data from a version of the saccade-task that included a variable "hold-period" *after* the saccade, and before the delivery of the reward, during which the monkey had to keep fixation on the saccade target. The inclusion of this hold-period allowed us to study the properties of post-saccadic responses in dlPFC. Surprisingly, we found that post-saccadic responses overall are stronger, and occur in a much larger fraction of the recorded neural population than pre-saccadic responses. Like pre-saccadic responses, post-saccadic responses are tuned for the direction of the saccade. Neurons that show both pre-saccadic and post-saccadic responses fall into two categories: *stable* neurons and *flip* neurons, for which the pre- and post- saccadic responses have, respectively, similar or opposite preferred directions. This time-dependent selectivity appears to be a largely fixed property of each neuron, as it accompanies not just the instructed saccades required in the center-out task, but also spontaneous saccades occurring between successive trials.
We studied how this dynamic selectivity is reflected at the level of neural population responses by identifying a linear time-dependent mapping between single-trial population responses and saccade angle. We found that the mapping between responses and saccade angle is

approximately constant throughout a pre-saccadic (-0.4 to -0.1s before saccade onset) and a post-saccadic epoch (0.05-0.35s after) but differs between the two epochs. Moreover, the representation of saccade direction in the post-saccadic epoch is robust to the type of saccade type (instructed or spontaneous) and only represents the angle of the previous saccade, not that of the upcoming, next saccade.
In conclusion, our findings are at odds with previously proposed functions of post-saccadic activity (e.g. planning the next saccade or saccade-related visual transients) and portrait post-saccadic activity as a novel functional signal that is distinct from the better-known, persistent pre-saccadic activity.

Title: Ventral premotor control of head and eye movements

Authors: *I. SMALIANCHUK[1], N. J. GANDHI[2]
[2]Dept. of Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: We redirect our visual axis to a stimulus of interest through a coordinated set of movements with our eyes and head. The specific properties of these gaze shifts are task dependent and rely on the initial head-in-space and eye-in-head positions. It is known that the premotor cortex plays a role in complex movements involving several muscle groups. In particular, a region of the ventral premotor cortex (PMv) projects polysynaptically to extraocular and neck muscles, through a pathway that bypasses the frontal eye field (FEF) and primary motor cortex (M1) (Billig and Strick, Program No. 371.05/LL12, SFN 2012). This relatively direct route suggests that PMv activity influences eye and/or head movements. Thus, we developed a paradigm in which a Rhesus monkey (*Macaca Mulatta*) was trained to produce an eye-only movement followed by a head-only movement, the same movements but in the reverse order, or a gaze shift without constraints on the effectors of action. We also incorporated in the design systematic control of initial eye-in-head and head-in-space positions as well as requirements to produce ipsiversive, contraversive, and centering movements, because all of

these factors have been associated with PMv function in previous physiological and/or anatomical studies. Neural activity in PMv and, for comparison, FEF was recording with single as well as laminar electrodes. Based on our current dataset, a majority of PMv cells exhibited enhanced activity ~100-200 ms before the movement onset and, notably, this activity returned to near baseline levels before movement onset; it's like the phasic burst typically observed in FEF was shifted ahead in time. Furthermore, many cells responded to ipsiversive movements, corroborating anatomical findings which show that PMv projects to neck muscles bilaterally. Additionally, a sub-population of cells responded to the first effector in the movement, regardless whether it was eye or head, potentially indicating the onset of a movement, but remaining agnostic of which effector is used to execute that movement. These observations are consistent with the notion that there is a neural code in PMV which coordinates the movements (in this case, head-unrestrained gaze shifts) across multiple effectors and muscle groups.

Title: A new computational model for decoding saccade-related activity in the frontal eye field

Authors: *M. A. SMITH[1,2], R. JOHNSTON[1,2], R. O. KONECKY[1,2]
[1]Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA

Abstract: The frontal eye field (FEF) is thought to play a major role in oculomotor function. For example, reversible inactivation of the FEF causes transient deficits in saccade production and electrical microstimulation at low currents elicits saccades with a characteristic direction and amplitude (Bruce et al., 1989). The FEF sends descending projections to subcortical structures that control saccades such as the superior colliculus (SC). Several computational models have been proposed to explain how brainstem circuitry decodes SC activity including a vector sum (VS) and vector average (VA). Although a similar scheme may be used to read-out FEF activity the precise nature of the computation is indeterminate. To address this issue, we microstimulated the FEF of two macaque monkeys using a 16-channel linear electrode array. The saccade evoked by simultaneously stimulating two contacts with equal current (90 or 100 υA) was compared to the saccades evoked by stimulating each constituent contact alone. We assessed the performance

of a novel polar average (PA) computation compared to the traditional VS and VA models. In the PA scheme, direction and amplitude are represented separately as the two constituent saccades are transformed into polar coordinates prior to averaging. Error, in terms of amplitude and direction, between actual and predicted saccades was significantly smaller for the PA model than the VS and VA. While the PA model was significantly better at predicting saccade direction overall, errors from the PA model were in the VS and VA direction when the difference in amplitude between the two constituent saccades was relatively large. These findings suggest that downstream regions may employ a PA computation to decode FEF activity. An underlying assumption of this model, which has key implications for current theories of oculomotor function, is that amplitude and direction are represented separately in the FEF.

Title: Neural oscillations in the marmoset parietal cortex during a saccadic task

Authors: *L. MA[1], L. K. H. SCHAEFFER[1], K. JOHNSTON[2], S. EVERLING[3]
[1]Robarts Res. Inst., [2]Dept. of Physiol. and Pharmacol., [3]Robarts Res. Institute, Dept. of Physiol. and Pharmacology, Brain and Mind Inst., Univ. of Western Ontario, London, ON, Canada

Abstract: Over the past 50 years, macaque monkeys have been successfully used as the main nonhuman primate model for understanding the neural processes underlying saccadic eye movements. Although macaque monkeys are in many ways ideal due to their close evolutionary linkage to humans, many of the saccade-related brain regions lie deep in a sulcus in this species, which makes it difficult to access them for large-scale neural recordings and manipulations. The common marmoset (*Callithrix jacchus*) is a promising additional nonhuman primate model with a lissencephalic brain, which allows for easy targeting of frontoparietal brain regions. We have recently shown that marmosets, like humans and macaques, exhibit a gap effect—a decrease in saccadic reaction time when the fixation stimulus is removed prior to the onset of a peripheral visual saccade target (Johnston et al., 2018). Here, we took advantage of the marmoset smooth cortex and implanted 32-channel microelectrode arrays (Utah arrays) in the posterior parietal cortex of two marmosets and recorded both spiking activity and local field potentials during this task. We observed an enhancement in high gamma activities above 60Hz, during the gap period

compared to the same time period in step trials. Discharge rates in a subset of single units were also elevated during the gap period. During the fixation and gap periods, it was possible to predict whether the monkeys were about to make a short latency “express” (SRT>=110ms) or longer latency “regular” saccade (SRT>=120ms) based on high gamma band activities. On express-saccade trials, gamma activities were stronger during the gap than the fixation period, whereas in regular-saccade trials this pattern was reversed. Additionally, high gamma activities were stronger during the gap period in express-saccade trials than in regular-saccade trials. This effect was especially strong for trials with saccades contralateral to the recording sites. Our findings suggest that the common marmoset is a valuable additional nonhuman primate model for the study of the neurophysiology and pathology of saccades.

Title: Oculomotor effects evoked by microstimulation of posterior parietal cortex in the common marmoset

Authors: *K. D. JOHNSTON[1,2], M. GHAHREMANI[1], L. SCHAEFFER[3], S. EVERLING[4,3,2]
[1]Univ. of Western Ontario, London, ON, Canada; [2]Brain and Mind Inst., London, ON, Canada; [3]Robarts Res. Inst., London, ON, Canada; [4]Physiol., Univ. Western Ontario, London, ON, Canada

Abstract: Frontoparietal networks have long been established as a critical neural substrate for cognitive processes and oculomotor control. The common marmoset (Callithrix jacchus) has recently emerged as a promising model for investigations of cortical circuitry, since the largely lissencephalic cortical surface of this small New World primate is readily amenable to laminar and high-density array recordings in frontal and parietal areas linked to oculomotor control such as the frontal eye fields (FEF) and the lateral intraparietal area (LIP), which are considerably more difficult to access in rhesus macaque due to their location within sulci.
Studies of cortical cytoarchitecture and comparative resting-state fMRI have established homology in the structure and connections of these areas between the rhesus macaque and common marmoset, but to date few studies have investigated in detail the functional properties of frontal and parietal areas in the marmoset model. Here, we sought to address one aspect of this gap by applying intracortical microstimulation in the marmoset posterior parietal cortex (PPC).

We implanted 32 channel planar electrode arrays (Utah arrays) in the PPC of two common marmosets. Array locations were determined using the stereotaxic coordinates of the area cytoarchitecturally defined as homologous to LIP, the location of resting-state fMRI functional connectivity between PPC and the midbrain superior colliculus, and for additional guidance the local cerebral vasculature of the cortical surface. Each array was positioned to cover as wide an area including and surrounding the putative LIP as possible. We applied 300ms trains of biphasic current pulses at variable amplitudes at sites across the arrays in awake animals while simultaneously monitoring oculomotor responses at 1000 Hz using a video-based eye tracker (EyeLink 1000). Similar to previous studies of PPC microstimulation in the macaque, we found that stimulation at some sites evoked contralateral saccades and eye blinks. In addition, we observed eye position effects such that the amplitudes of evoked saccades varied as a function of the initial eye position of the animals. These data provide evidence that PPC of the marmoset has a role in oculomotor function similar to that of the rhesus macaque. Together with structural studies, these data suggest that the common marmoset possesses a PPC homologus to that of rhesus macaques and humans, and further supports it's viability as a model species for investigating the detailed cortical circuitry underlying oculomotor control.

Title: Comparison of saccadic behavior between common marmosets, rhesus macaques, and humans

Authors: *C.-Y. CHEN[1], D. MATROV[1], R. VEALE[1], M. YOSHIDA[2], K. MIURA[3], T. ISA[1]
[1]Dept. of Neurosci., Kyoto Univ., Kyoto-Shi, Japan; [2]Dept Syst. Neurosci, Natl. Inst. Physiol Sci., Okazaki, Japan; [3]Grad. Schl Med, Kyoto Univ., Kyoto-shi, Japan

Abstract: Rhesus macaques are commonly used to study the oculomotor circuits. However, precise circuit manipulation is difficult because the relevant cortical areas are deep in the sulcus. Recently, the common marmosets have been proposed to have great advantages in oculomotor research because their cortex is almost flat. Nonetheless, before we undertake large-scale use of marmosets, characterizing their oculomotor behavior under standard saccade tasks is essential.

Here, we directly compared saccadic behavior from marmosets, macaques, and humans during three standard saccade tasks. In free viewing task, we let subjects to passively view the video clips previously used by Yoshida et al. (2012). For visually guided saccade task, we first asked our subjects to fixate a fixation point (FP) at the screen center. After 200 ms, we simultaneously turned the FP off and illuminated 1 target randomly selected from 8 potential targets. The targets were spaced equally around the FP at a radius of 6° visual eccentricity. The subjects had to make a saccade to the target and maintain their gaze for 200 ms to receive a reward. In gap saccade task, the process was identical to the visually guided saccade task, except that an additional gap period (0, 48, 96, 144, 192, and 240 ms) was added between turning off the FP and illuminating the target. During this period, the subjects had to maintain their gaze close to where the FP had disappeared. For the free viewing task, we found saccade amplitude increased with increasing saccade peak velocity (known as the "main sequence") in all three species. However, we observed larger saccade amplitude, shorter intersaccadic interval, and shorter saccade duration in marmosets comparing to humans. Also, the marmosets showed faster saccade reaction time (SRT) (median: 134 ms) than human (median: 188 ms) in visually guided saccade task. Finally, in the gap saccade task, we found that the mean SRT was shorter in the trials with gap period > 0 ms than without gap period in marmosets, which is similar to those of humans. Taken together, we found both similarities and differences in the saccadic behavior of marmosets, macaques, and humans under standard oculomotor tasks. More studies are needed to fully characterize saccadic behavior to establish marmosets as a valuable animal model for oculomotor research.

Title: The paradox of leveraging eye movements: Ocular rotational axis varies with vergence

Authors: *J. L. DEMER, R. A. CLARK
Jules Stein Eye Inst., UCLA, Los Angeles, CA

Abstract: Since the eye does not rotate about its center (Clark & Demer, *Ophthalmology*, 2018), determination of oculorotary torques requires consideration of both tensions & lever arms (LAs) of extraocular muscles (EOMs). We used magnetic resonance imaging (MRI) to determine

rotational axes & LAs of horizontal rectus EOMs.
In adult humans, 390μm resolution surface coil, T2 fast spin echo MRI was repeated in 2 mm thick axial planes in central gaze, abduction, and adduction during: unconverged monocular fixation; asymmetrical binocular convergence to a target at 20 cm; and fusional divergence to a symmetrically-placed accommodative near target at 20 cm with 8 PD base in prism, and divergence to a far target at 400 cm with 4 PD base in prism. Rotational axis was taken as the intersection of lines from cornea to globe-optic nerve junction in initial and final gazes. LA was then computed from axis to EOM scleral insertion for a 24 mm diameter eye.
Rotational axes were always highly eccentric ($P<0.002$). Mean (±SD, N=36 eyes) axis in unconverged abduction was 2.1±0.6mm medial & 0.6±1.1mm posterior to globe center, giving 12.6 mm LA for lateral rectus (LR) and 9.8 mm for medial rectus (MR). In unconverged adduction, axis was 2.3±0.01mm medial & 1.2±1.0 posterior, giving 14.6mm LA for LR & 10.7 mm for MR. Axis in 23±3° (N=10 eyes) asymmetric convergence was significantly more temporal than in adduction at 1.3±0.3 mm medial and 0.2±1.5mm anterior to globe center, giving 11.8mm LA for LR and 9.7mm for MR. Axis in 6.5±2.3° (N=20 eyes) near divergence was significantly less temporal than in abduction at 1.8±0.4 mm medial ($P<0.02$) and 0.1±2.4mm anterior to globe center, giving 12.1 mm LA for LR & 9.4 mm for MR. Axis in 3.6±1.3° (N=18 eyes) far divergence was also significantly less temporal than in abduction at 1.6±0.7mm medial ($P<0.002$) & 0.4±2.4mm anterior to globe center, giving a 12.4 mm LA for LR & 10.2mm LA for MR.
The LR lever arm is up to 36% longer than that of MR and varies more with eye movement type than for MR. The LR/MR lever arm ratio varies from 1.36 in adduction, 1.29 in abduction, to 1.22 for both convergence and divergence. Since torque, not simply tension, rotates the eye, eccentric rotational axis implies that neither motor neuron firing rate nor EOM tension should have constant relationships to eye movement. In convergence, for example, axis eccentricity predicts LR torque to decrease by 19%, and MR torque by 9%, without change in innervation of either EOM. Such co-relaxation and previously inexplicable relationship to motor neuron firing have been reported as a paradox during convergence in monkeys (Miller et al, *J. Neurophysiol.* 105:2863, 2011), but could be due to axis if also eccentric in monkey.

Title: Are vergence eye movements a myth? Observations from midline smooth pursuit

Authors: *S. J. HEINEN[1], A. CHANDRA[1], J. BADLER[1], S. N. WATAMANIUK[2]
[1]Smith-Kettlewell Eye Res. Inst., San Francisco, CA; [2]Psychology, Wright State Univ., Dayton, OH

Abstract: Generally, during smooth pursuit the two eyes are thought to rotate through the same angles, resulting in conjugate eye movements. An exception is during vergence, when a target moves on the midline and the eyes rotate in opposite directions. The vergence system is thought to provide a single signal, but with opposite innervation to each eye, and is separate from the conjugate system. However, almost all natural pursuit movements include a depth component, raising the question of why a separate vergence system evolved. It would seem reasonable that instead of having a separate vergence system, the eyes are controlled independently as Helmholtz proposed almost 200 years ago. Here we tested the feasibility of a putative vergence system by having observers pursue a physical target that moved in depth with either both or one eye. Observers (n = 7 humans, 4 female) pursued a small letter "E" mounted on a pole that moved along a mechanical track periodically forward and backward on the midline (peak velocity = 50 cm/sec; cycle amplitude = 33.3 cm). Observers pursued during binocular viewing, or monocular viewing with each non-viewing eye occluded separately. Binocular eye position was always recorded, as occluders were infrared-passable filters that allowed recording from the occluded eye. Either an Eyelink 1000 eyetracker, or a Plusoptix power refractor (which simultaneously measured accommodation) recorded eye movements. We found that when both eyes were viewing, a robust vergence movement was generated. Similarly, in monocular conditions, the viewing eye always followed the target well. However, the two eyes showed very different behaviors from each other when one was covered. When one eye was occluded, it showed minimal evidence of vergence movements, and often no movement at all. When the other eye was occluded, in most observers it moved *conjugately* with the viewing eye. The results question the existence of a vergence system, and suggest instead that the eyes are independently controlled to override a brainstem conjugate eye movement system in situations where conjugate eye movements are not appropriate. Furthermore, the asymmetry with different covered eyes suggests control of one eye supersedes that of the other, evidence of an *oculomotor* dominance.

Title: Voluntary inhibition of saccadic adaptation depends on adaptation direction

Authors: *M. LAPPE, F. HEINS, A. MEERMEIER
Inst. for Psychology, Muenster, Germany

Abstract: Saccadic adaptation is often assumed to be driven by an unconscious and automatic evaluation of post-saccadic visual error. We investigated if saccadic adaptation is accessible to volitional control. We exposed eight human participants to a post-saccadic visual error in a standard double-step paradigm in which a target dot first jumped 12 deg to the right and then, during the elicited saccade, jumped again by between 2 and 4 deg either in or against the direction of the primary saccade. In one condition, participants were instructed to follow the target and look at its final position. In another condition, participants were instructed to observe the first target jump and then saccade to that position and remain at that position irrespective of any further jumps if the target. We found that gain change differed between the two conditions, showing an influence of volition on saccadic adaptation. The difference depended on the direction of adaptation. When told to remain at the first target position, gain change was close to zero for outward intra-saccadic secondary target jumps. For inward jumps gain change was smaller than when instructed to look at the final target but larger than zero so that some adaptation occurred also in this condition. Analysis of saccadic latencies also showed a difference between adaptation directions. Latency was not affected by the instruction during inward secondary jumps, but when the target was stepped outward during the primary saccade, latencies of the primary saccade were longer when subjects were instructed to remain at the position of the first target jump. The results show that volitional control can be exerted on saccadic adaptation. The differences between inward and outward adaptation suggest that volitional control affects the remapping of the target, thus having a larger impact on outward adaptation.

Title: Early excitatory oculomotor processing encodes task information

Authors: *D. H. KEHOE[1], J. LEWIS[2], M. FALLAH[2]
[1]Dept. of Psychology, [2]Sch. of Kinesiology and Hlth. Sci., York Univ., Toronto, ON, Canada

Abstract: Influential accounts of oculomotor target selection processing posit that in critical oculomotor neural substrates like the superior colliculus (SC) and frontal eye field (FEF), early excitatory activity encodes sensory information about a potential saccade target, while later inhibitory activity encodes top-down information (Fecteau & Munoz, 2008). Recently, Kehoe and Fallah (2017) developed a non-invasive technique to measure the time course of excitatory and inhibitory activity encoding a peripheral distractor in which human saccade curvature is modeled as a continuous function of *saccade-distractor onset asynchrony* (SDOA): the time between the transient onset of a task irrelevant distractor and the initiation of a saccade to a target. The distractor processing time course observed using the non-invasive SDOA technique was closely corroborated by the reported time course of visuomotor neural activity in SC during target selection processing (McPeek & Keller, 2002). Here, we used the SDOA technique to investigate how varying the degrees of visual similarity between a distractor and the target affect the time course of excitatory and inhibitory distractor-related processing while human observers (N = 35) performed a discrimination saccade task for pairs of complicated, novel objects. Consistent with differences in target-distractor discrimination time between similar and dissimilar distractors in SC (Shen & Paré, 2012) and FEF (Sato et al., 2003) neurons, we observed that the latency of the distractor-related inhibitory response was 40-60 ms later for the high similarity distractor than for the intermediate/low similarity distractors. Interestingly, we also observed that the latency of the initial rapid excitatory response was ~60 ms longer for the high similarity distractor than for the intermediate/low similarity distractors, which suggests that the early excitatory response observed during oculomotor target selection processing does encode top-down information under certain task-related conditions. Such observations have important implications for the primacy of top-down "attentional control settings" over sensory salience observed during attentional capture (Folk et al., 1992, 1994; Yantis & Egeth, 1999) and also suggest that differences in search efficiency for similar and dissimilar distractors (e.g., Duncan & Humphreys, 1989; Treisman & Gelade, 1980; Wolfe et al., 1989, 1994) may be equally well attributed to activation of relevant features as supposed to just the inhibition of irrelevant features.

Title: Saccadic localization of moving objects is influenced by illusory perception

Authors: *Z. MA, S. J. HEINEN
The Smith Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Internal drift dramatically shifts the perceived location of a translating Gabor patch. Lisi and Cavanagh (2015) showed that unlike perception, saccades target a Gabor's physical location but not its perceived illusory one. In their experiment, a Gabor patch translated diagonally in the periphery, either with an orthogonal internal drift (illusory condition) or not (control condition). In the illusory condition, a dissociation between perceptual and saccadic localization happened: while the subjectively perceived translation path appeared vertical, saccade endpoints were arranged diagonally with the veridical motion. However, in a separate perceptual experiment, they showed that the perceived illusory path was shifted toward the Gabor's starting position. But in their saccade experiment, the Gabor underwent multiple direction reversals, potentially providing different "starting positions" at the reversal locations within a single trial. This might have obscured the influence of the Gabor's starting position and hence obscured an illusory bias in saccade endpoints. Here, we replicate their experiment, but using Gabors that followed a single, non-reversing motion path. The Gabor traversed a diagonal trajectory, and started with one of two possible horizontal displacements (9 or 11 degree eccentric) and moved upwards or downwards toward the other horizontal displacement. This resulted in two different horizontally displaced illusory trajectories, despite the fact that the veridical motion trajectories were exactly the same. We found that in the illusory condition, although the path of the saccade endpoints was not oriented strictly vertical as is the illusion, it was tilted away from the veridical diagonal path, ($t(4)=3.83$, $p<0.05$). More importantly, the starting position of the Gabors influenced saccade endpoint. We found that horizontal saccade amplitude was smaller when the Gabor started from a position that was closer to the fixation point ($t(4)=7.55$, $p<0.05$), suggesting that similar to the illusory perception, saccades were biased by the Gabor's starting position. Our results suggest that saccade endpoints are biased by perceived illusory position offsets, supporting that the saccadic system receives input from neural pathways subserving perception.

Title: Is saccade vigor modulated by subjective effort cost?

Authors: *C. KORBISCH[1], A. A. AHMED[2]
[1]Univ. of Colorado, Boulder, Boulder, CO; [2]Integrative Physiol., Univ. of Colorado, Boulder, CO

Abstract: Saccade vigor has been shown to reflect how individuals evaluate different financial decision outcomes and correlate with their subjective temporal discounting rate, as well as the intrinsic value of the saccade target [1,2]. Movement decision outcomes can be considered in similar ways as financial decisions. In both paradigms, individuals wish to maximize the utility of the decision outcome [3]. We propose that the same modulation of saccade vigor will hold when individuals evaluate movement decisions that differ in their metabolic costs. Just as individuals subjectively evaluate financial decision outcomes, we propose that metabolic costs are subjectively evaluated and discounted either exponentially or hyperbolically. To probe this, we examined how individuals' saccade vigor changed as they were given metabolically costly decisions. We measured the vigor of their
saccades as they chose between a reference incline and duration (either 4%/6min or 5%/5.5min) and an alternative movement of varying inclines and durations ranging from 0 to 10% and 0.5 to 10 minutes respectively. Participants' decisions were made by saccading to their preferred movement presented on either side of the screen. We then fit each participant's decisions using an iso-cost curve and compared the fit to assess objective (based on metabolic cost) and subjective cost models. A variational Bayesian method was performed to select the most likely cost model based. Our preliminary data (N=3) suggest that participants' decisions were best explained by a subjective model of effort in which the total metabolic cost is hyperbolically discounted by time. Using this subjective cost model, we then assessed how saccade vigor differed as a function of the cost difference of the two options presented. On a whole, we found that participants were more likely to saccade at faster peak velocities as the perceived cost difference increased and found a weaker relationship when considering the objective metabolic cost difference. Total deliberation time and reaction time followed the same trends. Our findings suggest that individuals modulate their saccade vigor and make movement decisions based on an individual perception of the metabolic cost of the movement, rather than simply the objective cost.

Title: Vigor of movements in a normative framework: An extension of the marginal value theorem

Authors: *R. B. GEARY[1], T. YOON[2], R. SHADMEHR[1]
[1]Dept. of Biomed. Engin., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Reward and effort modulate vigor of movements. Current theories account for this observation by suggesting that movements are governed by a utility, combining measures of reward, effort, and time. However, behavior of an animal depends on not only the contingencies of the current option, but the animal's history. To account for this behavior, we adopted a normative approach where the objective was to maximize average net capture rate, defined as the sum of all rewards and efforts accumulated, divided by total time. We found a novel solution to this finite horizon optimal control problem by extending marginal value theorem and tested the theory in two experiments. Our theory predicted the average net capture rate, reflecting a history-dependent utility, acts as a local cue that dictates vigor.

Theoretical results: Consider a scenario where the animal performs an action to acquire a reward, then repeats a similar action to acquire a reward at another location. During the time to travel between locations t_m, effort is expended. The animal spends time t_h to harvest the reward via $f(\alpha,t_h)$. The animal chooses its vigor t_m and harvest period t_h to maximize not the utility of the current action, but the average utility J across all actions. By extending marginal value theorem, we found J was maximized when the rate of effort expenditure during movement equaled the negative average utility. The basic prediction was that vigor should depend on the average net capture rate.

Experimental results: To manipulate J, we controlled harvest duration t_h. Subjects performed a saccade task, viewing images of faces. We considered the time period of looking at the image as the harvest period. If the harvest function $f(\alpha,t_h)$ is concave-downward, then $f(\alpha,2t_h) < 2f(\alpha,t_h)$. This implies as t_h decreases, J increases, resulting in faster saccades. To test this prediction, in Exp. 1 we recruited n = 16 healthy volunteers. On each trial, an image was presented at horizontal positions $\pm 20^o$ from the center, with a $0\text{-}5^o$ random vertical offset, for a variable duration. We observed that as harvest duration increased, saccade vigor decreased, and as harvest

duration decreased, saccade vigor increased. In Exp. 2 (n=19 subjects), we manipulated the history of harvest durations (short, long, or medium), followed by a control harvest (medium duration). We found the period of long harvest durations produced slower movements in the control environment, whereas the short harvest durations produced more vigorous movements. Together, these results suggest movement vigor may be a reflection of a process that attempts to maximize a global utility, the sum of rewards and efforts accumulated, divided by total time.

Title: Movement vigor and decision-making in a patchy reward environment

Authors: *T. YOON[1], R. SHADMEHR[2], A. A. AHMED[3]
[1]Johns Hopkins Med. Inst., Baltimore, MD; [2]Dept Biomed. Eng, Johns Hopkins Univ. Dept. of Biomed. Engin., Baltimore, MD; [3]Integrative Physiol., Univ. of Colorado, Boulder, CO

Abstract: Stimulus value modulates the vigor with which animals move toward a stimulus. Current theories account for this observation by suggesting a utility that combines measures of reward, effort, and time. However, behavior depends not only on the contingencies of the animal's current option, but also the animal's history. Here, we adopt a normative approach where our objective is to maximize average capture rate, defined as the sum of all rewards acquired and efforts expended, divided by total time.
Theoretical results: In a patchy reward environment, we considered the problem of maximizing average capture rate by controlling time spent harvesting reward, and time spend travelling between patches of reward. By including a realistic metabolic cost of travel, we found a novel solution to this problem through an extension of marginal value theorem (MVT). The theory predicting two aspects of behavior: how much time the subject will spend at the reward site, and how fast the subject will move between reward sites.
Experimental results: To test the theory, we measured human behavior in environments where each reward patch was a small image on a screen, and movements were executed via saccadic motion of the eyes. We manipulated reward magnitude via image content, and effort magnitude via image location. In Exp. 1 (n=17 subjects), on each trial subjects were presented with two

visual stimuli simultaneously and had 2 seconds to freely gaze. As theory had predicted, time spent gazing at a stimulus increased with its reward value, and decreased with required effort. Importantly, for a given eccentricity, saccade vigor not only increased with stimulus value at the destination, but also with stimulus value at the previous location. In Exp. 2 (n=21 subjects), we presented a patchy environment where on each trial the subjects were free to gaze at the current stimulus, and then move to another location, where a new stimulus would be displayed upon arrival. We found that time spent at the patch depended on both the past experience (increased with the effort expended to get there), and the expected future (increased with the effort expected to move to the next patch). In Exp. 3 (n=19 subjects), we modulated background rate (long term history and predicted future) by having sessions of differing distributions of reward and effort and found that long-term history of capture rate affected gazing duration and movement vigor. In summary, we found that both the time spent harvesting reward, and vigor of movements between reward sites, depended on history of reward and effort, in such a way predicted by our extended MVT.

Title: Dynamic overshoot in saccadic movement of pupil inside iris during pro- and anti-saccade tasks

Authors: *S. YAMAGISHI, M. YONEYA, S. FURUKAWA
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: Typical saccades have a dynamic overshoot. One previous study reported that the dynamic overshoot was larger for pupil movement than for iris movement (Nyström et al., 2013). The present study explores mechanisms that might determine the properties of the dynamic overshoot of pupil/iris movements. Specifically, we compared the properties during pro- and anti-saccade tasks. The execution of an anti-saccade is assumed to require top-down inhibition of a reflexive pro-saccade and is known to involve activity of the frontal cortex and basal ganglia (Munoz & Everling, 2004). Eye movements were recorded with high-speed camera at a sampling rate of 500 Hz. On the basis of the recorded images, we extracted trajectories of pupil and iris centers during pro- and anti-saccades. At the beginning of a trial, the participant (total n=13) was asked to fixate on a filled square (side 1°) at the center of the display, ignoring the two empty peripheral boxes on the left and right of the filled square (1.5 - 2 s). Then, after the filled square changed to an empty one (200 ms), one of the peripheral squares changed to a filled square

(Saccade part: 1.5 - 2 s). In the pro-saccade task, the participants were asked to make a saccade in the direction of the filled square. In the anti-saccade task, the direction of the saccade was opposite. After the saccade part, all visual stimuli disappeared (1 - 1.5 s). As in the previous report, we confirmed that the post-saccadic overshoot was larger for the pupil movement than for the iris movement. Interestingly, the overshoot of the pupil movement tended to be greater for pro-saccade than for anti-saccade, while the iris movement exhibited generally comparable overshoot between the conditions. This discrepancy between the pupil and iris movements indicates that the overshoot cannot be attributable solely to the characteristics of neural commands to the eyeball movement, whose effects on the pupil and iris should not be sensitive to the saccade task. We propose an explanation that considers the elasticity inside the iris: it is possible that the elasticity inside the iris is higher during pro-saccade, while the iris is relatively rigid so that it reflects more accurately the movement of the whole eyeball.

Title: Optimal feedback control of saccade trajectories can explain saccade variability

Authors: *V. VASUDEVAN, A. MURTHY, R. PADHI
Indian Inst. of Sci., Bangalore North, India

Abstract: Movements are thought to make use of a predictive forward model in conjunction with sensory feedback to allow for motor control and motor learning. This work aims at gaining further insights into the principles of motor control by investigating the nature of movement variability. Although earlier systems level descriptions of motor control were largely deterministic in nature, more recently developed optimal stochastic feedback control models provide a better framework to study motor control in the presence of noise (Todorov and Jordan, 2002). However, with a few exceptions ((van Beers, 2007),(West et al., 2009)), the predictions of these models have been confined to predicting the average kinematic profiles and the main sequence in case of saccades (Harris and Wolpert, 2006)(Chen-Harris et al., 2008). This work studies the inter-trial variability of repeated saccades made by 20 human subjects. Eye position was recorded at 240 Hz using a desktop mounted IR based camera (ISCAN, Boston USA) while subjects made 12° horizontally. Variability was calculated for each subject over normalised saccade time. Generally, the variability profile was observed to be an increasing function with

saturation or decrease towards the end of the saccade in a few cases. To examine the contribution of feedback control, two versions of optimal control model which optimized error and control effort were tested. In one version, a feedforward optimal control (FOC) model that minimized end-point variance without feedback (Harris and Wolpert, 2006) was tested. The second version tested a model (OFC model) that minimized the error in trajectory and velocity of saccades in the presence of feedback (Chen-Harris et al., 2008). Both models were able to predict the mean saccade trajectories, with root mean square prediction errors equal to 1.9 ± 0.39^{o} ($5.2 \pm 0.93\%$) for the FOC model and 1.53 ± 0.93^{o} ($4.19 \pm 0.73\%$) for the OFC model. However, the FOC model completely failed to explain the trajectory variances. The prediction errors were 1.94 ± 1.004 degree^2 ($99.7 \pm 0.03\%$), while the OFC model predicted trajectory variances with errors of 0.42 ± 0.198 degree^2 ($25.2 \pm 14\%$). Overall, the OFC model performed significantly better at predicting the trajectory variance than the FOC model (Wilcoxon signed-rank test: $p < .001$). These results suggest that realistic noisy saccadic system may use an internal feedback mechanism. Our analysis also suggests that understanding variability in movements is a powerful tool to investigate the architecture of movement control.

Title: Reward-prediction-error modulates learning from sensory-prediction-error

Authors: *E. SEDAGHAT NEJAD[1], D. HERZFELD[2], R. SHADMEHR[1]
[1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Neurobio., Duke Univ., Durham, NC

Abstract: Decades of psychophysical evidence suggests that there are at least two error signals that drive behavioral learning: reward-prediction-error (RPE), the difference between the predicted and actual reward, and sensory-prediction-error (SPE), the difference between the expected and realized sensory consequences of an action. During learning, we likely experience both types of errors, raising the question of whether these two systems interact with each other. Here, we hypothesized that during learning of a motor task, coincidence of an RPE with an SPE may modulate how the brain learns from that sensory error. We recorded eye movements as subjects were presented images with high (faces of people) and low (noise) value. Subjects

experienced two types of errors: sensory- and reward-prediction-errors. We controlled SPEs by manipulating the position of the stimulus on the fovea: on some trials, the position of the target was jumped while the eye was in motion, resulting in a foveal error at the end of the saccade. In response to this SPE, subjects performed a corrective saccade to the final target location, and then learned from this error and altered their next saccade. We controlled RPEs by manipulating the content of the image: the image that was presented as the initial target was occasionally switched to a new image after the eye began moving, resulting in an RPE. We considered two kinds of images: faces (high value), and noise (low value). In this way, we could produce positive RPEs in some trials (noise image switched to face), and negative RPEs in other trials (face image switched to noise). We quantified how the RPEs affected learning from the SPEs. We found that both the primary and the corrective saccades had shorter reaction times and greater peak velocities when they were made towards a high valued stimulus (face). RPE affected the corrective saccade: a positive RPE increased the velocity of the corrective saccade and reduced its reaction time, while a negative RPE had the opposite effects. Regardless of this prediction error, during gain down saccade adaptation, subjects learned more from their sensory errors when the final foveated target was more valuable (face). In contrast, during gain up adaptation, learning from SPE was modulated by the value of the initial stimulus. Together these findings demonstrate that vigor of movement is not only affected by the value of the stimulus but also the reward-prediction-error that coincided with experience of that stimulus. Furthermore, learning from a sensory-prediction-error is modulated by the reward-related events that took place at the time of experience of that sensory-prediction-error.

Abstract: When we explore a static visual scene, our eyes move in a sequence of fast eye movements called saccades, which are separated by fixation periods of relative eye stability. Based on uncertain sensory and cognitive inputs, the oculomotor system must decide, at every moment, whether to initiate a saccade or remain in the fixation state. Even when we attempt to maintain our gaze on a small spot, small saccades, called microsaccades, intrude on fixation once or twice per second. Because microsaccades occur at the boundary of the decision to maintain fixation versus starting a saccade, they offer a unique opportunity to study the mechanisms that control saccadic triggering. Abnormal saccadic intrusions can occur during attempted fixation in patients with neurodegenerative disorders. We have implemented a model of the triggering mechanism of saccades, based on known anatomy and physiology, that successfully simulates the generation of saccades of any size—including microsaccades in healthy observers, and the saccadic intrusions that interrupt attempted fixation in parkinsonian patients. The model suggests that noisy neuronal activity in the Superior Colliculus controls the state of a mutually inhibitory network in the brain stem formed by burst neurons and omnipause neurons. When the neuronal activity is centered at the rostral pole the system remains at a state of fixation. When activity is perturbed away from this center, a saccade is triggered. This perturbation can be produced either by the intent to move one's gaze or by random fluctuations in activity.

Title: Signatures of the fast and slow learning processes in the motor commands that move the eyes during a saccade

Authors: *S. P. OROZCO[1], D. J. HERZFELD[2], R. SHADMEHR[3]
[1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Neurobio., Duke Univ., Durham, NC; [3]Dept Biomed. Eng, Johns Hopkins Univ. Dept. of Biomed. Engin., Baltimore, MD

Abstract: Behavior during motor adaptation suggests that learning may be supported by two parallel processes, one that learns significantly from error but forgets quickly (fast process), and

one that learns little from error but forgets slowly (slow process). A limitation has been the inability to directly measure a behavioral proxy for each of the two hypothetical states. Here we report on motor commands that move the eyes during a saccade and show that during adaptation, separate components of the commands carry the signatures of the putative fast and slow processes. We hypothesized that changes to the later part of the saccade would behave like the fast process, whereas changes in the early part of the movement would proceed like the slow process. To test this idea, we designed a saccade adaptation paradigm in which the primary saccade direction was vertical but the target jump was horizontal. This design is akin to force field adaptation where the change in motor commands is perpendicular to the baseline commands, allowing for clear identification of the commands that result from error-dependent learning. Subjects (n=25) made 15^{o} vertical saccades and experienced 5^{o} horizontal perturbations of the target. We divided each saccade into early and late halves based on peak speed and found that the motor commands that were generated in the first half of the movement learned little from error, whereas the motor commands that came in the second half of the movement were more strongly affected by the same error. With passage of time, the motor commands that came before peak velocity showed strong retention, whereas the motor commands that came after peak-velocity showed rapid forgetting. These results suggest that during vertical saccades, the motor commands that arrived late in the movement show carried signature of the fast learning system. To test for this directly, we collected data from n = 21 subjects in a single trial learning (STL) experiment in which every trial had an equal chance of a 5^{o} leftward perturbation, no perturbation, or a 5^{o} rightward perturbation. We found that following a single error, the motor commands on the next movement change, correcting the error only in the second half of the movement, as the eye is decelerating. Together, signatures of the hypothetical fast and slow learning processes appear to be measurable in the motor commands that move the eyes.

Title: A 10-minute bout of moderate to very-heavy intensity aerobic exercise improves executive function in older adults at risk for cognitive decline

Authors: *A. PETRELLA, M. HEATH
The Univ. of Western Ontario, London, ON, Canada

Abstract: A 10-minute bout of moderate to heavy intensity aerobic exercise provides a boost to executive-related oculomotor function in healthy young adults. Notably, research suggests that older adults (> 55 years of age) at-risk or with early signs of cognitive decline may accrue the largest benefit from both single-bout and chronic exercise participation. Thus, and because the prevalence of older adults with executive deficits is an increasing population challenge it is important to determine whether engaging in brief, yet specific intensities of aerobic exercise ameliorate the deficits associated with cognitive decline. In the present study, participants with and without a self-reported cognitive complaint (sCC) completed a VO_2max test. Subsequently, participants completed three separate 10-minute treadmill-based aerobic exercise sessions at participant-specific moderate (i.e., 80% below lactate threshold), heavy (i.e., 15% of the difference between lactate threshold and VO_2max) and very-heavy (i.e., 50% of the difference between lactate threshold and VO_2max) intensities. Pre- and post-exercise executive function was examined using the antisaccade task (i.e., goal directed eye-movement mirror-symmetrical to a visual stimulus). Antisaccades provide a reliable tool for evaluating executive function in persons experiencing cognitive decline due to the temporal precision of the measurement technique combined with the task's hands- and language-free nature. Furthermore, work has shown that directionally correct antisaccades are supported via the same frontoparietal networks that show modulation following single and chronic exercise protocols. Results demonstrated that older adults with and without sCC experienced reliable decreases in post-exercise antisaccade reaction times without a concomitant change in the frequency of directional errors - a result that was independent of exercise intensity. Accordingly, our results demonstrate that older adults with and without a sCC show a benefit to executive function following moderate to very-heavy intensities exercise sessions as brief as 10 minutes.

Title: The effect of normal ageing on minimally delayed oculomotor response (MDOR) task performance

Authors: *P. C. KNOX, N. PASUNURU
Univ. Liverpool, Liverpool, United Kingdom

Abstract: The MDOR task (participants inhibit saccades to target onsets and instead saccade to target offsets), provides an oculomotor method of measuring behavioural inhibitory control (BIC; Wolohan & Knox, 2014, Exp Brain Res 232:3949). As the extent to which older patients

with neurodegenerative disease show BIC deficits is of considerable interest, we investigated the effect of healthy ageing on MDOR task performance. We compared 13 older, healthy participants (Group O: mean age:60y; range:50-70y) and 51 younger participants (Group Y: mean age:22y; range 19-27y) using a synchronous MDOR task. After a randomised fixation period (1-1.5s), a central fixation target was extinguished and a saccade target immediately appeared 5° to either left/right with a display time (DT) of either 200ms or 1000ms (DT and direction randomised). Participants were instructed to maintain fixation centrally and saccade to the target position on target offset. Eye movements were recorded using an infrared eye tracker; latency and amplitude of target directed primary saccades was measured. Saccades occurring <80ms post target *offset* were classed as errors. The pattern of response in Group O was identical to that observed previously; latency to offsets was much longer than for reflexive prosaccades. Latency also increased and error rate decreased for DT 200ms tasks (intersubject mean±SD latency: 453±88ms; error rate: 22±13%) compared to DT 1000ms tasks (latency: 355±111ms; error rate: 50±18%). Latency (Fig:Black) was longer and error rate (Fig: Grey) higher in Group O. When tested with a repeated measures ANOVA (DT: 200 vs 1000 within; O vs Y between factor), both factors returned a statistically significant result for latency (DT: $F_{1,62}=51$; $p<0.001$; Group: $F_{1,62}=15$; $p<0.001$) with no interaction. Error rates were affected similarly (DT: $F_{1,62}=140$; $p<0.001$; Group: $F_{1,62}=16$; $p<0.001$; DT x Group: $F_{1,62}=8$; $p=0.006$). These results confirm a significant effect of normal ageing on MDOR task performance, implying that normal ageing affects both oculomotor inhibition specifically and BIC more generally.

Title: Voluntary saccade training in healthy adults

Authors: *P. B. CAMACHO[1], R. CARBONARI[2], S. SHEN[3], C. LOPEZ-ORTIZ[4]
[1]Univ. of Illinois At Urbana Champaign, Urbana, IL; [2]Beckman Inst., [3]Col. of Applied Hlth. Sci., [4]Kinesiology and Community Hlth., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: During neurologically healthy aging, function of ballistic eye movements known as saccades gradually decreases. Saccades are key to maintaining the image of salient features of the environment on the high visual acuity fovea of the retina. Older adults display increased saccade latency and duration. Additionally, older adults perform greater numbers of compensatory saccades, which devote more cognitive resources to reaching a target(1). Studies have shown that visual function can be improved through various techniques, but none have shown improvement in voluntary saccade function using saccade training. We report on a training method that follows the principle of specificity to improve centrally guided voluntary saccade function. Five adults, between the ages of 40 and 65, were trained to perform voluntary saccades to points at angles 10°, 20°, 30°, 40°, 45°, and 50° from the center of a computer screen at the eight cardinal and intercardinal directions. In each of the eight sessions of the four-week intervention period, participants trained at three amplitudes. Participants performed 40 trials for each amplitude, in randomized directions, such that five trials were performed for each direction at that amplitude. All amplitudes were trained equally over the course of the intervention. Saccades were recorded with targets at 10°, 20°, and 30° pre- and post-intervention. During this testing, participants' saccades were recorded using the SR Eyelink-II system (SR Research Ltd., Ottawa, Ontario, Canada) and analyzed for amplitude, latency, and duration of the first saccade, as well as the number of saccades to reach the target. An ANOVA of mixed effects showed a decrease in saccade latency for the right eye, p-value = 0.03 (SAS Institute Inc, Cary, NC, USA). Increases in normalized saccade amplitude and decreases in saccade count needed to reach the target yielded p-value = 0.1 and p-value = 0.1 respectively. A statistical power calculation estimates the required sample size of n = 10 participants to achieve significance for these three measures of saccade performance. Decreased voluntary saccade latency may be caused by a decrease in required perceptual processing time. The results of the intervention on these outcomes are considered for the use of saccade training in healthy aging adults and neurological diseases that affect these aspects of saccades, such as Parkinson's disease.

Title: A study on characteristic of spontaneous eye blink and sustained attention between young and old adults while watching visual stimuli

Authors: *Y. SHIN[1,3], W. KIM[3], I. SHIN[3], D. CHOI[3], S. CHAE[3], K. KIM[2], D. JUNG[4]
[2]medical IT, [1]Eulji Univ., Gyeonggi-do, Korea, Republic of; [3]R&BD Ctr., Seongnam Senior Experience Complex, Seongnam, Korea, Republic of; [4]Seongnam Senior Experience Complex, R&BD Center, Korea, Republic of

Abstract: Many researches confirmed that eyeblink rate reflects visual attention, and many attempts have been made to understand the audience preferences through the changes in spontaneous eyeblink rate according to concentration levels on different visual stimuli. However, it is hard to find studies that considered the characteristics of spontaneous eyeblink rate and sustained attention while watching visual stimulus, therefore a study on the characteristics of spontaneous eyeblink rate and sustained attention while watching various types of visual stimulus between young adults and elders were compared in this research.
A total of 95 healthy subjects were participated in the experiment. The young adults group was consisted of 45 adults aged from 20 to 30(M = 24.0, SD = 3.1). The elderly group was consisted of 50 adults aged from 59 to 90(M=70.9, SD=6.6). There were five different types of visual stimuli: fixation (5min), documentary (5min), advertisement video clip (5min), TV program (60min), modified vigilance task (10min), and the order of task lists was randomized. First of all, the results from vigilance task were analyzed to verify the characteristics of sustained attention and spontaneous eyeblink rate. For analysis, (1) mean RT (mRT; the mean response times for all trials) and (2) Correct Rate (CR; the number of correct answers/all responses) were used to compared with the spontaneous eyeblink rate and the correlations between each element were evaluated.
The average response time (mRT) in young adults (0.50.1) was approximately 5 seconds faster than the average response time in elderly (1.00.4), and the rate of correct answer(CR) was

significantly higher($p<0.01$) in young adults (97.0%0.7) than it was in elderly (92.8%.4). Moreover, the rate of eye blink in young adults (0.470.12) was significantly lower ($p<0.01$) than the rate of eyeblink in old adults (0.930.19). Also, there was a significant positive correlation between eyeblink rate and the average response time ($r2=.456, p<0.01$), and a negative correlation between eyeblink rate and the rate of correct answer($r2=-.469, p<0.01$).
This research verified the characteristics of spontaneous eyeblink rate and sustained attention in young and old adults. Also, it was confirmed that the EBR and sustained attention ability are correlated. These results are expected to be used as an intuitive index for visual attention to explain the audience preferences in elderly.

Title: The interaction of eye and hand movements in visual reaching task in hereditary spinocerebellar degeneration

Authors: *S. INOMATA-TERADA[1], S.-I. TOKUSHIGE[1], S.-I. MATSUDA[2], M. HAMADA[3], S. TSUJI[3], Y. UGAWA[4], Y. TERAO[1]
[1]Kyorin Univ., Mitaka-shi, Japan; [2]NTT Med. center, Tokyo, Japan; [3]The Univ. of Tokyo, Tokyo, Japan; [4]Fukushima Med. Univ., Fukushima, Japan

Abstract: Introduction: Eye and hand movements are known to be closely linked in daily actions (eye-hand coordination), and the cerebellum plays important role not only in each movement but in their coordination. Negative reciprocal interactions between the eye and hand movements are reported when patients with cerebellar dysfunction perform a target tracking task (van Donkelaar et al.,1994). We devised a system in which we can record simultaneously the trajectory of hand and eye when subjects performed a visually guided reaching task, in a manner similar to the finger-nose test performed to detect the cerebellar dysfunction in clinical practice. The aim of this study was to investigate how cerebellar dysfunction affects this coordination.
Methods: Subjects were 8 SCA patients (SCA6 or SCA31) with pure cerebellar symptoms and 9 age-matched normal controls (NC). In a visually guided reaching task, a fixation spot was presented in the center of the touch panel, which the subjects fixated and touched with the index finger. At a random interval, this fixation spot moved to a peripheral position, to which the

subjects were to instructed to move their finger from the center position by sliding on the monitor. A video-based eye tracker recorded eye movements, while a touch panel recorded the trajectory of finger movements during the task. **Results:** In most trials, the eyes preceded the finger movements to the target. In SCA, the amplitude of both eye and finger movements was more dispersed than in NC, with the magnitude of dispersion is more pronounced for the eyes. The latency of finger movements in SCA was longer than that in NC. The interval between last saccade and start of the finger movement was also longer in SCA than in NC, resulting in further delay of finger movement. **Conclusion:** The accuracy of eye movements did not directly translate into that of hand movements. The time interval between the onsets of saccades and finger movements was significantly greater in SCA patients than in NC. This was not only because the eye took longer to reach the target location, due to the multiple saccades or curved trajectory of the saccade, but also because the start of hand movement after gaze fixation was delayed.

Title: Eye and hand movement characteristics during rapid go/no-go decisions in Parkinson's disease

Authors: *J. FOOKEN[1], G. K. MANN[1], C. B. JONES[2], M. J. MCKEOWN[2], M. SPERING[1]
[1]Ophthalmology & Visual Sci., [2]Dept. of Medicine, Div. of Neurol., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Parkinson's disease (PD) is a neurodegenerative movement disorder that classically causes motor symptoms such as muscle rigidity, tremors, and changes in gait. However, the majority of PD patients also experience non-motor deficits in sensation, perception, and cognition as well as characteristic eye movement impairments. Eye movements are critically important for a large range of natural tasks, including interactions with dynamic objects, such as hitting or catching a flying ball.
Here we investigate the role of eye movements in sensorimotor decision making and manual interception in early stage PD patients (n=12) with mild to moderate symptoms, tested ON and

OFF medication, and age-matched healthy controls (n=8). We developed EyeStrike, a go/no-go manual interception task, in which observers had to predict whether a ball-like target, shown on a computer screen, would pass through (hit) or go by (miss) a designated strike box. Observers were instructed to judge hits or misses by either intercepting the ball with their index finger in the strike box (hits), or by withholding the hand movement (misses). Only the initial launch (300, 500, or 700 ms) of the ball was shown, requiring observers to extrapolate the ball trajectory to decide whether and where to intercept. Observers tracked the ball with a combination of smooth pursuit and saccadic eye movements and received feedback at the end of each trial. Eye and hand movements were recorded with a video-based eye and magnetic hand tracker.
As expected, patients showed impairments in eye movement initiation, hand movement execution, and an overall reduction in movement speed. However, patients compensated for this deficit by initiating hand movements earlier, and exhibited overall similar hitting accuracy and decision-making ability as controls, regardless of medication status. These results indicate that early stage PD patients show preservation of function in rapid go/no-go decision making and are able to compensate for motor slowing by adapting their hand movement strategy.

Title: Increased dependence on saccades for ocular tracking with low-dose alcohol

Authors: *T. L. TYSON[1,2], N. H. FEICK[1,2], P. F. CRAVALHO[1,2], T. TRAN[1,2], E. E. FLYNN-EVANS[1], L. S. STONE[1]
[1]Human Systems Integration Div., NASA Ames Res. Ctr., Moffett Field, CA; [2]San José State Univ. Res. Fndn., San José, CA

Abstract: The decline in smooth pursuit performance following moderate-dose alcohol has been shown in previous studies. Fransson and colleagues (Clin Neurophysiol, 121(12):2134-2142, 2010) showed that a steady-state gain decrease of 2% and 7% at 0.06% and 0.1% blood alcohol concentration (BAC), respectively. The current study examines the detailed features of both the pursuit and saccadic components of the tracking response over a wider range of BACs extending down to zero. Thirteen healthy subjects (8 females, mean age $\pm$ SD = 25.2 $\pm$ 2.1 years) participated. Subjects completed a 3-day at-home pre-study schedule that included 8.5 hours in

bed at night with the timing verified by actigraphy, call-ins, and self-reported sleep logs. They then participated in a 2-day laboratory study where they consumed a single low-dose of ethanol (40% ABV Vodka with juice) adjusted to target either 0.02 or 0.06% initial BACs, and completed three pre-dose and 6-9 post-dose oculomotor test runs of a 5-minute Rashbass-like ocular tracking task with highly randomized target trajectories (Krukowski & Stone, Neuron, 45(2):315-323, 2005). From this oculomotor test, a set of largely independent measures of oculomotor (Liston & Stone, JOV, 14(14):12, 2014) and pupillary (Tyson, Flynn-Evans, & Stone, JOV, 17(10):660, 2017) performance were computed. For each of these metrics, for each subject, we computed the within-subject % deviation of each test run from their baseline (the average across their three pre-dose runs). We then combined the data across subjects and used linear regression to compute the slope and x-intercept (extrapolated threshold) of the mean % deviation from baseline as a function of BAC. We found significant linear decreases in steady-state pursuit gain (-3.8%/0.01%BAC, $p < 0.001$) and proportion smooth (-1.0%/0.01%BAC, $p < 0.01$) with estimated thresholds of +0.013 and -0.007%BAC, respectively. We also found a significant decrease in the precision of visual motion processing for direction (+9.2%/0.01%BAC with a threshold of +0.008%, $p < 0.01$), but not for speed ($p = 0.48$). Conversely, we found a significant increase in catch-up saccade amplitude (+9.4%/0.01%BAC, $p < 0.001$) and rate (+2.38%/0.01%BAC, $p < 0.05$) during steady-state tracking, with thresholds of +0.009 and -0.019%, respectively. Our study, using high-uncertainty target motion, reveals that the smooth pursuit system is more sensitive to ethanol than previously thought. Ethanol consumption generates a dose-dependent increase in reliance on the saccadic system to maintain steady-state tracking as pursuit becomes substantially less effective, starting at BAC levels around 0.01%.

Title: Changes in motor cost affect gaze-limb coordination

Authors: J. DOMINGUEZ-ZAMORA, *D. S. MARIGOLD
Biomed. Physiol. and Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada

Abstract: The brain usually tries to minimize the cost to move (or motor cost). When walking, for example, we normally select a step length and width that minimizes the motor cost of foot placement and the overall walking pattern. However, when the terrain and decision of where to step becomes more complex, moving optimally is not always an option. In these situations, we rely on vision to help select a step location. Here, we determined how motor cost affects the coordination of gaze behavior and foot placement. In one experiment, participants (N=5) walked while stepping on the center of four targets in sequence. To create six different levels of motor cost, we manipulated the step vector on a trial-to-trial basis by shifting the second or third stepping target from the established preferred step width based on the participant's leg length. Participants maintained the same level of foot-placement accuracy across all step motor costs. Participants also made a saccade away from the target they were about to step on sooner when encountering the lowest two motor cost targets compared to the highest two cost targets (one-way ANOVA: p=0.001). This suggests that participants adapted to the greater stepping motor cost by increasing the visual online control of the limb to maintain foot-placement accuracy. In a second experiment, participants (N=4) performed a similar walking task but had a choice of two targets in certain positions of the sequence. One target was always at the participant's preferred step width location (or lowest motor cost), whereas the other target was in one of the five remaining higher motor cost locations, as described above. When participants were free to choose where to step, they directed gaze to the low cost target and always stepped on it as well. In fact, they rarely fixated the higher cost target. However, when we forced participants to step onto the higher cost target, they had more variable gaze behavior. Specifically, we found an increase in the probability to direct gaze to both low and high cost targets, rather than just the latter (main effect of instruction: p=0.018). There are at least two possible explanations for this finding. First, the visuomotor system is primed to prioritize targets that are associated with low cost. Second, the visuomotor system explores both target choices to help calculate the change between the low and high cost target to generate the appropriate motor plan for the step. Taken together, our results suggest that motor cost affects gaze behavior, and that people can readily adjust their gaze patterns to ensure movement accuracy in complex environments.

Title: Eye-hand coordination during motor learning in humans

Authors: *Y. YANG[1], D. SUN[1], T. ZHU[2]
[1]State Key Lab. of Brain and Cognitive Sci., Inst. of Biophysics, CAS, Beijing City, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: When we reach for an object, our eyes often guide toward the object as well. The behavioral pattern of both eye and hand movements directing to an object is well known as eye-hand coordination. We investigate interactions between eye and reaching movements in two types of behavioral tasks: 1) motor control, where subjects were asked to reach a target randomly located in one of 13 positions in a half circle (from 0^o to 180^o, by every 15^o). 2) motor learning, where subjects were given visual feedback information of the reaching endpoints after a zooming transformation defined by a linear function. When introducing a zoomed visual feedback on a single position, subjects adapted their behavior performances toward to the zoomed point. This learned effect was generalized to all other positions after learning. When applying the function on two (or more) positions, subjects were able to gradually learn the function on the whole variable space. A Gaussian Process Regression model based on Bayesian Average reproduces the statistics of a complex set of behavioral data.

Title: To reach or not to reach: Coordination of eye, head and hand movements during visually guided reach

Authors: *H. AL-TAHAN[1], J. CRAWFORD[2,3,4,5]
[2]Ctr. for Vision Res., [3]Biol., [4]Psychology, [5]Kinesiology and Hlth. Sci., [1]York Univ., North York, ON, Canada

Abstract: Much emphasis has been placed on trying to understand the motor control principles behind the coordination of complex multi-movement systems in humans. Previous research has provided insight into eye-head and eye-hand coordination within a 2D plane, but there is little understanding of the more natural condition of eye-head-hand coordination during a 3D reach in humans. This study investigates the relative contribution of the head to gaze movement, in a head free paradigm. In this experiment, participants (n = 6) were instructed to perform a saccade

with and without an arm movement towards a visual target at any of the 25 predefined locations on a 40° horizontal x 20° vertical (visual angle) computer screen. Right eye movements were measured using *EyeLink II* eye tracker and two Optotrak cameras were utilized to monitor hand and head position in space. Preliminary results revealed that average head movements were greater when a saccade was accompanied by an arm movement towards a visual target (2.901 ± 0.103º) compared to the control gaze condition (0.722 ± 0.084º). Additionally, the overall peak velocity of head movements that were accompanied by arm movements were faster (6.065 ± 0.231º/sec) compared to the gaze control condition (2.014 ± 0.187º/sec). Contrary to previous research on rhesus monkeys and humans, analysis on eye movements revealed no significant interaction between the average peak eye velocity and the type of condition from 16.862 ± 0.339º/sec to 17.151 ± 0.4115º in gaze control and reach condition, respectively. However, the overall eye gaze error is significantly less when a saccade is accompanied by an arm movement from an average of 3.290 ± 0.088º in the gaze control to 2.766 ± 0.114º in the reach condition. These results show that reaching influences not only gaze behavior, but also eye-head coordination patterns, possibly to optimize 3D vision for grasping.

Title: Eye movements and their relation to motor performance during a simultaneous whole-body imitation task

Authors: *P. I. BURGOS[1,2], M. BOCAZ[2], K. MUÑOZ[2], J. MARIMAN[2]
[1]Dept. de Kinesiología, Facultad de Medicina, Santiago, Chile; [2]Kinesiología y Neurociencia, Univ. de Chile, Santiago, Chile

Abstract: Previous studies state that when imitating a motor task the gaze focuses on distal points of the segment to be imitated. However, these studies use static images of isolated body segments, partial segments of the body such (as the hand or face), which may limit their projections.
The aim of our study was to identify the patterns of eye movements that are related to a better motor performance during the simultaneous imitation of movements of whole-body in the frontal plane (video).
19 participants performed the task of simultaneous imitation, with recordings of eye movements and kinematics of 4 joints (shoulders and hips) by inertial sensors.
The results showed that the participants with better performance in the imitation sequence, had

fewer fixations, longer duration of fixations, shorter duration of saccades, and a greater preference for distal areas.
The partial conclusion of our analysis allows us to relate a pattern of fixations with a better performance during a simultaneous imitation of the whole body. These results may have implications in disciplines that require teaching this type of gestures such as physical therapy, sports or video games.

Title: Dynamic coding of sensory and motor information during hand movements directed to tactile targets

Authors: *T. HEED[1], W. MEDENDORP[2], J. BRANDES[3]
[1]Fac. of Psychology & Sports Sci., Bielefeld Univ., Bielefeld, Germany; [2]Radboud Univ. Nijmegen, Nijmegen, Netherlands; [3]Univ. of Hamburg, Hamburg, Germany

Abstract: The location of tactile information is initially coded with respect to the skin surface. To move towards the touch, skin location must be integrated with postural information to compute the external location to which the effector must be directed. Posterior parietal cortex (PPC) has been linked to external spatial coding, as well as to the transformation between different spatial codes in touch. However, it is currently unclear which PPC regions contribute to tactile-spatial coding, which spatial codes they employ, and how spatial transformations proceeds between them.
We performed multi-voxel pattern decoding of fMRI BOLD brain signal changes in a delayed, goal-directed pointing paradigm with tactile targets. Human participants pointed, with the right hand, to the precise location of tactile stimuli delivered to their feet, while the legs were either uncrossed or crossed over the shins. With crossed limbs, skin-based and external coordinates are in opposite sides relative to the body midline (e.g., right foot in left space). In each trial, a stimulus was presented, followed by a delay (sensory phase, 1-4 TR, with TR = 1.88 s). Hereafter, a cue instructed either a pro-pointing towards the precise stimulus location, or an anti-pointing towards the same location on the other foot, followed by a second delay (motor

planning phase, 1-4 TR). Anti-pointing, in combination with limb crossing, dissociates the movement goal from both skin-based and external sensory stimulus information. A final cue instructed movement execution.
During the sensory phase, skin-based coding was evident in primary somatosensory and an anterior region of PPC. External coding was evident in a distinct, more posterior PPC region. During the movement planning phase, both skin location and external stimulus location were no longer decodable from PPC activity. A network including primary motor, premotor and PPC now represented information about goal location of the movement. Many of these regions are known to be active when pointing and reaching to visual targets. Thus, goal-directed movement planning appears to recruit similar regions independent of the sensory modality of the movement target. Critically, the network active during movement planning included the regions in which skin-based or external coding had been decodable during the sensory phase. This result suggests that these anterior and posterior PPC regions dynamically adapted their spatial coding from different kinds of sensory-based codes to a common movement-based code during the course of a trial.

Title: Cerebellar outputs contribute to the activity of the primary motor cortex during arm-reaching movement in macaque monkeys

Authors: *N. SANO[1,2,3], Y. NAKAYAMA[1], E. HOSHI[1], S. CHIKEN[4,5], A. NAMBU[4,5], Y. NISHIMURA[1]
[1]Neural Prosthesis Project, Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Grad. Sch. Med. Dent. Sci., Niigata Univ., Niigata, Japan; [3]Japan Society for the Promoting of Sci., Tokyo, Japan; [4]Div. Syst. Neurophysiol., NIPS, Okazaki, Japan; [5]Dep. Physiol., SOKENDAI, Okazaki, Japan

Abstract: The cerebellum (Cb) plays an important role in coordination and execution of limb movements, as evidenced by the fact that Cb dysfunctions cause delayed movement initiation, dysmetria, and intention tremor. Cb outputs project to the contralateral motor cortices, including the primary motor cortex (M1), via the ventral lateral thalamic nucleus. Thus, Cb may contribute

to control of motor outputs by this cerebello-thalamo-motor cortical pathway. However, it is unclear how Cb outputs contribute to activity of the M1 during movements. In order to address this question, we identified M1 neurons that received Cb outputs (Cb-M1 neurons) and investigated their activity during arm-reaching movements in macaque monkeys. We recorded neuronal activity in the forelimb region of the M1 and examined Cb inputs by responses to the electrical stimulation (0.1-1.0 mA, 0.3 ms duration, single pulse) of the deep Cb nuclei through chronically implanted electrodes. Then, we recorded their activity during voluntary arm-reaching movements. The following results were obtained: 1) Cb-stimulation induced initial excitatory or inhibitory responses in 144 neurons among 559 neurons recorded in the M1. Initial excitatory responses were usually followed by inhibitory responses. Based on the initial response, M1 neurons can be classified into Cb-M1 neurons with excitatory response, Cb-M1 neurons with inhibitory response, and non-Cb-M1 neurons. 2) The majority of the Cb-M1 neurons with excitatory response to Cb-stimulation increased their activity during reaching movements. 3) The Cb-M1 neurons with inhibitory response decreased their activity more frequently than the Cb-M1 neurons with excitatory response. 4) Mean firing rate of the Cb-M1 neurons was higher than that of the non-Cb-M1 neurons during all period of the task. 5) Direction selectivity (feature of neuron that shows preferred direction in arm movement) of Cb-M1 neurons found to be similar to that of non-Cb-M1 neurons. 6) Cb-M1 neurons with excitatory response, those with inhibitory response, and non-Cb-M1 neurons showed different activity patterns during arm-reaching movement. These findings suggest that Cb outputs contribute to the activity of M1 neurons during arm-reaching movements.

Title: Explicit sense of agency emerges from dynamic network of neural oscillations

Authors: Y. SAKURAGI, *H. MIZUHARA
Kyoto Univ., Kyoto-shi, Japan

Abstract: Consciousness is a core function of human beings, and attracting many researchers in neuroscience. Sense of agency (SOA) is one of topics to investigate the underlying mechanism of consciousness. It is a sense that an action or its result is caused by a one's own intention. "Comparator model" could imply an importance of neuronal networks for an implicit SOA (feeling of agency). However how neuronal networks contribute to an explicit SOA (judgment of agency) is still an open question. We investigated neuronal networks for judgment of agency based on EEG synchronization.
Nineteen people participated in a scalp EEG experiment. The experiment procedure was approved by the institutional ethics committee, and all participants provided an informed consent before the experiment. During the experiment, the participants performed a reaching task of the right hand within a virtual reality environment wearing a head mount display. We manipulated SOA by a delayed visual feedback of the participant's right arm movements. The experiment was consisted of two conditions, including SOA judgment and delay judgment. The SOA judgment condition included the movement retrieved by the participant's own past actions as distractors. Participants were required to judge whether the arm movement was their own present action for the SOA judgment condition, and whether there was a temporal delay in the visual feedback for the delay judgment condition.
The behavioral results showed that the number of own action responses and no-delay responses were modulated with a function of temporal delay. The own action responses reached chance level with a large delay, while the no-delay responses were almost perfectly reported. We thus succeeded to manipulate the explicit SOA with our task. The EEG results showed that the low beta amplitude of the frontal midline electrodes increased in association with SOA judgment. Phase synchronization decreased between the lateral-central and occipito-parietal electrodes, and increased between the lateral-central and frontal electrodes. These results indicate that SOA emerges from the local network in the frontal region in combination with desynchronizing the global network between the sensorimotor and occipito-parietal regions.

Title: A comprehensive analysis of human wrist proprioception through robot-based assessment

Authors: *F. MARINI, P. MORASSO
Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: “A PubMed search on the subject of *proprioception* and *rehabilitation* will generate close to 2,300 related publications. If one adds the term *wrist*, however, the number of articles is dramatically reduced to 20”. This is how the scientist Elisabet Hagert introduced her brilliant review about proprioception of the wrist in 2010[1]. If one carries out the same search today, 7 years later, he will find 7640 scientific articles on proprioception in general, with 86 articles specific for the wrist joint. Although such numbers suggest an increasing interest in the field, nonetheless it remains an area of research not comprehensively and extensively investigated. An understanding of proprioception is essential to adequately rehabilitate patients with sensorimotor deficits resulting from neurological damages. Yet, at present, there is no established objective method for the assessment of proprioception, and despite clinical rating scales are available and currently in use, they allow to obtain only qualitative information with low resolution. Recent advancements in haptic interfaces, provide the starting point for an innovative robot-aided approach for the assessment of proprioceptive function. Such technologies may allow the implementation of tests for proprioceptive acuity assessment and for the collection of large normative data sets through a reliable procedure that yields objective data at a high resolution. Here we intend to present the results of a robot-aided assessment of joint position sense acuity for the three degrees of freedom of the wrist/hand complex in a cohort of adults and typically developing children. The task employed a joint position matching paradigm in which individuals must replicate a previously assumed reference joint position in the absence of vision. This test allowed us to characterize proprioceptive abilities of each degree of freedom (DoF) of the wrist (Flexion/extension, radial/ulnar deviation, pronation/supination) in term of acuity, measured as the error made while actively replicating a reference joint angle. Furthermore, we investigated the age-related changes of proprioceptive acuity during development and determine when children begin to reach adult levels of proprioceptive acuity. Finally we studied the contribution of external forces on our perception of body and joint configuration. The proprioceptive acuity was tested under five different external forces, in order to understand to what extent they affect proprioceptive acuity. [1]E. Hagert, “Proprioception of the wrist joint: a review of current concepts and possible implications on the rehabilitation of the wrist.,” J. Hand Ther., vol. 23, no. 1, p. 2-16;

Title: Information encoded by motor cortical neurons changes discretely during reaching

Authors: *S. B. SUWAY[1], A. B. SCHWARTZ[2]
[2]Dept Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Activity patterns of motor cortical (M1) neurons during reaching are often complex. Direction is encoded by M1 neurons during reaching, but this parameter by itself does not account for the complexity observed in firing rates. A recent study from our lab (Suway et al, 2017) found that simple components helped explain these complex patterns. We showed that directional tuning of M1 neurons is associated with discrete time epochs during a single reach. Tuning remains stable within an epoch, and changes abruptly between epochs. Although changes in encoding were found to be discrete upon analysis, the nature of the drivers responsible for these changes was unclear. Here, we present new findings that suggest separate neural operations may be taking place in each epoch. Two macaques were implanted with electrode arrays in M1 and were trained to make reaches in a virtual-reality (VR) environment. The animals could not see their hands directly, but instead observed a cursor in VR representing the hand's position. In the standard task, the direction of cursor movement matched the direction of hand movement. In a second condition, the direction of cursor movement was rotated relative to the direction of hand movement. Most neurons exhibited the same epochs in both conditions, but the tuning within an epoch was often better described in terms of the cursor direction rather than the hand direction. Crucially, this relationship changed discretely and abruptly between epochs for single neurons: a neuron with "hand direction" tuning in one epoch would often also display "cursor direction" tuning in another epoch. This effect was consistent over a large range of cursor rotation angles. There was no obvious temporal order across the population; some neurons displayed a "hand direction" epoch prior to a "cursor direction" epoch, and other neurons displayed the opposite ordering. While reach direction is a known driver of M1 activity, visual information is thought to be less prominent in this brain area (Schwartz et al, 2004). Here, we found visual information (the cursor direction) was strongly represented by many neurons throughout a trial, and reasoned this information would be evident in a low-dimensional view of population activity. Using a canonical correlation analysis, we found two orthogonal vectors in neural space that robustly represent the x- and y- dimensions of cursor movement, tracking its orientation accurately before and after the cursor direction was dissociated from the hand direction. Our findings lend key new insight into the operational principles of M1 and bolster the idea that tuning changes in single M1 neurons are related to discrete representations of information.

Title: The relationship between the sensory information and the awareness of action in reaching movement

Authors: ***J.-K. RYU**[1], S. KIM[2]
[1]Inst. for Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Neurosci. Res. Inst., Gachon Univ., Incheon, Korea, Republic of

Abstract: The feeling of being in control and of being the author of one's movements is an important aspect of bodily self-consciousness. During the voluntary motor performances the actor should experience physical phenomenon and sensory consequences about body movements. The consciousness of action can be constituted through the integration of information from the central motor command and the peripheral sensory signals. Those experiences are the most important sources of the sense of agency and the belief of being the author of one's movements.

To explore the relation between sensory information and the consciousness of action in perceptual motor performance, ten healthy adults were recruited and were instructed to perform a visually guided reaching tasks. The task was to trace sagittal lines on a perceptual-motor experimental device. The hand was hidden by a mirror in which participants saw the lines projected on a computer monitor. In unperturbed trials the cursor seen in the mirror exactly corresponded to the participant's hand. In perturbed trials a bias was introduced so that the cursor was deviated in one direction by experimental conditions. Subjects consistently compensated their hand in the opposite direction for producing a target trajectories. After each trial they were asked in which direction they thought their hand had moved. Data was processed and analyzed with customized computer software.

In perturbed trials participants largely could not estimate the actual hand direction. Multiple linear regression analysis revealed that the verbal responses were determined by visual feedback during early and late phase of the reaching tasks. In a second session using the same experimental paradigm a motor response was asked for subjects to retrace their hand trajectory during each trial by drawing a line without visual information. Participants' responses generally indicated an incorrect conscious monitoring of motor performance as well as verbal response. In addition the motor responses during late phase of the perceptual motor tasks largely reflected the kinesthetic feedback information.

The conclusions are as following:

First, Sensory information which arises during performing motor tasks are important ingredients of consciousness of motor action.

Second, in early phase of reaching movement consciousness of action mostly rely on visual information.

Third, Consciousness of action include information which can be presented by body movements whereas not be presented by verbal report.

Title: Spinal stretch reflexes show sophisticated tuning that supports hand control

Authors: *J. WEILER[1], P. L. GRIBBLE[3], A. PRUSZYNSKI[2]
[1]The Brain and Mind Inst., [2]Physiol. and Pharmacol., Western Univ., London, ON, Canada;
[3]Brain and Mind Institute, Dept. Psychology, Western University, Canada, London, ON, Canada

Abstract: The nervous system generates movement that adheres to the so-called 'minimum intervention principle' but it is unclear which neural circuits implement the control laws that produce such behaviour. One idea is that these control laws are exclusively derived within a transcortical feedback pathway centered on primary motor cortex. Here we show that even the fastest spinal feedback pathway can produce solutions consistent with the minimum intervention principle. In our first experiment, participants placed their hand on a spatial target and we mechanically flexed their elbow - stretching the triceps muscle - and simultaneously flexed, extended or did not change their wrist angle. These perturbations displaced the participants' hand off the target, but critically, the perturbation that yielded the largest hand displacement relative to the target did so with the least amount of elbow flexion. We found that the triceps' spinal stretch reflex was tuned to the hand's displacement, and thus the amount of elbow extension needed to return the hand to the target, and not the amount of elbow flexion. In our second experiment we ruled out the possibility that our initial results simply reflected hardwired connections from wrist afferents to triceps motorneurons. We applied the same perturbations as before, but critically, participants responded using two different arm orientations that diametrically altered how local wrist rotation translated to movement of the hand. For example, for one orientation, flexing the wrist moved the hand away from the target, whereas in other orientation, flexing the wrist moved the hand towards the target. Strikingly, the triceps' spinal stretch reflex was again tuned to the hand's displacement from the target rather than the elbow's rotation. In fact, changing the arm's orientation diametrically altered the pattern of the triceps' spinal stretch reflex and did so in a way that was appropriate for returning the hand to its initial location. In our third experiment, we tested whether our initial results are also observed during reaching actions. We occasionally applied the same perturbations as before, but did so when participants began reaching to a goal-target that required pure elbow extension. We found that the triceps' spinal stretch reflex was tuned to the hand's distance from the goal-target, and not the amount the elbow was flexed.

These collective findings reveal that the fastest spinal feedback pathway is capable producing corrective responses that adhere to the minimum intervention principle, forcing a re-evaluation of the how the nervous system derives the sophisticated control laws that support natural motor behaviour.

Title: Out of sight, not out of reach: Activity in the superior colliculus associated with reaching for tactile targets

Authors: *N. G. PRABHU[1,2], M. HIMMELBACH[1]
[1]Hertie Inst. for Clin. Brain Res., Tuebingen, Germany; [2]Intl. Max Planck Res. Sch. for Cognitive and Systems Neurosci., Tuebingen, Germany

Abstract: The superior colliculus (SC) has been implicated in orienting gaze and arms towards an object of interest. Electrophysiological studies in non-human primates so far have reported the involvement of the SC only in visually guided movements. Two previous studies from our lab reiterated this finding in the human SC using fMRI. With this study we sought to decipher if the SC is exclusively involved in visually guided reaching movements or might also be involved when targets are specified by proprioceptive and tactile information, i.e. somatic in nature.
The study was conducted using 3T BOLD fMRI on 6 subjects (5 females, 1 male, age range 22-44) with each subject performing the experiment 4 times, one session per day. Each experimental session had 4 conditions - visually guided reaching (VM), somatically guided reaching (SM), visual sensory (VS) and somatic sensory (SS) - with 2 conditions alternating in each of 4 runs. The left hand of the participants was fixed on a handrest with pneumatic stimulators under the fingertips and optic fibers presenting visual target stimuli above each finger. The right hand rested on a button box fixed on the participant's chest. In complete darkness, the participants either executed reaching movements with the right forearm to pneumatically stimulated left hand fingertips (SM) or to target lights presented through optic fibres (VM). In sensory control conditions, participants pressed a button if visual (VS) or somatic (SS) double stimuli occurred. Fixation at a central, dim fixation light was maintained throughout each run.
Our results showed activation in the deep layers of the SC for somatically guided reaching movements in addition to visually guided reaching movements. This goes beyond the

conventionally established role of the SC and opens up new avenues for exploration in the integration of sensory information towards reaching movements in subcortical systems.

Title: Grip force in preparation for collisions

Authors: *I. A. KULING[1], P. LEFEVRE[2]
[1]Inst. of Neurosci., Univ. Catholique de Louvain, Brussel, Belgium; [2]ICTEAM and Inst. of Neuroscience, Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract: From research on grip force during movements it is known that people modulate grip force in phase with the characteristics of an object held to make sure the object does neither fall nor slip (e.g. Flanagan & Wing, 1993; Bleyenheuft *et al.*, 2009). Grip force planning and anticipation for interactions have not been studied extensively yet. Both Bleyenheuft et al. (2009) and White at al. (2011) found that the peak of the grip force is after the collision, suggesting that the grip force motor command anticipates the impact of the collision. In this study, we explore both temporal and force characteristics of anticipatory grip force in collisions with the static hand.
Participants (N=19) were asked to hold both handles of a bimanual endpoint KINARM (BKIN) in a precision grip with custom made integrated grip force sensors. In a collision task, participants were asked to hold the hands at the same positions while an object collides with one of their hands. We analyzed grip force patterns during preparation and collision.
Objects were presented in series of 6 collisions (right and left hand alternated) with the same mass and stiffness. We used 3 masses (2/4/8 kg) and 2 stiffnesses (1000/6000 N/m) resulting in 6 objects, all with the same visual appearance. Each object was presented in 30 series. In each series a catch trial was introduced to get direct insights in the motor planning for the interaction.
The results show that for the first collisions of each series the grip force at collision was consistent (~15N). Starting from the second collision (which was with the opposite hand) the grip force at collision diverged based on the characteristics of the objects. For collisions 3-6 grip force at collision was consistent and adjusted to the mass and stiffness of the objects.
We compared the onset of grip force increase, i.e. time at which grip force exceeds 5 STD of the baseline grip force, for each collision. The anticipation was longer for the first collision

(~150ms) compared to the following collisions (~120ms), but did not depend on the characteristics of the objects. The difference in grip force at collision between objects can be explained by the findings that both the grip force rate at collision and the baseline grip force in between collisions were related to the mass and stiffness of the object. Evidence in the results of the catch trials showed that the grip force maximum is not at collision, but ~80ms later, with a slight modulation related to stiffness.
To conclude, the timing of the anticipatory grip force is very robust and there seems to be a standardized temporal component in predictive motor planning. Furthermore, grip force is adjusted very fast to the characteristics of the target object.

Title: Divergent encoding of arm kinematics in the cuneate nucleus and primary somatosensory cortex

Authors: *C. VERSTEEG[1], E. R. GASPER[2], R. H. CHOWDHURY[3], T. TOMLINSON[5], L. E. MILLER[4]
[1]Biomed. Engin., [2]Dept. of Biomed. Engin., Northwestern Univ., Chicago, IL; [3]Biomed. Engin., Northwestern Univ., Evanston, IL; [4]Physiol., Northwestern Univ., Chicago, IL; [5]Physiol., Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL

Abstract: Single neurons in the cuneate nucleus (CN), the initial site of somatosensory afferent convergence, have never been recorded during active behavior. To understand how the sensorimotor system processes feedback signals, we must first understand how sensory information is transformed as it moves centrally. We present novel data that show that the encoding of arm kinematics in the cuneate nucleus is quite different from its representation in the somatosensory cortex (S1). In S1, limb state is represented similarly, whether the result of a voluntary movement or an unexpected perturbation applied to the hand. In contrast, these kinematically-similar active and passive movements result in different responses in CN. The source of differences in CN, and subsequent processing that eliminates these differences, are unknown.
We implanted Utah multi-electrode arrays (MEAs) chronically in CN of two monkeys. One also had an MEA in area 2 of S1. These animals were trained to control a cursor by making reaching

movements while grasping a robotic manipulandum. We also used the robot to apply forces to the hand when it was at rest, that generated endpoint kinematics similar to those of reaching. We recorded from single neurons in CN and area 2 and fit Generalized Linear Models (GLMs) to neural firing as a function of hand movement. Neurons from area 2 had PDs that were approximately evenly distributed in all directions in both active and passive conditions, while neurons in CN had a significant directional bias in the active condition but not in the passive condition. This bias differed in the two monkeys. One had active CN PDs predominantly pointing away from the body, the other pointing towards the body. To confirm these biases were not an artifact simply of the highly stereotypic center-out task, we also fit GLMs to data from a random-target task in which the monkeys made rapid sequential movements to a series of target in random locations. CN PDs computed under these conditions were similarly biased, affirming that the encoding of arm kinematics in CN is dependent on movement context: whether movements are made voluntarily, or the result of a perturbation to the limb. In addition to these velocity PDs, a significant number of CN neurons were tuned to the static position of the monkey's hand in the workspace. By using vibration to activate muscle spindles, we also found CN neurons that responded to vibration of more than one muscle, an observation that conflicts with previously reported estimates of sensor convergence in CN. This knowledge has important implications for understanding how muscle length information is processed by spinal, brainstem, and transcortical loops for the control of movement.

Title: Dynamic measures provide unique insights into motor dysfunction after stroke

Authors: A. B. THOMAS, E. V. OLESH, A. ADCOCK, *V. GRITSENKO
West Virginia Univ., Morgantown, WV

Abstract: The most common long-term consequence of stroke is motor impairment, yet movement complexity makes the extent of impairment difficult to quantify. Standard clinical

assessments include kinematic measures such as speed of movement, or measures such as strength of individual muscle groups. However, the relationship of these measures with the underlying cause of movement deficit is non-linear and often subjective. We propose the use of dynamic torque-related measures into the assessment of motor disability that are more linearly related to the muscle activity underlying movement. We recruited 8 post-stroke individuals (MCA, n=4; lacunar, n=2; brainstem, n=2), 6 age-matched controls, and 9 young controls. During the experiment, participants reached to virtual targets in center-out task, as described in Olesh et al. (2017). Kinematics were recorded using 3-dimentional motion capture with Impulse by PhaseSpace, while electromyography (EMG) of 12 arm muscles was recorded with Motion Labs system. Kinematics were then used to calculate active muscle torques (τ_M), or joint moments that result from muscle activity, using inverse dynamic simulations with a 5-DOF model of the arm in MATLAB. By running simulations with and without gravity, τ_M can be divided into two components: support of limb segments against the force of gravity (τ_{MG}), and a residual dynamic torque related to phasic EMG (τ_{MD}) (Olesh et al. 2017). Principal Component Analysis was then applied to normalized EMG and torque components to compare features between groups and between affected and less affected limbs. To quantify the changes in EMG captured by τ_{MG} and $\tau_{MD,}$we projected the affected arm EMG onto the torque principle components from the less-affected arm. Despite differences in individual morbidities, EMG patterns in stroke group were consistent across repetitions of each center-out and return movement and across individuals. We observed larger EMG bursts in proximal muscles in the stroke group compared to age-matched controls (n=6), suggesting a smaller contribution of distal muscles to reaching movements in post-stroke individuals. Torque components captured a significant amount of variance in EMG in all groups, with the least amount captured in some post-stroke individuals. The proportion of variance captured by each component also varied between post-stroke individuals, potentially providing a unique profile of impairment. We suggest that dynamic measures capture aspects of stroke deficits that are more linearly related to the underlying deficit in neural motor control.

Title: Neurobehavioral effects of dissonant sensory feedback

Authors: *J. T. JOHNSON[1], F. L. HAMMOND[2], L. A. WHEATON[1]
[1]Applied Physiol., [2]Mechanical Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Motor planning and control are influenced by the availability and reliability of sensory feedback. Following an upper-extremity amputation, the patient loses not only motor and structural functionality, but also somatosensory feedback from both the hand and the hand's interaction with the world. Decreases in sensory availability have been shown to modulate shifts from feedback control to predictive feedforward control, and to increase recruitment of parietofrontal areas. Substituting a prosthetic limb's end effector for the hand can enable basic object interactions, but does not compensate for the dissonance between motor output and somatosensory feedback. This dissonance is exacerbated by the use of proximal muscles to control the prosthesis. Further, while prosthesis-to-object interactions may resemble grasp, whether neural areas specialized for grasp are recruited during prosthesis use is not known. Similarly, whether a prosthesis is treated as a tool during motor planning and control is not known. We hypothesized using a pair of hand-held tongs during reduced visual availability would result in an increase in recruitment of parietofrontal areas relative to a full-vision group. We also hypothesized increased parietofrontal activity during prosthesis use for both full vision and occluded vision. Electroencephalography data were gathered while persons (n=26) with sound limbs used either a prosthetic simulator (n=18) or a pair of hand-held tongs (n=8) to perform a repetitive reach and grasp task involving discs of three sizes. Results confirm our hypotheses, showing increased parietofrontal activity in the tongs group with occluded vision, and in both full vision and occluded vision in the prosthesis group. Increased predictive control in both prosthesis groups may be due to the dissonance of somatosensory feedback from the prosthesis and the change from distal to proximal muscles to control the end effector.

Title: Control of arm movements during activities of daily living

Authors: *N. DOUNSKAIA[1], D. SANSGIRI[1], D. MARSHALL[1], J. SARBOLANDI[1], M. VIDT[2]
[1]Arizona State Univ., Phoenix, AZ; [2]Pennsylvania State Univ., State College, PA

Abstract: The ultimate goal of human movement control research is to understand how natural movements performed in daily activities are controlled. Natural movements require coordination of multiple degrees of freedom (DOF) of the arm. We examined patterns of arm joint control during daily functional tasks, which are performed through rotation of the shoulder, elbow, and wrist with the use of seven DOF: shoulder flexion/extension, abduction/adduction, and internal/external rotation; elbow flexion/extension and pronation/supination; wrist flexion/extension and radial/ulnar deviation. Analyzed movements imitated the following 7 activities of daily living: moving an empty soda can from a table and placing it on a shelf set to 3 different heights, bringing the can to the mouth as for drinking, combing hair, turning a book page, and bringing the right hand to the left side of the chest. Kinematic and kinetic analyses were conducted. The studied kinematic characteristics were displacements of the 7 DOF and contribution of each DOF to hand velocity. These characteristics demonstrated that the shoulder and elbow transported the hand in space and the wrist provided the required hand orientation. The kinetic analysis involved computation of 3-dimensional vectors of muscle torque (MT), interaction torque (IT), gravity torque (GT), and net torque (NT) at each joint. Using a relationship NT = MT + GT + IT, we assessed the role of active control and the passive factors in rotation of each joint by computing MT contribution (MTC) to NT using the ratio of the signed MT projection on NT to NT magnitude. Despite the variety of joint movements required across the different tasks, 3 patterns of shoulder and elbow coordination prevailed in each movement: 1) active rotation of the shoulder and predominantly passive rotation of the elbow; 2) active rotation of the elbow and predominantly passive rotation of the shoulder; and 3) passive rotation of both joints. At the wrist, MT mainly compensates for passive torque and provides adjustment of wrist motion according to requirements of each task. We conclude that the 3 shoulder-elbow coordination patterns during which at least one joint moves largely passively represent a joint control strategy underlying performance of well-learned arm movements. We discuss that the advantage of this control strategy is that it requires minimal neural effort for joint coordination, and thus increases neural resources that can be used for cognitive tasks.

Title: Co-contraction improves upper limb endpoint tracking in the presence of perturbations

Authors: *C. M. SALIBA[1], M. J. RAINBOW[1], W. S. SELBIE[3], K. J. DELUZIO[1], S. H. SCOTT[2]
[1]Mechanical and Materials Engin., [2]Dept Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada; [3]C-Motion Inc, Kingston, ON, Canada

Abstract: The objective of this study was to determine the influence of co-contraction on the response to a physical perturbation during an upper limb tracking task. We examined the effect of pre-perturbation muscle activity on the motor response of muscles stretched and shortened by the perturbation.
Subjects interacted with a KINARM Exoskeleton robot (BKIN Technologies, Kingston, ON, Canada) to track a target between 80 and 100 degrees of elbow flexion at a constant angular velocity. Subjects were given visual feedback of their fingertip position and the target. A single trial consisted of an initial movement, tracking the target from one end of the trajectory to the other, and a return, tracking the target back to the initial position. A perturbation torque (5 Nm, 50 ms pulse) was applied near the midpoint of both the initial and return movements. Three perturbation torques were possible: no perturbation, or perturbations that flexed or extended the elbow. Subjects were instructed not to anticipate the perturbation and to return to the moving target as quickly and accurately as possible once perturbed. Surface electromyography (EMG) signals were recorded for muscles spanning the elbow. Trials were performed with and without intentional antagonistic co-contraction of the arm muscles.
Co-contraction produced a faster corrective response to the perturbation and improved task performance by decreasing the return time to the target and the maximum error between the elbow angle and the target angle. This was true for perturbations in the same direction and in the opposite direction of the movement. Decreases in elbow motion with co-contraction were evident less than 50 ms post-perturbation. This decrease can be primarily attributed to mechanical properties of the joint due to feedback delays in the motor response, indicating increased joint stiffness when co-contracting. When tracking with and without co-contraction, muscles stretched by the perturbation displayed a burst of EMG activity starting 60 ms post perturbation. When co-contracting, muscles shortened by the perturbation displayed an inhibition in EMG activity 60 ms post-perturbation.
Co-contraction exploits the reciprocal nature of the motor system to use two muscle groups for control. By increasing pre-perturbation muscle activity, co-contraction allows an inhibitory response in the shortened muscles to contribute to the overall response in addition to the excitatory response in the stretched muscles. This inhibitory contribution is not possible without pre-activation.

Title: An investigation of reach decision preferences during ongoing action control

Authors: J. MICHALSKI, A. M. GREEN, *P. E. CISEK
Univ. of Montreal, Montreal, QC, Canada

Abstract: Studies of decision-making, in both psychology and neuroscience, have primarily focused on situations in which subjects must first make a choice and then report it with an action. Such “decide-then-act” paradigms have led to theories in which the brain weighs the costs and benefits of different options, selects one, and then prepares and executes the associated action. However, in our daily lives, we often make decisions while we are already acting (e.g., when playing almost any sport), and the choice is between an action that is being executed and a new potential action that has become available. Given that the human brain evolved primarily to guide real-time behavior, our theories of decision-making must be able to address decisions made in real-time, during “decide-while-acting” paradigms. Here, we examine how subjects make decisions during ongoing action control as compared to static situations. In the “continuous tracking” task, human subjects use a hand-held cursor to track a target that moves in the horizontal plane. At certain moments, a new target choice is presented somewhere on the screen. The subjects can either ignore it and continue tracking the current target, or they can choose to switch to the new target, which then starts to move and becomes the tracked target. The placement and timing of the new target is designed to present subjects with decision scenarios that are analogous to situations already well-studied in “decide-then-act” paradigms. We found a strong preference for closer and larger targets, as expected from prior studies, as well as a preference for targets aligned with the current axis of hand movement. However, in contrast to previous observations in static paradigms where strong preferences were found for movement directions incurring lower biomechanical costs, during continuous tracking we found no such directional preference. To further investigate this difference in results, we examined a “discontinuous tracking” version of the task, in which the tracked target jumped discontinuously so that the choice was always between two point-to-point movements. In contrast to the continuous tracking task, we observed almost no effect of angular alignment with the current axis of movement, but larger directional preferences consistent with the influence of

biomechanical cost. Finally, we examined a version of the task in which subjects were presented with identical choice scenarios but outside the tracking task context. Here, we again observed an effect of biomechanical costs. Taken together, these data show that subject preferences are differentially affected by a variety of factors depending on the context in which choices are presented.

Title: Effect of repeated explicit instructions on visuomotor adaptation and intermanual transfer

Authors: *S. WERNER, C. RICKERS, H. K. STRUEDER
German Sport Univ., Cologne, Germany

Abstract: Intermanual transfer of visuomotor adaptation is related to explicit learning (Poh et al., J Neurophysiol, 2016). Yet, it is unknown whether intermanual transfer can be increased by repeated explicit instructions. To clarify this issue, we conducted an extensive experimental programme modulating the amount of awareness of visuomotor adaptation in four groups (GNI, SNI, SOI, SSI). All participants performed centre-out-and-back pointing movements with their right arm. During baseline they received veridical visual feedback about their movement. In a subsequent adaptation block, feedback was rotated by 60°. This rotation was either introduced suddenly (SNI, SOI, SSI) or gradually in steps of 3° (GNI). The groups either received no explicit instructions (GNI, SNI), instructions once before the onset of adaptation (SOI) or several instructions before and during adaptation (SSI) about the nature of the rotation. After adaptation an awareness test was conducted. The experiment concluded with an intermanual transfer block, in which movements were performed with the left arm under rotated feedback, and a washout block again under veridical feedback. We determined adaptation, awareness, unawareness, transfer and washout indices from the subjects pointing directions. Analysis of adaptation indices revealed less adaptation during gradual than during sudden adaptation and less adaptation without than with instructions. Repeated instructions did not increase adaptation compared to one-time instruction. These differences were pronounced during beginning of adaptation; however, at the end of adaptation all four groups reached a similar adaptation level. Besides, we found significant group differences only for awareness index with less awareness in GNI than SOI and SSI. Unawareness, transfer and washout indices did not differ between groups. However, we found a significant correlation between awareness and intermanual transfer indices.

The findings are discussed with reference to implicit and explicit processes in visuomotor adaptation.

Title: Effect of practice and expertise on producing slow, smooth movements

Authors: *J. FRIEDMAN[1,2], L. NOY[3]
[1]Physical Therapy, [2]Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv, Israel; [3]Arison school of Business, IDC (Interdisciplinary Center), Herzliya, Israel

Abstract: Point-to-point arm movements have been shown to have smooth, bell-shaped velocity profiles. However, when the duration of the movements is sufficiently slow (i.e. with a duration longer than approximately 500 ms), individuals are unable to produce smooth movements. Rather, they produce jittery movements where multiple peaks can be observed in the velocity profile. This naturally leads to the question of why are we unable to produce these movements? One possible explanation is that the motor system is simply unable to produce slow, smooth movements. An alternative explanation is that we can't make these movements because of a lack of practice. In day to day life, we rarely perform very slow movements, rather we want to achieve our movement goals in a relatively short amount of time. We want to bring the cup of coffee to our mouth quickly (without spilling it)! The implication of this is that slow, smooth movements may not be a part of our motor repertoire. To test whether this is the case, we examined whether training can add these movements to our motor repertoire, and whether experts in making slow movements already have these movements in their motor repertoires. We trained a group of naïve subjects to make slow, smooth movements using the single-player mirror game, where subjects track rhythmic stimuli which move at different frequencies and amplitudes using their arm. We found that following 10 days of training, 15 minutes per session, subjects improved in their ability to perform slow, smooth movements. Additionally, we tested experts in producing slow movements - long term Tai Chi practitioners. In this group of subjects, who all have extensive training in performing slow movements, we found that most of the participants were able to produce slow, smooth movements at frequencies at which participants from the general population were unable. In conclusion, the results from these two studies show that the previously observed lower limit in our ability to produce slow, smooth movements was likely due to a lack of practice in these movements and is not the true lower limit. An

understanding of the other causes which contribute to the lower limit in our ability to produce slow movements requires further investigation.

Abstract: Human muscle activation patterns have proven difficult to characterize due to the large number of degrees of freedom present in the system. The underlying characteristic behind the reduction in dimensionality is the ability to group together individual degrees of freedom (typically muscles) together to create new variables that act as the input to the system. In these experiments, two common grouping methods are explored: principal component analysis (PCA) and non-negative matrix factorization (NMF) subjected to a generalized Akaike information criterion (AIC) to serve as a quality of fit estimator. These are used to group the muscle activity of individuals during quasi-static force production tasks to synthesize reduced-order models that account for 90% of the muscle activity contributing to the task. Regression techniques are then utilized to obtain mathematical models that describe the system's behavior. Ultimately, we show that the system's response is a multi-valued function and linear combinations of predetermined functions perform poorly in terms of goodness of the t at capturing the data. However, a Fourier series parameterization through time yields promising results in terms of validity of studying reduced order models and how they may be used to further study robotic systems or form movement characterization and rehabilitation infrastructure.

Title: Control of forelimb joints during accurate stepping

Authors: *H. N. ZUBAIR[1,2], E. E. STOUT[1], I. N. BELOOZEROVA[1], N. DOUNSKAIA[2]
[1]Neurobio., Barrow Neurolog. Inst., Phoenix, AZ; [2]Kinesiology, Arizona State Univ., Phoenix, AZ

Abstract: Natural locomotion often requires accurate stepping when ground conditions change. How movements of limb joints are coordinated and how this coordination is adjusted to expected and unexpected ground perturbations remains unknown. In this study, coordination among forelimb joints was investigated during the swing phase of locomotion in the cat. Unperturbed and perturbed accurate stepping along a horizontal ladder was examined. In the unperturbed condition, all crosspieces of the ladder were spaced equally, 25 cm apart. In the perturbed conditions, one of the crosspieces was displaced 5 cm toward to or away from the cat, which required the cat to adjust step. The crosspiece was displaced at three different time points along the cat's progression: before the cat stepped on the ladder (known perturbation), two steps ahead (long notice), and one step ahead (short notice). Joint kinematics and kinetics were analyzed during the unperturbed and perturbed steps with a focus on the roles of the active muscle torque, passive gravitational torque, and interaction torque in rotation of each joint. We found that the paw was transported in space through translation of the body and shoulder and elbow rotations while the wrist provided paw orientation required to step on crosspieces. The underlying joint control pattern was consistent in all conditions. The movement was initiated with an active elbow flexion and mainly passive shoulder flexion. This was followed by a period of predominantly passive rotations of both joints. Shoulder muscle torque crucially contributed to generation of the last movement portion. This torque caused active deceleration of the shoulder flexion, while the elbow continued to move mainly passively, mainly due to interaction torque. The wrist was rotated predominantly passively, with the muscle torque contributing only at the very beginning and end of the motion to stabilize the joint against high interaction torque. This pattern of control was preserved in all perturbed conditions. Changes in the step length were accomplished predominantly by a change in shoulder movement during the last quarter of the swing motion. The influence of the timing of the crosspiece displacement was minor. We

conclude that joint coordination during locomotion is produced mainly passively, by exploiting gravity and the limb's inter-segmental dynamics, which may simplify neural control of locomotion. The use of shoulder musculature at the movement end enables flexible responses to environmental disturbances.

Title: Scaling of muscle activation during 3D reach actions

Authors: *C. R. SMITH[1], A. HETHERINGTON[1], S. SILFIES[2], J. STEWART[1]
[1]Univ. of South Carolina, Columbia, SC; [2]Drexel Univ., Philadelphia, PA

Abstract: Scaling of kinematic measures of reach control to targets that vary in distance is well-described. Scaling of muscle activity has also been shown, but such work has primarily been in single-joint or 2D workspaces. Many functional tasks of everyday living occur in 3D environments. Therefore, the purpose of this study was to investigate the scaling of shoulder and elbow muscle activity for 3D reaches to targets of increasing distance.
Twelve young, right-hand dominant participants (5F/7M, 23±4yrs) reached across midline with the right arm to 3D virtual targets placed at 7, 14, and 21cm. Participants were instructed to reach "as fast as possible" to targets presented in a pseudo-random order in 6 blocks of 18 trials each. EMG (2000Hz) and kinematic data (100Hz) were collected simultaneously. Hand position and joint angles were collected using electromagnetic sensors. Wireless surface electrodes were placed on the biceps, lateral triceps, anterior deltoid and posterior deltoid. All data were collected and time-synced using the MotionMonitor.
As expected, movement distance, peak velocity, peak acceleration, shoulder flexion, and elbow extension showed significant scaling with target distance ($p<0.001$). Anterior deltoid activity scaled significantly with target distance ($p<0.001$); posterior deltoid, biceps and triceps activity also scaled to target distance ($p<0.05$) although this scaling was less distinct. Anterior deltoid activation was positively correlated with movement distance across participants (mean $r=0.714$); the correlation between movement distance and posterior deltoid (r range: -0.723 to 0.166), biceps (r range: -0.025 to 0.694), and triceps (r range: -0.209 to 0.887) activation varied between individuals, suggesting different movement strategies were used to meet the demands of the task.

As the primary mover for this reach task, anterior deltoid activation scaled with target distance and had a strong correlation with movement distance. The role of the posterior deltoid, biceps, and triceps during this task was variable which may be due to differences in individual approaches to task performance. While the task required a 3D reach, some individuals moved with a relatively straight hand path, leading to activation patterns that mirror previous 2D findings; other individuals moved with a more curved hand path, resulting in muscle activation patterns that differed from those previously observed. An understanding of the movement patterns and scaling of muscle activation for reaches in 3D space can assist in the development of models that can be used to compare scaling used by individuals that have known motor deficits, such as after stroke.

Title: Aging and the neurocognitive mechanisms underlying corrective movements for obstacle collision avoidance

Authors: *I. FLINT[1], K. TREWARTHA[2]
[2]Cognitive and Learning Sciences; Kinesiology and Integrative Physiol., [1]Michigan Technological Univ., Houghton, MI

Abstract: The objective of this research is to identify the neurocognitive mechanisms that contribute to our ability to make rapid evasive actions in response to sensory feedback during an ongoing movement, and to establish how these mechanisms are impacted by aging. Rapid motor corrections allow us to make evasive actions to avoid knocking over objects in a cluttered workspace, and navigate around other people in a crowded room. In the current study, we used a robotic device (Kinarm, BKin Technologies) to apply unpredictable visual "cursor shifts" while participants reached for visual targets and tried to avoid visible haptic obstacles. The obstacles were positioned to the right and left of a straight hand path from the start position to the target, and upon contact with the participant's cursor a repulsive force was applied by the robot to simulate a collision with a real obstacle. On each trial the cursor briefly disappeared behind a rectangular occluder positioned in front of the start position, and emerged either unperturbed, or shifted by a small, medium, or large distance to the left or right of a straight line to the target. The medium-shift trials placed the cursor in a collision course with one of the obstacles, and

required a movement correction to avoid the obstacles. For the no-shift and small-shift trials, and the large-shift trials a movement correction was not necessary to guide the cursor between or around the outside of the obstacles, respectively. We tested the prediction that older adults (65-85 years old) would perform less optimal corrections more frequently than younger adults (18-35 years old). We also recorded EEG data while participants performed the obstacle avoidance task to examine age differences in the neurocognitive mechanisms involved in responding to the visual perturbations. Finally, we probed individual differences in the efficiency with which older adults made rapid corrective actions by administering a battery of perceptuomotor and cognitive tasks. The battery included simple and choice reaction time tests, a finger tapping test, a letter-digit substitution task, the flanker task, a task-switching test, the Wisconsin card sorting test, and an N-back task. This battery allowed us to identify the factors that best predict impairments in performance on the obstacle avoidance task in later adulthood. The results of this study add to a growing literature examining the impact of aging, and age-related cognitive decline, on adaptive motor behavior. The data also contribute to our understanding of the nature of cognitive contributions to rapid feedback control.

Title: The effect of the flexion synergy on arm and hand kinematics in hemiparetic cerebral palsy: Preliminary results

Authors: *N. M. HILL, J. P. A. DEWALD
Northwestern Univ., Chicago, IL

Abstract: Introduction: Unilateral brain injury before, during, or soon after birth resulting in hemiparetic cerebral palsy (HCP) causes movement impairments on one side of the body. One clinically observed impairment is the upper extremity flexion synergy, an involuntary coupling between shoulder abduction and elbow, wrist and finger flexion. With the use of haptic robotics and motion capture technology, these involuntary coupling patterns can be explored in the pediatric population. The purpose of this study is to test the feasibility of an integrative measurement technique to record reaching and hand opening/closing abilities in individuals with HCP. Retention of high resolution ipsilateral corticospinal projections in earlier injuries may reduce the presence of involuntary joint coupling observed in individuals with later injuries. We

hypothesize that individuals with earlier injuries (PRE) will be able to reach farther and open their hands more at higher shoulder abduction loads compared to those with later injuries (PERI and POST). **Methods:** Participants completed a set of reaching and hand tasks in an admittance controlled haptic robot which allows arm movement in three dimensions. With the arm rigidly coupled to the robot, participants were instructed to reach forward towards a virtual target set near full arm extension while lifting a percentage of their maximum shoulder abduction torque generation ability. Reaching ability was quantified using the reach distance deficit defined as the percent change between the overall max distance achieved and the max distance for each load level. A motion capture system using specialized markers with embedded optical patterns was used to measure hand movement during a grasping task. Hand opening ability was quantified using a pentagon area calculated from fingertip positions. **Results:** A total of eight participants (ages 11y-19y) completed the reaching tasks of this study with two individuals in each injury timing group and two typically developing (TD) controls. Preliminary results show a decrease in reaching ability at higher load levels with trend towards greater deficits in the latest injury timing group compared to earlier groups. Similar trends are expected with the hand pentagon area. **Conclusions:** Integration of haptic robotics and motion capture technologies enable quantification of the flexion synergy in pediatric populations. Knowledge gained from this study will enable the development of targeted therapies to address the underlying causes of motor impairments in different subpopulations of HCP.

Title: Interaction with a complex object: Exploiting stability to render perturbations predictable

Authors: *D. STERNAD[1], S. BAZZI[1], N. HOGAN[2]
[1]Departments of Biology, Electrical & Computer Engineering, and Physics, Northeastern Univ. Dept. of Biol., Boston, MA; [2]MIT, Cambridge, MA

Abstract: Interactions with objects are ubiquitous in our daily life and present specific challenges to our motor skill. When guiding acup of coffee to one's mouth, the hand applies forces on the cup and the coffee inside, and the sloshing coffee simultaneously exerts forces on the hand. To avoid spilling, subtle control is required to predict and compensate for those

complex interaction forces. To date, motor neuroscience has focused on simple movements but extrapolation of insights to tasks with complex dynamics is questionable. For such complex interactions, slow neural transmission and intrinsic noise make feedback control insufficient while prediction based on internal models of dynamic objects seems implausible. Previous work on rhythmic interactions showed that humans exploit dynamic stabilityor increased predictability of object dynamics to facilitate control. This exploratory study examined discrete movements and hypothesized that actors render the interaction stable to preempt and compensate for perturbations. Since discrete movements are not at equilibrium, traditional stability analyses are inapplicable. Instead, contraction analysis was used to identify contraction regions that stabilize trajectories, specifically in the presence of perturbations.Using a virtual set-up, a simple cart-and-pendulum model mimicked the task of carrying a cup of coffee: the pendulum bob represented the liquid moving inside a cup defined by the bob's semicircular path. Participants moved a robotic manipulandum to control the virtual cup with the ball "rolling" inside; the goal was to move the cup to a target as fast as possible without losing the ball. A small perturbation assisting or resisting the motion was presented at a fixed location along the path. Hypotheses: 1) For both perturbations, subjects learn to harness contraction regions to stabilize the interaction. 2) Contraction regions are utilized differently for assistive and resistive perturbations. To compute the contraction regions, a metric was obtained by solving a partial differential equation. Experimental results show that subjects stabilized their trajectories and attenuated the perturbations by moving through contraction regions of the free, unforced system. This stabilized performance and made the dynamics more predictable. Moreover, subjects chose the contraction regions with relatively slow guaranteed convergence rates, which is a trade-off between stability and flexibility. These results demonstrate that humans are sensitive to subtle stability properties of the task and exploit them to enable safe interaction with dynamically complex objects.

Title: Input shaping to control dynamically complex objects

Authors: H. GUANG[1], S. BAZZI[2], D. STERNAD[3], *N. HOGAN[1]
[1]MIT, Cambridge, MA; [2]Northeastern Univ., Boston, MA; [3]Departments of Biology, Electrical & Computer Engineering, and Physics, Northeastern Univ. Dept. of Biol., Boston, MA

Abstract: Physical interaction with objects, including tool use, is ubiquitous in activities of everyday life and humans have mastered this skill to a remarkable degree. The ability to manipulate objects with complex dynamics is particularly intriguing due to the subtleties required to perform such tasks. To date the primary focus of neuroscience studies has been on grasping or transporting rigid objects, but the insights gained thereby are unlikely to be sufficient to understand manipulation of dynamically complex objects. Motivated by our ability to transport a cup of coffee with minimal sloshing and without spilling, this study examined discrete movements of an object with nonlinear dynamics and internal degrees of freedom. The task of transporting a cup of coffee was implemented as a simplified 2D cart-and-pendulum model simulated in a haptic virtual environment; the cart represented the cup and the pendulum's bob emulated the liquid moving inside the cup. This study explored the strategies that humans use when the goal is to move the cup-and-ball to a target without any terminal oscillations. In the control theoretical literature, a strategy called input shaping was developed for such a task: if a desired motion profile is convolved with impulses at appropriate times, determined by the natural frequency of the pendular load, all terminal oscillations are eliminated. In the experimental study participants controlled the virtual "cup and ball" system by moving a robotic manipulandum. Subjects were instructed to move the cup into the target box without losing the ball along the way. They were allowed to move at their own pace, as long as the cup's forward velocity above a minimum, which was instructed verbally. Results showed that subjects used two different control strategies to complete the task, distinguished by trial completion time. Subjects who took a relatively longer time to complete the task used a minimum jerk profile. However, the jerk minimized was of the ball motion and not the cup motion. Other subjects took a shorter time to complete the task; their movement kinematics revealed a pattern with two pulses, consistent with input shaping. These results show that humans can apply finely-timed pulses dictated by the object's dynamics. We submit that, while free movements may reveal some aspects of neural control, to provide insight about the control of physically interactive tasks, new experimental paradigms are needed.

Title: Modification of the control law in reaching movements induced by online target change

Authors: *A. DE COMITE[1], F. CREVECOEUR[2], P. LEFEVRE[3]
[1]Catholic Univ. of Louvain, Louvain-la-Neuve, Belgium; [2]Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium; [3]ICTEAM and Inst. of Neuroscience, Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract: In order to control movements efficiently, the nervous system takes into account sensory inputs (kinaesthetic and visual signals) and provide appropriate reactions to mechanical perturbations applied to the limb. These feedback responses have delay of ~50 ms and ~100 ms respectively, depending on whether the perturbation engages the somatosensory or the visual pathway. However, whether this feedback controller is sensitive to an online modification of the structure of the goal, for example a change of the size of the target, has not yet been documented. The interest of considering such a change is that it cannot be handled only by modifying the state of the system, as for a target jump, but requires recomputation of the control policy. More specifically, we studied whether change in the structure of the goal occurring during movement could elicit rapid changes in the control law. We analysed this issue by modifying the size of the target, which switched from a square (2.5x2.5 cm) to a rectangle (40x2.5 cm) or vice versa during movement. The change in the size of the target occurred either before or after the mechanical perturbation. In addition to this target size modification, we applied mechanical perturbations to the hand, orthogonally to the main reach direction, to enhance change in the control policy associated with the target size. We analysed kinematics of the hand movement as well as surface electromyography (EMG) of shoulder flexor and extensor muscles involved in the movement to determine when the feedback responses to mechanical perturbations reflected changes in the goal structure. Position of the hand at the end of the reaching showed significant dependency ($p<0.05$) on the occurrence of a target change, such that earlier change from a square to a rectangle were followed by a larger hand deviation, and the opposite organisation of reach end-point was observed when the target changed from a rectangle to a square. When the target changed before the mechanical perturbation, the end-point position was closer to the one of the perturbed reaching to the modified target. In contrast, when the target changed after the mechanical perturbation, the end-point position was closer to the one of the perturbed reaching to the unmodified target. Surface EMG averaged in a window of [100 150] ms after the change in target displayed a significant modulation consistent with changes in behaviour (linear mixed ANOVA, $p<0.01$). Our results highlight a rapid and online modification of the control law following the modification of the size of the goal target.

Title: Fronto-parietal neural activity during multi-attribute decision-making with conflicting value information

Authors: *A. NAKAHASHI, T. LUSIGNAN, P. E. CISEK
Neurosciences, Univ. of Montreal, Montréal, QC, Canada

Abstract: Many studies have shown that delay-period activity in sensorimotor regions not only represents the action plans to be executed, but also reflects the reward values of the potential actions. This has led to the proposal that value-based decisions between actions emerge as a biased competition between potential actions taking place in sensorimotor regions. Here, we investigate how neural activity in dorsal premotor cortex (PMd) and posterior parietal cortex (PPC) unfolds when multiple attributes jointly indicate the reward value of a potential reach target. In our task, monkeys are presented with one or two reach targets whose reward value is determined by two attributes: a bottom-up (BU) feature based on luminance, and a top-down (TD) feature based on the orientation of a line drawn in the target. Each feature has three levels of desirability scores and the total of the two scores determines the number of rewards received upon a successful reach to that target, after a GO signal. When the decision is based entirely on the BU feature (EasyBU trials; line orientation is the same in both targets) or on the TD feature (EasyTD trials; luminance is the same for both targets), monkeys reliably select the more valuable target. In these trials, choice specific activity appears almost simultaneously in both PMd and PPC, within 100ms of target onset, at which time the activity associated with the unselected target begins to decrease sharply. When the targets are identical in terms of both BU and TD features and the monkey can choose randomly, choice predictive information appears earlier in PMd (within 100ms) than PPC (within 150ms). Most interesting are trials in which the targets differ in both attributes, but the total reward value is the same (Conflict trials). In these trials it doesn't matter which target the monkey chooses, but he must choose one, and we examine how neural activity unfolds when he chooses the target with a higher valued BU feature (ConfBU) versus when he chooses the target with a higher valued TD feature (ConfTD trials). In ConfTD trials, the activity looks similar to EasyTD trials - both PMd and PPC reflect the choice within 100ms, at which time the activity associated with the unselected target starts to decrease. In contrast, in ConfBU trials both regions show prolonged activity for both targets, with the unselected target activity decreasing at around 150ms in PMd and slightly later in PPC. These results are consistent with the proposal that reach choices are determined by a biased competition in sensorimotor regions, and suggest that in cases of indecision the conflict resolution appears to be primarily driven by activity in PMd.

Title: Humans do not minimize muscle effort to control constrained motion

Authors: *M. E. HUBER[1], R. KOEPPEN[1], D. STERNAD[2], N. HOGAN[1]
[1]Mechanical Engin., MIT, Cambridge, MA; [2]Departments of Biology, Electrical & Computer Engineering, and Physics, Northeastern Univ. Dept. of Biol., Boston, MA

Abstract: Tool use is a hallmark of human behavior, yet how humans control physical interaction is still poorly understood. For unconstrained motion, it is often proposed that musculo-skeletal coordination minimizes muscle effort. This study examined if this notion holds true for motor tasks that involve physical interaction, specifically when humans interact with a circular kinematic constraint. In the experiment, human subjects were instructed to move a robot handle around a virtual, circular constraint at a constant tangential velocity in both clockwise and counter-clockwise directions. To reduce the effect of forces that might arise from incomplete compensation for neuro-musculo-skeletal dynamics, the target tangential speed was set to an extremely slow pace (13.3 seconds per revolution). This ensured that subjects moved around the constraint under quasi-static conditions. First, under quasi-static conditions, subjects should exhibit the same behavior, irrespective of the direction of rotation (H1). Second, in this task, minimizing muscular effort requires muscles to be deactivated at positions where they cannot generate force tangent to the constraint and hence cannot contribute to mechanical work (H2). Third, if deactivated at these positions, muscles cannot offset radial components of force that may result from activation of other arm muscles. We hypothesized that subjects would exert repeatable patterns of workless, radial forces on the constraint (H3). While subjects exerted repeatable patterns of workless forces, supporting H3, those patterns differed with direction of rotation, contradicting H1. Most importantly, subjects did not deactivate muscles when they could not contribute to mechanical work, contradicting H2. These findings demonstrate that minimizing muscle effort is not a prominent factor in human performance of constrained motion.

Though no doubt important in some contexts, minimization of muscular effort or metabolic energy consumption may be subordinate to other concerns, such as predictability, in the context of tool-using behavior.

Title: Small errors in movement paths can induce dramatic changes in musculotendon velocities

Authors: *D. A. HAGEN[1], C. M. LAINE[2], S. CHAKRAVARTHI RAJA[3], F. J. VALERO-CUEVAS[1,2]

[1]Dept. of Biomed. Engin., [2]Div. of Biokinesiology & Physical Therapy, [3]Ming Hsieh Dept. of Electrical Engin., USC, Los Angeles, CA

Abstract: Deciding how to move the hand along a given path to produce activities for daily living (ADLs) involves multiple factors such as limb kinetics, choice of muscle activation patterns, online error corrections, robustness to perturbations, accounting for length/velocity muscle mechanics and time-sensitive reflex modulation. In Hagen & Valero-Cuevas (2017) we show how the joint rotations associated with different paths induce different musculotendon (MT) velocities. While *different* paths will naturally produce *different* MT velocities, we found that *similar* paths can exhibit *different* MT velocity profiles. This matters at the level of individual muscles because differences in MT velocities will require unique muscle activation strategies to compensate for force-length/force-velocity properties and modulation of their spinal reflex mechanisms. Importantly, these differences in MT velocities within and across paths establish the neuromechanical landscape that determines the robustness of muscle coordination patterns and reflex modulation strategies during ADLs.
Here we study how initial variability in the direction of a hand path affects the subsequent time histories of MT velocities. As in our prior work, we used an 18 muscle, 2 joint planar arm model to produce 100 random reaching paths for 6 different pairs of points on a tabletop (3 pairs shared the starting position, 3 pairs shared the ending location). Each valid, smooth reaching path was generated (and its MT velocities found) using a pseudo-random clamped cubic spline, parameterized to follow a bell-shaped tangential velocity curve, simulating reaching movements of 35 cm in length with initial errors compatible with those seen in reaching studies in humans. We find that uniform initial error (i.e., variability) across paths induces non-uniform distributions of MT velocities. That is, although the induced MT velocities follow a similar profile for each reaching movement, their distributions/deviations change across them. This implies that some reaching paths may be more or less forgiving to initial errors in muscle coordination or reflex modulation. This has important consequences to the study of healthy movement, as well as the rehabilitation of movement for ADLs in neurological conditions and stroke.

Title: Spatial averaging and inference of decision time in go-before-you-know tasks is not restricted to rapid movements

Authors: *P. ULBRICH[1,2], A. GAIL[1,2,3]
[1]Cognitive Neurosci. Laboratory, Sensorimotor Group, German Primate Ctr., Goettingen, Germany; [2]Georg August Univ., Goettingen, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany

Abstract: Movement trajectories in go-before-you-know action selection paradigms provide a continuous marker for ongoing decision processes. When tight time constraints require subjects to initiate reaching movements before knowing which one of multiple potential targets to choose ('go-before-you-know'), reach trajectories are initially often aimed at the spatial midpoint of the potential targets ('spatial averaging'). The time course at which the trajectory is corrected towards the ultimately chosen target serves as marker for the decision time. These effects are thought to require rapid movements, usually achieved with tapping a touchscreen under tight time constraints. It is unclear if spatial averaging depends on movements with such reduced need for motor control or if slower and more controlled movements can reveal underlying decision processes equivalently.
To test this, we asked subjects (N = 22) to reach towards two potential targets with different reward value using a haptic manipulandum and cursor feedback in 3D space. Different to a previous, touchscreen-based rapid-reach version (325ms reaction time limit and 425ms movement time limit, 40cm distance to target) of this task [1], movement here covered 18cm distance within a 325ms reaction time limit and 500, 700 or 900ms movement time limit. Since subjects did not receive haptic feedback on target acquisition and had to hit a spherical target zone (15mm radius) in 3D, movements required more visuomotor control than tapping on a screen. Actual average movement times were 318, 442, and 639ms, respectively.
Subjects showed spatial averaging with the 900ms time limit, but often guessed and performed direct reaches to one of the two targets with the 500 and 700ms limits. The movement time limit had a larger impact on optimal choice rates (on average 53%, 68% and 94% for 500, 700, and 900ms, respectively) than on successful target acquisition rates (68%, 73%, and 78%).
Our findings suggest that spatial averaging is not restricted to rapid movements, but that there is a minimum movement time needed to elicit these behavioral effects, set by the level of control the movements require. Thus, movements with higher level of control still allow for using go-before-you-know tasks as long as the movement time windows are adequately large. This allows studying decision processes in a wider range of applications, such as effort- based choice tasks , where effort can be operationalized via movement-resistive forces on the manipulandum.

Title: Examining online adjustments to visual and somatosensory target perturbations

Authors: *G. A. MANSON[1], J. BLOUIN[3], D. MANZONE[1], A. KUMAWAT[1], V. CRAINIC[1], L. TREMBLAY[2]
[1]Univ. of Toronto, Etobicoke, ON, Canada; [2]Fac. of Kinesiology and Physical Educ., Univ. of Toronto, Toronto, ON, Canada; [3]Aix-Marseille Univ., Marseille, France

Abstract: Movements to somatosensory targets could be planned using either a gaze-dependent or gaze-independent reference frame. The use of a gaze-dependent frame requires the remapping of somatosensory targets onto an extrinsic coordinate system. Because these additional remapping processes require time and could lead to transformation-induced errors, it is unclear if similar transformation processes are employed for limb trajectory amendments during movement execution. The purpose of the present study was to examine if different online control mechanisms exists for movements to somatosensory targets. For movements to somatosensory targets, it was hypothesized that reaches, made without visual feedback of the limb, would be controlled using gaze-independent reference frame. Because fewer sensorimotor transformations should be required, movements to somatosensory targets would exhibit earlier online trajectory corrections and greater correction amplitudes compared to movements to visual targets. Participants performed reaches to both somatosensory and visual targets in complete darkness. The target either remained stable (control) or was perturbed: 300 ms prior to the movement (before), or 100 ms, or 200 ms after movement onset (that is requiring online corrections). As hypothesized, participants exhibited shorter latencies and online corrections of greater amplitude when aiming to somatosensory targets compared to visual targets. These results provide evidence for the existence of a sensorimotor transformation network capable of performing rapid corrections in gaze-independent coordinates.

Title: Estimating functional muscle parameters using high-density electromyography with a flexible array

Authors: *R. L. HARDESTY, JR[1], V. GRITSENKO[2], S. YAKOVENKO[3]
[1]Neurosci., [3]Human Performance, [2]West Virginia Univ., Morgantown, WV

Abstract: Recent advancements in musculoskeletal modeling have bolstered the feasibility of myoelectric control of closed-loop myoelectric prostheses and functional electric stimulation. However, the transformation of electromyographic (EMG) signals into a device control signal is dependent upon accurate estimation of motor neuron recruitment. Several studies have shown the use of high-density surface EMG for extracting parameters of muscle activity and motoneuron recruitment, such as conduction velocity. We used a flexible, high-density surface EMG grid over extrinsic hand muscles to extract motor unit action potentials from healthy, human participants performing single and multijoint movements. The flexible grid of 96-electrodes 3mm in diameter, spaced 10 mm apart was manufactured by Ripple Inc. (UT). We recorded myoelectric potentials from single-ended electrodes at 30kHz with high-pass filter at 10Hz. Multiple sites provided correlated recordings from finger extensor muscles. A conductive electrolyte gel was applied under the recording sites and was shown to decrease electrode impedance (2-4kΩ) and facilitated the recording of motor unit action potentials. This resulted in selective EMG patterns for single finger extensor muscles with high signal-to-noise ratio, including small thumb muscles. We also isolated individual motor unit action potentials from specific muscles spanning the wrist and hand and calculated muscle fiber conduction velocity to approximate motor neuron recruitment levels. These high-quality signals can provide a more dexterous control signal to drive myoelectric prosthetics.

Title: Neural correlates of kinematic planning and execution

Authors: *V. N. THAKUR[1,3], A. N. MURTHY[2]
[2]Neurosci., [1]Indian Inst. of Sci., Bangalore, India; [3]Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: Studies of movement kinematics have largely focused on representations of target location and displacement concerning eye/hand position. Much less is known regarding the representation of other aspects of kinematics such as the velocity of the movement. To study this aspect of kinematic planning, we designed a delayed reaching task where subjects made hand movements with either slow or fast velocities during which we recorded EEG signals from the parietal area, motor cortex and premotor cortices in 10 human subjects. We hypothesized that such a task should reveal a velocity planning signal in the instruction period and hold time delay which would facilitate planning. However, no distinct velocity related signal was observed in the time domain in all the above mentioned cortical areas after normalizing for differences in reaction time. Furthermore, we analyzed the LRP signal in the frequency domain following movement onset. Even though alpha (8-12 Hz) and beta (12-30 Hz) band powers decreases during reaction time and movement duration, we observed that neither frequency power distinguished between the velocity conditions. However, interestingly, gamma band activity (30-70 Hz), which has been shown to correlate with target selection (Aoki et al., 1999), showed a modulation with velocity during movement execution. i.e., higher gamma band power (1.31 dB +/- 0.43) for higher velocity and lower (0.31 dB +/- 0.14) for slow velocity trials. Further, this modulation began relatively earlier for parietal cortex compared to premotor and motor cortices with respect to movement onset. Taken together, our study indicates that velocity signals are more robustly expressed in gamma oscillations and suggest that these computations may be generated during the execution of movements.

Abstract: The preparation of a desired motor action can influence both voluntary and involuntary movements, but it is unknown to what extent planning processes are shared between these mechanisms of movement initiation. Voluntary movements are relatively slow, but motor planning allows us to move more quickly in simple reaction time tasks. External stimuli can trigger faster initiation when a motor plan has been prepared. For example, a startling acoustic stimulus (SAS) can trigger initiation of a prepared movement faster than is possible with voluntary initiation. Differences in movement latencies are thought to result from the initiation mechanisms. SAS-triggering is mediated by subcortical pathways and causes a faster rise to threshold for motor output than voluntary initiation which is triggered cortically by the decision to move. However, voluntary initiation can be forced to occur faster than in typical reaction time tasks when the decision to move is made independently of planning processes to meet task requirements. It is unknown if shorter latencies result solely from differences in initiation mechanisms or if differences in the time required for motor planning also contribute. The objective of this work was to determine if a motor action is planned and accessible at the same latency for voluntary and involuntary movements. Ten subjects (26±4 years old, 6 females) were instructed in a ballistic reaching task. The dominant, right arm was supported on a table with a low-friction interface. Subjects were trained in a forced initiation paradigm to time voluntary reaches with a predictable cue given by a sequence of auditory tones (similar to Haith et al., *J Neurosci* 2016). One of four possible targets was presented 0-380 ms before the cue to reach. SAS was delivered 150 ms before the cue in 16% of reaches to investigate a subset of target presentation times, 20-200 ms. We quantified the probability of reaching to the correct target versus the time between target presentation and movement onset. We quantified motor planning time when the probability was 0.625. We chose 0.625 as it is halfway between chance and 1. Motor planning time for SAS-triggered movements did not significantly differ from voluntary initiation ($p>0.05$). Average motor planning time was 146 ms for voluntary (95% CI: [138, 156] ms) and 148 ms for SAS-triggered (95% CI: [112, 156] ms) movements. These results suggest a

motor action is planned and accessible for voluntary and involuntary movements at the same short latency. The novel use of SAS in a forced initiation paradigm suggests planning processes may be shared between the voluntary and involuntary initiation mechanisms used to trigger ballistic reaches.

Title: BOLD representations of arm movement rate and speed in fMRI

Authors: *S. SHIRINBAYAN, A. DREYER, J. RIEGER
Dept. of Psychology, Carl Von Ossietzky Univ. of Oldenburg, Oldenburg, Germany

Abstract: Among the kinematic variables of arm movements, movement speed (displacement per time unit) and movement rate (number of movement initiations per time unit) have been well-studied using electrophysiological and neuroimaging techniques. However, in most of the previous studies rate and speed of movement were highly correlated. This correlation hinders an unequivocal interpretation of the corresponding observed brain activations. In the current study we employed a two-by-two factorial design to investigate the pattern of the fMRI activation associated with rate and speed when they vary independently. We analyzed fMRI data acquired from 21 healthy subjects (10 females, age range: 20 – 32, mean age: 26) who were instructed to perform a target tracking task using a steering wheel. To examine whether rate and speed are the characteristic of successive or individual movements we performed block-based and event-related second-level GLM analyses. When data were analyzed with a block-based approach, no significant effects (FWE corrected at $p < 0.05$) of speed variation was observed, but we found differential rate-related BOLD-activation in contralateral primary sensorimotor cortex (SMC), bilateral putamen, contralateral thalamus and ipsilateral cerebellum. On the other hand, when we analyzed the data with an event-related GLM, taking individual movements into account, we found no significant rate-related activations, but contrasting levels of movement speed revealed activation in the contralateral primary SMC, contralateral thalamus, and ipsilateral cerebellum. The differential results for the block-based and the event-related analyses suggest that movement speed variations have stronger representation in fast BOLD-modulations following individual movements whereas rate variations have stronger representation in mean BOLD-activations. The latter effect could be due to build up effects caused by overlapping BOLD-responses. These

different representations of speed and rate in the BOLD-responses need to be considered when disentangling their effects.

Title: There is an energetic cost to movement jerk during human reaching

Authors: *J. D. WONG[1], T. CLUFF[2], A. D. KUO[3]
[2]Fac. of Kinesiology, Hotchkiss Brain Inst., [3]Fac. of Kinesiology, [1]Univ. of Calgary, Calgary, AB, Canada

Abstract: When people perform reaching movements, their hands typically follow smooth trajectories that may be predicted by minimizing the time-derivative of acceleration, or jerk. Minimization of jerk underlies a number of computational models for reaching, but its functional role remains unexplained. Reaching has been thought to entail trivial metabolic energy cost but non-trivial demands for speed and accuracy. In particular, accuracy is negatively affected by non-smooth neural control signals ("signal-dependent noise," Harris and Wolpert, 1998). The functional benefit of minimizing jerk might therefore be to improve accuracy. However, recent evidence (Huang et al., 2012) shows that reaching does exact a small but meaningful metabolic cost, in contrast to previous assumptions. But it remains unknown whether there are metabolic consequences to jerky movements. Here we show that jerky arm movements are indeed energetically costly, in an amount that increases with the time-derivative of acceleration. This suggests that energetic cost may help explain the minimization of jerk and its role in stereotypical reaching trajectories.

We tested the cost of movement jerk while healthy adults (N=12) performed reaching movements with their arms supported by a planar manipulandum (Kinarm, BKin Technologies, Kingston Canada). They performed cyclic movements between two points, at a series of four predetermined amplitudes and frequencies. Movement frequencies varied between 0.75 and 1.5 Hz, while amplitude was scaled with frequency to the -3/2 power, a relationship intended to increase jerk while keeping the average positive mechanical power approximately constant. We recorded reaching kinematics as well as oxygen consumption (Cosmed Inc,) to estimate the energetic cost of movement. Each trial lasted 6 min to allow time for steady state respirometry.

Despite mechanical power being held approximately constant, the metabolic power expended for reaching increased with greater jerk, from 25.4 to 52.2 W (P = 0.012). The cost increased more than twofold when movement frequency doubled from 0.75 to 1.5 Hz. These results support the hypothesis that jerky reaching movements have a metabolic energetic cost and may thus be one reason people tend to minimize it.

Title: The effects of biological sex and ovarian hormones on exercise-induced neuroplasticity

Authors: *J. EL-SAYES[1], C. V. TURCO[2], L. E. SKELLY[2], C. NICOLINI[2], M. FAHNESTOCK[3], M. GIBALA[2], A. J. NELSON[2]

Abstract: Acute aerobic induces short-term increases in excitability and reductions in inhibition of the motor cortex, as assessed via transcranial magnetic stimulation (TMS). To date, it is unknown whether biological sex and ovarian hormones impact exercise-induced neuroplasticity. Biological sex may influence the propensity for plasticity, as females show greater neuroplasticity induction via repetitive TMS compared to males. Further, ovarian hormones may impact the opportunity for exercise-induced neuroplasticity. Repetitive TMS yields greater neuroplasticity during ovulation, when estradiol levels are higher, compared to menstruation. The present study investigated the effects of biological sex and ovarian hormones on the magnitude and direction of neuroplasticity induced by acute aerobic exercise. Fourteen females and fourteen males (ages 18-30 years) participated in two sessions in which dependent measures were acquired before and following a single bout of aerobic exercise. The two groups were matched for cardiorespiratory fitness (VO_2max) as a function of fat-free mass (F: 58.9 ± 7.0; M: 55.7 ±7.4 ml/kgFFM/min). Females were tested in the follicular (~day 7) and luteal (~day 21) phases of the menstrual cycle. Males were also tested on two sessions separated by ~14 days. The exercise intervention consisted of 5 minutes of warm up, 20 minutes of moderate intensity cycling at 65-70% maximal heart rate, and 5 minutes cool down. Ratings of perceived exertion and heart rate were recorded throughout. TMS was used to obtain motor evoked potential (MEP) recruitment curves, short-interval intracortical inhibition (SICI), and intracortical facilitation

(ICF) from the right first dorsal interosseous muscle. MEP recruitment curves were assessed as a function of resting motor threshold (90-200%RMT). SICI and ICF were assessed using 80% and 90% active motor threshold as the conditioning stimulus intensities with interstimulus intervals of 2ms and 10ms, respectively. In addition, blood measures of estradiol, progesterone, testosterone, and brain-derived neurotrophic factor were assessed on both testing sessions. Preliminary results indicate that females show greater increases in MEP recruitment curve following exercise compared to males, and this occurs regardless of menstrual cycle phase. ICF does not change following exercise for males or females on either testing session. These data suggest that females show greater exercise-induced neuroplasticity compared to males, regardless of menstrual cycle phase.

Title: M1 tdcs does not influence performance of a fine-motor skill tweezer task

Authors: N. ZDANOWICZ, A. MEEK, D. GREENWELL, M. WOLFE, *Z. A. RILEY
Indiana Univ. Purdue Univ. at Indianapolis, Indianapolis, IN

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive brain stimulation technique that has been applied to the primary motor cortex (M1) to facilitate learning of skilled, dexterous hand tasks. Recent studies have even used it to shorten training periods for learning precise neurosurgical skills with small instruments. However, it is unknown if the acquisition of the motor skill is due to consolidation, or learning over many days, or if skill proficiency can be observed in as little as a single practice session. The purpose of this study was to examine performance of a fine-motor skill tweezer task with the non-dominant hand while the subject received either anodal (facilitate learning), cathodal (inhibit learning), or sham stimulation conditions. 53 healthy young adults (age: 22.8 ± 3.3) were randomized into either anodal (n=16), cathodal (n=19), or sham (n=18) stimulation groups. The Edinburgh Handedness Inventory was used to determine their hand-dominance. Subjects completed a pre-test of the O'Connor Tweezer Dexterity Test followed by 20 minutes of practice with concurrent tDCS (based on their randomized condition) and then a post-test. The task consisted of using tweezers to place small metal pins into individual holes on a test board with the non-dominant hand. Pre- and Post-test performance was assessed by the time it took to place 50 pins. For practice, subjects filled one row of pins at a time followed by 30 seconds of rest after each completed row. tDCS electrodes

were placed over the M1 cortical area for the non-dominant hand and the contralateral supraorbital area. A current strength of 1mA was applied for 20 minutes in the anodal and cathodal conditions. Sham stimulation was applied according to established blinding procedures with a brief ramp in current followed by the current ramping back down. Practice performance was assessed by dividing the total practice into quartiles and assessing the average time per row for each quartile. All data were logarithmically transformed for parametric testing of the geometric means. There was a significant main effect of time ($p<0.001$) as all stimulation groups increased their speed to place 50 pins from pre- to post-test ($p<0.001$ to $p=0.025$). During practice, the average time spent placing each pin increased significantly from the first 25% to the last 25% of practice in the cathodal condition ($p<0.001$). Performance remained consistent across practice for Anodal and Sham conditions. The results indicate that anodal stimulation did not facilitate learning in the tweezer task, but cathodal stimulation can slow the acquisition of the skill at least in a single-session of practice.

Title: Proprioceptive and sensorimotor neurophysiological changes associated with complex skill learning

Authors: *J. L. MIRDAMADI[1,2], C. R. SEIGEL[3], H. J. BLOCK[1,2]
[1]Dept. of Kinesiology, [2]Program in Neurosci., [3]Col. of Arts and Sci., Indiana Univ., Bloomington, IN

Abstract: Motor learning involves changes in behavior through practice and has been associated with plasticity in motor brain regions. It is well established that sensory information is important for motor control, yet its role in learning has only recently been investigated. Motor adaptation, a paradigm in which errors improve trial-by-trial in response to a perturbation, has been linked to plasticity in somatosensory cortex and shifted proprioception, or limb position sense. Further, individual differences in adaptation have also been linked to differences in somatosensory cortical activity. The importance of sensory processing in complex motor skill learning is less clear. Unlike adaptation, skill learning involves the acquisition of new movement patterns in the absence of a perturbation with performance limited by the speed-accuracy tradeoff. Here we

investigate the somatosensory contributions to motor skill learning at the behavioral and neurophysiological level in the right upper limb. Healthy young adults made visually-guided 2D reaching movements through an irregular-shaped track (20 cm x 20 cm horizontal workspace) as quickly and accurately as possible using a robotic manipulandum under null force. Subjects practiced movements over two consecutive days at a restricted speed range. Skill was quantified by measuring motor performance (accuracy inside track) across 5 speed ranges before practice on day 1 and again on day 3. Proprioception was measured across training and at retention using a passive two-alternative choice task to quantify bias (accuracy) and sensitivity (acuity). Short latency afferent inhibition, the reduction in motor evoked activity when a single pulse of transcranial magnetic stimulation (TMS) is preceded by a median nerve stimulus, was measured before and after practice. Based on previous findings linking the magnitude of SAI to somatosensory cortical (SI) activity, we hypothesized that changes in SAI would be related to proprioceptive changes and skill learning. Preliminary data (N= 7) indicate that proprioception largely improved, consistent with the literature. Excitability in primary motor cortex (M1) generally increased after practice, whether substantial skill learning occurred or not. We therefore speculate that M1 excitability changes result from motor execution rather than learning. However, SAI was reduced in some individuals, likely reflecting decreased S1 activity, and enhanced in others, likely reflecting increased S1 activity. This appears linked to individuals' amount of skill learning. Changes in SAI may be an important mechanism by which individuals learn new skills.

Title: Slow oscillating transcranial alternating current stimulation applied during a motor learning task enhances the effectiveness of learning

Authors: *M. V. SALE[1], A. KUZOVINA[2]
[1]Univ. of Queensland, St Lucia, Australia; [2]The Univ. of Queensland, Brisbane, Australia

Abstract: Repetitive training of a motor learning task can induce changes in motor performance arising from neuroplasticity. Retention of motor learning occurs via an encoding process, during which rapid neuroplastic changes occur in response to learning. Previous studies show that transcranial alternating current stimulation (tACS), a form of non-invasive brain stimulation, can

enhance encoding of declarative memories during wakefulness. However, the effect of tACS on *motor* learning in the awake brain is unknown. In this study, healthy 18-35 year old participants (n=28) received 0.75Hz tACS for 30 minutes during a ballistic thumb abduction motor learning task. Neuroplastic changes were quantified by measuring motor-evoked potential (MEP) amplitude of the *abductor pollicis brevis* muscle, and training-related behavioural effects were quantified by assessing changes in thumb abduction acceleration. These outcome measures were reassessed immediately after the motor learning task to quantify short-term changes, and approximately 24 hours later to assess longer-term changes. Participants in both active and sham stimulation conditions demonstrated significant increases in thumb abduction acceleration immediately after the motor learning. Further, participants in the active group maintained significantly higher thumb acceleration 24 hours later (t_{26}=2.0611, P=0.0494). There were no significant changes or inter-group differences in MEPs for both conditions. The results suggest that 0.75Hz tACS applied during motor learning enhances encoding, which manifests as enhancement in longer-term task consolidation. This has potential implications in neurorehabilitation where functional improvement relies on repetitive task re-learning, and may benefit from concurrent application of tACS to facilitate encoding.

Title: Optimized 10-cage video system for automated mouse phenotyping with open-source software

Authors: P. CHARLES[1], A. ISTUDOR[1], A. SCHATZ[1], *Y. WINTER[2]
[1]Humboldt Univ., Berlin, Germany; [2]Humboldt Univ. - Inst. Biologie, Berlin, Germany

Abstract: The distribution and chaining of basic behavior elements throughout the 24h-day mirrors the state of an animal's behavior control circuitry. Thus, the analysis of undisturbed voluntary behavior can be used to identify a brain phenotype or indicate behavioral disturbances. Recording behavior over 24-hours results in big data. The only realistically feasible approach to collect and analyze such data is through computer automated methods. One standard approach is to use machine vision algorithms to extract data from video and then use trained neural networks and machine learning methods to automatically assign behavior categories to streams of image data. For mice, both proprietary and open-source software packages are available. They make

increasing use of both deep learning toolboxes and GPU parallel computing for boosting PC processing. In consequence, even on a larger scale video based phenotyping is becoming feasible. One caveat remains the initial quality of the images which greatly influences subsequent behavior processing. Image quality depends on the combination of cage setting, illumination, camera positioning, focal length, shutter speed and depth of field. We developed a multiple-cage platform for video phenotyping mice where we optimized each of these image acquisition parameters. The result is a compact and self-contained 10-cage video acquisition system suitable for long term usage in any environment. These videos can be used with any software for mouse behavior analysis, but it is optimized for our updated version of the (open source) software developed by the group of T. Poggio, M.I.T. (Jhuang et al., 2010, Nature Communications) that reliably detects the eight most common mouse behavior categories. With our platform, the parallel data acquisition and behavior analysis for 10 mice is possible in effectively real-time running three PCs in parallel. One PC acquires data and two PCs, with graphic card processing, perform post hoc analysis. This technology is setting the stage for the economical, large scale, automated video-phenotyping of mice.

Title: Center-surround organization of short-term plasticity induced by transcranial static magnetic field stimulation of the human motor cortex

Authors: *C. AMMANN[1], M. DILEONE[1,2], A. OLIVIERO[3], G. FOFFANI[1,3]
[1]CINAC, Univ. Hosp. HM Puerta del Sur, Mostoles, Spain; [2]Advanced Neuro-rehabilitation Unit, Hosp. Los Madroños, Brunete, Madrid, Spain; [3]Sescam, Hosp. Nacional de Parapléjicos, Toledo, Spain

Abstract: Transcranial static magnetic field stimulation (tSMS) is a new non-invasive brain stimulation technique that decreases corticospinal excitability of the stimulated motor area (Oliviero et al., J Physiol 2011). Temporal features of tSMS effects indicate that the duration of tSMS-induced cortical plasticity is dependent on the duration of stimulation (Dileone et al.,

Brain Stimul 2018). However, spatial features of tSMS modulation have not been explored yet. The aim of this study was to examine the spatial organization of tSMS-induced effects. We recruited thirteen healthy subjects that participated in a crossover, double-blinded and counterbalanced study receiving 10 min tSMS through a cylindrical neodymium magnet of 45 mm diameter on the motor area corresponding to the first dorsal interosseous (FDI), in one session contralateral and in another session ipsilateral to the studied muscles of the left hand. Motor evoked potentials (MEP) induced by transcranial magnetic stimulation (TMS) were recorded from the FDI and extensor ulnaris carpis (EXT). For each session we determined two optimal 'hot spots' (mean distance between 'hot spots' = 26.8 ± 4.4 mm) for eliciting MEPs in the resting FDI and EXT. Before and after tSMS we recorded 80 MEPs randomizing 'hot spots' and TMS output intensities (110%, 120%, 130%, and 140% of resting motor threshold - RMT). As expected, tSMS significantly reduced corticospinal excitability of the FDI, when TMS output intensity that evoked a peak-to-peak MEP amplitude of ~ 1 mV was selected and at 110% RMT. Interestingly, most subjects that showed decreased excitability at the stimulated FDI 'hot spot' experienced an increased excitability at the nearby EXT 'hot spot'. Specifically, we found a significant positive correlation between the individual FDI-EXT cortical distance and the effect induced by tSMS on the EXT 'hot spot', i.e., the more distant the two 'hot spots' the greater the increase of EXT MEP amplitude. The interhemispheric modulation of corticospinal excitability was highly variable and will require further investigation. In conclusion, 10-min-tSMS induces short-term changes in corticospinal excitability with a specific spatial pattern of center-inhibition and surround-facilitation. These results uncover a center-surround organization of short-term plasticity in the human motor cortex.

Title: Corticospinal transmission in healthy humans is facilitated by repeated pairing of motor cortical and transcutaneous spinal stimulation

Authors: *R. HANNAH[1], P. BORGAS[1], L. DUFFELL[2], J. C. ROTHWELL[1]
[1]UCL Inst. of Neurol., London, United Kingdom; [2]Med. Physics and Biomed. Engin., UCL, London, United Kingdom

Abstract: Electrical stimulation of the spinal cord combined with volitional motor activity has been reported to improve motor control in individuals with spinal cord injury, but the mechanism for these improvements is unknown. Studies in primates suggest that timing spinal cord stimuli to coincide with descending motor commands enhances transmission at the corticospinal-motoneuronal synapse as a result of spike-timing dependent plasticity (STDP). Here we sought evidence for similar STDP-like mechanisms in the human spinal cord using non-invasive transcranial magnetic stimulation (TMS) and transcutaneous spinal stimulation (TSS). An advantage of this approach is that we can precisely control the timing of descending corticospinal and afferent (dorsal root) volleys, evoked by TMS and TSS respectively, converging on the spinal motoneurones. Eleven healthy volunteers (5 females, mean age 27 years) completed two sessions in which they received repeated pairing of TMS over the leg motor area and TSS over the lumbar region (100 pairs, 8 seconds apart). Corticospinal and afferent volleys were timed either to converge on spinal motoneurones at the same time, i.e. 0 ms delay between their arrival (Pstim0), or such that afferent volleys reached the spinal motoneurones 5 ms before the corticospinal volleys (Pstim5). Motor evoked potential (MEP) and spinal root reflex (SRR) amplitudes were recorded via surface EMG from the tibialis anterior and soleus muscles. In two individuals electrical stimulation was used to evoke thoracic MEPs (TMEPs) that activate corticospinal axons directly and therefore test transmission at the corticospinal-motoneuronal synapse. Agonist and antagonist EMG, peak force and peak rate of force development were recorded during ballistic dorsiflexion contractions as measures of motor control. Measurements were completed prior to and 5 minutes post the paired stimulation intervention. The Pstim0 protocol facilitated MEPs, whereas PStim5 had no effect. PStim0 also increased the amplitude of TMEPs (N = 2), implying that the changes were due to altered corticospinal-motoneuronal transmission rather than cortical excitability. SRRs, and performance and muscle activation during the ballistic contractions were unaffected by either protocol. The present data are consistent with the notion that spinal cord stimulation paired with descending corticospinal activity may induce STDP-like changes at the corticospinal-motoneuronal synapse. More sensitive measures of motor control may be required to uncover the functional consequences of this enhanced corticospinal transmission.

Title: Theta burst electrical stimulation of the motor cortex produces functional reorganization of the corticospinal system in rats

Authors: *A. AMER[1,2,3], A. SARKAR[2,3], E. HARA[2,3], A. KHAN[3], Z. MIYFA[3], K. REN[4], L. RAMEAU[2,3], J. H. MARTIN[1,2,3]
[1]The Grad. Ctr. At CUNY, New York, NY; [2]Molecular, Cell. and Biomed. Sci., CUNY Sch. of Med., New York, NY; [3]Neurosci., Ctr. of Discovery and Innovation of CCNY, New York, NY; [4]Psychology, Hunter Col., New York, NY

Abstract: Theta burst stimulation (TBS) of motor cortex (MCX) is a powerful neuromodulatory protocol for producing augmentation of MCX-evoked muscle responses and strengthening of synaptic transmission in healthy human and animal subjects and after motor systems injury. After a single epoch of TBS, stimulation-evoked motor responses (MEPs) are facilitated for approximately 30 minutes in humans and animals. Whereas acute TBS is well-studied, and its role in motor LTP has been characterized, the effects of chronic TBS are not-well understood. The aims of this study were to determine if there is day-to-day carryover of MEP augmentation produced by TBS and to further elucidate the anatomical and molecular underpinnings of this robust corticospinal system plasticity.
In this study, we activated MCX by intermittent TBS (iTBS) for varying times daily and for one or more days to drive the establishment of strong connections with spinal cord circuits in naïve rats. We aimed to identify MEP amplitude changes, corticospinal tract (CST) structural changes, and signaling pathway changes. We found that one epoch (3 minutes) of iTBS produced strong EMG potentiation lasting for up to 45 minutes. Five contiguous epochs of iTBS during a single session (27 minutes), prolonged EMG potentiation for 24-48 hours. Five epochs of iTBS daily, for 10 days, increased the slope of contralateral M1-to-muscle recruitment curves, and this augmentation persisted for at least 10 days after the end of stimulation. We next assayed CST structural changes that could support the enhanced motor responses. Chronic stimulation promotes outgrowth of the stimulated CST in the contralateral spinal cord intermediate zone. 3D reconstruction of CST synapses, defined by the co-expression of the pre- and post-synaptic markers; VGlut1 and PSD95 in labeled CST axons, revealed a significant increase in the total number and volume of PSD95 puncta as well as the total number and volume of colocalized VGlut1 and PSD95 clusters. Finally, we identified upregulation of mTOR and Jak/STAT signaling (Ps6 and PSTAT3) using Western blotting of MCX homogenates (whole cell and synaptosomal fractions) and immunohistochemistry of layer 5 pyramidal neurons.
Our findings suggest incremental carryover of MEP LTP after repeated epochs of iTBS and, remarkably, emergence of persistent MEP augmentation that associates with upregulation of known axon growth signaling and cortical plasticity markers. We hypothesize that iTBS both lays the groundwork for enhanced plasticity in MCX and activates an axon growth program. Together, these changes in spared corticospinal motor circuits could support recovery after injury.

Title: Timing and intensity of vagus nerve stimulation influences motor cortex plasticity

Authors: *R. A. MORRISON, D. HULSEY, K. ADCOCK, Y.-Y. TSANG, A. KUO, J. JOHN, R. L. RENNAKER, M. P. KILGARD, S. A. HAYS
Univ. of Texas At Dallas, Richardson, TX

Abstract: Stroke and traumatic brain injury (TBI) are two of the leading causes of long-term motor disability in the United States. While extensive rehabilitation after these injuries can lead to partial recovery, many still suffer chronic motor impairment afterward. Recovery is widely believed to be a result of plasticity in brain areas surrounding the injury. Recently, studies have suggested that administering vagus nerve stimulation (VNS) during rehabilitation can enhance recovery by increasing plasticity in activated motor circuits. If VNS-mediated recovery is dependent on enhanced synaptic plasticity, it is possible that optimizing VNS delivery for plasticity could yield even greater recovery. Here, we test the effect of varying the timing and intensity of VNS to characterize parameters that would yield the greatest enhancement of plasticity. To determine the effect of varying stimulation intensity, rats were trained to perform a skilled motor task in which a lever was pressed for a food reward. Once proficient, rats underwent five additional days of behavioral training in which low intensity VNS (0.4 mA), moderate intensity VNS (0.8 mA), high intensity VNS (1.6 mA), or sham stimulation was paired with forelimb movement. After completion of behavioral training, intracortical microstimulation (ICMS) was used to document movement representations in the motor cortex. We find that moderate intensity VNS significantly enhances reorganization of motor representations, while low and high intensity VNS fail to enhance motor cortex plasticity. Additionally, to ascertain whether the interval between stimulations influenced the degree of plasticity, a separate cohort of animals underwent five days of VNS pairing with short stimulation intervals (8 sec) or long stimulation intervals (30 sec). These results suggest that it may be critical to titrate the intensity of VNS that patients receive during rehabilitation, and highlight the importance of determining the optimal stimulation parameters for clinical implementation of VNS.

Title: The use of tDCS to enhance learning of a dart throwing task

Authors: *A. W. MEEK[1], D. GREENWELL[1], M. WOLFE[1], B. J. POSTON[2], Z. A. RILEY[1]
[1]Dept. of Kinesiology, Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN;
[2]Kinesiology and Nutr. Sci., Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive brain stimulation technique that is used to increase (anodal stimulation) or decrease (cathodal stimulation) skilled motor performance depending on the polarity of the applied current. Most studies using tDCS have focused on simple hand and finger based motor skills such as pinch force tasks or tracing tasks, though it is unknown if tDCS can influence learning of more complex unilateral motor skills such as throwing. The purpose of this study was to examine how tDCS influences the acquisition of dart throwing skills with the non-dominant hand in healthy subjects. 58 subjects (age: 23.3 ± 3.9) were randomized into either anodal (n=20), cathodal (n=19), or sham (n=19) stimulation groups. The Edinburgh Handedness Inventory was used to determine their hand-dominance. Subjects completed a pre-test of throwing accuracy followed by 20 minutes of practice with concurrent tDCS (according to their randomized condition) and then a post-test. The task consisted of throwing darts at the center (bulls-eye) of a dartboard from a distance of 10 feet. Accuracy was measured as the distance of each throw from the center of the bulls-eye. Gain scores (score - baseline) were calculated for each quartile of the practice throws and the post-test. tDCS electrodes were placed over the M1 cortical area for the non-dominant hand and the contralateral supraorbital area. A 1mA current was applied for 20 minutes in the anodal and cathodal conditions. Sham stimulation was applied according to established blinding procedures with a small ramp in current followed by the current shutting off. The results showed that anodal stimulation significantly improved performance between the first 25% and second 25% of practice throws ($p < 0.001$) and this improvement was maintained through the post assessment ($p = 0.013$). Cathodal and sham stimulation conditions showed no significant increase in gain scores across time. The gain scores for the anodal group were significantly higher than cathodal gain scores at the second 25% of practice ($p=0.036$) and remained significantly better through the post-test ($p=0.03$). There was a significant difference between the anodal and sham group gain scores in the last 25% of practice ($p=0.017$) with the anodal group showing greater

improvement. These results indicate that the acute application of anodal tDCS during a single short-term practice session can enhance the acquisition of a complex skilled motor task such as dart throwing, whereas the sham stimulation condition did not show improvement with practice. The results were polarity dependent as well, since the cathodal stimulation appeared to block learning.

Title: Kinesthetic illusion shapes motor cortex plasticity induced by action observation

Authors: *M. BOVE, M. BIGGIO, P. RUGGERI, L. AVANZINO, A. BISIO
Univ. of Genoa, Genoa, Italy

Abstract: Acquisition of new motor abilities depends heavily on movement execution. However, recent evidences pointed out the role played by action observation (AO) in acquiring new motor skills and evoking cortical plasticity. These phenomena could happen only when AO immediately precedes or is concurrent to movement execution, or when peripheral electrical stimulation congruent with the observed action are delivered during AO. In the present study, we combined action observation with the sensory afferent signals specific for movement execution, i.e. the proprioceptive information coming from the lengthening muscle, which was generated by means of a mechanical vibration able to evoke a kinesthetic illusion (KI) of movement. The proprioceptive stimulation was delivered by means of a vibrator positioned over the extensor pollicis brevis muscle, the latter generating an illusory sensation of thumb abduction. The experiment was composed of two conditions where the observed action and the afferent signal could be either congruent or incongruent. In the congruent condition (AO-KI CONGR) participants observed a 10-sec video showing the thumb abduction of the right hand (generated by the activation of the abductor pollicis brevis muscle - APB), whilst in the incongruent condition (AO-KI INCONGR) they observed a thumb adduction. The activity of the primary motor cortex (M1) in correspondence to the APB muscle area was evaluated by means of recruitment curves before, immediately after and 30 and 60 minutes after the end of the stimulation. The results showed a significant increase of the M1 excitability, as measured by the slope of the recruitment curves lasting until 60 minutes after AO-KI CONGR. No differences were observed before and after the administration of AO-KI INCONGR. Furthermore, in a control experiment we tested whether this effect was specific for the kind of sensory input, and a

tactile vibration was delivered during the observation of thumb abduction. This protocol did not evoke any changes in M1 excitability. Following these results, we proposed that AO, when combined to KI evoked by a proprioceptive stimulation, was able to evoke plastic changes in M1 activity. Since the illusory sensation of movement was crucial for this to occur, we might speculate that the locus where the two afferent signals combined was M1. These results candidate AO-KI as possible methodology to train the motor system without moving.

Title: Performance of a timing-based hand dexterity video game with M1 tDCS

Authors: *M. WOLFE[1], A. ZAKERESFAHANI[1], M. WILSON[1], A. W. MEEK[1], B. J. POSTON[2], Z. A. RILEY[1]
[1]Dept. of Kinesiology, Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Kinesiology and Nutr. Sci., Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Transcranial direct current stimulation (tDCS) has been applied to the motor cortex (M1) to facilitate learning of skilled, dexterous hand tasks. However, when there is a timing component to the motor skill, tDCS is usually applied to the cerebellum. The purpose of this study was to determine if M1 tDCS could improve performance of a motor skill that required dexterous finger movements and timing. 34 healthy adults (age: 22.8 ± 2.7) were randomized into either anodal (n=19) or sham (n=15) stimulation groups. The Step Mania game is a timing-based video game that involves pressing the correct arrow keys on a keyboard at specific times when scrolling icons overlapped on a computer screen. Each subject practiced the task at least two times to obtain a pre-practice score. Each key press corresponded to a time relative to the optimal key pressing time. This put each key press into bins corresponding to an accuracy score. If the subject pushed the key optimally they were given a score of 1, and this score decreased as they were further away from the target (0.75, 0.5, 0.25, 0, and a complete miss, -1). Scores for each trial were an average these numbers. Each subject completed ~2 minutes of practice followed by ~2 minutes of rest and repeated this 5 times for 20 total minutes of practice. Post-test scores were obtained 5 and 10 minutes following practice. During practice, tDCS electrodes placed over the M1 cortical area for the non-dominant hand and the contralateral supraorbital area delivered a current of 1mA in the anodal condition. Sham stimulation was applied according to established blinding procedures with a brief ramp in current followed by the current ramping

back down. Gain scores (score – baseline) were calculated for each condition. Gain scores were similar for practice trials 1 and 2, but the anodal stimulation produced significantly greater gain scores during practice trials 3 and 4 (p=.047 and p=0.043, respectively). Gain scores did not significantly improve across time with sham stimulation, whereas anodal stimulation resulted in significantly higher gain scores at both 5 minutes (p=0.04) and 10 minutes (p=0.04) post-practice. These results show that after the initial few trials subjects not receiving anodal tDCS did not continue to improve for the duration of the practice, whereas the anodal stimulation resulted in continued improvements. In the context of motor learning, within a single session, it appears that anodal tDCS paired with practice can be more effective than practice alone for a timing-based video game task.

Title: Movement-dependent electrical stimulation for promoting cortico-cortical plasticity

Authors: *S. MOORJANI, S. WALVEKAR, S. I. PERLMUTTER, E. E. FETZ
Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: The strength of synaptic connections between motor-cortical sites in monkeys has been modified by spike-triggered stimulation[1] and electromyographic-activity-triggered stimulation.[2] We investigated a conditioning protocol in which electrical stimuli were triggered by movement to induce simultaneous activation of neurons at two motor-cortical sites. Such movement-triggered stimulation (MTS) led to strengthening of cortical connections that was strongly dependent on the behavioral context of the conditioning stimuli. Conversely, preventing co-activation led to weakening of connections.
Two monkeys were implanted with microwire electrodes placed bilaterally in the sensorimotor cortex. The strength of synaptic connections between sites was documented by the size of cortical evoked potentials (CEPs) recorded at one site after stimuli were delivered at the other site. Monkeys performed an alternating wrist flexion-extension target-tracking task involving a 1.6-s hold time. MTS was delivered for 90 min during flexion or extension holds while monkeys

performed the task. Movement-related activity at two motor-cortical sites (Nrec and Nstim) was inferred from the motor output elicited by stimulation at those sites. When MTS was delivered to Nstim during movements that activate neurons at Nrec, MTS produced dramatic strengthening of connections when paired with relevant activity, as seen by an increase in the size of CEPs evoked at Nstim by test stimuli at Nrec. In some cases, CEPs were over 300% larger after conditioning compared to preconditioning level. The resultant plasticity persisted for over 2 weeks during which the monkey's wrist activity dictated the strength of the connection, with larger gains coinciding with the monkey's higher activity levels. Importantly, neither activity nor conditioning alone produced similar effects, emphasizing the importance of behavioral context on the resultant plasticity. Conversely, when MTS was delivered to Nstim during movements that reduced activation of neurons at Nrec, the connection was depressed by 180%. We are investigating the mechanisms underlying MTS-induced plasticity, but our analyses to date suggest that modifications in CEP size were unlikely to have been produced by changes in general excitability.
Our data show that MTS can create conditions in which behavior drives conditioning-induced gains long after the stimulation has ended. Combining MTS with use-dependent physical therapies may enhance recovery outcomes after injury, a research direction we are pursuing in spinal-cord injured rats.

Title: Prevalence of BDNF polymorphism in musicians: Evidence for compensatory motor learning strategies in music?

Authors: *T. L. HENECHOWICZ[1], J. L. CHEN[2], L. G. COHEN[3], M. H. THAUT[1]
[1]Music and Hlth. Sci. Res. Collaboratory, [2]Kinesiology, Univ. of Toronto, Toronto, ON, Canada; [3]NIH/NINDS, Bethesda, MD

Abstract: Objective/Rationale. The study compared the prevalence of Val66Met BDNF SNP polymorphism (r6265) in musicians in professional training (N=30, M=15) to an ethnically matched general population sample from the 1000 Human Genome Project (N=424). The polymorphism is present in 25-30% of the general population and is associated with deficits in motor learning and neuroplasticity (Nooshabadi et al., 2016; Kleim et al., 2006; Morin-Moncet et

al., 2014). Therefore one may predict that musicians have a reduced polymorphism prevalence compared to the general population due to the high skill demands on motor learning and performance.
Methods. For genotypic and allelic frequency analysis DNA extraction and genotyping OG 500 kits from DNA Genotek were processed on the QIAsymphony SP magnetic bead DNA extractor using the 1.0 mL Oragene saliva protocol and QIAsymphony DSP DNA Midi Kit (QIAGEN). The samples were genotyped for the SNP rs6265 (BDNF; Val66Met) using a pre-designed TaqMan® SNP Genotyping Assay and were analyzed using the ViiA™ 7 Real-Time PCR System using ViiA™7 software. Fisher's exact test was used to assess difference in genotype frequencies between groups. Chi-square test assessed the difference between A allele frequencies (A allele = Met allele; G allele = Val allele).
Results. Genotypic and allelic frequencies in the musicians' sample were not statistically different from the general population sample. Genotypic Frequency: G/G 62.7% Controls vs 58.6 % Musicians; A/G 33.3% Controls vs 37.9 Musicians; A/A 4.0% Controls vs 3.5% Musicians ($p=0.88$). Allelic Frequency: G Allele 79.4% Controls vs 77.6% Musicians; A Allele 20.6 % Controls vs 22.4% Musicians ($p=0.75$). In the musician cohort no significant demographic differences were found for age and achievement except Met-Carriers had 4.4 more years in primary and 3.2 years in total training ($p<.01$).
Conclusion. Presence of Val66Met BDNF polymorphism did not bias against high-end motor skill learning in music. Learning strategies specific to music may exist to compensate for genotype predisposition. Motor learning in music is temporally 'overstructured', sonifies movement into sound patterns, and relies on high practice repetition rates. Interestingly in our cohort Met carriers had significantly more training years, indicating earlier entry ages into music training than Val carriers. Since Val66Met polymorphism is also associated with decreased rates of stroke recovery (Kim et al., 2016) data may have relevance for translations of music-based training strategies to stroke rehabilitation.

Title: Changes in spindle induced spiking activity after motor learning

Authors: *D. B. SILVERSMITH[1], D. RAMANATHAN[2], S. M. LEMKE[3], K. GANGULY[4]
[1]Bioengineering, [2]Univ. of California San Francisco, San Francisco, CA; [3]Univ. of California, San Francisco, San Francisco, CA; [4]UCSF, San Francisco, CA

Abstract: Thalamo-cortical sleep spindles are thought to play an important role in the acquisition and consolidation of new motor skills. Spindles have been studied extensively using EEG and ECoG recordings, and this body of work has consistently reported a link between the rate of sleep spindles and improvements in performance. Moreover, spindles nested within cortical up-states have been implicated as a substrate for neural plasticity. However, the mechanisms tying sleep spindles to learning remain unclear. To better understand the role that sleep spindles play in motor learning, it is critical to understand the relationship between spindles and the fine-scale structure of spiking activity.

To that end, we recorded local field potentials (LFPs) and extracellular spiking activity from the primary motor cortex (M1) as four rats learned a skilled reach-to-grasp task. The task was split into four blocks: $Sleep_1$, $Task_1$, $Sleep_2$ and $Task_2$. Rats improved their performance (i.e. increased their accuracy and speed) during the reach-to-grasp task and showed further offline improvements in speed after sleeping. After task engagement we observed a significant increase in both the rate of sleep spindles in M1 and the degree of spindle nesting within slow oscillations.

We next analyzed the evolution of fine-scale spiking structure during spindles. Single neurons tended to spike at a preferred phase within the ongoing oscillation; importantly, this increase in phase-locking coincided with an increase in the pairwise cross-correlation (or *synchrony*) between neurons. Interestingly, both the phase-locking and spiking synchrony were larger for nested spindles compared to unnested spindles.

After learning a motor task, rats showed a marked increase in the rate of sleep spindles in M1, consistent with human and animal studies monitoring sleep after motor learning. We also observed changes in spindle-induced modulation of spiking activity and synchrony following learning. The spindle effects were magnified for spindles that occured within up-states, consistent with the idea that nested spindles play an important role in offline learning. Overall, our results suggest that spindles precisely modulate the timing of spiking activity and thereby support offline gains in motor performance.

Title: tDCS over dorsolateral prefrontal cortex does not affect prefrontal-to-M1 interhemispheric inhibition

Authors: *S. UEHARA[1,3], F. MAWASE[1], K. CHERRY-ALLEN[1], K. RUNNALLS[1], M. KHAN[2], P. CELNIK[1]
[1]Dept. of Physical Med. and Rehabil., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Fac. of Rehabil., Fujita Hlth. Univ., Toyoake, Japan

Abstract: The lateral prefrontal cortex (PFC) plays a wide range of crucial roles in higher-order cognitive functions. Malfunction in this region has been associated with several mood disorders, and cognitive abnormalities. Previous studies have attempted to modulate PFC function by applying non-invasive transcranial direct current stimulation (tDCS) and demonstrated positive effects on behavioral functions. Although tDCS effects on cortical excitability have been well demonstrated when the primary motor cortex (M1) was targeted, neurophysiological evidence underlying PFC-tDCS effects remain poorly understood. In this study, we aimed to examine changes in PFC excitability by assessing inter-hemispheric inhibition (IHI) from the lateral PFC to M1 (PFC-M1 IHI) before and after anodal, cathodal, or sham tDCS. We hypothesized that the magnitude of PFC-M1 IHI would be modulated in a polarity-specific manner. We used a double-blinded, crossover and counterbalanced design. Each volunteer (n = 15) participated in three sessions for different tDCS conditions. For tDCS, one electrode was placed over the right lateral PFC and the other electrode was on the left supra-orbital area. For active (anodal, cathodal) or sham tDCS, the current was applied at 2 mA for 15 min or 30 s, respectively. PFC-M1 IHI was assessed using a paired-pulse TMS paradigm before and at 0, 10, and 20 mins after tDCS application. We also assessed corticospinal excitability by applying single pulse TMS over the left M1 to prove that potential modulation in PFC-M1 IHI was not accompanied with corticospinal excitability changes. Against our hypothesis, we found no modulation in the magnitude of PFC-M1 IHI and corticospinal excitability after anodal, cathodal, or sham tDCS. To rule out the possibility that PFC-M1 IHI could not be modulated by an intervention, we assessed the same measure while another group of participants (n = 15) performed on two different types of visuomotor reaction time tasks. Results showed that the magnitude of PFC-M1 IHI decreased during a pre-movement period (between visual cue appearance and initiation of physical reaction), suggesting that PFC-M1 IHI could change depending on movement contexts.

These findings indicate that PFC-M1 IHI may not be a powerful proxy to detect possible excitability changes in PFC modulated by tDCS application.

Title: Neurophysiological correlates of maladaptive plasticity in the population code of the intact hemisphere of rats after an ischemic infarct of primary motor cortex

Authors: *M. D. MURPHY[1,2], A. R. PACK[2,5], D. T. BUNDY[3], S. BARBAY[6], D. J. GUGGENMOS[3], R. J. NUDO[4]
[1]Univ. of Kansas, Kansas City, KS; [2]Landon Ctr. on Aging, [3]Dept. of Physical Med. and Rehabil., [4]Univ. of Kansas Med. Ctr., Kansas City, KS; [5]Neurosci. Doctoral Program, Emory Univ., Atlanta, GA; [6]Physical Med. and Rehabil., Univ. Kansas Med. Ctr., Kansas City, KS

Abstract: Behavioral impairment following acquired brain injury in primary motor cortex (M1) can often be improved with behavioral rehabilitation, as a result of neuroplastic reorganization of spared regions. Post-injury functional recovery has been observed to result in changes of motor map representation, redistribution of neuroanatomical connections, and shifts in the patterns of neural excitation relative to behavior, but the functional role of such changes remains unclear. Is reorganization in a given area a sign of maladaptive compensation, or a mechanism to adaptively overcome the loss of damaged tissue? We correlated the gross kinematic covariates of a reaching behavior with neurophysiological data collected in spared motor areas of neocortex in rats receiving either a sham or ischemic infarct in M1 contralateral to the preferred reaching forelimb. Regions of interest (ROIs) describing the extent of the reaching forelimb and paw were identified in 49,240 video image frames. A model was developed to estimate the relative contribution to accuracy in decoding the kinematic ROI using multi- and single-unit activity recorded from either M1 of the intact hemisphere, or premotor cortex (PM) of the injured hemisphere. Relative contributions to decoding accuracy from each area were then used to determine the likelihood of successful pellet retrieval in individual trials using a logistic regression model. The ability to predict trial outcomes based on relative accuracy contributions of the two areas suggests that population coding in M1 of the intact hemisphere initially plays an

adaptive role in control of behavior during the first week after injury, but gradually shifts to a maladaptive role by three weeks after the injury. Injured rats had an increased number of interhemispheric pairs of units with a roughly 5 Hz oscillatory cross-correlational structure, suggesting the increased involvement of a slow field potential coordinating activity in these regions. While no shift in this rhythmic correlation was evident over the course of 3 weeks, the phase offset between interhemispheric pairs of units is affected in injured rats, suggesting that the timing of coupled activity between intact M1 and PM is disrupted after injury.

Title: Real-time fMRI neurofeedback for bi-directional modulation of ipsilateral sensorimotor cortex

Authors: *Z.-B. SANDERS[1], C. SAMPAIO-BAPTISTA[1], K. DIOSI[1], M. LUEHRS[2], R. GOEBEL[2], H. JOHANSEN-BERG[1]
[1]Oxford Univ., Oxford, United Kingdom; [2]Maastricht Univ., Maastricht, Netherlands

Abstract: Sensorimotor activity patterns during executed movements are altered in stroke patients with hemiplegia, with patients showing increased bilateral activity compared to healthy individuals. Modulating these activity patterns may help improve motor functioning. However, different patients may benefit from either increased or decreased recruitment of ipsilateral sensorimotor cortex, depending on impairment level and corticospinal tract integrity. In this study, we investigated whether healthy individuals are able to use real-time functional magnetic resonance imaging (fMRI) over several days to bi-directionally alter brain activity in the ipsilateral sensorimotor cortex. We recruited 15 healthy right handed participants to participate in 6 sessions of 7T real time fMRI neurofeedback. During neurofeedback participants were asked to make unimanual movements with their left hand and were shown two bars representing activity from regions of interest (2x2x2cm) in each sensorimotor cortex. Each participant completed two different neurofeedback conditions separated by at least 1 month. In one condition, they were instructed to maximally co-activate the two sensorimotor cortices (Association), whereas in the other they were instructed to increase contralateral and decrease ipsilateral activity (Dissociation). Participants were scanned three times for each condition with

24 hours between the first two scans and 48 hours between the second and third scan. Participants were able to use neurofeedback to increase activity in the ipsilateral sensorimotor cortex during the Association condition compared to the Dissociation condition on all three days (whole brain voxel-wise paired sample t-test). To assess whether multiple sessions enhance the neurofeedback effect, we looked at within-condition changes over days. In the Association condition, ipsilateral activity was increased on Day 2 compared with Day 1 and contralateral activity was increased on Day 3 compared with Days 1 and 2. This suggests that participants initially learn to increase activity in the ipsilateral hemisphere, followed by increasing the contralateral hemisphere. In contrast, in the dissociation condition participants learned to decrease ipsilateral activity within each day, but not across days as no significant changes between days were found. These findings demonstrate that individuals are able to use neurofeedback to bi-directionally modulate brain activity in sensorimotor cortices and that multiple sessions can enhance these effects. This highlights the feasibility of tailoring neurofeedback interventions to patients depending on their characteristics.

Abstract: Background: As interhemispheric inhibition (IHI) is essential for dexterous motor control, bimanual skill developed with instrument playing may result in increased IHI in musicians. However, it is unclear whether there is any difference in the relationship between interhemispheric inhibitory circuits and bimanual motor skills in skilled musicians compared to non-trained individuals. Therefore, the current study aimed to compare the relationship between IHI and bimanual coordination in skilled musicians compared to non-musicians. **Methods:** Thirty-six musicians and 36 non-musicians participated. An 8-element finger sequence task (FST) was used to test bimanual coordination. Speed, accuracy, and evenness of key pressing interval were recorded. The Purdue pegboard test was used to test asymmetric coordination, by

measuring the number of assembled objects. Using transcranial magnetic stimulation, IHI was measured as ipsilateral silent period (iSP), both in left (L) and right (R) hemispheres. Canonical correlation analysis (CCA) was used to identify linear relationships between the IHI and bimanual coordination measures. A general linear model was used to compare the IHI-bimanual coordination relationship between musicians and non-musicians. Permutation testing was used to validate whether the observed differences of IHI-bimanual coordination relationship between musicians and non-musicians occurred by chance. Variable reduction CCA was performed with only the highly-contributing variables based on multiple regression analysis. **Results:** Compared to non-musicians, musicians demonstrated significantly better bimanual coordination (faster speed, higher accuracy, and more evenness). No differences in iSP were observed between the two groups. However, canonical correlation analysis (CCA) showed that the composite IHI variables (iSP-L, iSP-R) were significantly related to bimanual coordination in musicians ($r = 0.52$), but not in non-musicians ($r = -0.06$). The strength of the relationship was significantly greater in musicians than in non-musicians ($p = 0.016$). Variable reduction CCA showed that greater L-to-R IHI was related to increased evenness but at the cost of reduced speed in musicians. **Discussion:** Musicians demonstrated superior bimanual coordination in an instrument-like task compared to non-musicians. Prolonged musical training strengthened the relationship between interhemispheric inhibitory circuits and bimanual motor skills. The trade-off between evenness and speed was dependent on IHI and may result from long-term musical training as reducing variability is an important skill in instrument playing.

Title: Changes in human white-matter architecture following sensorimotor adaptation

Authors: *A. J. DE BROUWER, J. Y. NASHED, D. STANDAGE, J. R. FLANAGAN, J. P. GALLIVAN
Queen's Univ., Kingston, ON, Canada

Abstract: Sensorimotor adaptation is thought to reflect the resultant combination of two separate, but interacting processes: an implicit, error-based process linked to slow learning and an explicit, strategic process linked to fast learning and savings (i.e., faster re-learning). To

explore the neuroanatomical basis of these processes, we investigated the effects of a brief sensorimotor adaptation task on structural plasticity in human white matter using diffusion tensor imaging (DTI). Specifically, we examined whether individual differences in rates of (re)learning are related to short-term changes in structural organization of white matter. Participants performed two sessions (separated by 24 hours) of center-out cursor movements to visual targets using a force sensor, while adapting to an instantaneous 45° rotation of the visual feedback of the cursor. DTI scans were obtained at the beginning of each session. Preliminary analyses suggest that individual changes in diffusivity indices in regions in prefrontal cortex are related to faster relearning in the second session. Further tract-based analyses will be used to investigate the extent of these short-term changes and whether they are linked to individual differences in white matter connectivity.

Title: Pharmacological lesion of the rat motor cortex induces spinogenesis in spinal cord motor neurons

Authors: *M. N. VÁZQUEZ HERNÁNDEZ[1], N. G. MARTÍNEZ-TORRES, 44340[2], D. GONZÁLEZ-TAPIA[3], M. E. FLORES-SOTO[1], H. SALGADO-CEBALLOS[4], I. GONZÁLEZ-BURGOS[1]

Abstract: Motor function is impaired in multiple neurological diseases associated with corticospinal tract degeneration affecting communication between the cortical neurons and the spinal cord motor neurons. Motor impairments has been linked to plastic changes at both the presynaptic and postsynaptic levels. However, there is no evidence of changes in those postsynaptic structures mediating synaptic transmission between motor cortex and spinal cord, namely, dendritic spines. In this study, 26 Sprague-Dawley adult female rats were used. These were divided in two groups: experimental group (Exp) and control group (Ctrl). For the Exp group kainic acid was used to induce a pharmacological lesion to the primary motor cortex.

Fifteen days later, motor function was evaluated by the BBB scale and the Rota-rod device. Also, the density of thin, stubby, and mushroom spines was quantified in motor neurons from a thoraco-lumbar segment of the spinal cord, using a modification of the rapid-Golgi method. Spinophilin, synaptophysin, and β iii-tubulin content was semi-quantified. For the Ctrl group were used the same procedure, except that saline solution was used instead kainic acid. Pharmacological lesion resulted in inefective motor performance in both behavioral tests. Spine density and the proportion of thin and stubby spines were greater in group Exp in comparison with the Ctrl group. The proportion of mushroom spines was unchanged. Spinophilin, synaptophysin, and β iii-tubulin increased in the Exp animals. The clinical symptoms of neurological damage secondary to Wallerian degeneration of the corticospinal tract were associated with spontaneous, compensatory plastic changes at the synaptic level. Based on these findings, spontaneous plasticity is a factor to consider when designing strategies in the early phase of rehabilitation.

Title: Targeted neuromodulation of interhemispheric connectivity after stroke

Authors: S. LIN, *J. A. PALMER, M. R. BORICH
Emory Univ., Atlanta, GA

Abstract: Introduction: After stroke, atypical interhemispheric connectivity has been observed in stroke survivors with poor motor recovery and may affect post-stroke motor function. Specifically, findings from previous research have indicated the presence of excessive interhemispheric inhibition (IHI) from the contralesional to ipsilesional motor cortex, creating a model of interhemispheric competition after stroke that may contribute to motor recovery. However, the relationship between levels of IHI and motor function after stroke remain unclear. Further, it is unknown how modulation of IHI through transcranial magnetic stimulation (TMS)

might influence post-stroke motor function. The purpose of this study was to 1) investigate the relationship between IHI and post-stroke motor function and 2) determine the effect of a session of interhemispheric paired associative stimulation (ihPAS) on neuromodulation of IHI and motor performance in stroke survivors. Methods: Eight participants (3 male) with ischemic chronic (>6 mo.) stroke were tested during two separate sessions with two different ihPAS conditions: $ihPAS_{8ms}$ (interstimulus interval [ISI] of 8ms) and $ihPAS_{1ms}$ (ISI of 1ms). ihPAS consisted of 100 paired TMS pulses to contralesional M1 (cM1)followed by ipsilesional M1 (iM1)delivered at 0.25HZ. We assessed IHI bilaterally prior to and at three time points following ihPAS (POST 0', POST30', POST 24hrs) using the dual coil paired pulse paradigm with the conditioning pulse delivered 10ms prior to the test pulse on contralateral M1. Electromyography (EMG) was used to measure the motor evoked potential of first dorsal interosseous muscles bilaterally. Results: Significantly greater IHI (p=.004) from iM1-to-cM1 than cM1-to-iM1 was observed at baseline. Baseline iM1-to-cM1 IHI was positively correlated with paretic arm motor function. There was no relationship between cM1-to-iM1 IHI and paretic arm motor function. Following $ihPAS_{8ms}$, there was a decrease in iM1-to-cM1 IHI (p=.03) at POST 30'. Neither ihPAS condition modulated cM1-to-iM1 IHI. Discussion: The preliminary results suggest that greater iM1-to-cM1 IHI is present in individuals post-stroke and may be important for post-stroke motor recovery, a finding that contrasts the previous model of interhemispheric competition. Results also suggest that ihPAS may reduce iMi-to-cM1 IHI. Further analyses are needed to compare IHI values in stroke versus healthy individuals and to determine the relevance of this unanticipated directional change in IHI to change in motor performance and behavior following ihPAS.

Title: Is there an instrument-dependent effect on interhemispheric inhibition and bimanual coordination in musicians?

Authors: Y.-L. KUO[1], J. E. GORDON[1], C. J. WINSTEIN[1], J. J. KUTCH[1], S. S. KANTAK[2], *B. E. FISHER[1]
[1]USC, Los Angeles, CA; [2]Moss Rehabil. Hosp., Elkins Park, PA

Abstract: Functional reorganization in musician's brain has been considered strong evidence of experience-dependent neuroplasticity. However, it is unclear whether musician's motor

performance was driven by, or independent of auditory process. Highly coordinated bimanual movements stem from intensive instrument training require abundant communication between both hemispheres. Interhemispheric inhibition (IHI) is one form of communication between hemispheres and changes with instrument type. Instrument type may also impact bimanual coordination given the dissimilar hand use with different instrument performance. However, it was yet to know whether bimanual skill developed with musical training in association with adapted IHI in musicians was dependent on instrument type. Therefore, we aimed to 1) investigate the impact of sound on the bimanual coordination; and 2) investigate instrument-dependent effects on the relationship between IHI and bimanual coordination in keyboard players compared to string players. An 8-element finger sequence task (FST) with and without auditory tones were used to test symmetric bimanual coordination. Speed, accuracy, and evenness were recorded as performance. Asymmetric bimanual coordination was measured by a force tracking task (FTT) with one hand performing sine wave tracking, while the other hand performing constant contraction. Error was measured as performance. Ipsilateral silent period (iSP) was obtained using transcranial magnetic stimulation to index IHI in both left (L) and right (R) hemispheres. Canonical correlation analysis was performed to identify linear relationships between the IHI and bimanual coordination outcomes. Keyboard and string players did not show significantly different performance in FST and FTT, nor in the iSP outcomes. In FTT, better performance with the R hand tracking sine wave and the L hand performing constant contraction was observed in both groups, compared to the L hand tracking sine wave and the R hand performing constant contraction. Canonical correlation analysis showed that better bimanual coordination performance was related to increased IHI from the L hemisphere as well as decreased IHI from the R hemisphere in both groups. Musicians were able to transfer their bimanual coordination acquired from instrument training to novel laboratory motor tasks without the presence of auditory tones as part of the performance outcome. Adding both symmetric/asymmetric tasks washed out differences in IHI-bimanual coordination relationship between instruments. Better L hand control through enhanced interhemispheric communication may be critical for advanced bimanual coordination.

Title: Changes in cortical excitability during ischaemic nerve block

Authors: *S. NAULLS, P. SARAI, P. H. STRUTTON
Imperial Col. London, London, United Kingdom

Abstract: Following injury to the peripheral nervous system (PNS) there is a period of neuroplasticity associated with alterations in cortical excitability. The phenomenon of deafferentation, where there is a loss of afferent input to the brain which often arises following injury to the PNS, can be modelled using ischaemic nerve block (INB). Topographic changes to the representation of muscles within the motor cortex and changes in corticospinal excitability are thought to mediate this plasticity. Motor evoked potentials (MEPs) proximal to the site of the block have been observed to increase and we recently demonstrated that MEPs on the contralateral side to the block are also increased, but the mechanisms underlying these changes are poorly understood. Using non-invasive transcranial magnetic stimulation (TMS) over the motor cortex, we examined MEPs in left and right abductor pollicis brevis (L/RAPB) in healthy participants using single pulse TMS. We also used paired-pulse TMS to explore the extent to which short-interval intracortical inhibition (SICI) and facilitation (SICF) contribute to the increase in MEP amplitudes contralateral to the site of occlusion. INB induced by a tourniquet inflated around the left forearm resulted in a reduction in MEP amplitude in LAPB, distal to the site of occlusion. However, MEPs in RAPB (contralateral to the occlusion site) increased in amplitude. We also observed a reduction in the degree of SICI and an increase in SICF. Our findings suggest that alterations in intracortical inhibitory and facilitatory circuits contribute to the increase in cortical excitability during INB. The functional relevance of the increases in corticospinal excitability to contralateral muscles remains unclear.

Title: Mechanisms underlying changes in cortical excitability following ischaemic nerve block of the upper limb

Authors: *M. CONSTANTINESCU[1], P. SARAI[2], P. H. STRUTTON[2]
[1]Musculoskeletal Laboratory, Dept. of Surgery and Cancer, Fac. of Medicin, [2]Imperial Col. London, London, United Kingdom

Abstract: Reorganisation of the motor cortex due to injuries to the peripheral nervous system, such as limb amputation, is in part mediated by alterations in cortical excitability. Such injuries cause loss of afferent input to the brain and induce plasticity. Ischaemic nerve block (INB) is a

model of acute reversible deafferentation and results in changes in the motor cortex of both hemispheres. This causes a decrease in motor evoked potential (MEP) amplitudes in muscles distal to the site of occlusion and an increase in MEP amplitudes in muscles proximal to the occlusion and in the contralateral limb muscles. The mechanisms underlying the contralateral changes are not well understood and were the focus of this study. A cuff was inflated around the left forearm for 30 minutes and measures of corticospinal excitability, intracortical inhibition and facilitation were assessed using single and paired-pulse TMS in healthy subjects. Electromyographic activity was recorded from left and right abductor pollicis brevis (L/RAPB) muscles. Paired-pulse TMS was used to examine the contribution of long-interval intracortical inhibition (LICI) and intracortical facilitation (ICF) on changes in corticospinal excitability contralateral to the side of occlusion. INB resulted in a reduction in MEP amplitudes in LAPB, distal to the occlusion. MEP amplitudes increased in the muscle contralateral to the side of occlusion (RAPB). We observed an increase in ICF of RAPB and a reduction in LICI towards the end of the occlusion period. These findings suggest that alterations in intracortical faciliatory and inhibitory circuits within the motor cortex may mediate the increase in cortical excitability of muscles contralateral to the occlusion. The functional relevance of INB-induced changes to corticospinal pathways controlling contralateral muscles remains unclear, but greater understanding may aid the development of rehabilitative strategies to improve hand function following stroke or incomplete spinal cord injury.

Title: Use of ischaemic nerve block to assess the potential of transcranial magnetic stimulation to monitor spinal cord perfusion

Authors: *A. M. WATSON, P. SARAI, P. H. STRUTTON
Imperial Col. London, London, United Kingdom

Abstract: Spinal cord injury due to prolonged ischaemia is a major complication of vascular surgery and current methods of monitoring are insufficient in detecting injury intra-operatively. During vascular procedures such as thoraco-abdominal aortic aneurysm (TAAA) repair, iatrogenic blood supply restriction to lower limbs results in deafferentation, thereby reducing motor evoked potentials (MEPs) from the ischaemic limbs. Previous work using ischaemic nerve blocks (INB) as a model of deafferentation has shown increases in transcranial magnetic stimulation (TMS)-induced MEPs in muscles proximal and contralateral to the block site

reflecting changes in corticospinal excitability. In order to use TMS as an intra-operative monitor of spinal cord perfusion, a greater understanding of the effects of ischaemia is required. The use of TMS to monitor MEPs during INB provides a comparable model for changes likely to occur to MEPs during TAAA surgery. However, the extent to which the degree of deafferentation influences cortical excitability remains unexplored and was the aim of this study.
We used non-invasive TMS and INB in the left upper limb for 30 minutes to investigate corticospinal excitability in left and right abductor pollicis brevis (L/RAPB) and left and right biceps brachii (L/RBB) in healthy subjects. The INB was applied, using inflation of a cuff, on two separate days to different locations on the limb (forearm and arm) to induce deafferentation of varying degrees. INB resulted in a reduction in the amplitudes of MEPs distal to the occlusion and increases in MEPs proximal and contralateral to the block. The greater degree of deafferentation, however, was associated with smaller increases in MEP amplitudes in the RAPB, LBB and RBB, suggesting that greater limb deafferentation results in smaller changes in corticospinal excitability. This may be, in part, due to the influence of pain, since greater degree of INB was associated with higher average pain scores. The results of this study may help interpretation of intra-operative TMS-induced MEPs used to monitor spinal cord perfusion during TAAA surgery.

Title: Effect of acute exposition to Toluene on cortical excitability, neuroplasticity, and cognitive functions in healthy humans

Authors: *M.-F. KUO[1], F. YAVARI[2], C. VAN TRIEL[3], M. NITSCHE[2]
[1]Psychology and Neurosci., Leibniz Res. Ctr. For Working Envrn., Dortmund, Germany; [2]Psychology and Neurosciences, [3]Leibniz research Ctr. for Working Envrn. and Human Factors, Dortmund, Germany

Abstract: Toluene is a well-known organic neurotoxicant and a major component of many industrial and commercial products such as adhesives, paint thinners and gasoline. Many workers come into daily contact with toluene in working environment. Due to heterogeneity of the findings from existing animal and human studies about its behavioral and mechanistic effects, toluene occupational and short-term exposure limits (OEL and STEL) vary from 14 to 300 ppm across countries. Furthermore, its acute effects, especially in humans, remain poorly understood. The purpose of this study was to investigate the effects of acute exposure to toluene on cortical

excitability, plasticity, and implicit motor learning in a population of healthy humans. Seventeen subjects were assessed with different transcranial magnetic stimulation measurements: motor thresholds, short-latency intracortical inhibition and intracortical facilitation, and short-interval afferent inhibition (SAI) before and after placebo or toluene (single peak of 200 ppm) administration. Furthermore, we evaluated long term potentiation-like neuroplasticity induced by anodal transcranial direct current stimulation over the motor cortex, and the participants conducted a motor sequence learning task, the serial reaction time task (SRTT). Our findings revealed that toluene abolished the plasticity induced by anodal tDCS, attenuated intracortical facilitation, and increased inhibition in the short-latency afferent inhibition measure, while cortico-spinal excitability and intracortical inhibition were not affected. On the behavioral level, toluene did not alter performance of the motor learning task. These results suggest that toluene might act by modulating NMDA receptor activity, and cortical glutamatergic and cholinergic systems in the human brain. This study encourages further research to obtain more knowledge about mechanisms of action and effects of toluene on both naïve and chronically-exposed populations.

Title: Titrating the neuroplastic effects of cathodal transcranial direct current stimulation (tDCS) over the primary motor cortex

Authors: *M. A. NITSCHE[1,2], M.-F. KUO[3], D. AGBOADA[3], A. JAMIL[3], M. MOSAYEBI[3,4]
[1]Leibniz Res. Ctr. for Working Envrn., Dortmund, Germany; [2]Neurol., Univ. Hosp. Bergmannsheil, Bochum, Germany; [3]Psychology and Neurosci., Leibniz Res. Ctr. For Working Envrn. and Human Factors, Dortmund, Germany; [4]Inst. of Biomed. Engin. and Informatics, Ilmenau Univ. of Technol., Ilmenau, Germany

Abstract: Background: Transcranial direct current stimulation (tDCS) non-invasively induces polarity-dependent excitability alterations in the human motor cortex lasting for more than an hour after stimulation. Clinical applications with encouraging results have been reported in several pilot studies, but the optimal stimulation protocols remain to be determined. This is also important because the efficacy and directionality of tDCS effects follow non-linear rules

regarding neuroplastic effects for the stimulation parameters duration and intensity. Methods: In this study, we systemically explored the association between tDCS, these parameters and induced after-effects on motor cortex excitability. Cathodal tDCS was applied in four different intensities (sham, 1, 2 and 3mA) and three durations (15, 20 and 30mins) in 16 young healthy subjects and the after-effects were monitored with TMS-induced motor evoked potentials (MEP) until the next day evening after stimulation. Results: The results revealed nonlinear after-effects: 1mA-15min, 1mA-30min and 3mA-20 min cathodal tDCS induced LTD-like plasticity, while LTP-like plasticity was observed after 2mA-20min stimulation. Conclusions: Our study thus provides further insights on the dependency of tDCS-induced neuroplasticity from the stimulation parameters, and therefore delivers crucial information for future applications.

Abstract: Kinesthetic information is critical to plan and adapt movements to behavioral goals and environmental constraints. For instance, we not only use our hands to manipulate objects, but also to communicate with and understand our environment. While touch as feedback modality has been extensively studied, the specific contribution of proprioception in the control of upper limb movements is less understood. To address this question, we established a series of electrophysiology and behavioral experiments to examine the integration of touch, proprioception, and motor execution in the cerebral cortex of a chronically implanted human primate (NHP). Specifically, we periodically map individual finger joint and wrist movements as well as touch stimuli applied to the hand to cortical activation maps in M1 and S1 area 2. In addition, single unit activity is recorded while the animal is performing a reach, grasp, and pull

task with objects of varying types and shapes that require the use of different grip patterns. The task involves proprioception and touch sensory modalities in addition to the motor execution. These multimodal recordings of sensorimotor intracortical activity, arm and hand joint kinematics and grip forces during well-controlled behavioral manipulations will increase our fundamental understanding of the processes through which kinesthetic information in integrated into cortical networks to produce task-specific movements.

Abstract: Cervical spinal cord injury (SCI) and stroke severely impact grasping movements required for activities of daily living. Intraneural peripheral nerve stimulation enables specific activation of passing fibers. This paradigm has restored precise leg movements in animal models of SCI and selective sensation in human amputees. Intraneural peripheral nerve stimulation may also restore fine grasping in paralyzed hands, but this possibility has not been investigated. Here, we assess the feasibility of using intrafascicular electrical stimulation of peripheral nerves to

produce precise hand movements in the non-human primate (NHP). We first extensively characterized the branching points of the median, radial, and ulnar nerves to their target muscles in the adult macaca fascicularis in order to identify the optimal implantation site for intraneural electrodes. We then reconstructed the tridimensional structure of the identified portion of each nerve in order to analyze the fascicular organization within the nerve at this level. Additionally, we assessed the distribution of motor fibers within the fascicles using immunohistochemistry. The obtained data was used to build realistic computational models of intraneural peripheral nerve stimulation for each nerve. The simulations confirmed the advantages of using intrafascicular electrodes to induce precise hand movements, demonstrating the possibility to selectively recruit patches of motor fibers without a priori knowledge of the electrode placement. We validated these results during electrophysiology experiments using transverse intrafascicular multichannel electrodes (TIMEs) implanted in the nerves of anesthetized NHPs. The stimulation achieved a selective recruitment of wrist and finger flexors and extensors in a reproducible manner across animals. We exploited these results to determine stimulation sequences that aimed at reproducing the muscle activation patterns underlying different grasping movements. For this, we mapped the obtained muscle recruitment maps to continuous EMG recordings during behavioral experiments and automatically optimized the selection of stimulation channels for each phase of the movement such as to reproduce the desired EMG pattern. Taken together, these results suggest encouraging evidences for the usability of the TIMEs to restore fine hand control after paralysis.

Abstract: For people with high cervical spinal cord injury (SCI), restoring the ability to reach and grasp is a high priority. Epidural electrical stimulation (EES) of the spinal cord has been shown to improve voluntary control of the lower limbs by modulating spinal motor circuits through direct activation of afferent fibers. Brain-controlled EES neuromodulation may also be applied to the cervical spinal cord to restore lost hand and arm function. Neural signals in the primary motor cortex (M1) are commonly used for neuroprosthetic control. Yet, movement-related neural activity is also strongly influenced by the sensory feedback from the primary somatosensory cortex (S1). This sensorimotor loop is perturbed following upper limb paralysis. Furthermore, signals from the afferent fibers recruited by EES directly activate the sensorimotor cortex. The functional effect of spinal EES on natural cortical dynamics during movement planning and execution is currently unknown. Recovery of dexterous hand and arm movements will require a technique that can obtain accurate and comprehensive control signals robust to both the effects of paralysis and EES-based therapy on the cortical signals. Here, we recorded neural population activity from multiple areas of the sensorimotor cortex to study sensorimotor coordination during reaching and grasping. We trained two facicularis macaque monkeys to perform a reach, grasp, and pull task while interacting with a robotic arm. We then surgically implanted two Utah electrode arrays in the contralateral hemisphere of each monkey. The first monkey received arrays in the primary motor and dorsal premotor (PMd) cortices, while the second was implanted in primary motor and somatosensory cortices. We recorded neural activity during the unconstrained reaching, along with arm kinematics and EMG signals from proximal and distal muscles of the arm. We studied the interactions between neural populations within and between the implanted brain areas. We used sensorimotor cortical responses to cervical EES during reaching to probe the effect of direct afferent input on cortical sensorimotor activity. Ultimately, we aim to apply these techniques to understand how the sensorimotor cortical signals are disrupted following cervical SCI and how sensorimotor cortical dynamics is affected by subsequent EES-based rehabilitation.

Abstract: Recovery of reaching and grasping is a priority for people suffering from cervical spinal cord injury (SCI). Following up on the encouraging results obtained with Epidural Electrical Stimulation (EES) in improving motor control of lower limbs, several groups are exploring the applicability of EES to the recovery of arm and hand function after cervical SCI. However, the neural control of arm and hand is markedly different from the patterned and reflex-based control of locomotion. Indeed, EES enhances locomotion by recruiting large primary afferent fibers thus increasing the excitability of the reflex circuits that are prominently active during locomotion. The efficacy of cervical EES may be limited by the reduced importance of spinal reflexes in the planning and execution of voluntary three-dimensional reaching movements. To address this question, here we studied the muscle responses elicited by continuous EES of the cervical spinal cord in intact, awake, and behaving non-human primates. We implanted a macaque monkey with a tailored soft spinal implant with eight stimulation contacts targeting C6 to T1 dorsal roots and n=8 bipolar EMG electrodes in the left arm and hand muscles. The animal was trained to perform a three-dimensional reaching and grasping task with a robotic interface while we recorded arm joint kinematics and EMG signals, along with the interaction forces of the robot. We delivered continuous supra-threshold EES at different rostro-

caudal locations and stimulation frequencies. We found that each stimulation pulse elicited muscle responses locked to the stimulation frequency. As for lumbar EES, the amplitude of the evoked responses was strongly modulated during behavior, suggesting a pre-synaptic recruitment of arm motoneurons. Stimulation delivered at distinct rostro-caudal locations recruited muscles innervated by the corresponding dorsal roots mostly during their naturally active phases. For instance, stimulation of the C7 root, strongly potentiated the EMG of Triceps muscles but only during the elbow extension phase. However, the activity of non-targeted muscles was affected as well, showing both potentiation and inhibition phase-dependent effects, contingent to the stimulation parameters. These non-functional muscle activations induced by continuous EES, impaired the normal execution of the subsequent grasping and pulling phases. Consequently, time-varying stimulation profiles at different spatial locations will be required to selectively potentiate functional muscle activity for three-dimensional reaching and grasping after severe SCI.

Abstract: Reaching to grasp is natural movement and it happens frequently for serving useful daily functions in human life. For this reason, it is important that external device in brain-machine interface (BMI) provide high-precision movement like actual arm to paralyzed or amputated patients. To accomplish this goal, we set up behavioral task to investigate neural mechanism of three dimensional (3D) reaching and grasp in rhesus monkey (*Macaca mulatta*). In this task, a monkey was required to reach and grasp targets presented by robot arm (Manipulator-H, Robotis). The target position was pseudo randomly selected out of eight positions. The experiment was composed of blocks in which trial of target of same position was presented five times (40 trials/block). When the monkey successfully grasped the presented

target, it was rewarded with a drop of water. If not, the target was presented at the same position again until the monkey acquired the target without giving water. All the position of arm and hand was recorded with motion capture system (Optotrak 3020, Northern Digital, Inc.). For 11 days, the monkey performed 4450 trials and achieved 86% of success rate (3845/4450 trials). After training, we implanted two 96-channel intracortical microelectrodes (Utah array, Blackrock® Microsystems) in the primary motor cortex (M1, limb area) and posterior parietal cortex (5d), respectively. Recording began one week after implantation. We have recorded both M1 and 5d while the monkey performed 3D reaching and grasp task. For 7 days, the number of neural units were 124 and 31 per session on average from M1 and 5d, respectively. We are planning to use behavioral task result and the collected neural data for developing 3D movement of BMI system near in the future.

Title: Impact of macro and microanatomy of the cervical spinal cord on the recruitment of arm motoneurons in primates and humans

Authors: *N. GREINER[1,2], B. BARRA[1], G. SCHIAVONE[3], S. BORGOGNON[1], E. PRALONG[4], S. P. LACOUR[3], J. BLOCH[4], G. COURTINE[2], M. CAPOGROSSO[1]

Abstract: After spinal cord injury (SCI), the communication between supraspinal centers and spinal sensorimotor circuits below the lesion is impaired, leading to paralysis. However, these circuits remain functional. Epidural electrical stimulation (EES) of the lumbar spinal segments can modulate the motoneuronal activity of these spared circuits via the direct recruitment of their afferent component. This modulation enabled volitional control of lower limb muscles in animal models and humans with SCI. Similar circuits at the cervical level of the cord contribute to coordinating upper-limb movements, suggesting that EES could also improve arm and hand

function in tetraplegia. However, the ability of cervical EES to target individual or groups of upper-limb muscles is poorly understood. To address this question, we coupled an anatomically realistic Finite-Element model of the cervical spinal cord with realistic microanatomy of Ia-fibers and alpha-motoneurons. Specifically, the Ia-fibers running in the dorsal roots branched in the dorsal columns and spawned collaterals towards the ventral horn of the grey matter where they innervated realistic models of alpha-motoneurons. Simulations indicated that targeting EES to somatotopically relevant dorsal roots could activate specific motoneuron pools. However, muscles innervated with a large number of Ia-fibers were recruited more often and at lower thresholds than muscles with low Ia-fiber count, significantly impacting the stimulation specificity. We compared these results with electromyographic activity recorded in arm and hand muscles in three nonhuman primates and three humans who received single pulses of EES at various rostro-caudal levels of the cervical cord. Experiments confirmed the ability of EES to engage specific groups of muscles reproducibly across subjects. Nonetheless, variability across subjects suggested a muscle- and subject-dependent nature of the Ia-mediated motoneuronal excitability; likely applying also to the motoneuronal modulations mediated by Ib- and II-pathways, implicated during EES. Taken together, these results highlight the importance of further quantitatively document the composition and connectivity of the proprioceptive feedback circuit to deepen our mechanistic understanding and refine the design of EES therapies.

Title: Grasp representation in posterior parietal cortex and premotor cortex in a tetraplegic human

Authors: *S. K. WANDELT[1], S. KELLIS[1,2], M. ARMENTA SALAS[1], L. BASHFORD[1], M. JAFARI[1], H. JO[1], K. PEJSA[1], D. KRAMER[2], B. LEE[2], C. LIU[2], R. A. ANDERSEN[1]

Abstract: Tetraplegia from spinal cord injury leaves patients paralyzed below the neck and unable to perform many activities of daily living. Brain-machine interfaces (BMIs) could give tetraplegic patients more independence by reading signals out of the brain directly and using these signals to control external devices such as robotic arms or hands. Object manipulation is of foremost importance for tetraplegic persons, as this is a critical aspect of human independence. Regaining arm and hand function is therefore ranked the highest priority in a survey among this population (Anderson, Journal of Neurotrauma, 2004). In this work, two tetraplegic patients participated in a clinical trial of a BMI in which motor intentions for grasping were read-out from high-level areas of the cortical grasp circuit including premotor cortex and posterior parietal cortex. Patient EGS suffered spinal cord injury at level C3-4 and has microelectrode arrays implanted in anterior intraparietal cortex (AIP) and Broadmann's Area 5 (BA5). Patient FG has a C5-C6 spinal cord injury and is implanted in the supramarginal gyrus (SMG) and in the area of the ventral premotor cortex (PMv). While this work builds on prior work studying grasp-related activity in AIP and BA5, SMG and PMv have never been studied before using intracortical recordings from microelectrode arrays in human. A task was designed to examine the neural activity related to imagined grasps in the implanted areas. Each trial began with a brief inter-trial interval, followed by a visual cue for one of five specific grasps. Then, after a delay period, the subject was instructed to imagine performing the cued grasp. In a variation of this task, a subset of trials, pseudorandomly interleaved throughout the task, instructed the subject to do nothing during the last phase of the trial. We found that grasps were well represented by firing rates of neuronal populations recorded from each of these cortical areas. We observed that neuronal signals recorded during grasp cues were most predictive of motor imagery in SMG, suggesting that this area is involved in planning of grasp activity early in the visual-motor control circuit. Importantly, the data collected from AIP and BA5 for this work were recorded more than four years after implantation and provide strong evidence for viability of the electrodes years after implantation. Together, these findings suggest that grasp signals can be robustly decoded from high-level areas of cortex in human over multiple years of implantation, and further demonstrate the potential for BMIs to provide increased independence through grasp capabilities for persons living with tetraplegia.

Abstract: Background: Intracortical brain-computer interfaces have the potential to improve functional independence for individuals with motor impairment from disorders such as amyotrophic lateral sclerosis (ALS). Previous work has demonstrated that individuals with tetraplegia can control robotic limbs using neural signals decoded from electrodes implanted in the precentral gyrus. However, it is not known whether the severity of paralysis affects the encoding of motion-related neural features in motor cortex. To address this question, we characterized how well we could decode 4 commonly used hand movements (power, pinch, and key grasps, and forearm supination/turn) from intracortical signals recorded from the precentral gyrus of people with ALS who had varying degrees of motor impairment.
Methods: Three research participants with ALS participated in this study. Participant T6 had an ALS Functional Rating Scale (ALSFRS) score of 14 and was able to visibly perform all 4 hand movements; T7 had an ALSFRS score of 17 and had no visible residual hand movement; and T9 had an ALSFRS score of 12 and had trace residual movement of only the thumb. All participants had intracortical arrays placed in their dominant motor cortex as part of the ongoing BrainGate2 pilot clinical trial. On each trial, participants were asked to “perform, or attempt to perform” one of the above 4 actions while neural signals were recorded. Each action was cued using a text display, followed by a visual go command after a variable delay period.
Results: A total of 719 trials were analyzed between the 3 participants over 6 sessions (2 sessions

per participant, with 45 - 155 trials per session). In offline analysis, data was spike-sorted using an automated spike sorter, yielding between 114 and 303 spiking units per session. 45 trials and 114 units were pseudorandomly sub-sampled from each session to control for signal quality and the amount of data used for decoding. These were used to train a linear discriminant analysis classifier, whose accuracy was tested on hold-out sets using Monte Carlo cross-validation without replacement. This was repeated across 100 different subsamples per session. Mean decoding accuracy during the action epoch was 75%, 78%, and 87% for T6, T7 and T9, respectively (chance = 25%), which did not correlate with either ALSFRS scores or degree of observable residual hand motion.
Conclusion: Multiple functionally relevant grasp types could be decoded from the intracortical signals of the precentral gyrus in people with ALS with differing levels of motor impairment. However, from this limited sample, no obvious relationship was observed between level of impairment and decoding accuracy.

Title: A feedback controller for sustained functional grasps using neuromuscular electrical stimulation

Authors: *J. G. CIANCIBELLO[1], S. PADMANABAN[4], K. KING[2], M. STRAKA[3], C. BOUTON[5]
[1]Ctr. for Bioelectronic Med., Feinstein Inst., Manhasset, NY; [2]Feinstein Inst., New Hyde Park, NY; [3]Feinstein Inst., Manhasset, NY; [4]Feinstein Inst. for Med. Res., Manhasset, NY; [5]Ctr. for Bioelectronic Med., The Feinstein Inst. for Med. Res., Manhasset, NY

Abstract: Motor neuroprostheses using neuromuscular electrical stimulation (NMES) must be able to evoke movements in a predictable manner, especially for sustained grasps. Current NMES-based devices suffer from rapid muscle fatigue and variable muscle force generation

given electrical stimulation parameters. To account for these variations in flexion strength, we implemented a traditional proportional-integral-derivative (PID) controller, which has an input of the movement force, to adapt the NMES stimulation current in closed-loop. We evoked finger movements in a participant with a C5 spinal cord injury using an NMES system that delivered biphasic, charge-balanced pulses transcutaneously on the forearm. The force of individual finger flexion was measured with thin-film FlexiForce sensors and used for feedback to the PID controller. Trials consisted of enabling the PID controller to match a desired force for a given time (6-15 s). We observed a compensatory effect from the PID controller, since muscle fatigue is present after stimulating for a long period of time (>6 s). Furthermore the controller matched the desired force relatively quickly (<1 s), and can be applied to individual finger movements. Future directions will support functional isometric grasps that incorporate several PID controllers. These PID controllers could be used in conjunction with a brain-computer interface to allow volitional, sustained movements in a paralyzed limb.

Title: Behavioural and neurophysiological effects of concurrent transcranial direct current stimulation and motor training in young and older adults

Authors: *R. A. MOONEY[1,2], J. CIRILLO[1,2], W. D. BYBLOW[1,2]
[1]Dept. of Exercise Sci., [2]Ctr. of Brain Res., Univ. of Auckland, Auckland, New Zealand

Abstract: Healthy ageing is typically accompanied by a reduced capacity for both structural and functional plasticity which has important implications for the acquisition and retention of novel motor skills. The application of transcranial direct current stimulation (tDCS) to primary motor cortex presents as a promising intervention to enhance skill acquisition and retention in older adults. However, the underlying neurophysiological effects of concurrent anodal tDCS and motor training has received little systematic investigation in this population. Fourteen neurologically healthy young and twelve older adults participated in the present study. To determine skill, the speed-accuracy function for a sequential visual isometric wrist extension task was assessed by measuring error at fixed execution speeds. Participants then completed discrete training blocks at a self-selected pace during which they received real or sham anodal tDCS in a repeated measures double-blinded crossover design. The speed-accuracy function was reassessed immediately after, 24 hours post and 7 days post training. Threshold-hunting paired-pulse

transcranial magnetic stimulation protocols were used to examine corticomotor excitability, short- and long-interval intracortical inhibition and short-interval intracortical facilitation in the non-dominant extensor carpi radialis before and after training. Overall skill was reduced in older adults compared with young ($P < 0.001$). Both age groups exhibited skill improvements after training which were retained at the 24 hour and 7 day follow up sessions (all $P < 0.05$). Corticomotor excitability increased ($P < 0.001$) and short-interval intracortical inhibition decreased ($P = 0.033$) similarly in both age groups after training. There was no modulation of long-interval intracortical inhibition or short-interval intracortical facilitation (all $P > 0.12$). Anodal tDCS had no effect on training-induced skill improvements or retention ($P = 0.16$), or the modulation of neurophysiological variables (all $P > 0.20$). These findings suggest that older adults maintain the ability to acquire and retain a novel motor skill, although absolute performance is lower than young adults. Furthermore, training-induced skill improvements are accompanied by an increase in corticomotor
excitability and reduction in intracortical inhibition within primary motor cortex which are not modified by concurrent anodal tDCS.

Title: Using inertial measurements to automatically identify and calibrate neuromuscular stimulation patterns for restoring movement in paralysis

Authors: *K. KING, J. G. CIANCIBELLO, C. BOUTON, M. STRAKA
Feinstein Inst., Manhasset, NY

Abstract: Neuromuscular electrical stimulation (NMES) can be used to activate muscles and generate movements in individuals living with paralysis from spinal cord injury (SCI), stroke, or other conditions. To restore isolated and synergistic finger and wrist movements, NMES systems require a large number of electrodes placed on the forearm. Given the possible combinations of stimulation patterns as well as the variety of movement outcomes possible, sensors that detect movements would significantly decrease calibration times while also quantifying the evoked movements. Moreover, as the position of the muscle bodies relative to the skin surface changes with hand orientation (e.g. pronated, supinated), an effective clinical device would need to detect this and deliver appropriate stimulation. To characterize and validate movements, we developed

wearable devices, placed on the fingertips and on the wrist, that incorporated inertial measurement units. With these devices, we measured linear and angular motion while evoking hand movements in two participants with C5 SCI as well as one able-bodied participant. Individual finger movements and coordinated grasps were evoked by delivering current transcutaneously with biphasic, charge-balanced pulses. We recorded acceleration and angular velocity of finger tips and wrist and applied a complementary filter to interpret the orientation of the hand in real time. We demonstrate that these devices can detect and classify forearm orientation, evoked finger and hand movements. These devices were also used in preliminary calibration experiments, where various finger movements were automatically identified while stimulating randomized electrode pairs. Future dsirections include incorporating these devices to calibrate neuromuscular stimulation patterns while restoring volitional movement via a brain-computer interface.

Title: Effects of a compliant surface on cognitive agency during hand grasp loading

Authors: *R. NATARAJ, S. SANFORD, A. SHAH
Biomed. Engin., Stevens Inst. of Technol., Hoboken, NJ

Abstract: Individuals needing restoration of hand grasp function due to spinal cord injury or upper-limb amputation may employ a prosthesis device. Identifying operational parameters such that an individual feels greater cognitive integration may optimize performance of object manipulation with such a prosthesis. How grasp loads are generated by the device onto objects such that users feel more agency, the perception of being the “true author” of one’s movements, could provide the cognitive link between user and device for better functional grasp. Furthermore, this link may not only be predicated on the loads applied to an object, but how hand kinematics are generated due to object surface deformation. In this study, we investigate how agency and grasp performance depend on perceived task-specific loading, provided through visual feedback, for a compliant object surface. These results are directly compared and contrasted against those utilizing a rigid object surface. Understanding the repercussions of hand force operations and proprioceptive shifts with a deforming surface may be a strong platform for better prosthesis design. How loading is triggered and postures are formulated for this complex

manipulation task should be key considerations in identifying parameters of feedback control systems driving device operation. Our long-term goal is to continue developing a virtual reality system to design better controller operation of prostheses that co-maximize cognitive integration and performance. We have previously employed motion and rigid-surface force protocols to observe relationships across virtual prosthesis operation, agency, and successful task performance. In the next phase, we aim to create complex manipulation tasks that challenge user-device abilities and refine device operation for better cognitive integration. Such a test-bed can be extended as a concept platform for more efficient movement rehabilitation following neuromuscular pathologies such as spinal cord injury, stroke, or upper-limb amputation. Related findings should identify more optimal parameters for controllers, generate greater motor gains with fewer practice repetitions, and better incorporate the user in device operation. Foundational methods could be employed towards improved development of exoskeletons, approaches using functional electrical stimulation, and sensory-feedback prostheses.

Title: The stabilization of M1 neural modes for the control of muscle activity through a Brain Computer Interface

Authors: *X. MA[1], J. A. GALLEGO[2], A. FARSHCHIAN[1], K. L. BODKIN[1], S. A. SOLLA[1], L. E. MILLER[1]
[1]Northwestern Univ., Chicago, IL; [2]Spanish Natl. Res. Council, Madrid, Spain

Abstract: A Brain Computer Interface (BCI) that uses functional electrical stimulation (FES) to activate paralyzed muscles under the control of signals recorded from primary motor cortex (M1) should provide users with a stable tool for implementing their intended motion. However, changes in the neurons recorded by implanted arrays can cause undesired variations in the actions produced by the BCI. Fortunately, the encoding of motor commands across the millions of neurons in M1 is highly redundant, and motor intent can be represented by a much smaller number of collective signals, the “neural modes”. These modes span a low-dimensional manifold embedded in the high-dimensional space of activities of recorded neurons; neural modes are likely to provide more stable signals for the control of muscle activation.
We consider M1 recordings while monkeys perform a variety of wrist and reach-to-grasp tasks,

and compare linear methods for dimensionality reduction, typically principal component analysis (PCA), to nonlinear dimensionality reduction achieved through deep neural network autoencoders. For an isometric wrist flexion task, a PCA based dimensionality reduction from the D ~100 neural space into a d=16 manifold captures 64% of the variance; the d=16 manifold found by the autoencoder captures a comparable 65% of the variance. Data collected from a week-long series of sessions allow us to analyze the stability of the manifold signals. If the autoencoder is not retrained, the variance accounted for (VAF) drops below 10% after three days. This deterioration in performance, due to loss of existing neural signals or capture of new ones, needs to be compensated by a retraining of the neural autoencoder. While a full retraining of the autoencoder on a daily basis maintains the initial 65% VAF, we find that partial training suffices to maintain VAF within 5%. This partial retraining involves only the initial autoencoder layer, from neural inputs onto the first layer of hidden units, and the final autoencoder layer, from the last hidden layer onto the reconstructed neural outputs. This partial retraining is achieved with less than 40% of the data required for full retraining.
The activation of neural modes can be used as decoder inputs to predict muscle activations (EMGs), with performance within 90% of that achieved when using all neural signals. We find that although the partial retraining of the autoencoder does not suffice to maintain this level of EMG prediction for a full week, if this partial retraining is coupled to the retraining of the module that maps neural modes onto EMGs, performance is sustained, providing a stable BCI over this time scale.

Title: Electrocorticographic dissociation of alpha and beta rhythmic activity in the human sensorimotor system

Authors: *A. STOLK[1], L. BRINKMAN[2], M. VANSTEENSEL[3], E. J. AARNOUTSE[4], R. T. KNIGHT[5], F. LEIJTEN[3], C. DIJKERMAN[3], F. DE LANGE[6], I. TONI[7]

Abstract: Alpha (8-12 Hz) and beta (15-25 Hz) rhythmic activities over the sensorimotor cortex are prominent and functionally relevant [Brinkman et al., 2014; 2016]. However, it remains unclear whether alpha and beta rhythms build on the same neuronal ensembles, and whether those ensembles actually contribute to computing a forthcoming movement. Complicating the issue is the fact that rhythmic activity rides on top of concurrent power-spectral 1/*f* modulations, making it difficult to yield robust insights into the fundamental properties of oscillatory activity. A further challenge is to disentangle movement-related computations from somatosensory reafferent signals associated with the execution of a movement.

Here we assess the cortical and functional specificity of those sensorimotor rhythms by using electrocorticographic (ECoG) data acquired during the performance of a psychophysically controlled movement imagery task. The preferred manner in which participants imagined grasping an object depended on the object's orientation and followed the biomechanical constraints of the body. We used irregular-resampling auto-spectral analysis to distinguish subject-specific rhythmic effects from arrythmic 1/*f* components of the ECoG signal [Wen & Liu, 2016]. Mean and spread of alpha and beta spectral distributions were individually defined with a two-term Gaussian model. We also considered (arrythmic) high-frequency activity (60-120 Hz) and the 1/*f* slope of the ECoG power-spectrum. The latter is a putative index of excitation-inhibition balance shown to closely track fluctuations in consciousness states in anesthetized macaques [Gao et al., 2017].

Both sensorimotor rhythms displayed effector-specific trial-by-trial modulation and were each spatiotemporally correlated with arrhythmic high-frequency activity. However, alpha and beta rhythms were weakly correlated and differed in their cortical and functional properties. Peaks of sensorimotor alpha were distributed on the postcentral gyrus, with the majority of electrodes yielding predominantly somatosensory sensations during electrical stimulation. In contrast, sensorimotor beta was strongest at electrodes directly above the central sulcus, with electrical stimulation yielding both movements and somatosensory sensations. Beta rhythmic activity closely tracked fluctuations of the 1/*f* slope in both time and space across sensorimotor cortex. Alpha rhythms were not influenced by that index of excitation-inhibition balance.

These findings suggest that sensorimotor alpha and beta rhythms involve different neuronal ensembles, and support different computations.

Abstract: Chronic experiments exploring the human cortex produce enormous datasets that offer a unique opportunity to study neural circuits over extended periods of time. In these data sets neural information is recorded from the same location, in similar experimental contexts, over several years. These recordings may therefore benefit from current innovations in the analysis of large datasets which, applied to other data types, are offering novel and exciting possibilities to identify high-order correlations in data. What therefore could be revealed in neural data where single and multiunit activity is recorded over multiple time scales from multiple electrodes?
In a clinical trial a single human subject has been implanted with two Blackrock Neuroport arrays in the posterior parietal cortex: the anterior intraparietal cortex (AIP) and Brodmann area 5 (BA5). The arrays were implanted in April 2013, at which point the subject began a range of tasks designed to investigate the control of a Brain-Machine Interface (BMI). One task in particular has continued, almost unaltered, since the beginning of the clinical trial--a center out training paradigm for cursor control. In this task, a cursor, presented on a display screen, moves from the center to one of eight targets located around the start point. Data collected while the cursor moved under computer control was used to train a decoder that would then be used in an online control task. Across sessions the decoder varies, slightly changing the relationship between the neural signals and the control; however, during training periods, nothing alters the relationship between the observation and the imagined movement signal. This subset therefore provides a data set of over ten thousand trials, with a consistent task, collected across four years. We are exploring the stability of the signals in these recordings as metrics to measure the long-

term viability of BMI use and investigating the spatial, temporal and cross-channel relationships that evolve between neurons and behavior over time. We have identified features in the neural signals which we interpret as learning over multiple time scales, in addition to features which correlate with measurements in the viability of the electrode-tissue interface. Further work aims to identify the formation of stereotyped activity that result from task familiarization over many trials.

Abstract: Functional connectivity of the brain, defined as the temporal dependency in neural activity between different brain areas, has long been studied as a mechanism to explore neuronal circuits and systems. Many different approaches have been used to quantify connectivity using spikes and/or local field potentials (LFPs) as inputs. In this study, we analyzed functional connectivity between primary somatosensory cortex (S1) and either the supramarginal gyrus (SMG) or ventral premotor cortex (PMv). Our goal is to establish a baseline network structure that will allow us to evaluate changes due to learning and cortical plasticity in future experiments. We recorded from SMG, PMv, and S1 of a 34-year-old tetraplegic subject with Neuroport microelectrode arrays (Blackrock Microsystems). From these data we quantified

functional connectivity using spike correlations. We identified pairs of channels whose correlation was more than three times the median absolute deviations (MADs) away from the median correlation of all possible pairs of channels. On average, we found 5% and 7% of channel pairs with significant correlations in S1-PMv, and S1-SMG, respectively. These correlations were relatively stable in three sessions recorded over a period of a month, with 1% and 4% of the channel pairs in S1-PMv and S1-SMG respectively exceeding the threshold of three MADs in at least two sessions. These results demonstrate one measure of functional connectivity between areas of cortex involved in sensorimotor processing. Future analysis and data collection will allow us to compare the above functional connectivity result with other standard measures such as spike-field coherence and field-field coherence.

Title: Effect of varying stimulation parameters on elicited sensation with intracortical microsimulation in human somatosensory cortex

Authors: *L. BASHFORD[1], M. ARMENTA SALAS[1], S. KELLIS[1], H. JO[1], M. JAFARI[1], K. PEJSA[1], B. LEE[2], C. LIU[2], R. A. ANDERSEN[1]

Abstract: We recently demonstrated that Intracortical Microsimulation (ICMS) in the primary somatosensory cortex of a human subject can elicit natural sensations, both proprioceptive (the sense of movement) and cutaneous (touch on the skin) in nature. We seek to understand in more detail the relationship between the stimulation parameters of ICMS and the sensations they produce in order to accurately deliver task-relevant feedback. Furthermore, we continue to explore the range of potential sensory responses produced under different stimulus configurations. We delivered ICMS to primary sensory cortex (S1) in a human clinical trial

participant. The subject has a C5-C6 level spinal cord injury resulting in quadriplegia. Implant surgery was performed approximately two years post-injury, two Blackrock stimulation microarrays were positioned in S1 and two recording microarrays in premotor and parietal areas. Recording and stimulation began in December 2016, two weeks post-surgery, and has continued on a regular basis. We have extended previous mapping results by beginning to vary new features of the stimulation: discriminating between sets of stimulations from a wide range of amplitude and frequency values, stimulating at multiple electrode sites concurrently and varying the timing and duration of the stimulation. We note the sensory outcomes of ICMS by recording features of the percepts (i.e. the subject's verbal description of the character, duration, intensity, and location). Preliminary evidence suggests that stimulation at multiple electrode sites elicits sensations that are much stronger in intensity than when the same stimulation is delivered to the electrodes individually. Additionally, these stimuli often produce sensations different in description to the sensations elicited by stimulation to the individual electrodes, and biases the sensations to be more proprioceptive in nature. Stimulation discrimination amongst a subset of electrodes shows a stable threshold for detection at 22-25μA. The aim of the current work remains to reliably produce percepts that will be useful in the context of brain controlled systems with direct somatosensory feedback. Future experiments are planned to explore the neural mechanisms of S1 that govern the formation of sensory percepts as well as combining sensations with the decoding of brain behavior to produce a bidirectional brain-computer interface.

Title: Spatiotemporally overlapping haptic and direct cortical stimulation in humans results in simultaneous perception with a range of delays predicted by the response time delay to cortical stimulation

Authors: *D. J. CALDWELL[1], J. A. CRONIN[2], K. E. WEAVER[3], A. L. KO[4], R. P. RAO[5], J. G. OJEMANN[4]

[1]Dept. of Bioengineering, [2]Bioengineering, [3]Radiology, [4]Dept Neurosurg., [5]Paul G. Allen Sch. for Computer Sci. and Engin., Univ. of Washington, Seattle, WA

Abstract: Objective: Direct cortical stimulation (DCS) may help close the loop in brain computer interfaces. Recent work by our group has shown a significant delay in response times to DCS of primary somatosensory cortex (S1) compared to natural sensory stimulation in humans. In the current on-going study we extend this finding to examine psychometric response timings and perception, and conduct spectro-temporal analyses of human electrocorticographic (ECoG) signals during near-simultaneously delivered DCS of hand area of S1 and natural haptic stimulation to equivalent areas of the subject's hand.
Methods: A subject was implanted with subdural electrodes for epilepsy monitoring. We provided haptic stimulation through digital touch probes to the same cutaneous region where sensation was perceived during DCS of S1 hand cortex. DCS was applied in close temporal proximity to natural haptic touch with varying time lags. The subject was asked after each trial which stimulus was perceived first, and also responded via button press to stimulus onset.
Results: Only in trials where haptic touch trailed DCS by over 200 ms did the subjects reliably perceive DCS as arriving first. From haptic touch trailing DCS by 200 ms to approximately both arriving concurrently, there was ambiguity in the subject's perception of which stimulus arrived first (Fig. A, left). As previously seen, responses to DCS (when perceived first) were slower than trials when haptic was perceived first (Fig. A, right). The subject described perception of both sensations as distinct in all conditions, indicating that perception of both stimuli was not masked by simultaneous application.
Conclusions: There is a range of latencies for which overlapping spatial and temporal DCS and natural stimuli are perceived as arriving simultaneously. This has implications for future brain-computer interfaces, where both cortically-delivered feedback and natural feedback may arrive synchronously. Furthermore, our results demonstrate that spatially and temporally overlapping natural feedback and DCS can be isolated as distinct sensations.

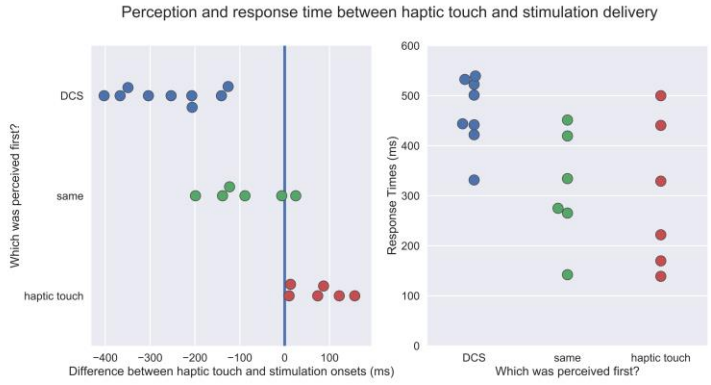

Figure A: With DCS delivered before haptic stimulation with a range of time deliveries from 400 ms to -200 ms, all trials were distinctly perceived as DCS arriving first. Between -200 ms and 25 ms, with 25 ms representing DCS onset 25 ms after haptic touch onset, the subject reported the stimuli arriving at approximately the same time. With DCS arriving between 75 ms to 150 ms after haptic touch, the subject always reported perceiving haptic touch first (Left panel). The plot shows a distribution of response times, where following a Kruskal-Wallis test and Nemenyi's multiple comparisons test, the haptic touch condition stochastically dominates the DCS condition, consistent with our previous results that haptic touch results in faster reaction times than DCS (right panel).

Abstract: Introduction: Direct cortical stimulation (DCS) of primary somatosensory cortex (S1) may provide a means of delivering somatosensory feedback in a brain-computer interface. Previous work from our group has demonstrated that human subjects can perceive and discriminate the intensity of DCS based on varied current amplitude or frequency, use DCS as feedback in a motor task, and respond more slowly to DCS of S1 than to natural sensory stimulation. There remains, however, a sizeable gap in our understanding of the stimulation parameters that may be used to convey a wide range of uniquely discernable percepts. Here we report results from our ongoing work exploring human subjects' perception of DCS by varying stimulation parameters and computing psychometric functions for DCS.
Methods: Human subjects were implanted with subdural electrodes for epilepsy monitoring. We used Tucker-Davis Technologies hardware to deliver bipolar, constant-current stimulation using trains of biphasic square pulses. We varied the current amplitude using a staircase method to quantify subjects' perceptual thresholds. Five subjects completed the experiment with staircases converging on a 50%, 89%, and 79% threshold for Subjects 1-3, respectively. Subjects 4 and 5 also converged on a 79% threshold using a double-interleaved staircase in which two 1-up, 3-down staircases were randomly interleaved to discourage pattern recognition. The resultant data were fit with a Weibull function using a maximum likelihood method.
Results: Using 200 ms DCS trains with 200 Hz pulses, we found perceptual current thresholds

of 0.77, 1.38, and 1.31 mA for Subjects 1-3, respectively, in single experiments with 205 µs pulse widths (PWs). Subject 4 completed the experiment on two consecutive days with 205 µs PWs and thresholds of 1.29 mA on the first day and 0.88 mA on the second day. Subject 5 also completed the experiment twice; once with 205 µs PWs resulting in a 3.76 mA threshold and once with 819 µs PWs resulting in a 2.56 mA threshold. Figure 1 illustrates the results of the staircase procedure and psychometric function for Subject 5.

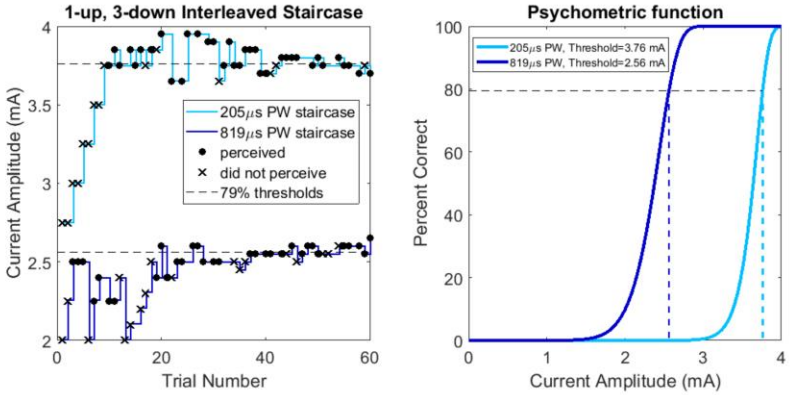

Figure 1. Comparison of perceptual thresholds (79%) and psychometric function for Subject 5. Subject 5 completed two 1-up, 3-down double-interleaved staircases both with 200 ms DCS train durations and a 200 Hz pulse frequency. Each experiment's two staircases included 25 test and 5 catch trials, randomly interspersed. In a given experiment, the two staircases were randomly interleaved to discourage pattern recognition, but are displayed as a single merged staircase here. The first staircase experiment used a pulse width (PW) of 205 µs (light blue), while the second staircase used a PW of 819 µs (dark blue). **Left panel:** Subject 5's responses to each of the non-catch trials. This subject completed 10 catch trials, with no stimulation delivered, to estimate the subject's guessing rate. He did not perceive any of the catch trials, so his guess rate was estimated as 0%. **Right panel:** Estimated psychometric function with 79% thresholds overlaid. The subject's guess rate (0%) dictated the lower bound of the psychometric function. Using the fitted psychometric function, we estimate Subject 5's perceptual current thresholds to be 3.76 mA and 2.56 mA for the 205 and 819 µs PWs, respectively.

Title: Human perception of biomimetic intracortical microstimulation in somatosensory cortex

Authors: *C. L. HUGHES[1], J. M. WEISS[2], S. J. BENSMAIA[3], R. A. GAUNT[2]
[1]Dept. of Bioengineering, [2]Physical Med. and Rehabil., Univ. of Pittsburgh, Pittsburgh, PA;
[3]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Brain-computer interfaces are powerful technologies that may allow for the restoration of motor function to individuals with damage to the brain, spinal cord, or limbs. A critical component of restoring this function, and indeed of natural motor control, is somatosensory feedback. In an ongoing experiment, we are studying the use of intracortical microstimulation (ICMS), delivered through Utah arrays implanted in somatosensory cortex, to restore tactile percepts in a human participant with a C5/C6 spinal cord injury. ICMS can elicit sensations of the contralateral hand ranging from less natural percepts, such as tingle, to more natural percepts, such as pressure and touch. However, it is not well understood what leads to these different qualities and reported levels of naturalness. One technique that may elicit more naturalistic percepts is to stimulate with "biomimetic" pulse trains that mimic normal neural activity. Although these pulse trains only represent a small component of what occurs in the cortex in response to natural peripheral stimuli, we hypothesized that single-channel pulse trains, where the pulse timing was based on recorded spiking activity, would be distinguishable from fixed-frequency pulse trains and further that these biomimetic pulse trains would feel more natural to the participant.
We began by building a biomimetic pulse train from neural data recorded from non-human primate cortex during finger indentation. We then used a two-alternative forced choice task in which the participant had to determine which of the two presented pulse trains, either the biomimetic or a fixed-frequency (100 Hz) pulse train, felt more natural. Each pulse train was presented at 60 μA for 1-s. The participant was not made aware of which pulse train was normal or biomimetic and the ordering of the trains was varied randomly throughout a set. On eight of the sixteen electrodes tested, there was a significant difference in the pulse train selection (z-test with Benjamani-Hochberg correction for multiple comparisons, Q=0.05) with six of the eight rated as being more natural with biomimetic pulse trains. Although improved naturalness does not guarantee improved function for bidirectional BCI technology, and further testing will be required to establish functional gains from biomimetic feedback, naturalistic artificial touch will likely improve the user experience and embodiment of the device. Understanding which stimulation features or electrode properties drive improved naturalness will inform the development of more natural and possibly more useful stimulation regimes.

Title: Sciatic intraneural stimulation evokes selective sensations from the phantom leg of trans-femoral amputees

Authors: *F. M. PETRINI[1,2], G. VALLE[3], M. BUMBASIREVIC[4], F. BARBERI[3], D. GUIRAUD[5], T. STIEGLITZ[6], S. MICERA[1], S. RASPOPOVIC[2]

Abstract: Leg amputation destroys the communication between brain and environment during walking. Leg amputees rely on practically inexistent and often uncomfortable haptic feedback from the stump-socket interaction to monitor ground and obstacles contact, climb stairs, or walk in challenging environments. The lack of sensory feedback causes specific impairments to subjects that do not perceive the prosthesis as part of their body and risk falls, have decreased mobility, increased cognitive burden during walking resulting in prosthesis abandonment. In hand amputees, to restore the bidirectional communication, nerve interfaces have directly linked sensors readout from robotic hands to direct stimulation of nerves above injury. We believe that this strategy could also restore sensations from missing legs, with many scientific and technological barriers to overcome. It has never been proved that the electrical stimulation of the leg nerves by implantable neural interfaces can induce reliable sensations from missing leg and foot. In this work we developed a leg prosthesis restoring sensory feedback by means of direct nerve stimulation injected through transversal intraneural electrodes (TIME) implanted in the sciatic nerve. The stimulation was driven by the readout of pressure sensors placed under the prosthetic foot, and an encoder embedded in the prosthetic knee. We assessed the capability of 3 transfemoral amputees to recognize, blindfolded and acoustically insulated, the location where the prosthetic foot was touched and the degree of flexion of the prosthetic knee. The subjects were asked to recognize only touch, only flexion and then both conditions at the same time. We compared the performance when sensory feedback was restored and when no nerve stimulation was delivered. We found that single and double condition-tasks were executed on average respectively with a success rate of about 85% and 75%, when sensory feedback was provided. Without nerve stimulation the average success rate dropped to 25%.

Title: A vision of touch

Authors: *S. CHIVUKULA[1], T. AFLALO[1], C. Y. ZHANG[1], M. JAFARI[1], E. ROSARIO[2], D. OUELLETTE[3], K. PEJSA[1], N. POURATIAN[4], R. A. ANDERSEN[1]

Abstract: Growing evidence suggests that the brain integrates sensory information across modalities in proportion to its predictive value in estimating properties of the body and its surroundings. Within this framework, the lack of one sensory modality may at least partially be compensated by alternate modalities. A powerful example is the ventral visual stream recruitment of tactile and auditory information in the congenitally blind (Ptito et al., 2012). In a unique opportunity, we examined the neural encoding of seen (but not felt) touch on insensate arm regions of a tetraplegic human subject arising from visual feedback alone. We recorded from 2179 single neurons in the posterior parietal cortex (PPC) of a C3/4 spinal cord injured subject. Three task paradigms involving observed brush strokes to bilateral, insensate arm regions were used to 1) investigate the existence of, and limb coverage of, visual receptive fields (RFs), 2) explore their sensitivity to touch versus non-contact stimuli, and 3) determine their specificity to the native limb versus substitute objects. Single units (25.2%) were identified with significant response to seen touch. Bilateral visual RFs were encoded, and RFs collectively covered the entirety of the limbs. Visual RFs were encoded in a mix of reference frames (gradient analysis; Pesaran et al., 2006). In 39.5% of units, RFs were anchored to a region of the limb, independent of gaze (i.e., field or body-part centered). In most others (57.0%), the response depended on the relative gaze location and stimulated body part (i.e., eye-centered units). Next, touch was compared to non-contact stimuli. Response intensity was strongest for touch, with little responsiveness to stimuli above (visually overlapping) the limb, adjacent to the limb, or distant from the limb ($p<0.001$). In separate experiments, we examined the specificity of neural responses to the native limb by comparing them against touch to substitute objects. The population responsiveness varied across tested objects. Response patterns were selective (greater

specificity for the native limb (p<0.001) and distinct (multiple objects discriminably encoded). Moreover, the reference frames encoding touch responses to a substitute effector were less field centered than for the native limb (p=0.024). Taken together, our results suggest a neural basis within the human PPC for the processing of seen (but not felt) contact with oneself. Shared neural mechanisms also appear to selectively and discriminably encode contact-based interactions between objects in our sensory environment, hinting at a role for the PPC in a broader, visuospatial interpretation of our sensory surroundings.

Title: Representation of face, head and leg movements in “arm/hand” area of human motor cortex

Authors: *F. WILLETT[1,2], P. REZAII[1], L. R. HOCHBERG[8,9,11,12,10], J. M. HENDERSON[1,3,4], K. V. SHENOY[2,5,6,7,3]

Sch., Boston, MA

Abstract: Neural activity in motor cortex is thought to have a mixed somatotopic organization, in which face, arm and leg movements are represented in distinct areas of cortex but individual muscles within any one body part may be mixed (e.g. wrist and finger movements may overlap within arm area). However, these conclusions have been supported mainly by electrical

stimulation, intracortical recordings of arm movements only, or recording technologies with low spatial resolution (e.g. fMRI). Here, we revisit motor somatotopy using intracortical recordings from “hand knob” area of motor cortex while a participant in the BrainGate2 pilot clinical trial (T5) attempted a variety of face, head, leg and arm movements. Since T5 has a C4 level spinal cord injury, he could make face and head movements freely but could only attempt to make arm and leg movements.

Surprisingly, we found that face, head, and attempted leg movements are robustly represented in arm/hand area of motor cortex. Surveying 33 different movements, we found that changes in firing rate evoked by non-arm movements was 27% (face), 56% (head), and 46% (leg) as large as that evoked by attempted arm movement. This modulation was movement-specific and enabled accurate decoding of individual face, head and leg movements (94% accuracy across 25 different movements). We also found substantial representation of the ipsilateral limbs, with ipsilateral leg and arm movements generating modulation 60% and 55% as large as the contralateral limb. Next, we investigated how neural activity changed if two movements were executed simultaneously. Surprisingly, we found that modulation for the “secondary” effector (the effector with the least modulation when measured in isolation) was substantially attenuated during simultaneous movement (67% attenuation), while modulation for the “primary” effector remained mostly intact (15% attenuation). If these results are due to plastic reorganization after spinal cord injury, they suggest a larger reorganization than once thought (especially given the substantial leg-related activity). If not, the results suggest an update to the conventional somatotopy, given that we found overlapping representations even for widely separated areas of the body (e.g. face vs. leg).

For neuroprosthetics, the results show that while a variety of isolated movements can be decoded from a single cortical area, recording from multiple areas may help when decoding multiple effectors (to mitigate attenuation of the secondary effector). The results also imply that concurrent face / head movements could interfere with (or contribute to) arm movement decoding if not explicitly decorrelated.

Title: Assessment of functional benefits afforded by sensory-enabled prostheses to upper-limb amputees

Authors: *J. J. ABBAS[1], S. S. KUNTAEGOWDANAHALLI[2], K. HORCH[2], L. RINCON GONZALEZ[2], A. E. PENA[2], A. K. THOTA[2], B. K. HILLEN[2], D. AGUILAR[2], R. JUNG[2]

Abstract: Recent developments in prosthetic systems have been directed at providing sensory feedback to enhance the functional capacity of users. These systems aim to improve the ability to manipulate objects and/or reduce the attentional demands by providing sensory feedback that is synchronized with signals derived from prosthesis-mounted sensors. Some systems utilize electrodes implanted either near peripheral nerve fibers or central nervous system structures; others use skin-mounted vibrotactile actuators or electrocutaneous stimulation. We have developed a battery of tests to be performed with sensory-enabled prostheses in order to characterize the ability of the sensory stimulation to elicit graded percepts and to characterize the impact of sensory feedback on the ability of the user to control the prosthesis in a graded manner and use it to perform functional tasks. To assess the ability of stimulation to elicit graded percepts, we have developed two perceptual modality matching paradigms: one in which the subject uses the intact hand to report sensations elicited by stimulation on the side with the amputation and one in which the subject first uses the intact hand to reach a target level of the modality being tested (e.g. hand opening, force) and then adjusts stimulation on the side with amputation to match the percept on the intact side. To assess the ability to control the prosthesis in a graded manner, we have developed two graded control tasks: one in which the subject uses the prosthesis to match a target level of the output (e.g. hand opening, force) and one in which the subject first uses the intact hand to match the target level and then uses the prosthetic hand to match the contralateral percept. To assess the user's ability to perform functional tasks, we have developed two fragile object tasks (one in which the subject picks up fragile cookies and one in which they pick up a 'mechanical egg', which is an adjustable device designed to break when too much force is applied but can be readily reset after breaking), a controlled squeeze task (in which the subject uses a squeeze bottle to fill small cups with water), and a sensorimotor exploration task (in which the subject uses the prosthetic hand to ascertain the size and stiffness of an object). To assess the impact of stimulation or attention, the individual prosthesis control tests can be performed with or without stimulation and either in a single-task or dual-task paradigm. These tests have been designed to be used in conjunction with standardized clinical outcome measures and surveys to assess the functional benefits afforded by sensory-enabled prostheses.

Title: Neural-enabled prosthetic hand system to restore sensation in upper-limb amputees

Authors: *R. JUNG[1], S. S. KUNTAEGOWDANAHALLI[1], A. K. THOTA[1], A. E. PENA[1], K. W. HORCH[1], J. PATRICK[2], J. J. ABBAS[3]

Abstract: Today's upper limb amputees have needs that are not being met by current prosthetic technology because these systems do not provide effective sensory feedback from the prosthesis. This results in reduced quality of life and limitations in performing duties that require manipulation and high-quality grasp control. To address this problem, we have developed the Neural Enabled Prosthetic Hand (NEPH) system to provide amputees with sensations that are synchronized with sensor-derived signals from the prosthetic hand. The system includes an implanted electronic neurostimulator to deliver stimulation via fine-wire longitudinal intrafascicular electrodes (LIFEs) implanted in peripheral nerves of the residual limb and an external, prosthesis socket-mounted module that utilizes a wireless link to communicate stimulation commands to the implanted electronics. The NEPH system has been designed for daily use; donning, doffing, daily operation and maintenance are all similar to use of a commercially-available myoelectric prosthetic hand. The system has been approved as an investigation device by the FDA for evaluation in a first-in-human early feasibility clinical trial in transradial amputees and has a CMS Category B4 classification, thereby facilitating Medicare coverage. Detailed surgical procedures have been developed to implant multiple LIFEs for targeted stimulation of fibers in the median and ulnar nerves, routing the lead and passing the electronic housing from the medial to the lateral aspect of the upper arm and implanting the electronic housing with attached antenna in a subcutaneous pocket. The implanted components are all fabricated at a commercial manufacturing facility. There is no implanted battery and a single prosthetic frame-mounted battery powers the commercially available instrumented prosthetic hand, external electronics and implant electronics (via RF). The external electronics, which are embedded in the prosthetic hand frame, allow real-time wireless delivery of stimulation parameters to the implanted neurostimulator based on sensors in the prosthesis. The

user can select from stored, customized stimulation mapping functions and adjust stimulation intensity during use.

Title: Acquisition of body schema to control a virtual tail via EEG-based brain-computer interface

Authors: *S. KIMURA[1], S. KASUGA[2], N. MIZUGUCHI[3], J. USHIBA[3,4]
[1]Grad. Sch. of Sci. and Technol., Keio Univ., Kanagawa, Japan; [2]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [3]Dept. of Biosci. and Informatics, Keio Univ. Fac. of Sci. and Technol., Kanagawa, Japan; [4]Keio Inst. of Pure and Applied Sci. (KiPAS), Kanagawa, Japan

Abstract: Body schema refers to self-body representation that is considered to be acquired through integration of multimodal information. Previous studies suggest that body schema can be modulated as extension of the existing body. However, it remains unknown whether adult humans can acquire body schema of a novel body part that they do not innately have. In the current study, to evaluate body schema of a "tail" after training by using electroencephalogram (EEG) based Brain-Computer Interface (BCI) technology, we assessed kinematical, psychological, and neurophysiological data throughout successive 3-days interventions.
Nine healthy adults conducted BCI control training (100 trials/day). One trial consisted of the rest (with eye opening), the preparation, the task (motor imagery), and the interval phase. Participants were instructed to find a free image by which the tail was well controlled without regard to tail-related images. Participants were allowed to freely change the images every 10 trials, and they verbally reported what they would image in the next 10 trials. The scalp EEG signal was derived from the Cz of the International 10-20 System, and α-band (8-13 Hz) event related desynchronization (ERD) was calculated every 100 ms with a 90% overlapped 1-s sliding time window processed. The virtual tail movement was determined by ERD value. If more than 20% of ERD was detected during the task phase, the tail reached the target and that trial was defined as succeeded. Participants were not informed by what algorithm the tail movements are controlled. Body ownership of the tail was measured by Body Ownership and Agency Questionnaire (Osimo et al., 2015) which answers with 7-levels of Likert scale in every 10 trials.

We found significant increase in the success rate ($p < 0.05$) and score of the body ownership ($p < 0.05$) after 3-days of training. Since participants changed their images exploratorily in day 1, the number of image variation was larger than day 3 ($p < 0.05$). In the middle days of training, the success rate improved 16 % on average, however they rarely imagined the tail movement. Finally, their imagined movements converged on the tail movement in six subjects and body ownership of the tail enhanced 1.8 points on average. These results suggest that the capability of "controlling of the tail" improved, then body ownership of the tail acquired.
Our finding demonstrated for the first time that BCI training had a potential to acquire body schema of a novel body part in adult human. The present study would not only contribute to understanding of neural mechanisms of body schema, but also to rehabilitation of patients who have distorted self-body perception due to neurological disorders.

Title: Central circuits for CO_2 chemosensory regulation of breathing in freely behaving mice

Authors: *A. M. BHANDARE, R. T. R. HUCKSTEPP, N. E. DALE
Sch. of Life Sci., Univ. of Warwick, Coventry, United Kingdom

Abstract: The regulation of breathing by blood PCO_2 is critical for survival in animals. Central CO_2 chemosensory circuits contribute to the regulation of breathing, however their respective contributions remain unclear in freely behaving animals. In the retrotrapezoid nucleus (RTN), neurons and astrocytes are sensitive to CO_2/H^+ and their activation may increase breathing frequency and tidal volume. This has been shown: *in vitro* in slice preparations; *in vivo* under anaesthesia; and via molecular detection of activated cFos. As anaesthesia depresses neural and glial activity, the response of RTN neurons and astrocytes to hypercapnia in freely behaving animals remains unknown, though optogenetic stimulation/inhibition of RTN neurons in conscious rats would suggest that its contribution is significant. We have investigated dynamic cellular activity of putative chemosensitive RTN neurons and glia in conscious animals by means of genetically-encoded calcium indicators and implanted gradient refractive index optic fibres (GRIN lens). Our novel microendoscopic approach has allowed us to record Ca^{2+} transients *in vivo* from individual RTN neurons and astrocytes in mice (12-20 weeks old of either sex) during hypercapnic and hypoxic challenges. We find that RTN neurons and astrocytes are transiently

activated by changes in inspired CO_2. A transient drive for breathing from chemosensory RTN neurons and astrocytes during hypercapnia suggests that other central circuits may be required for the full respiratory response to hypercapnia in freely behaving animals.

Title: Cardiorespiratory regulation by glutamatergic neurons in the caudal solitary nucleus

Authors: *S. YOKOTA[1], K. TAKEDA[2], M. LAZARUS[3], Y. ARIMA[1], M. FUJITANI[1], Y. OKADA[4]
[1]Dept. of Anat. and Neurosci., Shimane Univ., Izumo, Japan; [2]Sch. of Hlth. Sci., Fujita Hlth. Univ., Toyoake, Aichi, Japan; [3]Intl. Inst. for Integrative Sleep Med., Univ. of Tsukuba, Tsukuba, Japan; [4]Murayama Med. Ctr., Tokyo, Japan

Abstract: The caudal solitary nucleus (cNTS) is the site receiving general visceral afferent, which conveys information on arterial gas partial pressures and blood pressure from the carotid body and carotid sinus, respectively. Glutamatergic cNTS neurons are activated under hypoxia and hypercapnia. However, the role of these neurons in cardiorespiratory regulation is not completely understood. In this study, we chemogentically activated glutamatergic cNTS neurons to examine the role of these neurons in cardiorespiratory regulation. For this purpose, we injected Cre-dependent adeno-associated viral vectors expressing a mutated M3-muscarinic receptor into the cNTS of genetically modified mice that expressed Cre recombinase under the control of the endogenous vesicular glutamate transporter 2 gene (VGLUT2-Cre mice). We then measured respiratory parameters by whole body plethysmography and blood pressure using a non-invasive sphygmomanometer after intraperitoneal injection of clozapine-N-oxide. As a result, chemogenetic activation of glutamatergic cNTS neurons increased tidal volume and minute ventilation with no significant change in respiratory rate and slowed heart rate with no significant change in blood pressure. Next, we demonstrated, by using Fos expression combined with retrograde tracing or tyrosine hydroxylase (TH) immunohistochemistry, that some phrenic nucleus-projecting neurons and many TH-immunoreactive neurons in the ventrolateral medulla expressed Fos protein after chemogenetic activation of glutamatergic cNTS neurons. We further showed, by using Cre-dependent conditional anterograde tracing combined with retrograde tracing or TH immunohistochemistry, that axon terminals of glutamatergic cNTS neurons were

apposed to phrenic nucleus-projecting neurons and TH-immunoreactive neurons in the ventrolateral medulla. These results suggest that glutamatergic cNTS neurons may regulate the tidal volume of respiration via projections to neurons that send axons to the phrenic nucleus, whereas glutamatergic cNTS neurons regulate heart rate via projections to TH-positive ventrolateral medullary neurons.

Title: Molecular and functional diversity of pulmonary sensory neurons revealed by single-cell RNA sequencing

Authors: *Y. LIU, A. DIAZ DE ARCE, M. A. KRASNOW
Biochem., Stanford Univ., Stanford, CA

Abstract: Pulmonary sensory neurons monitor the state of the lung and communicate with the brain to regulate breathing and pulmonary physiology. In pulmonary diseases, the activity of pulmonary sensory neurons is altered, leading to debilitating symptoms including chronic cough, dyspnea, and airway hyperresponsiveness. To understand the molecular and cellular mechanisms underlying these symptoms, a comprehensive characterization of pulmonary sensory neurons in health is required. Over the past several decades, the electrophysiological properties of pulmonary sensory neurons have been characterized, which revealed intriguing heterogeneity. However, the full molecular and functional diversity of these neurons was poorly understood. Here, we obtained genome-wide transcriptome of mouse vagal sensory neurons that are retrogradely labeled from the lung using single-cell RNA sequencing technology. By unbiased cluster analysis, we defined eight molecularly distinct subtypes of these neurons and identified molecular marker genes for each subtype. Detailed analyses on expression patterns of genes involved in sensory function and cell-cell communication enable predictions on which endogenous and exogenous stimuli each subtype of neurons can sense, what neurotransmitters and neuropeptides they can release, and their potential interactions with non-neuronal cells. Following the initial classification, we further quantified the number of each identified subtype and characterized their terminal morphologies and locations in the lung by combining antibody

staining, in situ hybridization, and genetic labeling. This work provides a systematic and comprehensive molecular and anatomical characterization of vagal pulmonary sensory neurons, enabling subtype-specific manipulation of these neurons to interrogate their physiological functions.

Title: Respiratory load compensation and perception during submaximal exercise in collegiate athletes

Authors: *S. ADAMS[1], D. C. MALLOY[2]
[1]Hlth. and Exercise Sci., Pfeiffer Univ., Concord, NC; [2]Drexel Univ., Philadelphia, PA

Abstract: Respiratory perception is complex and combines the emotional state of the subject, as well as, the magnitude and duration of the respiratory load. Emotion affects respiratory load perception regardless of physiological ventilatory changes (Tsai et al., 2013). A respiratory load results in inadequate respiratory compensation with high loads but may not show an effect at mild loads (Lind and Hesser, 1984). It is not known if respiratory compensation and perception are compromised during submaximal exercise with a mild respiratory load in healthy collegiate athletes. **PURPOSE:** To determine respiratory function and perception with a respiratory load in submaximal exercise post-concussion. **METHODS:** Healthy male collegiate athletes (age 19-23) performed a VO_2 maximal graded exercise test (Bruce protocol) followed a week later by 60% VO_2 submaximal (submax) exercise with/without respiratory load (10% restriction). Athletes were assigned to responder (R) or non-responder (NR) groups: R (n=4) and NR (n=4). Restricted load (RL) physiological and perception parameters were compared using T-test measurements. **RESULTS:** R during submax RL exercise had increased VO_2 13% (28.02±0.64 ml/min/kg SEM, p=0.01) compared to NR (24.90±0.83 ml/min/kg SEM), HR 13% (133.22±3.78 bpm SEM, p=0.001) compared to NR (118.24±3.21 bpm SEM), RPE 23% (12.1±0.87 SEM, p=0.35) compared to NR (9.85±0.1.32 SEM), Urge to Stop (UTS) 52% (11.46±0.72 SEM, p=0.02) compared to NR (7.55±0.38), Rating of Breathing Exertion (RBE) 28% (11.95±0.55 SEM, p=0.18) compared to NR (9.30±1.11 SEM), but decreased Ve 11% (48.37±5.33 SEM, p=0.26) compared to NR (54.57±1.65 SEM) and Rf 8% (32.30±0.86 bpm SEM, p=0.31) compared to NR (34.96±2.46 bpm SEM). **CONCLUSION:** Compensation was evidenced by increased oxygen consumption, heart rate, and perception to respiratory load in R athletes. The NR athletes had

blunted responses to the respiratory load. Future research including anxiety and stress measurements pre- and post-respiratory load are warranted.

Abstract: Hypoxia transiently increases ventilation via the excitation of peripheral chemoreceptors. However, peripheral chemoreceptor-denervated animals increase ventilation in response to hypoxia when unanesthetized and awake, indicating the existence of the central respiratory hypoxia-sensing mechanism. Recently, it has been elucidated that astrocytes play active roles in various brain functions, and we have hypothesized that astrocytes are involved in modulation of respiration in a hypoxic condition. To investigate this hypothesis, we conducted experiments using arundic acid, an inhibitory modulator of astrocytic function. Firstly, we examined the astrocyte/neuron specificity in cell activation blockade action of arundic acid, by comparing its effects on high potassium-induced activation in cultured cortical astrocytes and cerebellar granule neurons of the mouse by ratiometric calcium imaging. Arundic acid inhibited activation of astrocytes in a dose-dependent manner. However, arundic acid did not suppress

activation of neurons. Secondly, we examined hypoxic responses of astrocytic activities in the ventrolateral medulla and respiratory frequency in the isolated medulla-spinal cord preparation of newborn rats, which is ideal for the study of the purely central mechanism of respiratory control. Each preparation was superfused first with control oxygenated (95% O_2, 5% CO_2) artificial cerebrospinal fluid (aCSF), followed by brief hypoxic exposure by replacing the superfusate with a hypoxic (95% N_2, 5% CO_2) aCSF. Astrocytic activity in the ventrolateral medulla was measured by confocal calcium imaging. Neural respiratory output was recorded from ventral roots of the 4th cervical cord. We found that a number of astrocytes were activated in a hypoxic condition in the ventrolateral medullary respiratory region. Without pretreatment with arundic acid, respiratory frequency increased in a hypoxic condition. However, increases in respiratory frequency of the preparation pretreated with arundic acid tended to be smaller during hypoxic exposure. We conclude that astrocytes in the medulla play an important role in facilitation of respiration in a hypoxic condition.

Title: PACAP expression in RTN chemosensory neurons contributes to CO_2-stimulated breathing

Authors: *Y. SHI, D. STORNETTA, A. SAHU, K. LI, Y. WABARA, A. DHAKAL, E. PEREZ-REYES, R. STRONETTA, P. GUYENET, D. BAYLISS

Abstract: CO_2/H^+-sensitive neurons of the retrotrapezoid nucleus (RTN) are a nexus for integration of multiple respiratory-related inputs, providing homeostatic regulation of blood gases and arterial pH by driving the networks that determine the rate and depth of breathing. Firing activity in RTN neurons is a critical determinant of respiratory output. These excitatory glutamatergic RTN neurons also express a number of neuroactive peptides, for which a physiological function remains enigmatic. Among these, recent single cell RNA-Seq and *in situ* hybridization studies revealed that pituitary adenylate cyclase-activating peptide (PACAP) is

expressed universally in mouse RTN neurons. In global knockout mice, PACAP deletion is associated with reduced whole animal CO_2 sensitivity and a sudden infant death syndrome (SIDS)-like phenotype. Here, by using single cell qRT-PCR and *in situ* hybridization, we show that PACAP expression is developmentally regulated in mouse RTN neurons, with low levels in the late embryonic period, and a prominent peak in the days immediately after birth that tapers to moderate levels that are maintained into adulthood. In adult mice, viral shRNA-mediated knockdown of PACAP selectively in RTN neurons decreased ventilatory stimulation by CO_2 assessed by whole-body plethysmography. After PACAP knockdown, activation of RTN neurons *in vivo* by CO_2, determined by Fos expression, was unaffected; by contrast, CO_2-dependent Fos expression activation was decreased in neurons of the preBötzinger complex (preBötC), which contains respiratory rhythm-generating neurons targeted by the RTN. In anesthetized mice, direct injection of PACAP into the preBötC region increased the rate and amplitude of diaphragmatic activity, consistent with stimulation of central respiratory output. Conversely, viral shRNA-mediated knockdown of PAC1, the PACAP receptor, in the preBötC region reduced CO_2-stimulated breathing. Collectively, these data indicate that PACAP expression by RTN neurons is necessary for normal ventilatory responses to CO_2, likely via actions in the preBötC. The particularly prominent expression of PACAP around the time of birth, an especially vulnerable period, may provide a critical mechanism to facilitate and maintain the transition to air breathing required for extrauterine life.

Title: Baseline activity and CO_2/H^+-sensitivity of neurons in the retrotrapezoid nucleus are increased in a mouse model of Rett syndrome

Authors: *C. M. GONÇALVES[1], M. L. OLSEN[2], D. K. MULKEY[1]
[1]Dept. of Physiol. and Neurobio., Univ. of Connecticut, Storrs Mansfield, CT; [2]Sch. of Neurosci., Virginia Polytechnic and State Univ., Blacksburg, VA

Abstract: Rett Syndrome (RTT) is an X-linked neurodevelopmental disorder that is caused by loss-of-function mutations in the methyl-CpG-binding protein 2 (MeCP2) gene. A profound and life-threatening symptom of RTT is disordered breathing, characterized by forced or irregular breathing, hyperventilation, and frequent episodes of apnea. Mouse models of RTT recapitulate this respiratory phenotype and suggest disruption of the mechanism by which the brain regulates breathing in response to changes in CO_2/H^+ (i.e., respiratory chemoreception) may be a contributing factor. The retrotrapezoid nucleus (RTN) is an important chemoreceptor region; however, the functional consequence of MeCP2 deficiency yet to be explored in RTN neurons. To make this determination, we made cell-attached recordings of RTN chemoreceptor activity in brainstem slices (230μM) from male $MeCP2^{-/y}$ and wild type littermate ($MeCP2^{tm1.1Jae}$) mouse pups between 9 and 12 days of age. Chemosensitive RTN neurons in slices from wild type mice had a baseline activity of 0.19 ± 0.2 Hz under control conditions (5% CO2; pH=7.30) and showed a robust increase in activity (Δ 1.58 ± 0.4 Hz; N = 7) in response to 15% CO2 (pH 6.9). RTN neurons from $MeCP2^{-/y}$ mice had a higher basal firing rate (1.48 ± 0.40 Hz; N = 9) ($p < 0.05$) and responded more vigorously to 15% CO2 (Δ 2.90 ± 0.4 Hz; $p < 0.05$). This is interesting because enhanced chemoreceptor gain may cause periodic or irregular breathing; therefore, these results support the possibly that MeCP2 deficiency disrupts RTN chemoreceptor function and contributes to disordered breathing in RTT.

Abstract: The brain regulates breathing in response to changes in tissue CO_2/H^+ by a process termed central chemoreception. Neurons and astrocytes in a brainstem region known as the retrotrapezoid nucleus (RTN) function as respiratory chemoreceptors. The role of astrocytes in this process involves CO2/H+-dependent release of ATP to enhance activity of chemosensitive RTN neurons. Considering that in most brain regions extracellular ATP is rapidly broken down to adenosine by ectonucleotidase activity, we wondered whether adenosine signaling contributes to RTN chemoreceptor function. To explore this possibility, we characterized the effects of exogenous adenosine on the activity of chemosensitive RTN neurons in slices from rat pups (7-12 days postnatal). Cell-attached recordings from RTN chemoreceptors show that bath application of adenosine (1 μM) strongly inhibited neural activity under control conditions and during high CO2. Adenosine-mediated inhibition of chemoreceptor activity was blunted by prior incubation with the A1 receptor antagonist DPCPX (30nM). We also found in whole-cell voltage clamp mode (Vhold=-60 mV, 1μM TTX) that exposure to adenosine increased outward current 10.42 ± 0.68 pA ($p < 0.001$) and conductance 0.26 ± 0.02 ($p < 0.01$) by activation of an inward rectifying K+ conductance. Furthermore, exposure to adenosine also decreased the frequency of excitatory post-synaptic currents recorded from chemosensitive RTN neurons ($p < 0.05$). These results suggest adenosine/A1 receptor signaling inhibits RTN neurons by pre- and post-synaptic mechanisms. To test this possibility in vivo, we characterized respiratory activity in A1 receptor knockout mice. Contrary to our expectations, A1 receptor knockout mice showed a reduced respiratory frequency under room air conditions ($p < 0.05$) and showed a reduced ventilatory response to CO2 (balance O2) compared to litter mate control mice ($p < 0.05$). Although it is not clear why ablation of inhibitory A1 receptors results in a hypoventilatory phenotype, we consider the most likely possibility to be that A1 receptor knockout mice are also seizure prone and seizure activity can suppress breathing. Nevertheless, at the level of the RTN we conclude that adenosine signaling through A1 receptors inhibits chemoreceptor activity.

Title: $P2Y_2$ receptors contribute to specialized CO_2/H^+ dependent regulation of arteriole tone in the retrotrapezoid nucleus

Authors: *C. CLEARY, D. MULKEY
Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: Regulation of cerebral blood flow is critical for normal brain function; the accumulation of CO_2/H^+ causes vasodilation leading to enhanced delivery of O_2 and removal of CO_2/H^+, thus helping to match blood flow with tissue metabolic needs. Tissue CO_2/H^+ also functions as the primary stimulus for breathing by activating respiratory chemoreceptors. Interestingly, recent evidence suggests that CO_2/H^+-dependent regulation of blood flow in a chemoreceptor region, known as the retrotrapezoid nucleus (RTN), is opposite to the rest of the cerebrovascular tree; exposure to high CO_2/H^+ decreases arteriole tone by a mechanism that may involve $P2Y_2$ receptors. However, it is not clear which cells at the astrocyte-arteriole interface express $P2Y_2$ receptors. Making this determination is important since regulation of blood flow in the RTN influences respiratory behavior. Therefore, the goals of this study are to confirm *in vitro* that $P2Y_2$ receptors are important determinants of RTN vascular tone and, using qRT-PCR, to characterize $P2Y_2$ mRNA expression within each component of the astrocyte-arteriole interface in chemoreceptor regions, including the nucleus tractus solitarius (NTS), midline raphe, and RTN as well as non-respiratory brainstem regions. Brainstem slices (150 υm thick) were isolated from adult C57BL6/J mice and maintained under control conditions (5% CO2, balance air) plus thromboxane A2 receptor agonist U46619 (125 nM) to induce a partial constriction. While monitoring vessel diameter with fluorescent video microscopy, we found that bath application of a selective P2Y2/4 agonist UTPyS (100 υM) constricted arterioles by 10.5% +/- 0.41%, whereas exposure to a selective $P2Y_2$ antagonist AR-C 118925XX (10 υM) blocked the CO_2/H^+-evoked vasoconstriction. Next, using cell type specific reporter lines (smMHCCre/eGFP, Aldh1l1Cre/TdTomato, Tie2-Cre/TdTomato) we isolated astrocytes, endothelial cells, and smooth muscle cells from each region of interest (NTS, Raphe, RTN) for subsequent FACS and qRT-PCR. Consistent with our hypothesis, we found that $P2Y_2$ mRNA was highly expressed in smooth muscle cells from RTN arterioles but was not detectable in endothelial cells across all regions of interest. $P2Y_2$ mRNA did not appear to be enriched in astrocytes from either region. Since activation of $P2Y_2$ in smooth muscle is known to constrict arterioles, whereas activation of these receptors in endothelial cells does the opposite, these results identify $P2Y_2$ receptors in smooth muscle cells as a likely candidate for the CO_2 dependent regulation of vascular tone in the RTN seen *in vitro* and *in vivo*.

Title: A Trpm4-like subthreshold oscillation underlies repetitive firing in mouse chemosensitive RTN neurons

Authors: K. LI[1], Y. SHI[1], *D. A. BAYLISS[2]
[1]Univ. of Virginia, Charlottesville, VA; [2]Dept Pharmacol, Univ. of Virginia Dept. of Pharmacol., Charlottesvle, VA

Abstract: The firing activity of CO_2/H^+-chemosensitive neurons of the retrotrapezoid nucleus (RTN) provides a critical drive to brainstem respiratory networks that regulate breathing. These neurons display a highly regular repetitive firing pattern when recorded *in vivo*, or when depolarized beyond action potential threshold *in vitro* (e.g., by lowering pH or current injection). The ionic basis for this steady firing pattern has not been established. Here, we demonstrate a role for the Trpm4 channel that underlies pacemaker-like firing activity in other neurons. By single cell RNA-Seq and *in situ* hybridization, we found that a majority of mouse RTN neurons express *Trpm4* transcripts (~60-70%). In the presence of tetrodotoxin (TTX), RTN neurons in mouse brainstem slices exhibited a prominent subthreshold oscillation that increased in amplitude with membrane depolarization. Consistent with a role for the Ca^{2+}-sensitive and Na^+-permeable Trpm4 channel, TTX-resistant membrane oscillations in RTN neurons were inhibited by blocking calcium currents (with Cd^{2+}) or by replacing bath sodium (with NMDG); moreover, they were also blocked by the general Trp channel blocker, flufenamic acid, and by the Trpm4-selective inhibitor, 9-phenanthrol. Under conditions of bath acidification in the presence of TTX, the typical pH-dependent membrane depolarization of RTN neurons was associated with a marked enhancement of oscillatory subthreshold activity. The firing activity of RTN neurons, measured by cell-attached recordings *in vitro*, was strongly diminished by 9-phenanthrol, although the stimulatory effect of pH on action potential discharge from this lower baseline firing rate was unaffected. Together, these data implicate Trpm4 in determining the repetitive firing activity of RTN neurons; these channels influence RTN neuron firing responses by enhancing membrane oscillatory behavior during acidification-induced depolarization in a manner seemingly independent of the basic intrinsic neuronal pH-sensing mechanisms.

Title: Metabolic inhibition of astrocytes reduces the respiratory response induced by hypercapnic acidosis of the raphe nucleus

Authors: *M. J. OLIVARES[1], S. BELTRAN-CASTILLO[2], J. L. EUGENÍN[1]
[1]Dept. de Biologia, Univ. de Santiago de Chile, Santiago, Chile; [2]Dept. de Neurología, Pontificia Univ. Católica De Chile, Santiago, Chile

Abstract: Homeostatic regulation of breathing is achieved through feedback information provided by peripheral and central respiratory chemoreceptors. Peripheral chemoreceptors sense $O_2/CO_2/H^+$ in the arterial blood and central chemoreceptors CO_2/H^+ in the interstitial fluid of the CNS and cerebrospinal fluid. In the brainstem, respiratory chemoreceptors are found, among other sites, in the retrotrapezoid nucleus, nucleus tractus solitarius, ventral lateral medulla, preBötzinger complex and raphe nucleus obscurus (RNO). Astrocytes play a key role as chemosensory interoceptors in the brainstem, they can release ATP, D-serine and glutamate in response to hypercapnia (increased levels of CO_2). We addressed here whether astrocytes from the RNO can modulate the respiratory response to hypercapnia *in vitro* and *in vivo*. In caudal brainstem slices obtained from neonatal CF1 mice (P0-P4), the fictive respiration was recorded from the ventral respiratory column (VRC) with glass suction electrodes while were superfused with artificial cerebrospinal fluid (aCSF) equilibrated with O_2/CO_2 = 95%/5%, (pH 7.4, 30 ± 1°C) or during hypercapnia, by gassing aCSF with O_2/CO_2 = 90%/10%, (pH 7.2). The local acidosis at the RNO was obtained by microinjection of aCSF-Pipes buffer (pH 6,5). The metabolic inhibition was done by superfusing the slices with fluoroacetate (5 mM, FA) with glutamine (1.5 mM, Gln) for 30 min before and during each hypercapnic test. Tidal volume (VT), minute volume (VE) and frequency (fR) were obtained by plethysmography from adult CF1 mice which were implanted with a cannula into the raphe obscurus nucleus 4 days before. We evaluated their ventilatory responses to hypercapnia before and after FA-Gln and saline solution microinjections into the RNO on the awake animals.Hypercapnia in slices increased the fR in about 30% whereas local acidosis of the RNO with aCSF-Pipes increased this fR in about 21%. Application of FA-Gln reduced both the basal fR and the hypercapnia-induced increase in fR in about 20%. In conscious adult mice microinjections of FA-Gln, decreased the hypercapnia-

induced ventilatory response in VT and VE. These results are compatible with the notion that caudal medullary astrocytes from RNO are interoceptors mediating central chemoreception.

Title: Brainstem mechanisms of cardio-ventilatory coupling

Authors: W. H. BARNETT[1], R. CAPPS[1], E. LATASH[1], D. M. BAEKEY[2], T. E. DICK[3], J. PATON[4], *Y. I. MOLKOV[1]
[1]Dept. of Mathematics and Statistics, Georgia State Univ., Atlanta, GA; [2]Dept. of Physiological Sci., Univ. of Florida, Gainesville, FL; [3]Med., Case Western Res. Univ., Cleveland, OH; [4]Univ. of Auckland, Auckland, New Zealand

Abstract: The respiratory and cardiovascular systems are integrated physiologically to oxygenate tissues and remove carbon dioxide. Brainstem neural circuits control cardio-respiratory functions, generate rhythms spontaneously and integrate central and sensory input to maintain gas homeostasis. Respiratory and cardiovascular outputs are partially synchronized/modulated by each other, and the respective brainstem neuronal networks have reciprocal synaptic connections. However, no quantitative mechanistic description was suggested to explain specific aspects of the cardio-respiratory interactions and their alterations in certain pathophysiological conditions.The influences of respiration on heart rate and blood pressure are well-recognized attributes of cardio-respiratory coupling; however the influence of a heart beat on respiration, known as cardio-ventilatory coupling (CVC), is just being recognized. CVC is a form of partial synchronization between cardiac and respiratory rhythm that is characterized by an increased probability of a heartbeat occurring at specific phases of the respiratory cycle. The neuronal circuitry that mediates CVC is not well understood.Previously, we suggested that baroreceptor input facilitates the activity of an inhibitory neuronal population of the respiratory central pattern generator (rCPG) that is active during the expiratory phase. Here, we introduce a closed loop model of the integrated respiratory and cardiovascular control system to describe our hypothesized mechanism for CVC. In this model, CVC is mediated by the pulsatile inputs from

arterial baroreceptors to neurons of the respiratory central pattern generator. Projections from 2nd order baro-sensitive neurons of the nucleus of solitary tract (NTS) excite a population of expiratory neurons in the rCPG. Excitation of these rCPG expiratory neurons makes the onset of inspiration less likely to occur right after the heartbeat thus reproducing a characteristic structure of the heartbeat probability distribution. To validate our *in silico* design, we utilized a dataset of single-unit ensemble recordings acquired from *in situ* rat preparation. The neurons were located primarily in the ventrolateral medullary cardio-respiratory column and were characterized by their firing patterns, by connectivity to other neurons and motor nerve recorded simultaneously and by their response to acute increases in perfusion pressure. These recordings captured the central coordination of cardio-respiratory network during the baroreflex and supported neural connectivity proposed in our model.

Abstract: Swallow-breathing coordination is critical for maintaining a clear airway during the act of swallowing. The initiation of a swallow is driven from afferent feedback to swallow pattern generators that coordinate with respiratory pattern generators for appropriate timing. As feedback plays a central role in swallow generation, swallowing is subject to many reflexes and feedback responses impacting the upper airway and respiration such as the pulmonary stretch feedback and the laryngeal adductor reflex (LAR). While the laryngeal adductor reflex has largely been thought of as a reflexive close of the vocal folds upon laryngeal mechanical stimulation, we are beginning to uncover its role in affecting pattern generation of both swallowing and respiration. Here we examined the role of the laryngeal adductor reflex on swallowing-breathing coordination in room air and 10% CO2. Swallowing was induced in

anesthetized spontaneously breathing cats by infusion of water into the oropharynx and experiments were conducted under conditions of room air or 10% CO2. Electromyogram activity was measured using bipolar electrodes inserted into upper airway muscles (mylohyoid, thyroarytenoid, and thyropharyngeus), inspiratory muscles (parasternal muscles and costal diaphragm), and expiratory muscles (external oblique). Previous work investigating the changes in swallow-breathing coordination during hypercapnia demonstrated swallows occurred more frequently during inspiration and the transition from expiration to inspiration. Accompanying these changes, we report a decreased occurrence of the LAR, and a change in its recruitment pattern during hypercapnia. In all cases, initiation of the LAR produced an abrupt stop of respiratory activity and in many cases a series of sequential swallows. These preliminary results inform on the potential connections of the laryngeal feedback to swallow and respiratory pattern generators, and imply an enhanced role of the larynx in swallow-breathing coordination.

Title: Anatomical characterization of Olfr78-expressing pulmonary sensory neurons

Authors: *A. J. DIAZ DE ARCE, Y. LIU, M. KRASNOW
Dept. of Biochem., Stanford Univ., Stanford, CA

Abstract: Pulmonary sensory neurons monitor the physiological state of our respiratory tract and regulate breathing to maintain homeostasis. This process is disrupted in many common respiratory diseases, for example asthma, COPD, and respiratory tract viral infections. Altered activation levels of these sensory neurons can cause chronic cough and other respiratory symptoms, and they may contribute to disease progression. Classical studies have divided these sensory neurons into four classes: mechanosensitive rapidly adapting receptors, slowly adapting receptors, cough receptors, and chemosensitive C-fibers. However, recent single cell genome-wide expression profiling studies in mice have revealed greater diversity among these neurons. One newly discovered class of pulmonary sensory neurons expresses olfactory receptor 78 (Olfr78), a lactate receptor that is part of the acute blood oxygen-sensing pathway in the carotid

body. We used a Cre-driver mouse line and an adeno-associated virus that expressed a fluorescent reporter in a Cre-dependent manner to selectively label Olfr78-expressing neurons. Each neuron terminated at multiple sites in the lung. The terminals were either free nerve endings in the alveolar region or in neuroepitheilial bodies, clusters of neuroendocrine cells located at branch junctions along the bronchial tree that are activated by hypoxia. Together, expression of Olfr78 and the innervation of neuroepithelial bodies suggest that these neurons may be part of a pulmonary hypoxia sensing pathway. Further characterization is necessary to understand the role of these neurons in lung physiology and pulmonary diseases.

Title: Relation between song preference and song learning in male Bengalese finches

Authors: *T. FUJII[1,2], M. IKEBUCHI[3], K. OKANOYA[1,3]
[1]Dept. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan; [2]JSPS, Tokyo, Japan; [3]RIKEN, Wako-Shi, Japan

Abstract: Juvenile songbirds memorize song of an adult bird (song tutor) and match their own vocalizations to it through subsequent sensorimotor learning. They can also discriminate song of their tutor from songs of other individuals, both as juveniles in the early phase of sensorimotor learning and as adults long after song crystallization (Clayton, 1988; Gobes and Bolhuis, 2007). In these studies, such discrimination ability was tested by measuring responses to playback of two different songs. Selective approach to a tutor song over an unfamiliar song indicates both recognition and preference for the tutor song. Whether such song preference has any function in ongoing song learning has not been directly investigated. In this study, we quantified tutor song preference of juveniles, and evaluated their song learning performance after song crystallization. We used male Bengalese finches for song tutoring and preference tests. The birds were raised by both parents until around 2 weeks of age, but afterwards kept only with their mother and siblings until around 40 days old. They were then moved to tutoring cages and housed with an unrelated male (tutor) for 2-3 weeks. This procedure led to varied song similarity between the tutee and tutor. We tested song preference 3 times; at 60-70 days (soon after tutoring finished), 90 days, and 120 days old. In the preference test, subjects were exposed to alternate playbacks of tutor

song from one end of a test chamber and novel song from the other. We measured the duration they spent in proximity to the speakers that broadcasted songs. We evaluated song learning performance by the percentage of tutor song elements that a subject eventually sang. So far, we tested 11 birds and found that tutor song preference measured at 60-70 days, but not at 90 nor 120 days, was positively correlated with song similarity. This raises the possibility that tutor song preference during song learning has some impact on the accuracy of learning. Currently we are testing another set of birds with different conditions of tutoring and test stimuli to examine this hypothesis more strictly.

Title: Functional connectivity signatures accurately distinguish male zebra finches who have been isolated from song during the sensitive period for vocal learning

Authors: *E. A. LAYDEN, K. E. SCHERTZ, M. G. BERMAN, S. E. LONDON
Psychology, The Univ. of Chicago, Chicago, IL

Abstract: Juvenile male zebra finch (*Taeniopygia guttata*) songbirds learn to sing from an adult male tutor during a sensitive period spanning Posthatch (P) days P30 to P65. If male zebra finches do not have tutor experience during this period, tutor song learning capability extends past P65. Tutor song learning is linked with the juvenile's emerging song stereotypy, often high at P90. Here we used longitudinal fMRI functional connectivity (FC) analyses to investigate neural signatures of learning capability and song stereotypy in males scanned at P25, P45, P65, and P90. Birds were randomly assigned to one of three conditions: normal (Norm, $N = 5$) birds were aviary-reared with multiple potential adult male tutors; tutored (Tut, $N = 7$) birds were housed with two adults, 1 male tutor and 1 female; and isolated (Iso, $N = 6$) birds were housed with 2 adult females. We partitioned the brain into a set of six bilateral song regions of interest (ROIs: Area X, LMAN, RA, HVC, Auditory Forebrain (NCM, CMM), and Field L) and measured the Pearson correlation between the fMRI signals of each ROI pair during a resting state period. Additionally, we recorded song bouts at P60 and P90 and computed measures of stereotypy. Implementing a linear mixed-effects model, we found that Iso birds exhibited lower FC between symmetrical bilateral ROI pairs (i.e., homotopic FC) from P45-P90 than either

Norm (B = -0.130, $t(2895)$ = -3.88, $p < 0.001$) or Tut (B = 0.067, $t(2895)$ = 2.06, p = 0.040). Importantly, we noted strong associations between average homotopic FC at P65 and song stereotypy measures at P60: %similarity ($r(7)$ = 0.71, p = 0.033), accuracy ($r(7)$ = 0.66, p = 0.055), and %sequential ($r(7)$ = 0.31, $p > 0.40$). We next implemented linear discriminant analyses to examine whether FC could successfully distinguish between conditions across ages P45-P90. Norm vs. Tut could not be accurately classified. However, a linear discriminant incorporating just three connections (L HVC-L RA, L Aud. Forebrain-L HVC, and R HVC-L HVC) distinguished between a combined Norm/Tut group and Iso with 88.6% accuracy. Iso showed lower FC for L HVC-L RA ($t(42)$ = -2.94, p = 0.005), higher FC for L Aud. Forebrain-L HVC ($t(42)$ = 2.72, p = 0.009), and marginally lower FC for HVC homotopy ($t(42)$ = -1.79, p = 0.081). These results highlight putative neural signatures of vocal learning capacity in zebra finches, including L HVC-LRA FC and L Aud. Forebrain-L HVC FC, two ipsilateral connections with known anatomical connectivity and previously established importance for song. We also find novel evidence supporting the role of interhemispheric coordination, in the form of homotopic FC, for the development of song stereotypy.

Title: Correlation between song learning and perineuronal nets development in song control nuclei of juvenile canaries

Authors: G. CORNEZ[1], C. COLLIGNON[1], W. MÜLLER[3], G. F. BALL[4], C. A. CORNIL[1], *J. H. BALTHAZART[2]
[1]GIGA Neurosciences, [2]Giga Neurosciences, Univ. of Liege, Liege, Belgium; [3]Behavioural Ecology and Ecophysiology, Univ. of Antwerp, Antwerp, Belgium; [4]Dept. of Psychology, Univ. of Maryland, College Park, MD

Abstract: Perineuronal nets (PNN) are aggregations of extracellular matrix components surrounding the soma of specific neurons, mainly GABAergic interneurons expressing the calcium binding protein parvalbumin (PV+). In mammals, the development of PNN limits

synaptogenesis around PV+ neurons and PNNs have been identified as a marker of the end of sensitive periods for brain plasticity in several neuronal systems. In songbirds, vocal learning requires exposure to conspecific vocalizations by male tutors during a sensitive period. This is followed by a sensorimotor period when birds progressively match their vocalizations with the memorized tutor's song until the fully mature song is crystallized. In a closed-ended learner, the zebra finch, PNN expression in select song nuclei is higher in males than in females and higher in adults than in juvenile males. The timing of PNN appearance in the developing zebra finch brain correlates with the timing of sensitive periods for song learning. We also showed that PNN are more densely expressed in the song control system of zebra finches than in two open-ended learners, the European starling and the canary and that testosterone (T) induces song crystallization in early spring and increases the number of PNN in castrated canaries. Together these data suggest that PNN might regulate the end of the sensitive period(s) for vocal learning during ontogeny. To elucidate this question further, we quantified PNN expression at critical time points during the first year of life in canaries and correlated these data with their song development. Brains were collected from groups of males (n=6-8/group) at time points corresponding to specific vocal developmental stages: first spring (subsong), summer (early plastic song), fall (plastic song), winter (ongoing song crystallization), and second spring (fully crystallized song/adults). In winter, one additional group received T implants to test whether this accelerates PNN development and song crystallization. The number of PNN reached their maximum in the fall in HVC but only in the winter in RA and Area X. In the group treated with T there was no further enhancement of PNN expression over what was observed in untreated birds at the same age. Total song duration and song developmental score only reached their maximum in the spring and were enhanced by T in the winter. Other song characteristics such as the energy or bandwidth were already at the adult levels during the winter. Most of these song measurements correlated with the number of PNN in the song nuclei suggesting that PNN contribute to song crystallization that starts in the winter and is completed at the onset of spring.

Title: Single cell resolution and seasonal distribution of neuronal phenotypes in the song control system of canaries

Authors: C. FRANKL-VILCHES[1], P. ALCAMI[1], *S. LEITNER[2], N. WILHELMI[1], A. BAKKER[1], M. L. GAHR[1]

Abstract: Plasticity in brain-behaviour relationships can best be investigated in seasonal breeding species. However, conclusions on the degree of seasonal plasticity of the neural circuits such as the song system of songbirds may depend on the neuronal characterisation method used. Comparative studies have typically investigated the relationships between neuronal morphology and neuronal markers using immunohistochemistry or in situ hybridization. Both techniques are difficult to implement for a number of reasons. First, a relatively small number of antibodies are available for immunohistochemistry in birds. Second, conventional in situ hybridization is time demanding, offering limited flexibility and sensitivity. In this report, we describe a fast, highly sensitive, and specific detection of RNAs using confocal imaging of RNAscope® technology in frozen brain slices collected year-round from domesticated canaries; a species that shows seasonal variation in song behaviour. This method allowed the accurate location of mRNAs at the single cell level, and at the same time allowed their co-localization with neuron type-specific markers. Through the use of this technique, we detected the presence of androgen and estrogen receptors. These observations allow us to postulate which neuron types are responsive to hormones.

Title: Age and sex differences in vitamin A signaling across the songbird vocal circuit

Authors: *C. R. OLSON, V. PRASAD, R. M. POTTER
Dept. of Physiol., Midwestern Univ., Glendale, AZ

Abstract: Vitamin A is a diet-derived hormone that is converted to retinoic acid in the brain to potentiate a number of memory-related brain functions. When exposed to deficits or excesses during the juvenile vocal learning critical period, zebra finches experience detrimental effects on the learning of their songs. Through differential display and in situ hybridization, previous

studies have found expression of ALDH1A2, the terminal enzyme for retinoic acid synthesis, in the forebrain vocal nuclei HVC (a proper noun) and LMAN (the lateral magnocellular nucleus of the nidopallium), but not expressed in surrounding tissue or other nuclei in the vocal circuit. This view suggests a restricted role of vitamin A signaling in a subset of the vocal circuit. Here we report the immunohistochemical labeling of ALDH1A2, and show more wide-spread vitamin A signaling across the vocal circuit. We found this enzyme present in axonal projections and target vocal nuclei outside its areas of expression, including the striatal nucleus Area X and RA (the robust nucleus of the arcopallium). This represents an important mechanism by which complex learned behaviors are regulated through vitamin A signaling across distant functional domains of the nervous system. Furthermore, sex and age-related changes in the ALDH1A2 transport and signaling may be related to the establishment of vocal brain nuclei during development or to critical periods of juvenile vocal learning.

Title: Changes inSCN4B and the resurgent sodium current during a critical period may be important for the production of crystalized song in adult zebra finches

Authors: *B. ZEMEL[1], P. V. LOVELL[2], S. R. FRIEDRICH[3], C. V. MELLO[2], H. P. VON GERSDORFF[4]
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR; [3]Behavioral Neurosci., [4]Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: How the brain develops the ability to acquire and produce learned vocalizations is not understood. Zebra finches, unlike rodents and non-human primates, produce learned vocalizations, and thus are a model for studying this phenomena. Like other vocal learners, finches acquire their vocalizations in two phases: a sensory phase, in which a tutee memorizes a tutor song, and a sensory-motor phase, in which the tutee refines it's vocalizations to match those of the tutor. Finches are initially non-vocal, but later enter a critical period in which vocalizations are increasingly refined from the babbling of unstructured notes known as subsong, to a more

structured, yet plastic song that becomes increasingly stable and reproducible in a process known as crystallization. In order to produce crystallized song the vocal nuclei must develop and maintain reliable and robust electrical signals. Little is known about the molecular determinants underlying the intrinsic excitability of these vocal nuclei. In this study, we examined the developmental expression of ion channel subunits that we hypothesize enable fast and reliable firing of action potentials in nucleus RA, a nucleus that is required for the production of learned vocalizations in songbirds. We found that the voltage-gated sodium channel beta 4 subunit, Navβ4, undergoes dramatic developmental changes in expression. This subunit is associated with resurgent sodium currents in several systems where it enables neurons to fire at high frequencies. Thus, we hypothesized it might be critical for maintaining fast and reliable firing in RA neurons. We performed *in situ* hybridizations and patch-clamp slice recordings in RA. *In situ* hybridization reveals expression of Navβ4 mRNA in the RA of adult male finches, with little to no expression in the surrounding arcopallium. In sharp contrast, this subunit shows no expression in the RA of post-hatch day 20 juvenile males, which cannot vocalize. Whole-cell voltage clamp recordings in adult males revealed resurgent sodium currents from cells within RA, but not the surrounding arcopallium, which demonstrate the functional expression of Navβ4 protein. In addition, whole-cell current clamp recordings reveal that RA projection and interneurons fire APs at higher frequencies than neurons from the surrounding arcopallium. These results indicate that Navβ4 is not only developmentally regulated, but may also contribute to intrinsic firing properties of adult, but not juvenile RA neurons. Together, these findings reveal evidence for a development program of regulated gene expression that is implicated in the maturation of cellular properties important for producing adult birdsong.

Title: Cell type specific investigation of corticalstriatal premotor neurons in song learning

Authors: M. SÁNCHEZ-VALPUESTA[1], Y. SHIBATA[1], N. C. ASOGWA[1], *K. WADA[2]
[1]Grad. Sch. of Life Sci., Hokkaido Univ., Sapporo, Japan; [2]Fac. of Sci., Hokkaido Univ., Sapporo, Hokkaido, Japan

Abstract: Complex vocalizations like human speech are formed by a sequence of precise vocal movements, both acoustically and in temporal order. The learning of such vocal motor sequences depends in mammals on the motor cortex and basal ganglia. Such areas develop parallel temporal sequence representations over learning practice, but it remains unknown how necessary for vocal motor skill learning the coordination between cortical and basal ganglia activity is. Studying this question has suffered several drawbacks, as mammalian motor cortices serve multiple motor skills and most experimentally tractable mammals do not exhibit vocal learning. To solve this issue, songbirds can be used as a model, as they develop their songs along easily quantifiable vocal motor skill learning and possess a specialized neuronal circuit for song learning. This circuit has cortical-like (nucleus HVC) and basal ganglia (Area X) components, with a neuronal type connecting from the cortical to the basal ganglia areas: the HVCx neuron population. We investigated the function of the cortical-basal connection by ablating the HVCx cells and analyzing the effects on the young birds' song learning process. In order to cell-specifically ablate the HVCx neurons, a Cre-dependent toxin system was expressed in the target cells using a combination of Adeno-Associated Vectors. This cell-specific ablation was performed on juvenile Zebra finches before the start of subsong and exposed them to playback of the same tutor song in sound isolation boxes alongside control virus-injected juveniles. Severe HVCx ablation, with one third of HVCx cells remaining, caused a failure of the song to crystallize its sequence and acoustics both remaining highly variable until 200 days post hatch, a time point when normal birds have crystallized their songs. Less severe ablation, with one half remaining, allowed for the emergence of stereotyped syllables and motif sequence, albeit with reduced acoustic similarity to the tutor song. The results suggest that HVCx neurons are important for the robustness of song learning, understood as the development of acoustically and sequentially stable birdsongs.

Title: DNA methylation: A contributing mechanism for specializing vocal learning brain circuits

Authors: *C. GILBERT[1], G. GEDMAN[1], L. CANTIN[1], T. CARROLL[1], E. D. JARVIS[1,2]
[1]Rockefeller Univ., New York, NY; [2]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Vocal learning is the ability to produce novel vocalizations based on an auditory input, and it forms the basis of human language acquisition. Not surprisingly, vocal learning is a rare trait, as only five groups of mammals (cetaceans, pinnipeds, elephants, bats, humans) and three groups of birds (songbirds, parrots, and hummingbirds) have evolved it independently. Strikingly, when examined, the behavior, neuroanatomy, and specialized gene regulation in vocal learning brain circuits are convergent. Microarray and RNA-seq comparative studies between vocal learning and vocal non-learning birds with humans and vocal non-learning non-human primates in our lab have found over 100 convergent differentially expressed genes in the vocal learning circuits relative to non-vocal learning circuits and vocal non-learners. These genes are enriched in neural connectivity, neural protection, and synaptic plasticity functions. I hypothesize that one potential driver for these brain specializations in these genes is DNA methylation, a known mechanism to cause differential gene expression between brain regions and cell types, in mammals. To test this hypothesis, we examined whether differential DNA methylation exists in zebra finch (a songbird) vocal learning brain regions. We used whole-genome bisulfite sequencing (WGBS) to analyze the methylation patterns of cells in the RA song nucleus relative to the adjacent non-vocal motor learning regions (lateral arcopallium, LAI). In concert with ongoing RNA-Seq and ChIP-Seq studies, pilot WGBS studies show that some of the differentially expressed genes in RA versus LAI are also differentially methylated. Notably, the specialized DNA methylation patterns were often present in a non-CG methylation (mCH) context, which is known to be important for mammalian neuronal development and cellular differentiation. These findings indicate the differential DNA methylation could be contributing to specialization of gene regulation and thereby circuitry and function of vocal learning brain circuits.

Title: AAV-siRNA targeting miR-128 enhances learned vocal communication

Authors: *C. M. AAMODT[1], S. A. WHITE[2]
[1]Neurosci. Interdepartmental Ph.D Program, UCLA, Los Angeles, CA; [2]Integrative Biol. & Physiol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Currently, no pharmacological interventions exist for vocal communication deficits arising from autism spectrum disorder (ASD) or intellectual disability. This is largely due to the lack of pre-clinical models with construct validity, since learned vocal communication cannot be modeled in rodents or cell culture. Fortuitously, recent advances in songbird genetics show that gene expression in the striatum of songbirds is highly similar to that in humans, indicating evolutionary convergence of the molecular mechanisms that govern vocal learning.
Within a recently published data set from our lab we identified ~1000 human autism and intellectual disability-related genes that are expressed in the striatal song control nucleus, Area X, during the developmental critical period for song learning. These genes are part of larger transcriptional modules that are correlated to key features of learned vocal behavior, including several that are significantly enriched for high confidence autism-related genes.
We have identified a compound that remediates learned vocal communication deficits in songbirds as follows: We used a social isolate paradigm to generate songbirds with impaired vocalization. Isolated birds were returned to their social environment well after the normal critical period closure then treated with oral ginsenoside Rh2 (GRh2) or vehicle for four weeks. Birds that received vehicle failed to organize their syllables into stable sequences, whereas GRh2 treatment enhanced syllable sequencing. Moreover, acute administration of GRh2 altered expression of multiple autism-related genes in Area X including *KMT2C, CACNA2D3,* and others.
In cultured human glioma cells, GRh2 treatment alters levels of miR-128, a brain-enriched microRNA that increases *in vivo* over development in songbirds and humans. Aberrant elevation of miR-128 is associated with autism in humans, suggesting a potential role in social communication. We used a siRNA sponge designed to decrease miR-128 levels in Area X during the critical period for song learning. Strikingly, bilateral injection of the sponge into Area X enhanced learned vocal sequencing in young songbirds relative to scramble controls. Ongoing work will characterize the molecular effects of the AAV constructs. These preliminary results suggest that the molecular mechanisms underlying speech and language can be pharmacologically and genetically targeted to accelerate the development of novel therapeutics for disorders like autism and intellectual disability.

Title: “Enhancing" vocal learning: Gene regulatory specializations in song circuits

Authors: *L. CANTIN[1], M. WIRTHLIN[2], J. CAHILL[1], G. GEDMAN[1], C. GILBERT[1], A. PFENNING[2], E. D. JARVIS[1,3]
[1]The Rockefeller Univ., New York, NY; [2]Carnegie Mellon Univ., Pittsburgh, PA; [3]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Vocal learning is a rare trait shared by a small number of distantly related species, including songbirds, parrots, and hummingbirds among birds, and humans, cetaceans, bats, elephants and pinnipeds among mammals. As a result of convergent evolution, these species (at least as studied in birds and humans) share similar vocal learning behavior development and analogous vocal learning brain circuitry with similar specialized gene expression profiles. A previous study from our groups identified a distinct set of ~50-70 convergent specialized genes between the human laryngeal motor cortex (LMC) and the songbird robust nucleus of the arcopallium (RA), and between the human anterodorsal striatum and the songbird Area X when normalized to their surrounding non-song/speech motor regions. When disrupted, some of these genes in humans are associated with communication disorders. Non-coding regulatory regions usually control the expression of genes. Identifying and comparing these regions across vocal learning species may provide clues into the molecular basis for evolution of this complex trait and into the genetic causes of the associated disorders. We performed Native ChIP-seq, ATAC-seq, bisulfite-seq and comparative genomic experiments to identify non-coding regulatory regions of these gene in the song learning nuclei of songbirds. We found several hundred open chromatin H3K27ac peaks with differential activity between the songbird RA or Area X and the surrounding motor regions, including those associated with specialized genes identified in our RNA-seq experiments. We aligned the genomes of avian vocal learning species and their closest vocal non-learning relatives to test for possible convergent accelerated non-coding regions that may be playing a role in the gene specializations of avian vocal learning lineages. We found accelerated regions overlap with the differential chromatin activation peaks of genes with specialized gene expression in song learning nuclei. Future studies will focus on similar analyses of post-mortem human brains. Our findings suggest that convergent changes in regulation of specific sets of genes in vocal learning brain regions may have been associated with convergent accelerated changes in gene expression enhancers of those genes.

Title: A combined convolutional-recurrent deep neural network for accurate annotation of large birdsong datasets

Authors: *D. A. NICHOLSON[1], T. J. GARDNER[2], Y. COHEN[2]
[1]Emory Univ., Decatur, GA; [2]Biol., Boston Univ., Boston, MA

Abstract: Songbirds provide an excellent model system for investigating how the brain learns and controls motor skills. Because they sing spontaneously, songbirds produce terabytes of behavioral data. However, many analyses require labeling the elements of song, called syllables. Labeling syllables by hand consumes many hours, and labeling all the song is often infeasible, preventing full analysis of this data.
This bottleneck calls for the development of automated tools (Kogan Margoliash 1998, Tchernichovski et al. 2001, Wu et al. 2008). Many analyses are easily automated when applied to song that contains highly stereotyped syllable sequences, such as that of the commonly studied zebra finch. However such methods are challenged by songs with variable syllable sequences, such as the songs of Bengalese finches or canaries. Several groups have demonstrated accurate labeling of Bengalese finch syllables with supervised machine learning (Troyer 2012, Tachibana et al. 2014, Nicholson 2016). These methods depend on features extracted from syllables, which are segmented from song by threshold crossings of amplitude. Such methods are impaired when segmentation fails because of background noise or experimental manipulations.
One remedy to this issue is to use an algorithm that both segments song into syllables and then classifies those syllables, such as a neural network (Koumura Okanoya 2016). Here we present a neural network architecture which uses convolutional layers to learn features of song syllables from spectrograms, and uses recurrent layers to capture temporal correlations in song. Using a repository of Bengalese Finch song to benchmark (https://figshare.com/articles/BirdsongRecognition/3470165), we show our network approximately halves the previously-reported lowest error rate, using half the training data. With another repository (https://figshare.com/articles/Bengalese_Finch_song_repository/4805749), we

show the network's predictions are accurate on thousands of songs recorded across days. Current tests of the network with canary song suggest it also accurately labels thousands of songs from individuals of this species, in spite of the species' lengthy song bouts and large repertoire of song syllables. To make the network easy to install, test, and use, we have developed a Python package built on Tensorflow, and made the code available here: https://github.com/yardencsGitHub/tf_syllable_segmentation_annotation. We conclude that we have provided an easy-to-use method that is robust across species of songbird. Beyond birdsong, our method may also be applicable to other vocalizations, like those of bats, dolphins, and marmosets.

Title: Redefining the convergent brain transcriptome for human speech and birdsong

Authors: *P. V. LOVELL, C. V. MELLO
Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: Song learning birds and humans share the rare ability to acquire their vocal sounds by imitation. In humans, this trait (vocal learning) subserves the acquisition and production of speech and language. Remarkably, humans and three orders of birds (i.e. songbirds, hummingbirds, parrots) share a striking number of parallels with regards to vocal learning, including the presence of infant babbling, dialects, a need for intact hearing, and in several cases a critical period. Such parallels long hinted that similar parallels might be found in the neural substrates underlying vocal learning. Indeed, the vocal control systems of humans and vocal learning birds have been found to share a number of important features. These include a specialized cortico-striatal-thalamo-cortical loop for vocal acquisition, and a robust direct projection from cortical vocal motor areas (i.e. laryngeal motor cortex - LMC - in humans, analogs of the robust nucleus of the arcopallium - RA - in birds) to brainstem circuits controlling the muscles of the vocal organ (i.e. the larynx in humans, syrinx in birds). By analyzing microarray datasets, Pfenning et al. (2014) found that human LMC and songbird RA also share a set of 55 genes representing convergent molecular specializations, as well as another 78 genes

representing molecular specializations shared by human putamen (Put) and striatal area X in songbirds. In a recent study defining the constitutive transcriptome of the zebra finch song control system, Lovell et al. (2018) reanalyzed the microarray datasets from the Pfenning study, and found a number of discrepancies that warranted further analysis. After removing ~27% of probes deemed non-informative based on poor genomic alignments, correcting or annotating ~10% of previously mis- or un-annotated probes, and redefining p-value cutoffs based on a large collection of *in situ* patterns (ZEBrA), high-confidence sets of shared LMC/RA markers and X/Put markers were defined. *In situ* hybridization verified this more complete analysis of microarray data, confirming >90% of RA markers, but also defining a subset of markers that also label a dorsal intermediate arcopallial domain lateral to RA that has previously been shown to be active during flight. This latter finding suggests that while RA is a highly specialized for song production, some of it's properties may play a broader role in circuits that govern more general motor behaviors. Lastly, a deep-dive into the literature and further bioinformatics analysis provided a better understanding of the biological roles that shared genes and pathways may play in the organization and function of vocal pathways in vocal learning species.

Abstract: Studies in zebra finches, a songbird species, have made seminal contributions to our understanding of the behavioral and neural basis of vocal learning, a rare that subserves speech acquisition in humans. However, a deeper understanding of the molecular mechanisms of vocal learning has been hindered by the limited availability of gene manipulation tools, including the ability to generate transgenic birds. Here we provide an update on the activities carried out by

our collaborative consortium funded through an NSF EDGE grant. We have made progress in 3 main lines of research: 1) We have generated mosaic zebra finches that express the genome-editing enzyme Cas9, using our proven method of injecting VSVg-pseudotyped lentiviruses into freshly-laid fertilized eggs. These Cas9 constructs are expressed ubiquitously or are regulated by the recombinase CRE. We are currently screening the resulting mosaics for germline transmission. These Cas9 lines are expected to have broad applicability, including brain gene manipulations through local injections of viral vectors with guide RNA (gRNA) constructs. 2) We have further developed protocols for isolating and culturing zebra finch primordial germ cells (PGCs). Our early stage cultured PGCs are transfectable and are able to incorporate into the embryonic gonads of recipient embryos when injected in the blood stream. Our goal is to create PGC-mosaics that can differentiate and generate genetically modified germ cells that can be transmitted. Being able to isolate and culture PGCs that become germ cells is expected to increase the efficiency and speed of generating zebra finch transgenic lines. Manipulating PGCs *in vitro* would also allow for more targeted gene manipulations in transgenic lines such as knockins and knockouts. 3) We have further developed efficient viral vectors for manipulating genes in zebra finch cells. Direct viral injections in tissues or PGCs of birds from research lines 1) and 2) could then be used to perform intersectional approaches such as with CRE-gRNA (with tissue specific promoters) or Cas9-gRNA vectors. Towards this goal, we are working on developing and testing new viral strains for efficient gene delivery into zebra finch cells, including screening a mutagenized AAV capsid library to identify capsids conferring high infectivity as well as for regional and cell-type specificity in the brain. Overall, we believe this consortium effort will help developed tools for more advanced genetic manipulations in a vocal learning species.

Title: Zebra finch Expression Brain Atlas (www.zebrafinchatlas.org): Update and recent analyses

Authors: *C. V. MELLO, P. V. LOVELL
Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: The Zebra finch ExpressionBrain Atlas (ZEBrA; www.zebrafinchatlas.org) is a publicly accessible online resource for investigating the brain distribution of genes of relevance to the development and physiology of functional brain circuits in songbirds. It consists of an *in situ* hybridization database for transcripts expressed in the brain of adult male zebra finches (*T. guttata*), a songbird species and the major model organism for studying vocal learning. ZEBrA's major features and recent updates include: (1) The *In situ* database - an expanding collection of high-resolution (0.46 µm/pixel) digital images presented along with annotated drawings from a reference Histological Atlas. ZEBrA currently houses >2,000 images (>100 GB) corresponding to ~660 brain expressed genes, including markers of all major nuclei that comprise the song system. Notably, in 2018 we have added several dozen image series for genes that are either convergent molecular specializations of cortical vocal motor areas shared between vocal learning birds and humans, or linked to speech and language functions and disorders in humans. (2) A reference Histological Atlas Browser - A set of 18 annotated drawings prepared in registration with Nissl- and Myelin-stained images of sagittal brain sections derived from the Karten/Mitra atlas. (3) Homepage portals that highlight and provide fast access to genes of great interest to songbird biology (e.g. song system markers), human speech and language disorders (e.g. FOXP2 and targets), human neurological diseases (OMIM-based), rodent behavioral and neurological phenotypes (MGI-based), comparative neuroanatomy (e.g. markers from the Allen's mouse brain atlas), and gene functions. Recent uses of ZEBrA include: (1) validation and establishing cut-off criteria for microarray studies of the song system; (2) quantitative analysis of regional gene expression patterns to define molecular signatures of specific avian brain areas; (3) obtaining evidence of heterogeneity of cellular patterns of gene expression as a basis for cellular phenotyping within vocal control nuclei; (4) obtaining molecular data to characterize the internal organization of major avian brain subdivisions (e.g. arcopallium, mesopallium, hippocampus).

Title: Norepinephrine in auditory processing areas enhances auditory learning and responsiveness in developing songbirds

Authors: *Y. CHEN[1], S. YANAGIHARA[3], Y. YAZAKI-SUGIYAMA[3], J. T. SAKATA[1,2]
[1]Biol., [2]Ctr. for Res. in Brain, Language, and Music, McGill Univ., Montreal, QC, Canada; [3]Okinawa Inst. of Sci. and Technol. (OIST) Grad. Univ., Okinawa, Japan

Abstract: Auditory learning serves as the foundation for vocal learning and imitation. Catecholamines such as norepinephrine (NE) have been implicated in various forms of sensory learning but the extent to which they contribute to sensory learning for vocal learning remains largely unknown. Further, little is known about how NE modulates auditory processing during the period of sensory and vocal learning. We investigated how NE impacted the sensory learning of vocal communication signals ('songs') and auditory responses to song in juvenile zebra finches, a species that learns its vocalizations during a sensitive period in development. We previously demonstrated that NE-synthesizing neurons in the locus coeruleus (LC) express more immediate early genes under conditions that promote developmental song learning (Chen et al., 2016), suggesting that NE could facilitate the sensory learning of song. NE-synthesizing neurons in the LC project to parts of the avian auditory cortex that are important for the sensory learning of song, including the caudomedial nidopallium (NCM; Yanagihara and Yazaki-Sugiyama, 2016). To determine the extent to which NE acting within the NCM modulates the sensory learning of song, we infused NE or vehicle into the NCM of juvenile zebra finches as they were briefly tutored with song. Relative to control birds that were infused with vehicle, birds that were infused with NE in the NCM during song tutoring produced songs as adults that were significant more similar to their tutor song. Furthermore, birds given NE during tutoring (but not control birds) showed evidence of rapid song learning (i.e., within days of tutoring). To investigate how NE affects neurophysiological responses to song in developing songbirds, we infused NE into the NCM while recording single unit activity in response to song playbacks. In general, following NE administration, NCM neurons displayed stronger and more temporally precise auditory responses as well as decreased spontaneous firing. Taken together, our data indicate that NE acting within the NCM significantly and rapidly promotes the sensory learning of song and could do so by potentiating auditory responses to song.

Title: Distribution and physiology of dopamine D1 receptors in the songbird secondary auditory cortex

Authors: *M. MACEDO-LIMA[1,2], H. BOYD[1], A. MCGRATH[1], L. REMAGE-HEALEY[1]
[1]Univ. of Massachusetts Amherst, Amherst, MA; [2]CAPES/Brazil, Brasília, Brazil

Abstract: Midbrain dopaminergic projections to the cortex are essential for learning of goal-directed behaviors. In mammals, projections to prefrontal regions govern decision-making, for example, by increasing the drive to seek rewards. Dopaminergic projections to sensory cortices are likely involved in improving and fine-tuning stimulus-response relationships. In humans, dopamine is thought to be central for speech learning and songbirds provide a prominent model for studying auditory learning. In songbirds, a secondary auditory cortical structure, the caudomedial nidopallium (NCM), is thought to play a significant role in the perception of song as well as in the association between songs and behaviorally relevant consequences. Furthermore, NCM is enriched with aromatase (estrogen synthase) and is a site of action of neuromodulators including estradiol and norepinephrine. Despite the abundance of dopamine D1 receptor mRNA in NCM, the presence and distribution of its protein, as well as its physiology has not been explored. Thus, in the present work we analyze the protein distribution and the physiology of dopamine D1 receptors in NCM. First, we validate a primary antibody against D1 receptors in zebra finch telencephalon and use tissue immunofluorescence to show that D1-receptor containing neurons colocalize with the majority of GABAergic neurons and virtually all parvalbumin-GABA positive neurons. Additionally, we observe that more than half of aromatase-positive neurons contain D1 receptors. Third, in whole-cell patch clamp experiments, we observe that the D1 agonist SKF-38393 decreases the amplitude of spontaneous inhibitory post-synaptic currents (under excitatory neurotransmission blockade) and also increases the frequency of spontaneous excitatory NMDA currents (under inhibitory neurotransmission blockade). Our data indicate that D1 receptor protein is abundant in NCM and associated with GABA- and estradiol-producing cells, and that it also exerts effects on both GABAergic and NMDA currents. This suggests that NCM is an important target of dopamine modulation and a site of interaction between neuroestradiol and dopamine, which could be key to NCM's role in auditory learning and memory. Title: Synchronized cortical activity in auditory perception in canaries

Authors: *S. BOARI, G. B. MINDLIN, A. AMADOR
Physics Dept., Univ. of Buenos Aires and IFIBA-CONICET, Ciudad Autónoma De Buenos Aires, Argentina

Abstract: Songbirds have been the focus of neuroethological research of the principles underlying vocal production, perception and learning. The 'song system' is a network of neural nuclei of a songbird's brain dedicated to these tasks. Telencephalic nucleus HVC is involved in the generation of the motor commands for vocal production and receives highly processed auditory inputs. In asleep or anesthetized adult male zebra finches (*Taeniopygia guttata*), HVC selective single units respond to a playback of the bird's own song (BOS). This elicited auditory response presents a similar firing pattern to the one measured while the bird is singing, suggesting a shared coding mechanism for the motor production and sensory perception of the BOS. For singing zebra finches, a recent study showed that HVC local field potentials (LFP) present defined oscillations in the 25-35 Hz band (Markowitz et al. 2015). While a correlation between LFP features and neuron firing was reported, it remains to be seen whether a link between LFP rhythmicity and song features can be established.
In this work, we studied the auditory responses to BOS at HVC in urethane-anesthetized male adult canaries (*Serinus canaria*). Differently than the highly stereotyped song of zebra finches, canaries present song bouts that are longer and more variable, composed of subunits called phrases. Each phrase is, in turn, composed by the repetition of the same syllable, with repetition rates that range from 2 Hz to 35 Hz. For this species, the BOS was determined by assessing the most probable song bout within the bird's natural repertoire. Acute extracellular neural recordings were conducted at HVC with 32 channel multi-electrode arrays, which provided the possibility to study spatial information together with temporal modulations of the neural activity. We recorded the LFP at different HVC sites and depths. As was reported for singing zebra finches, we have found that the LFPs at HVC present rhythmic oscillations. In this case, we found them to be locked to the syllabic rate of different song phrases, which could provide a new

perspective on the study of the neural coding of auditory processing of song and its link to vocal behavior in songbirds.

Title: Premotor control of coordinated vocalizations in zebra finches

Authors: *J. BENICHOV, S. WILCZEK, D. VALLENTIN
Biol., Freie Univ. Berlin, Berlin, Germany

Abstract: Our social lives, and those of many animals, largely rely on the capacity for interactive vocal communication. The male zebra finch, for instance, sings a learned song to court females, who do not sing. Both sexes, however, produce and coordinate acoustically simple short calls. Although the neural principles underlying song production have been studied extensively, the brain mechanisms that enable the coordination of vocal interactions, as in duets or turn-taking, remain unknown. We address this topic in zebra finches as they exchange social calls. To do so, we implement a vocal robot that flexibly engages birds in antiphonal call interactions. Using this paradigm, we have previously shown that birds dynamically control the timing of their calls with reference to a vocal partner. While subcortical brain regions are sufficient for the production of calls, we and others have demonstrated that cortical vocal structures are involved in and necessary for precise call coordination. Here, we begin to identify the neural mechanisms that underlie the coordination of vocal interactions by combining pharmacological perturbation and intracellular recordings in zebra finches during interactions with the vocal robot. Specifically, we focus on the cortical premotor nucleus HVC (proper name) which is known to control the timing of song. Our results suggest that HVC is necessary for the temporal coordination of calls during social interactions. We also found that pharmacological manipulation of HVC affects call structure. Furthermore, we demonstrate that individual cells within HVC can play multiple roles: HVC premotor neurons generate learned song and long calls, and also initiate non-learned social calls. These findings support the notion that a highly specialized cortical vocal motor pathway supports developmental vocal motor learning as well as dynamic vocal regulation for social interactions.

Title: Roles of sensory and motor activity in coordinating a cooperative behavior between female and male wrens

Authors: *M. J. COLEMAN[1], N. F. DAY[2], P. RIVERA PARRA[3], E. S. FORTUNE[4]
[1]Keck Sci. Dept., Claremont McKenna, Pitzer and Scripps Colleges, Claremont, CA; [2]Integrative Biol. & Physiol., Univ. of California Los Angeles, Los Angeles, CA; [3]Escuela Politécnica Nacional, Quito, Ecuador; [4]New Jersey Inst. of Technol., Newark, NJ

Abstract: Cooperation between animals requires that individuals integrate sensory information produced by partners to modulate their own behavioral output. We investigated how sensory cues generated by each partner modifies motor programs in the brain to achieve tightly coordinated cooperative performances. Female and male plain-tailed wrens (*Pheugopedius euophrys*) alternate vocal output to produce duet songs that sound as if a single bird is singing. These duets are well-suited for studying the mechanisms for coordination of behavior because duetting can rely on a single sensory modality (audition), use sex-specific syllable types, and involve the rapid (on the order of 10s to 100s of milliseconds) interchange of information between females and males. This rapid exchange requires self-generated 'autogenous' auditory feedback, and auditory cues from the partner, known as 'heterogenous' feedback. To understand the roles of both autogenous and heterogenous feedback we recorded chronically from HVC, a sensorimotor area of the songbird, from duetting wrens. Subsequently, we anesthetized both birds with urethane and measured HVC responses to playbacks of their duets. Unexpectedly, heterogenous cues did not generate changes in HVC activity in awake birds. In males, activity during singing occurred during autogenous syllable production, but shifted to responding to playback of female syllables when under urethane anesthesia. In contrast, female activity also occurred during autogenous syllables in awake birds, but HVC neurons responded equally well to both autogenous and heterogenous syllables. These data demonstrate that female and male wrens use different neural mechanisms for coordinating the shared duet performance. Further, these data suggest a role for HVC in the coordination of the duet performance.

Title: Mating posture and female choice in songbirds

Authors: *A. PERKES[1], C. MESSIER[1], M. WILD[1], B. PFROMMER[2], M. F. SCHMIDT[1]
[1]Biol., [2]Engin., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Female cowbirds produce a copulation solicitation display (CSD) in response to male courtship, both inviting and facilitating copulation. This behavior can be generated with song playback under isolation, where the frequency with which females produce CSD reveals the relative potency of male song. The highly selective nature of the behavior makes this species a valuable model for studying sexual preference, but the mechanisms driving selectivity are still poorly understood. We have previously shown (Maguire et al. 2013) that targeted lesions to the forebrain nucleus HVC cause a loss of CSD selectivity. While this suggests a testable model for modulating sexual preference, no precise method exists for quantifying or comparing postures, and the connectivity of HVC is poorly characterized in the female songbird.
Our findings reveal that the overall connectivity pattern of HVC is identical in females to that observed in males, even though females do not sing. To quantify CSD, we use an array of cameras to record birds with high temporal and spatial precision, combined with computer vision approaches to reconstruct posture. Given a quantitative model of bird pose, we can observe intrinsic variability in posture and whether this variability correlates with song preference. We can then observe the neural correlates of the CSD behavior, as well as measuring the impacts of lesions to downstream targets of HVC. We hypothesize that this circuit serves the broader function of controlling courtship behavior and selectivity rather than driving song learning and production alone.

Title: From perception to action: Sensory cortices and motor pathways underlying female mate choice

Authors: *J. F. PRATHER[1], K. S. LAWLEY[1], J. L. DUNNING[2]
[1]Dept Zoology and Physiol., Univ. of Wyoming, Laramie, WY; [2]Vanderbilt Univ., Nashville, TN

Abstract: Females of many species use male courtship displays as a proxy of male fitness to inform decisions of mate choice. Female mate choice has been studied extensively in songbirds in which females identify males based on their songs, evaluate the quality of those songs, and use that information to guide their mate selection. Song plays a central role in that choice, as female songbirds will exhibit copulatory behaviors (i.e. copulation solicitation displays (CSDs) and calls) in response to songs played through a speaker, even when no male is physically present. Studies of female response to song have implicated auditory cortical regions such as the caudal mesopallium (CM) and the caudal nidopallium (NC) in perception of song quality and the associated influence on production of copulatory behaviors. Here we are employing a combination of excitotoxic lesioning, anterograde and retrograde pathway tracing, and optogenetic stimulation to investigate: 1) the role of those cortical areas in song evaluation and mate choice, 2) the connectivity of those areas with other cortical sites and motor sites that underlie production of courtship behaviors, and 3) the role of specific pathways in specific aspects of song evaluation and mate selection. Our preliminary results from lesion studies demonstrate roles for each of CM and NC in female evaluation of song quality. In ongoing experiments, those results are confirmed and extended to specific pathways using optogenetic stimulation. Furthermore, our pathway tracing data reveal projections from each of those cortical sites to areas implicated in behavioral motivation and production of courtship behaviors, demonstrating possible pathways through which sensory perception may influence motor activation. Future experiments will seek to disambiguate the degree to which activity in specific pathways contributes to sensory perception versus motor activation, and thus the degree to which activity in those brain regions contributes to specific aspects of song evaluation and mate selection.

Title: Monitoring of social interactions in western jackdaws by a 3D tracking system

Authors: *A. L. VYSSOTSKI[1], S. J. VAN HASSELT[2], G.-J. MEKENKAMP[2], A. N. ABRAMCHUK[3], N. C. RATTENBORG[4], P. MEERLO[2]

Abstract: Corvids exhibit some of the largest relative avian brain sizes, as well as the most flexible cognition in the animal kingdom. The most striking example of outstanding cognitive abilities of corvids is tool fabrication by New Caledonian crows. Other representatives of this family, ravens and jackdaws are famous for their abilities of vocal imitation, an ability to copy sounds of other birds and even some human words. Crows have fixed dominance ranking helping to decrease stress of group leaving, and jackdaws are known for food sharing, a behavior when one individual gives food to another and can get food reciprocally later. We are interested in social interactions laying the bases of dominance formation, as well as in social interactions associated with solving creative tasks, such as adaptation to novel environments.
Social interactions in animals are mediated by a large variety of signals including body movements and vocalizations. In many species, the exchange of signals is often too fast for direct observation and interpretation by human experimenters. While posthoc analysis of videos can partly overcome this problem, this approach can be time-consuming. We are therefore developing a 3D tracking system that allows for automated and detailed data collection of behavior and brain activity of socially interacting animals.
To study social interactions in jackdaws we equipped birds with small data loggers (Neurologger 3, Evolocus LLC, USA). Each logger, attached to an animal head, recorded brain activity from 28 epidurally implanted electrodes (15.625 kHz), 3D animal position (15 Hz), and head orientation (625 Hz, by 3D magnetometer, 3D accelerometer and 3D gyroscope). Vocalization of animals was recorded by a built in microphone (125 kHz, similarly to Nature Methods, 2014, doi:10.1038/nmeth.3114). Position measurement was based on detection of time of intersection of infrared (IR) planar laser beams with the IR sensor on the logger. Planar laser beams scanning the environment periodically were emitted by four sources in the upper corners of the aviary. This method of tracking achieves sub-centimeter accuracy necessary for determination of relative positions of birds.
We monitored social interactions during habituation to modified environment in two stable

groups consisting of 4 males and 4 females respectively. Then, we observed social interactions initiated by introduction of unfamiliar members to stable social group. Males and females were unfamiliar to each other as they were always kept separately before the experiment. Thanks to advanced 3D tracking we detected complicated dynamics of social interactions and classified interesting behavioral patterns.

Title: Immediate early gene response to gargle calls of intact and HVC-lesioned black-capped chickadees (Poecile atricapillus)

Authors: *S. K. MISCHLER[1], R. A. FERNÁNDEZ[2], S. A. MACDOUGALL-SHACKLETON[3], C. B. STURDY[1]
[1]Psychology, Univ. of Alberta, Edmonton, AB, Canada; [2]Inst. de Neuroetologia, Univ. Veracruzana, Veracruz, Mexico; [3]Psychology Dept., Univ. of Western Ontario, London, ON, Canada

Abstract: Bird calls play a crucial role in social interactions among flock members, whether it be by communicating information about movements, food sources, or an impending predator. Similar to songs, which are used for mate attraction and territory defense, some songbird calls require imitative vocal learning in order to produce them. Songbirds possess a series of discrete nuclei, together known as the song-control system, that are critical for learning and producing both song and learned calls. This circuit includes the brain region HVC (proper name), which when lesioned has an impact on learned call production. Black-capped chickadees are songbirds that produce a variety of highly complex calls used in a variety of contexts, such as the *gargle* call which is an aggressive vocalization used primarily in male-male agonistic encounters. Lesioning HVC in male chickadees alters the bioacoustic properties of the *gargle* call, rendering it acoustically simpler overall. In this study, we measured immediate-early gene (IEG) immunoreactivity to assess whether the auditory forebrain, specifically the caudomedial mesopallium (CMM) and the caudomedial nidopallium (NCM) regions, were similarly active when female birds heard either intact or HVC-lesioned male produced *gargle* calls. Subjects

were either exposed to recordings of intact male *gargle* calls, *gargle* calls produced from HVC-lesioned male chickadees, or pink-noise within the same frequency ranges as these calls. Following playback, brains were processed using immunohistochemistry to visualize IEG protein in the auditory forebrain (CMM and NCM). Chickadees that heard either intact or HVC-lesioned *gargle* calls did not show significantly different levels of IEG activation in CMM or NCM; however, both of these calls elicited more IEG activation than the pink-noise condition. The post-lesion *gargle* calls differed from intact ones by having increased end frequency, decreased peak frequency, and decreased branching in complex notes. Although these types of *gargle* calls were bioacoustically different it appears that they are processed similarly by the female chickadees according to IEG response. Since male chickadees typically produce *gargle* calls and produce them in male-male agonistic interactions, it is possible that the females are not attuned to differences in these calls, thus perceiving them similarly. It is also possible that because the *gargle* call varies greatly across individuals, both in note composition and complexity that differences between HVC-lesioned *gargle* calls and intact *gargle* calls are within the normal range of acoustic variation of *gargle* calls.

Title: Calcium imaging in canary (serinus canaria) HVC reveals latent states supporting behavioral sequencing with long range history dependence

Authors: *Y. COHEN[1], J. SHEN[1], D. SEMU[1], D. P. LEMAN[1], W. A. LIBERTI, III[2], N. PERKINS[1], T. J. GARDNER[1]
[1]Biol., Boston Univ., Boston, MA; [2]Biol., UC Berkeley, Berkeley, CA

Abstract: Orchestrating sequential movements in real time is required in many tasks. In skills like speech or dance, this control follows syntactic rules with long range dependencies - behavioral transitions that depend on what actions were taken multiple time steps in the past. Songbirds have a learned and naturally recurring behavior, song, whose temporal structure is largely governed by the premotor nucleus HVC (Hahnloser 2002, Long 2008, Wang 2008, Nottebohm 1976). Canary song repertoires are defined by repeated syllables, known as phrases,

whose syntax is controlled separately from the syllables' identity (Gardner 2005) and which exhibit long range order (Markowitz 2013). Specifically, certain phrase transitions have history dependence, originating 2-3 phrases upstream. Accordingly, the neural underpinning of the phrase sequence must either rely on a complex memorized repertoire or maintain historic context to influence ongoing transitions. To discriminate such mechanisms, we expressed the calcium indicator GCaMP6f in projection neurons and used head-mounted fluorescence microscopes to record from HVC in freely behaving canaries.
We find that song history is reflected in identified Ca^{2+} ROI signals (purported single neurons) up to 4 phrases apart — a temporal separation of up to 3 seconds and 40 individual syllables. Examining correlations to past phrase types we find that many ROIs exhibit mixed selectivity — suggesting that the network dynamics does not follow a memorized, but instead reflects historic context relevant to flexible transitions. Moreover, we find that signals, reflecting sequence history information are more frequently found during phrase transitions that are history dependent compared to history insensitive ones - suggesting that the necessary information is indeed carried by hidden network states.
Beyond phrase-restricted signals, we find ROIs with signals that last several seconds and span 3-4 phrases. Such Ca^{2+} changes cannot be explained by syllable type or transition specific HVC projection neuron bursting (Fujimoto 2011). These signals are often not modulated by syllable or phrase boundaries and appear mostly during highly stereotyped phrase sequences. These properties suggest distinct network dynamics during stereotyped and variable phrase sequences. That long order syntax generation is reflected by hidden network states and signals with qualitatively different time scales suggest that behavioral sequencing may be specified by ongoing network dynamics. Investigating the underlying mechanisms may reveal neural substrates that also exist in other motor and cognitive functions such as inference and decision making.

Abstract: Birdsong is a neuroethological model of speech learning and language acquisition (Brainard & Doupe, 2013). A key premotor area of the songbird brain, HVC, plays a major role in song learning and takes part in both song perception and song production (Nottebohm et al., 1990; Brainard & Doupe 2002). Mapping the wide network of afferent and efferent connections of HVC neurons presents an important step towards understanding the neural mechanisms underlying song production and learning. A major challenge for mapping neural circuits is to achieve sufficient optical resolution for identifying morphological fine structures while preserving the topographic information of neural origin. Recent advances in fluorescent light microscopy (LM) imaging allows for imaging beyond Abbe's diffraction limit (Hell, 2007), sufficient to reliably quantify dendritic spines and fluorescently labeled synaptic markers. However, trade offs among acquisition times, resolution, and photo damage hinder investigations of large sample volumes using traditional light microscopy.
To probe for new avenues into circuit-level investigations of the songbird brain, we use single plane illumination microscopy (SPIM) in combination with expansion microscopy (ExM). SPIM improves on both imaging speed and reduced bleaching by virtue of simultaneous excitation and acquisition of entire cross sectional planes of large tissue volumes. However, the quantification of morphological fine structures remains challenging, because the physical characteristics of the excitation light sheet limits the resolution to the micrometer range. Expansion microscopy (ExM) improves on imaging resolution thanks to physical magnification of the brain prior to imaging (Tillberg et al., 2016). Thus, the combination of ExM and SPIM (ExSPIM) enables us to look at intact long range projections in the zebra finch brain while preserving morphological fine structures on the synaptic level.

Title: Viral methods for reversible knockdown of speech-related genes in the songbird

Authors: *L. XIAO[1], M. CAO[3], F. GARCIA OSCOS[3], M. CO[2], G. KONOPKA[3], T. F. ROBERTS[3]

Abstract: Songbirds are the preeminent animal model for studying neural circuit mechanisms for vocal communication and vocal learning. Songbirds learn their songs by imitating adult birds during a developmental critical period, a rare behavioral feat with strong parallels to speech learning. Moreover, knocking down genes, like FoxP2, or disrupting neuronal circuits, like the basal ganglia, that are known to be involved in speech, disrupts birdsong in ways that largely phenocopy speech disruptions in people, illustrating the strong behavioral, circuit and genetic parallels between song and speech learning. However, the translational potential for research in the songbird field has long been hampered by a lack of sophisticated genetic tools. We have developed a new viral method for the reversible KD of genes in songbirds using Cre-switch site-specific recombinase vectors for expression of shRNAs. Cre-switch vectors contain protein coding sequences inserted with inverted orientations relative to each other, downstream of a single promoter. Cre-mediated recombination flips the orientation of the protein coding sequences, switching the protein expressed. We generated shRNAs against FoxP2 downstream of a fluorescent protein in our Cre-switch AAV construct, such that Cre-mediated recombination will turn off expression of the shRNA and change the fluorescent protein being expressed from mCherry to TagBFP. In vitro and in vivo work demonstrates significant knockdown of FoxP2 using this construct and that expression of Cre reliably restores FoxP2 expression levels. Surprisingly, we found that AAV mediated knockdown of FoxP2 in the basal ganglia (Area X) of adult zebra finches caused severe vocal deficits, including changes in syntax, repetition (similar to ‘‘stuttering’’), deletion and creation of individual syllables or strings of syllables. However, these abnormal vocalizations are rescued following restoration of FoxP2 levels in Area X in adult birds. These results suggest a greater role for FoxP2 in adult song maintenance than previously appreciated. This novel viral approach opens the door for dissecting developmental contributions of FoxP2 and examining additional genes implicated in speech development using reversible genetic knockdown techniques.

Title: A neural circuit for renewed motor exploration in birdsong

Authors: *D. ALAM[1], T. F. ROBERTS[2]
[1]Neurosci., [2]UT Southwestern Med. Ctr., Dallas, TX

Abstract: Learning of skilled motor behaviors involves consolidation of motor patterns that result in better performance outcomes. This process of consolidation is thought to depend critically on sleep. However, the synaptic circuits contributing to sleep-based consolidation of skilled motor behaviors are still poorly defined. Birdsong is learned during a developmental critical period and provides an experimentally tractable model for examining the mechanisms underlying sleep-based consolidation. Previous studies indicate that birds achieve daily improvements in their song performance during this critical period and that these improvements are consolidated during sleep. This consolidation is thought to permit renewed vocal exploration each morning, which in turn is thought to fuel further improvements in song. The brain regions involved in this sleep-based consolidation and renewed vocal exploration are not known. Here we test the role the cortical premotor song nucleus RA in sleep based consolidation renewed motor exploration. RA is necessary for production of learned song and receives afferents from two functionally distinct premotor cortical circuits, HVC and LMAN. The premotor region HVC is vital for production of learned aspects of song while the premotor region LMAN is necessary for song plasticity. We show that reversible pharmacological silencing of RA during the night is sufficient to disrupt increased vocal exploration in the morning. Nightly silencing of RA does not disrupt vocal practice or reduce normal vocal variability, but does reduce the transient increases in vocal exploration seen during this stage of development. To examine if increased vocal exploration is important to song learning, we tracked changes in similarity to the tutor song over development. We find that nightly silencing of RA does not disrupt consolidation of the previous day's improvements in song, but significantly reduces within day improvements in song similarity. These findings indicate that RA is at least one region where activity during sleep functions to allow renewed plasticity of motor patterns which drive learned improvements in song performance, and supports the idea that activity in premotor cortical circuits during sleep is important for motor flexibility and learning of motor skills.

Title: Reafferent thalamo-cortical pathway connects motor and auditory circuits important for song

Authors: *M. Z. IKEDA[1], T. F. ROBERTS[2]
[1]Neurosci., [2]UT Southwestern Med. Ctr., Dallas, TX

Abstract: Circuits relaying a copy of descending vocal motor commands back to the auditory system are thought to facilitate vocal learning by allowing comparison of vocal motor goals with performance outcomes. In songbirds, a descending projection from the cortical song nucleus RA controls production of song. RA receives excitatory projections from two vocal-motor cortical regions, HVC and lMAN. HVC is necessary for producing the learned components of song and lMAN, the output structure of a basal ganglia circuit, is necessary for vocal plasticity. A circuit connecting the premotor song nucleus HVC with the auditory region Avalanche (Av) has been recently identified. Consistent with longstanding models, genetic lesions show that this circuit is important for normal song learning and for certain forms of adult vocal plasticity. However, since HVC provides only one arm of the vocal-motor input to RA, the projection from HVC to Avalanche is likely to provide the auditory system with only an incomplete picture of 'vocal motor goals'. Here we ask if circuits emanating from RA's descending projections provide a unique feedback circuit back into the auditory system. A subset of RA neurons that provide descending motor commands for song also send collaterals to the ipsilateral thalamic nucleus DMP (dorsal medial thalamus (DMP)), which in turn projects bilaterally back to the cortex, to the medial magnocellular nucleus of the anterior nidopallium (mMAN). Using dual tracer injections into premotor nuclei and the auditory system we find that the auditory region Avalanche receives a direct projection from mMAN. This indicates that Avalanche receives input from two separate vocal motor sources, a direct projection from the song nucleus HVC and a relayed projection from RA. Future studies involve testing the specific roles of mMAN-Av neurons and mMAN-HVC neurons in varying aspects of song learning and vocal plasticity.

Title: Inception of vocal memories for song syllable timing

Authors: *W. ZHAO[1], F. GARCIA OSCOS[2], T. F. ROBERTS[2]
[1]Neurosci., [2]UT Southwestern Med. Ctr., Dallas, TX

Abstract: Songbirds, like humans, learn their vocalizations by imitating their parents or other adults. Juvenile zebra finches learn their courtship song by first memorizing the song of their father and then use this memory to guide iterative changes in their own song. However, the networks and synapses in the brain involved in encoding a memory of the fathers' song are still poorly defined. Previous studies suggest that the premotor nucleus HVC (proper name) is necessary for production of song and for encoding a memory of the tutor song. Moreover, it is thought that tutor song information is relayed to HVC from the cortical nucleus NIf (Nucleus Interface). Using dual tracer injections we confirmed that NIf connects to HVC via two, largely non-overlapping pathways: a primary pathway projecting directly to HVC and a secondary pathway projecting to HVC via another auditory forebrain structure termed Avalanche (Av). To investigate NIf's role in tutor song learning, we manipulated activity in the direct NIf-HVC pathway by injecting an AAV expressing axon-targeted Channelrhodopsin 2 in NIf of juvenile birds prior to tutoring. We then conducted closed-loop experiments in which the optogenetic manipulation of NIf axon terminals in HVC was yoked to the tutor's singing behavior. We found that tutoring-contingent optogenetic manipulation of the NIf-HVC pathway blocks tutor song imitation, indicating that the NIf-HVC pathway is necessary for encoding of tutor song memories. To test the sufficiency of this pathway in tutor song learning we optogenetically manipulated NIf axon terminals in HVC of juvenile birds that were never tutored. Even in the absence of song tutoring, optogenetic activation of the NIf axons in HVC of juvenile birds is sufficient to direct learning of their adult songs. Long light pulses (300ms) or short repetitive light pulses (50ms) in tutor-naïve juveniles resulted in birds singing songs containing either abnormally long syllables, or short trilled notes, respectively. This indicates that NIf inputs to HVC provide temporal information about a 'song model' that is sufficient to guide vocal imitation. Together, these results indicate that the direct NIf to HVC pathway is necessary for learning from a song tutor and that this circuit is also sufficient to guide learning of song syllable timing.

Title: Precise neural sequences for birdsong emerge from functionally distinct networks of premotor neurons

Authors: *V. K. DALIPARTHI[1], B. G. COOPER[2], S. J. SOBER[3], T. F. ROBERTS[4]
[1]Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [2]Psychology, Texas Christian Univ., Fort Worth, TX; [3]Biol., Emory Univ., Atlanta, GA; [4]UT Southwestern Med. Ctr., Dallas, TX

Abstract: Precise neural sequences underlie the voluntary production of well-learned skilled behaviors. A key question is how these neural sequences are initiated and brought to a close to begin and end behavioral performances, and how these transitions relate to changes in descending motor commands and movements. We used cell-type specific calcium imaging from populations of premotor neurons, and recordings from the respiratory system and from cortical output neurons that innervate brainstem vocal and respiratory motor nuclei in songbirds to examine the neural correlates of song initiation and cessation. Premotor projection neurons in the cortical song nucleus HVC (HVC-RA neurons) are necessary for the production of learned song and exhibit precise sequential activity during singing. Imaging from populations of HVC-RA neurons reveals distinct transitions in activity patterns as birds prepare to sing and following song cessation. We characterize populations of HVC-RA neurons that are active immediately preceding and or following song production, but not during singing, or at other times. These neurons predict impending song and also mark silent periods between song bouts. We also identify populations of neurons that increase their activity before song and transition into precisely sequenced activity during singing. Our results suggest that precise neural sequences emerge from transitions among anatomically intermingled, but functionally distinct groups of cortical premotor neurons. Recordings from cortical output neurons in the song nucleus RA and from the respiratory system identify changes in activity that are temporally coincident with peri-song activity observed in HVC, suggesting that peri-song activity results in descending motor commands that help coordinate respiratory patterns as birds prepare to sing and as they recover

from singing-related respiratory exertion. We suggest that transitions between functionally identified groups of HVC-RA neurons may set network dynamics important for initiation and cessation of precise neural sequences and the coordination of respiratory patterns necessary for vocal production. Together, these results shed light on the neural origins of precise neural sequences and how network transitions relate to the initiation and termination of voluntarily produced skilled behaviors.

Title: Forebrain control of behaviorally-driven social orienting in zebrafish

Authors: *S. J. STEDNITZ[1], E. MCDERMOTT[2], D. NCUBE[2], P. E. WASHBOURNE[3]
[1]Biol., Univ. of Oregon, Eugene, OR; [2]Univ. of Oregon`, Eugene, OR; [3]Inst. of Neuroscience, Univ. of Oregon, Eugene, OR

Abstract: Deficits in social engagement are diagnostic of multiple neurodevelopmental disorders, including autism and schizophrenia. Genetically tractable animal models like zebrafish (*Danio rerio*) could provide valuable insight into developmental factors underlying these social impairments, but this approach is predicated on the ability to accurately and reliably quantify subtle behavioral changes. Similarly, characterizing local molecular and morphological phenotypes requires knowledge of the neuroanatomical correlates of social behavior. We leveraged behavioral and genetic tools in zebrafish to both refine our understanding of social behavior and identify brain regions important for driving it. We characterized visual social interactions between pairs of adult zebrafish, and discovered that they perform a stereotyped orienting behavior that reflects social attention. Furthermore, in pairs of fish, the orienting behavior of one individual is the primary factor driving the same behavior in the other individual. We used manual and genetic lesions to investigate the forebrain contribution to this behavior and identified a population of neurons in the ventral telencephalon whose ablation suppresses social interactions, while sparing other locomotor and visual behaviors. These neurons are cholinergic and express the gene encoding the transcription factor Lhx8a, which is required for development of cholinergic neurons in the mouse forebrain. The neuronal population identified in zebrafish lies in a region homologous to mammalian forebrain regions implicated in social behavior such

as the lateral septum. Our data suggest that an evolutionarily conserved population of neurons controls social orienting in zebrafish.

Title: Understanding the cellular and genetic bases of sexually dimorphic vocal behaviors in the African clawed frog

Authors: *T. STEELE[1], C. J. WILSON[1], C. L. BARKAN[2], E. ZORNIK[2]
[2]Biol., [1]Reed Col., Portland, OR

Abstract: Sexually dimorphic circuits provide a framework to study the role of hormones in establishing behavioral diversity. The vocal behaviors of the African clawed frog, *Xenopus laevis*, offer a unique opportunity to study sexually dimorphic behavior. The mating vocalizations of male and female *X. laevis* are dimorphic both in rate and pattern: females produce monophasic calls with slow pulse frequencies, while male advertisement calls are biphasic with faster pulse frequencies. The circuit responsible for these vocalizations is a central pattern generator consisting of androgen sensitive premotor and motor nuclei. Cells in the premotor nucleus of males exhibit activity closely correlated with song production. Androgen treated female *X. laevis* develop the capacity for male-like call production. We utilized comparative electrophysiological and transcriptomic approaches to characterize differences in function and gene expression in the premotor nuclei of males, females, and testosterone-treated females (T-females). We identified cells in the premotor nuclei of T-female *X. laevis* with activity during song resembling that of male premotor vocal cells. These cells increased in size over the course of testosterone treatment, reaching male-like sizes by eight weeks; they also possessed the hyperpolarization activated cation current, I_H, as well as NMDA receptor-dependent oscillations, both of which are characteristic of male premotor cells. RNA sequencing of the premotor nuclei of males, females, and T-females identified 10211 genes of interest, of which 821 were significantly differentially expressed (padj < 0.05) between groups. Gene ontology analysis identified the Wnt pathway and signal transduction as categories of significant enrichment. Within the signal transduction category, genes upregulated in T-females and males compared to females included: tweety family member 3 (a Ca^{2+}-activated large conductance Cl^-

channel); GTPases implicated in cell morphology changes; and prostaglandin E(2)-9 reductase (which may influence sexually dimorphic responses to prostaglandins). The Wnt pathway is downregulated in T-females compared to males and females; however, the function of this pathway in the regulation of vocal behavior is unknown. Our findings suggest that changes to cell morphology, intrinsic currents, and intracellular signalling are all involved in the transition between the production of male and female vocal behavior in *X. laevis.*

Title: Speech-related gene FOXP2 expression in the central vocal pathways of the African clawed frog

Authors: *A. YAMAGUCHI, D. J. WOLLER, K. MEREDITH, A. NGUYEN
Biol., Univ. of Utah, Salt Lake City, UT

Abstract: Forkhead box protein P2 (FOXP2) is a transcription factor known to be critical for the development of speech and language in humans; a mutation in the FOXP2 gene results in devastating linguistic impairments. Orthologs of FOXP2 are found across vertebrate species including birds, crocodiles, and fish. FOXP2 has a highly conserved amino acid sequence as well as conserved expression patterns in the brain of vertebrate species. FOXP2 disruption in mice and songbirds results in loss of pup calls and incomplete imitation of adult songs, respectively, suggesting the involvement of the gene in vocal communication. Here, we asked if FOXP2 is expressed in the central vocal pathways of African clawed frogs, *Xenopus laevis*. Male and female *X. laevis* generate sex-specific vocalizations to coordinate reproduction during the breeding season. The vocalizations of *X. laevis* are generated by central pattern generators (CPGs) contained in the brainstem that consist of the dorsal tegmental area of medulla (DTAM, homologue of parabrachial nucleus in mammals) and the laryngeal motor nucleus (n.IX-X, homologue of nucleus ambiguus in mammals). We found FOXP2 immunopositive neurons in a variety of brain regions including the telencephalon, optic tectum, cerebellum, and brainstem of *X. laevis*. In particular, we found dense labeling of FOXP2-positive neurons in the DTAM in both males and females. Given that FOXP2 is known to be expressed in the parabrachial nucleus of mammals, our results represent a conserved expression pattern of the FOXP2 gene. There

were no sex differences in the expression patterns of FOXP2 immunopositive neurons. Further immunohistochemical analyses showed that FOXP2-positive neurons in the DTAM do not express GABA or parvalbumin, but may express cholinacetyltransferase. The discovery of FOXP2 expression in the *X. laevis* DTAM suggests a contribution of this gene to vocal communication in amphibians.

Title: Dietary tuning of begging behavior in a social tadpole

Authors: *L. A. O'CONNELL[1], S. V. EDWARDS[2], K. SUMMERS[3]
[1]Stanford Univ., Stanford, CA; [2]Harvard Univ., Cambridge, MA; [3]East Carolina Univ., Greenville, NC

Abstract: Adequate nutrition during infancy is required for the development of healthy children and lifelong wellbeing in adults. Infants must integrate their nutrition levels with the decision to spend energy reserves communicating need to parents. Although diet is an important factor in infant behavior, little is known about the underlying neural mechanisms driving this social communication. We examined the neural basis of infant communication of nutritional need in the Mimetic poison frog (*Ranitomeya imitator*). In order to receive food from their mothers, tadpoles perform a begging display characterized by vigorously vibrating back and forth. This begging behavior is an honest indicator of need because it is a costly display for the tadpole and is more likely to occur when nutritional state is poor. We first examined the neural basis of begging behavior by quantifying neural activation (via a phosphorylated ribosome marker) throughout the brain and found several hypothalamic and forebrain regions that are more active in begging tadpoles compared to non-begging controls. We then quantified gene expression specifically in active neurons using ribosome capture and found that neurons active during begging behavior are enriched for arginine vasopressin and orexin pathways, suggesting circuitry involved in social behavior and nutritional state are important. Moreover, we also found that neurons active during begging behavior express *forkhead box protein 2* (*foxp2*), which is important for communication in humans. Current experiments involve disrupting the function of these pathways and testing the effect on tadpole begging behavior. Overall, this work suggests that social- and nutrition-related neuronal pathways interact to promote begging behavior in neonates.

Title: Effects of acquisition and maintenance of social status on cytochrome oxidase activity in the preoptic area and amygdala in green anole lizards

Authors: D. SHUKLA, L. DUMANOWSKY, J. KIM, G. M. GUTZMAN, J. HONG, *W. WILCZYNSKI
Georgia State Univ. Neurosci. Inst., Atlanta, GA

Abstract: Male green anole lizards form dominant-subordinate dyads when paired together that remain stable over time. Acquisition and maintenance of social status results in a change in a multitude of behaviors in anoles and many other species. Previous studies in our lab have consistently shown a decline in aggression and courtship behaviors in subordinate anoles after cohabitation with a dominant animal for 1 week. Such a change in territorial behaviors suggests a change in the activity of or relationship among the nodes in the social behavior network (SBN). The social behavior network is an evolutionary conserved set of reciprocally connected forebrain nuclei that have been implicated in a number of social behaviors including aggression and appetitive sexual behaviors. We investigated changes in the amygdala and preoptic area by quantifying changes in cytochrome oxidase activity in these nuclei. Cytochrome oxidase is a rate-limiting enzyme in the electron transport chain in the mitochondria and cytochrome oxidase activity reflects long-term changes in metabolic activity of neurons due to changes in the amount of excitation and inhibition received by the neurons. Individually housed male anoles were paired with size-matched opponents to form subordinate-dominant dyads that were housed together for 10 days. At the end of the cohabitation period, brains were flash frozen, cryostat sectioned, and cytochrome oxidase histochemistry was carried out using 3,3'-diaminobenzidine as the chromogen in the reaction. The sections were imaged at 40x magnification and the images were analyzed to obtain optical density values using Image J that reflected changes in cytochrome oxidase activity. We observed a difference in optical density values in the preoptic area with dominants possessing higher O.D values relative to subordinates (n=6 pairs, paired t test: t= 2.652, p= 0.045) but not in the amygdala (n=6 pairs, paired t test: t= 1.453, p= 0.211). The higher activity in the preoptic area in dominants is consistent with its role in aggression and sexual behavior and the decline in territorial behaviors in subordinates. Furthermore, the correlation between activity in the amygdala and preoptic area in the subordinates (r= 0.258) was

stronger relative to the dominant animals where it was negligible (r= 0.0346) suggesting a change in functional connectivity in addition to changes in mean activity levels.

Title: Epigenomic dissection of regulatory elements underlying the evolution of learned vocal behavior

Authors: *M. WIRTHLIN[1], L. CANTIN[2], S. ANNALDASULA[1], T. PARK[1], E. D. JARVIS[2], A. R. PFENNING[1]
[1]Computat. Biol. Dept., Carnegie Mellon Univ., Pittsburgh, PA; [2]The Rockefeller Univ., New York, NY

Abstract: Complex behaviors, such as vocal learning (the ability to actively modify vocal production in response to auditory feedback, as in human speech), require tight organization of gene activity across a vast array of interconnected cell types and tissues. In the brain regions that control the production of learned vocalizations, we previously identified convergent changes in gene expression that were unique to multiple vocal learning species, and not present in their vocal non-learning relatives. Given that convergent evolution of behavior is associated with convergent specializations in gene expression, we sought to discover whether this convergence also exists at the level of gene regulation, specifically within the domain of epigenetic modification of enhancer sequences that control gene expression. To study enhancer regions across large evolutionary distances, we built and validated a specialized pipeline. First, we used multiple sequence alignments to map a set of ~150,000 known brain enhancers to the genomes of 100 different vertebrate species. In the orthologous enhancers of macaque, mouse, and zebra finch, we estimated enhancer activity using ChIP-Seq for an associated chromatin modification (H3K27ac) in two brain regions, the cortex and the striatum. Despite the extensive nucleotide turnover occurring over the >300 million years of evolutionary distance between birds and mammals, we found conservation of cortical vs. striatal enhancer specificity. Using this framework, we next identified enhancers found near critical genes associated with specialized expression in vocal learning songbirds and humans, that also show specialized enhancer activity in speech motor cortex of humans. Remarkably, investigations of this set revealed that the

change in enhancer activity correlated with the specialized transcriptional changes in brain gene expression in vocal learners. In sum, our work has identified conserved enhancers that control convergently specialized genes, supporting enhancer evolution as a prime candidate for driving the evolution of complex behavior.

Title: Neural adaptations for coding social communication in the presence of social noise

Authors: *K. M. ALLEN[1], G. T. SMITH[2], G. MARSAT[1]
[1]Biol., West Virginia Univ., Morgantown, WV; [2]Indiana Univ., Bloomington, IN

Abstract: Studying the production and reception of social communication signals represents a unique opportunity to examine how sensory systems evolve and specialize. Selective pressures can act on both the production and reception of the signal within the same organism, leading to marked sender-receiver matching. Behavioral context can also influence the shape of the signal to be perceived and social species might have to evaluate a single signal from a complex sensory stream. Using three species of weakly electric fish, this study demonstrates changes within the electrosensory system correlated to changes in divergent communication strategies. The fish *Aperotonotus leptorhynchus*, *Apteronotus albifrons*, and *Adontosternarchus devenanzii* have large differences in social behaviors such as group size, communication frequency, and signal structure. By studying the social behavior of these three species, we show that communication signal production and use varies between these three species. Recordings from the primary electrosensory area of the brain show differences between species in frequency tuning and feature coding. These adaptations correlate with enhanced ability to detect social signals and discriminate signal features, particularly in conditions simulating noisy group interactions. In both behavior and physiology, species that are more socially gregarious exhibit distinct adaptations that support the detection and discrimination of social signals in large and complex social groups.

Title: A midbrain-to-hindbrain circuit for the control of vocalization

Authors: *K. A. TSCHIDA, V. MICHAEL, J. TAKATO, S. ZHAO, B.-X. HAN, R. MOONEY, F. WANG
Duke Univ., Durham, NC

Abstract: Vocalizations are an essential medium for communication and courtship in numerous mammalian species ranging from mice to humans. In mammals, the midbrain periaqueductal gray (PAG) serves as an obligatory node in a vocalization-related network that spans the forebrain and brainstem, as bilateral lesions of the PAG result in mutism. Despite the PAG's importance for vocal production, the identity, function, and connectivity of PAG neurons involved in vocalization has remained elusive, in part because the PAG is a functionally and anatomically heterogeneous structure that serves myriad roles including nociception, defensive behaviors, and autonomic regulation. To this end, we previously used a viral genetic strategy to identify and characterize PAG neurons whose activity is necessary and sufficient for the production of ultrasonic vocalizations (USVs) in the mouse. While this work established the identity of the PAG neurons selectively required to gate the production of USVs (i.e, PAG-USV neurons), an important remaining issue is to determine how descending projections from PAG-USV neurons recruit brainstem premotor circuits to shape the spectral and temporal acoustic features of vocalization.

In the current study, we test the hypothesis that PAG inputs to the nucleus retroambiguus (RAm), a vocal/respiratory premotor region of the caudal brainstem, are a key site whereby descending vocal motor commands recruit premotor circuits to shape vocal output. We have observed that PAG-USV neurons send a dense axonal projection to RAm, and that RAm neurons upregulate the immediate early gene Fos following the production of USVs, suggesting that PAG inputs to RAm may be important for vocal control. We are currently using optogenetic methods to activate and silence PAG inputs to RAm to test the role of this projection in vocal control. We are also monitoring the activity of PAG-USV and RAm neurons to understand how they are recruited during both vocalization and by different patterns of respiration. Taken together, these experiments will shed light on how midbrain neurons essential to USV production recruit premotor circuits to ultimately control the complex acoustic features of vocalizations.

Title: A 'Go-signal' for vocal production in the brain of a developing vocal learning mammal

Authors: *M. C. ROSE[1], M. M. YARTSEV[2]
[1]Helen Wills Neurosci. Inst., [2]Bioengineering, Univ. of California Berkeley, Berkeley, CA

Abstract: Infants and children are expert vocal learners; however, the neural mechanisms supporting vocal learning in mammals have never been studied before due to the remarkable sparsity of vocal learning capabilities across mammalian species. To address this knowledge gap we study vocal learning in one of the only known non-human vocal learning mammals: bats, specifically, the Egyptian fruit bat (*Rousettus aegyptiacus*). We chose bats not only because of their mammalian brain organization, but also for their impressive social vocal repertoire and learning capabilities. Previous neurophysiological investigations in bats have focused primarily on the perception of acoustic signals and not on the production of learned vocalizations. Importantly, no study to date has examined the detailed neural computations which might support vocal production in a developing mammal of any species at cellular resolution. To bridge this gap, we have made first efforts toward studying the mechanisms that support vocal production and learning in the developing mammalian brain during free, naturalistic behavior. We used lightweight wireless electrophysiology to study the activity in a frontal motor cortical area (FMA) of juvenile bats engaged in natural social interactions. We observed a substantial fraction of single neurons exhibiting responses tightly aligned to the production of learned vocalizations, but not during auditory playback. Consistent with the single neuron results, we observed a strong modulation of high-frequency local field potential power aligned to vocal production. FMA responses were independent of both the temporal ordering, acoustic structure, and rhythmic structure of the produced vocalizations, but were tightly locked to the onset of learned vocalizations. Furthermore, only a relatively small number of the same FMA neurons modulated their activity during the production of echolocation calls - a major component of the

bat acoustic production system that is believed to be innate. These results suggest a potential encoding of a "go-signal" for the production of learned vocalizations. With ongoing experiments, we will compare these results to neural activity in the FMA of fully developed adult bats to determine the effect of vocal learning on neural activity in this region. Combined, we present here the first evidence of cellular-resolution neural activity related to the production of learned vocalizations in the developing mammalian brain.

Title: A hypothalamic-to-midbrain circuit for the control of vocalization

Authors: *V. C. MICHAEL[1], K. A. TSCHIDA[2], S. ZHAO[1], F. WANG[3], R. D. MOONEY[4]
[1]Neurobio., Duke, Durham, NC; [3]Dept. of Neurobio., [2]Duke Univ., Durham, NC; [4]Duke Univ. Dept. of Neurobio., Durham, NC

Abstract: Vocal communication is a key social behavior by which humans and other mammals form and maintain social bonds, convey information about social status and mating fitness, and engage in cooperative behavior. Successful vocal communication is essential for social affiliation and impairments in vocal communication typify neuropsychiatric disorders. Mice produce complex ultrasonic vocalizations (USVs) in a variety of social contexts, allowing researchers to study the circuits underlying vocal control using genetic tools. The midbrain periaqueductal gray (PAG) is a critical node in the vocal motor circuit whose activity is obligatory for vocalizations. Studying the identity and connectivity of PAG neurons that control vocal production is challenging as these neurons reside amidst a heterogenous population of neurons controlling defensive behaviors, nociception, and respiratory modulation. In previous studies, we used a viral genetic method (CANE, Capturing Activated Neuronal Ensembles) to identify and tag a subpopulation of PAG neurons whose activity are necessary and sufficient to produce USVs (PAG-USV neurons). An important remaining question is how PAG-USV neurons integrate upstream information to appropriately gate vocal output. Engaging in appropriate vocal behavior requires the active integration of dynamic sensory cues, as well as state-dependent internal signals that relate to the individual's motivational drive and social experience. We sought to understand how inputs to PAG-USV neurons convey information about social context to drive or

shape USV production.
We used CANE-based trans-synaptic rabies tracing from PAG-USV neurons to identify their afferents to dissect the larger circuit in which these neurons reside. We found that PAG-USV neurons receive input from a variety of cortical and subcortical regions implicated in social behavior, supporting the idea that PAG-USV neurons integrate information about social context to gate vocal output. Amongst these various inputs, we focused on the identity and function of neurons in the preoptic area (POA) of the hypothalamus that project to PAG-USV neurons. We used genetic tools to selectively activate subpopulations of POA neurons that project to the PAG in order to identify the projection cell types that drive vocalization. We then monitored the activity of PAG-projecting POA neurons during social interaction assays to test when these neurons are active during social encounters and what information they convey to PAG-USV neurons. Overall, these experiments further our understanding of how vocal communication is embedded in and recruited by networks that control social behavior.

Title: DeepSqueak: A deep learning based system for quantification of ultrasonic vocalizations

Authors: *R. MARX, K. R. COFFEY, J. F. NEUMAIER
Psychiatry, Univ. of Washington, Seattle, WA

Abstract: Rodents engage in social communication through a rich repertoire of ultrasonic vocalizations (USVs). Recording and analysis of USVs has broad utility during diverse behavioral tests and can be performed non-invasively in almost any rodent behavioral model to provide rich insights into the emotional state and motor function of the test animal. Despite strong evidence that USVs serve an array of communicative functions, technical and financial limitations have been barriers for most laboratories to adopt vocalization analysis. Recently, deep learning has revolutionized the field of speech recognition and computer vision, allowing computers to see, listen and speak with near-human accuracy. Such systems are constructed from biomimetic, 'deep', artificial neural networks. Here we present DeepSqueak, an open source USV

detection and analysis software suite designed around cutting edge regional convolutional neural network architecture (Faster-RCNN), capable of performing human-quality USV detection and classification automatically, rapidly and reliably. DeepSqueak was engineered to allow non-experts easy entry into USV detection and analysis yet is flexible and adaptable. DeepSqueak has a user friendly graphical user interface, is freely available, flexible, feature packed, and systematically addresses the limitations of other available software. This package allows USV recording and analysis to be added inexpensively to existing rodent behavioral procedures, revealing a wide range of innate responses that provide another dimension of insights into behavior, especially when combined with conventional outcome measures.

Title: Long-term and persistent vocal plasticity in adult bats

Authors: *M. M. YARTSEV[1], D. GENZEL[2]
[1]Bioengineering, Univ. of California Berkeley, Berkeley, CA; [2]Helen Wills Inst. of Neurosci. and Dept. of Bioengineering, Univ. of California, Berkeley, CA

Abstract: Most bat species exhibit a diverse and complex vocabulary of social communication calls with which they can facilitate intraspecific information exchange. Evidence is accumulating that a vocal learning mechanism is underlying this capability resulting in a high-degree of vocal plasticity. As many bats live in socially tight-knit and acoustically noisy communities and live up to a relatively high age they most likely require long-term vocal plasticity to exist not only in adolescence but in adulthood as well. The goal of this project was therefore to investigate for the existence of persistent vocal plasticity in different groups of adult Egyptian fruit bats (*Rousettus aegyptiacus*) in response to long-term noise exposure. When exposed long-term to acoustic background noise, the groups independently adapted their vocalizationsto minimize interference with the noise.Different spectral shapes of the background noise targeted different frequency bands of the bats' calls and influenced how the bats adapted their call parameters. Next, we

examined the hypothesis that changes in call parameters emerging from the noise exposure would persist even after cessation of the noise. Our results indicate that not only do these bats modify distinct parameters of their vocalizations in response to the presented noise but that these changes persist for multiple weeks after cessation - suggestive of vocal plasticity. Further analysis shows that this change is not driven by a switch of call type or influenced by group constellation - supporting a global adaptation of the produced sounds. The obtained results demonstrate persistent vocal adaptation in an adult bat and extensive vocal plasticity abilities of this bat species. As a conclusion, bats could potentially play an important role acting as a model system for vocal production plasticity and learning.

Univ. Sch. of Med., Portland, OR; [5]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [6]Sch. of Biol. Sci., Washington State Univ., Vancouver, WA

Abstract: The production of learned vocalizations is one of the most complex motor skills that humans effortlessly perform, requiring the coordinated control of numerous respiratory, orofacial, and phonatory muscles. Among the latter, the cricothyroid muscle in the larynx is solely responsible for controlling an increase in pitch during phonation. Though many animals vocalize, the ability to produce learned vocalizations has only been found in a few animal groups, including some birds, cetaceans, and bats. Notably, humans and songbirds share several features related to vocal learning, including the presence of specialized corticobulbar projections

onto brainstem motor circuits that control a vocal organ, and shared molecular specializations in cortical vocal-motor areas. Yet, the absence of a tractable mammalian model system for probing vocal learning behavior has limited our ability to explore the neural basis of this trait in mammals. Recent evidence has shown that Egyptian fruit bats (*Rousettus aegyptiacus*) are capable of learning their social communication calls, thus suggesting that this species may be a suitable model for mammalian vocal learning studies. Here, we use molecular profiling and neuronal tracing techniques to investigate whether bats possess a corticobulbar projection that may facilitate the fine motor control needed for the acquisition and production of learned vocalizations. Specifically, we first performed *in situ* hybridizations for convergent markers of cortical vocal-motor neurons shared between songbirds and humans (e.g. GPM6A, PVALB, GAP43, SLIT1) in order to identify brain regions that may correspond to a laryngeal motor cortex (LMC) in two species of bats, Seba's short-tailed bats (*Carollia perspicillata*) and Egyptian fruit bats. We also injected anterograde tracers into putative LMC simultaneously with retrograde tracers into the cricothyroid muscle of Egyptian fruit bats. The *in situ* data provide evidence of molecular cortical specializations reminiscent of LMC. We also show that cortical projections from putative LMC may directly synapse onto nucleus ambiguus motoneurons that innervate the cricothyroid muscle. We are working towards verifying these findings in both species and testing them functionally to further establish bats as a mammalian model for vocal learning.

Title: Investigating the role that social status plays in vocal courtship behavior using a sound source localization system

Authors: *R. S. CLEIN[1], D. T. SANGIAMO[3], J. P. NEUNUEBEL[2]
[1]Psychological & Brain Sci., [2]Psychological and Brain Sci., Univ. of Delaware, Newark, DE; [3]Univ. of Illinois, Urbana-Champaign, Urbana-Champaign, IL

Abstract: Across the animal kingdom, social status profoundly affects access to the resources necessary for survival and reproductive success (Chase, 1982). Hierarchical rank is determined by the outcomes of agonistic behaviors and stabilizes over time (Williamson et al., 2017). In established, stable dominance hierarchies, vocal courtship displays are more prevalent in animals with a higher social status (Wang et al., 2011). However, as an animal's rank in a hierarchy

emerges, it is unknown how male agonistic social interactions impact their courtship displays. To answer this question, we employed a sound-source localization system (Warren et al., 2018) to track ultrasonic courtship vocalizations and the social behavior of individual mice (B6.CAST-Cdh23Ahl+/Kjn, 13-21 weeks old) during 5-hours of unrestrained group interaction between 2 males and 2 females after a minimum of two weeks of isolation (n = 11 groups). Using a machine-based learning program (Kabra et al., 2013), male courtship and agonistic behaviors were extracted (courtship: chasing female, 368.6 ± 32.1 (average ± SEM); agonistic: chasing and fleeing, 311.2 ± 51.9). A step function was calculated for every recording based on instances males performed agonistic behaviors and was normalized by the total number of aggressive behaviors. Each function provided a metric for quantifying the magnitude of the overall difference in social status. Large differences in the number of aggressive behaviors performed by each mouse indicated bigger disparities in status. Moreover, each function allowed us to define discrete periods of time where one male was engaging in all of the agonistic behaviors (aggressive state), or in all of the submissive behaviors (submissive state). Using the functions, we quantified the number of times that the identity of the male performing agonistic behaviors changed (state changes). Across experiments, the number of state changes (14-125) and the overall differences in status (absolute values: 0.02-0.97) was variable. When examining the courtship behavior of males in aggressive and submissive states, we found that the number of times a male interacted with a female was negatively correlated to the proportion of courtship chases with vocalizations (aggressive state: $r = -0.46$, $p < 0.002$; submissive state: $r = -0.31$, $p < 0.05$). The relationship was significantly influenced by the overall difference in social status ($r = -0.61$, $p < 10^{-5}$). These results suggest that establishing social rank is a highly dynamic process, and both the behavioral state of an animal and the overall difference in status impact courtship.

Title: Using a sound source localization system to quantify autism-like deficits in mice during naturalistic group interaction

Authors: *M. R. WARREN[1], J. P. NEUNUEBEL[2]
[2]Psychological and Brain Sci., [1]Univ. of Delaware, Newark, DE

Abstract: Autism is a behaviorally classified disorder characterized in part by deficits in social interaction and communication. As numerous genetic perturbations are associated with autism, multiple mouse models have been genetically engineered to target candidate genes for autism. To

subsequently evaluate behavioral deficits similar to those observed in humans diagnosed with autism, numerous assays have been developed to measure discrete facets of autism-like behavior in these mouse models (Moy et al., 2007). Quantifying autism-like behavioral phenotypes during naturalistic interactions between mice, however, has been difficult. To overcome this challenge, we used a novel microphone array system (Warren et al., 2018) and two established mouse models of autism (Cacna1c (Bader et al. 2012) and Shank3b (Peca et al. 2011)) to examine the vocal and behavioral repertoires of individual adult animals (8-12 weeks old) during unrestrained group interactions. Groups of four mice, two males and two females, all of the same genotype (Cacna1c groups: wild-type, n = 7, heterozygous TS2-neocassette knock-in, n = 6; Shank3b groups: wildtype, n = 7, homozygous knockout, n = 6), were allowed to freely interact over a 5-hour period. For Cacna1c model mice, the number of social interactions between heterozygous males was similar to the number between wildtype males ($t_{11} = 1.11$, $p > 0.2$). Further, the number of vocal signals each male emitted was comparable regardless of genotype ($t_{24} = 1.28$, $p > 0.2$). For the Shank3b model, however, homozygous males interacted with each other less frequently than wildtype males ($t_{11} = 3.72$, $p < 0.01$). Moreover, the Shank3b knockout mice emitted significantly fewer vocal signals than their wildtype counterparts ($t_{24} = 3.59$, $p < 0.002$). Together, these data indicate that assessing behavior in a more naturalistic setting for longer periods of time may be a more sensitive measure of autism-like behavior in mice. Strikingly, however, we found that the relationship between vocal and behavioral repertoire remained constant regardless of genotype. By using an automatic behavioral classification program (Kabra et al., 2013) to extract discrete instances of behavior, and a novel vocal classification program to group similarly shaped vocal signals, we found that regardless of genotype, male mice emit discrete types of vocalizations depending upon their role in a social encounter. These results suggest that autism-like behavior quantified via typical measures may not be indicative of behavior in more naturalistic settings. Additionally, vocal emission appears to be linked to behavioral repertoire, regardless of genotype.

Title: Acoustic characteristics of vocal motor units in phee vocalizations of marmoset monkeys

Authors: *C. RISUENO SEGOVIA[1], S. R. HAGE[2]
[1]Werner Reichardt Ctr. For Integrative Neuroscien, Tübingen, Germany; [2]CIN, Univ. of Tubingen, Tübingen, Germany

Abstract: The common marmoset, *Callithrix jacchus*, is endowed with a flexible vocal apparatus leading to an extensive vocal repertoire. The species-specific contact call, the phee call, is normally uttered as a simple call with one or multiple consecutive syllables. Previously, we reported the occurrence of periodically segmented phees indicating that vocalizations do not consist of one discrete call pattern but are built of many sequentially uttered units. Interestingly, the duration of these units matches the duration of other call types suggesting a general principle of vocal pattern generation. In the present study, we aim to characterize the acoustic features of segmented phee vocalizations. Our first results indicate a flexible yet constrained complex vocal pattern generating mechanism.

Title: Does Limiting parental interaction interrupt or regress vocal development in marmoset monkeys?

Authors: *Y. GÜLTEKIN[1], D. G. HILDEBRAND[2], S. R. HAGE[3]
[1]Neurobio. of Vocal Communication, Ctr. of Integrative Neurosci., Tübingen, Germany; [2]Lab. of Neural Systems, Rockefeller Univ., New york, NY; [3]CIN, Univ. of Tubingen, Tübingen, Germany

Abstract: Vocalizations of human infants change dramatically across the first year by becoming increasingly mature and speech-like, a process that is driven by learning from caretakers. In contrast, vocalizations of non-human primates are mainly innate and traditionally thought to change during development purely due to maturation. Like humans, marmosets exhibit infant-specific vocal behaviour including distinct infant call types that become increasingly mature during the first postnatal months until the proper adult vocal behaviour and repertoire is maintained. Although non-human primate vocalizations are largely innate, recent studies revealed vocal developmental processes in marmoset monkeys are influenced by parental feedback. However, the extent of this influence remains unclear. In particular, it is not yet known whether parental feedback in marmosets is an obligate requirement for proper vocal development as in humans, or whether it simply accelerates vocal development without a detrimental effect if

absent. To address this question, we tracked the vocal development of subadult marmosets with different parental experiences at different postnatal stages in a comparative study. We first studied two sets of offspring from the same parents: one set was normally raised, while the other was separated from the parents after the third postnatal month. Using quantitative measures to compare distinct call parameters and vocal sequence structure of the litters, we showed that parental feedback is necessary for normal vocal development in marmosets. While normally raised monkeys exclusively produced adult calls at the age of seven months, monkeys that had limited parental feedback still produced infant calls at the age of 13 months. In addition, limited parental feedback monkeys still exhibited the infant-specific babbling behaviour. To determine the extent to which their vocal development matured, we now investigate whether the limited parental interaction monkeys got stuck at or even regressed from the level of vocal development at separation by comparing their vocal behaviour with vocal output from normally raised monkeys at multiple developmental stages. Our aim is to thoroughly understand the impact of losing direct parental interaction on the vocal behaviour of marmosets in long term. Overall, our findings suggest a significant role for social feedback on primate vocal development that can be modified by postnatal experiences and show that marmoset monkeys are a compelling model system for human vocal development.

Title: Neurobehavioral and vocal development in marmoset infants

Authors: *R. LANDMAN[1], O. MEISNER[2], S. PARMAR[2], R. DESIMONE[4], G. FENG[3]
[1]MIT, Broad Inst., Cambridge, MA; [3]Brain and Cognitive Sci., [2]MIT, Cambridge, MA; [4]MIT, McGovern Inst. Brain Res., Cambridge, MA

Abstract: The prospect of transgenic models in the Common marmoset (Callithrix jacchus) monkey creates a need for baseline data on development in wild type animals. To create a baseline for neurological, social and behavioral functioning in our colony, we used the Primate Postnatal Neurobehavioral Assessment Scale for marmoset monkeys (PPNAS-M) (Brain et al, 2015). This scale is based on a similar scale for Rhesus monkeys and the human infant scales Brazelton Newborn Behavioral Assessment Scale and Bayley Scales of Infant Development. The 41-item screening consists of 5 testing categories: visual orienting, auditory and spatial orienting,

motor responses, righting and body strength, and temperament tests. Marmoset infants were tested on the scale at age 5, 10, 15, 20, 30, 45 and 60 days of age. In addition, the infants' vocalizations were recorded for a 10 minute period while an audio recording of calls of an unfamiliar adult marmoset was played. On the PPNAS-M, our results are similar to the original publication. For most categories, the biggest development took place between 10 and 30 days of age. The general curve is similar between the different categories. To examine changes in vocalization in response to other animals, we evaluated the rate of vocalizations uttered by the infants just after recorded calls. Starting at 45 days of age, we noted an approximately 5 sec inhibition of calling by the infant following recorded calls. There was a weak correlation between scores on the PPNAS-M and inhibition of vocalization. The results confirm the usefulness of the PPNAS-M as a measure for development in the first month. Our vocal interaction test could be an indicator of vocal communication abilities starting at 45 days of age.

Title: Operant conditioning of vocal behavior in marmoset monkeys

Authors: *T. POMBERGER[1,2,3], C. RISUENO-SEGOVIA[3,2], D. DOHMEN[3,2], Y. B. GULTEKIN[3,2], S. R. HAGE[3]

Abstract: Current studies have revealed distinct learning mechanisms during vocal development and observed rapid vocal flexibility in vocalizations of marmoset monkeys. However, it is still a matter of debate whether they are able to achieve cognitive control over their vocalizations and, therefore, to decouple them from accompanied levels of arousal or specific events. We show that marmoset monkeys (*Callithrix jacchus*) can be trained to elicit vocalizations on command in response to arbitrary visual cues. Furthermore, we show that these animals can learn to produce distinct call types in response to different visual cues on a trial-by-trial basis. These findings indicate that marmoset monkeys are able to volitionally initiate their vocal production and,

therefore, are able to instrumentalize their vocal behavior to perform a behavioral task successfully. This conditioning approach will pave the way for further electrophysiological investigations of vocal motor control in marmoset monkeys, a highly loquacious monkey species, in a highly controlled experimental approach.

Title: The anterior cingulate cortex as a nexus for vocal communication and energy allocation in marmoset monkeys

Authors: *D. A. LIAO[1], Y. S. ZHANG[1], D. Y. TAKAHASHI[1], A. EL HADY[1,2], A. A. GHAZANFAR[1]
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: We recently showed that arousal levels are linked, but not inextricably, to vocal production (Liao et al., PNAS, 2018). In contexts where marmosets are interacting, the production of different call types is determined by both arousal levels and extrinsic factors such as the timing of a conspecific's vocalization. These data suggested that primates use their vocalizations strategically in that the changes in vocal output (i.e., different call types) as a function of context seem to reflect the tradeoffs between the drive to perpetuate vocal contact and conserving energy usage. For example, the production of loud, long, and tonal contact calls when conspecifics are out of sight is energetically demanding, eliciting a high metabolic cost. Increases in arousal could serve to allocate metabolic energy in order to prepare the body for this adaptive action.
Given how intrinsic states like arousal and external factors such as the vocalizations of conspecifics are intertwined, we investigated the neural circuits that might coordinate both processes. The anterior cingulate cortex (ACC) has long been implicated in modulating arousal, self-monitoring and vocal production . However, the ACC is broad and heterogeneous, with multiple functional subdivisions. Thus, we are using functional ultrasound imaging (fUSi) combined with heart rate measures via electromyography to capture the network of medial brain areas engaged when marmosets participate in vocal communication. Analyses of fUSi signals,

vocal playbacks, and heart rates identified a region spanning segments of pre- and sub-genual ACC responsive to call perception. Further analyses will investigate the relationship between the heart rate and the fUSi signal, and how together they might be modulated by social context. Interrogation of the interplay between intrinsic and extrinsic factors and their effects on neural activity will provide insights into the mechanisms governing vocal behavior.

Title: Dynamic functional ultrasound imaging of socio-vocal network in marmoset monkeys

Authors: *D. Y. TAKAHASHI[1], A. EL HADY[2,3], G. MONTALDO[4], A. URBAN[4], A. A. GHAZANFAR[2]

Abstract: Vocal communication is the quintessential form of social interaction. Humans and other animals coordinate their social behaviors by producing and perceiving distinct vocalizations. Brain networks related to vocal communication include areas at the intersection of social behavior and vocal production-perception networks. Recent studies of primate vocal communication focused on lateral cortical regions, despite the fact that medial cortical and subcortical areas constitute the main vocal production and social behavior network (SBN). Hence, we aim to describe the brain-wide network underlying social communication focusing on the role played by medial cortical and subcortical areas. We use as our model the marmoset monkey, a highly vocal New World species. To image large-scale neural activity, we use functional ultrasound imaging which has a large spatial coverage and high spatio-temporal resolution. Furthermore, we built a stochastic dynamical systems model of vocal behavior that interacts with the marmoset in a closed-loop to fully control the vocal interaction and make quantitative predictions about brain dynamics during communication. We first show the existence of a medial brain system at the intersection of vocal production-perception and SBN; we call it the *socio-vocal network* (SVN). These areas differentially respond to affiliative vocalizations—contact, trillphee, and trill calls—produced in different contexts, exhibiting the

highest and quickest response to contact calls. Given that the contact calls reflect the highest arousal state of the vocalizing animal, this is consistent with the hypothesis that SVN is related to the monitoring of others motivational state through vocalization. Second, through a closed-loop interaction between the computational model and a marmoset, together with large-scale functional imaging, we found that the marmoset anterior cingulate cortex (which is part of SVN) and the model's "SVN" are entrained. These results demonstrate what the SVN encompasses and its roles in vocal communication.

Title: Neurovascular anatomy of the marmoset brain: Links to the default mode network

Authors: *Y. S. ZHANG[1], T. J. PISANO[1,2], D. Y. TAKAHASHI[1], A. EL HADY[1,3], D. A. LIAO[1], S. S.-H. WANG[1], A. A. GHAZANFAR[1]
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Rutgers-Robert Wood Johnson Med. Sch., New Brunswick, NJ; [3]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Dynamically correlated brain activity during resting state consistently reveals a large-scale network of functionally-linked areas known as the "default mode network". One hypothesis is that—in addition to neural connectivity—the structure of the default network is determined by the vascular architecture of the brain. This architecture represents the physical constraints of energy transport necessary for neural activity. In this study, we present our progress towards building the connection between the stationary vascular structure and the dynamics of blood flow in the primate brain. We combined the high-throughput technique of brain clearing (iDISCO) and high-contrast vascular staining with light-sheet microscopy to reconstruct the whole brain vasculature. Using an automated image processing pipeline, we quantitatively analyzed the vessel morphology and distribution, down to the level of microvessels. To link structure to function, we used functional ultrasound imaging which has a high spatiotemporal resolution to

image changes in cerebral blood volume in the medial sagittal section of the brain during the resting state. We found that temporally-correlated activity forms distinct clusters in cortical and subcortical areas as a function of both the brain area and the size of the blood vessels. Using current models of hemo-neural coupling, our results could provide a new approach to predict large-scale neural dynamics using neurovascular anatomical data.

Title: CRISPR/Cas9-based genome editing of the FoxP locus in *Drosophila*

Authors: *A. E. ERIKSSON, O. PALAZZO, B. BREMBS
Inst. für Zoologie - Neurogenetik, Univ. Regensburg, Regensburg, Germany

Abstract: In humans, variants of the Forkhead Box P2 (FOXP2) gene can cause severe speech and language disorders (verbal dyspraxia). The FoxP2 gene sequence is highly conserved in vertebrates and orthologs of the FoxP gene family exist in all bilaterians. Paralleling the interpretation of the verbal dyspraxia in FOXP2 patients as a motor deficit, FOXP1 patients show additional motor deficits, e.g. delayed development of walking. The Drosophila melanogaster ortholog, dFoxP, provides an opportunity to study the evolutionary conserved function of this gene family in operant self-learning, a type of motor learning. Operant self-learning of yaw torque (attempted rotations around the vertical body axis) in tethered flies is conceptually analogous to vocal learning: Vocal learning by imitation is a form of motor learning that proceeds slowly from “babbling” in humans and “subsong” in birds, towards speech and language in humans and crystallized song in birds. Analogously, flies tethered at the torque meter first initiate erratic exploratory actions followed by a reduction in behavioral variability as a result of sensory feedback. In vocal learning, the feedback shaping the motor actions is auditory, in flies we use heat to indicate motor errors. The analogy between fly operant self-learning and vocal learning is more than superficial: In humans and song birds, alterations of the FOXP2 gene cause a deficit in vocal learning. Also in flies, alterations of the dFoxP gene cause a deficit in operant self-learning, but leaving other forms of learning intact. In this work, we generated three transgenic Drosophila lines using the CRISPR/Cas9 technology: a conditional knockout of the dFoxP gene in a spatio-temporally controlled manner, a null-mutant knockout, and a knock-in of the Gal4 reporter gene sequence directly into the FoxP gene. Due to this latter knock-in reporter, we were able to study FoxP gene expression at the cellular level and compare

it with previously existing fly lines where FoxP had been tagged. These lines also enabled us to specifically study the expression of the IsoB isoform, which was previously associated with operant self-learning. Gene expression profiles were generated at the embryonal, larval, pupal and adult stage. In addition to the expression pattern, we also performed a behavioral characterization of the FoxP manipulated lines with regards to their performance in experiments testing spontaneous behavior, operant learning and decision making.

Title: Role of the anti-inflammatory cytokine IL-10 on anxiety and sickness-like behaviors in adult male rats

Authors: *S. MUNSHI[1,2], V. PARRILLI[2], J. A. ROSENKRANZ[2,3]
[1]Dept. of Neurosci., [2]Dept. of Cell. and Mol. Pharmacol., [3]Ctr. for Stress Resilience and Psychiatric Disorders, Rosalind Franklin Univ. of Med. & Sci., North Chicago, IL

Abstract: Anti-inflammatory cytokines are known to counteract damage caused by inflammatory processes and are beneficial in limiting the severity of inflammation. A growing body of evidence suggests that pro-inflammatory cytokines produce manifestations of sickness-like behaviors seen during inflammation, such as malaise and lethargy, and contribute to effects of inflammation on mood. Very little is known about the role of anti-inflammatory cytokines in this regard. Interleukin (IL)-10 is a cytokine whose anti-inflammatory effects have been studied extensively. However, its effects on sickness behavior and mood changes caused by inflammation have not been extensively explored. This aspect is commonly tested in rodents by measuring changes in behavioral activity levels that reflect lethargy or malaise and anxiety-like behaviors that represent changes in affective state. The first step towards understanding if IL-10 exerts effects opposite of pro-inflammatory cytokines is to determine if IL-10 itself produces a change in behavioral activity level and anxiety-like behavior. In the present study, we tested the effects of peripherally injected IL-10 on these behaviors of adult male Sprague Dawley rats. Rats were injected with a single dose of IL-10 (1 μg, i.p.) and its acute effect on open field exploration, social interaction and elevated plus maze tests were measured at 30 min post-treatment. IL-10 caused anxiety-like behavior as evidenced by reduced central area exploration

in the open field and reduced open arm exploration in elevated plus maze, but without any effect on locomotor activity. While the prototypical pro-inflammatory cytokine IL-1β (1 μg, i.p.) caused a decrease of locomotor activity, indicative of lethargy/malaise, rats co-treated with both IL-10 and IL-1β showed locomotor activity, open field, social interaction and elevated plus maze behaviors very similar to that of the control groups. This suggests that IL-10 is capable of mitigating the sickness-like effects caused by IL-1β. This provides a significant insight into the therapeutic potential of IL-10 in the management of depression.

Title: Immunization with mycobacterium vaccae induces an anti-inflammatory milieu in the CNS: Attenuation of stress-induced microglial priming, alarmins and anxiety-like behavior

Authors: *M. G. FRANK[1], L. K. FONKEN[2], S. D. DOLZANI[3], J. L. ANNIS[3], P. H. SIEBLER[3], D. SCHMIDT[3], L. R. WATKINS[3], S. F. MAIER[3], C. A. LOWRY[3,4,5,6]
[1]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]Div. of Pharmacol. and Toxicology, Univ. of Texas at Austin, Austin, TX; [3]Univ. of Colorado, Boulder, CO; [4]Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [5]Denver Veterans Affairs Med. Ctr., Denver, CO; [6]Military and Veteran Microbiome Consortium for Res. and Educ., Denver, CO

Abstract: Exposure to stressors induces anxiety- and depressive-like behaviors, which are mediated, in part, by neuroinflammatory processes. Recent findings demonstrate that treatment with the immunoregulatory and anti-inflammatory bacterium, *Mycobacterium vaccae* (*M. vaccae*), attenuates stress-induced exaggeration of peripheral inflammation and stress-induced anxiety-like behavioral responses. However, the effects of *M. vaccae* on neuroimmune processes have largely been unexplored. In the present study, we examined the effect of the *M. vaccae* NCTC11659 on neuroimmune regulation, stress-induced neuroinflammatory processes and anxiety-like behavior. Adult male rats were immunized 3x with a heat-killed preparation of *M. vaccae* (0.1 mg, s.c.) or vehicle. *M. vaccae* induced an anti-inflammatory immunophenotype in hippocampus (increased interleukin (Il)4, Cd200r1, and Mrc1 mRNA expression) and increased IL4 protein 8 d after the last immunization. Central administration of recombinant IL4

recapitulated the effects of *M. vaccae* on Cd200r1 and Mrc1 mRNA expression. *M. vaccae* reduced basal levels of genes (Nlrp3 and Nfkbia) involved in microglial priming; thus, we explored the effects of *M. vaccae* on stress-induced hippocampal microglial priming and HMGB1, which mediates priming. We found that *M. vaccae* blocked stress-induced decreases in Cd200r1, increases in the alarmin HMGB1, and priming of the microglial response to immune challenge. Furthermore, *M. vaccae* prevented stress-induced increases in anxiety-like behavior. The present findings suggest that *M. vaccae* enhances immunomodulation in the CNS and mitigates the neuroinflammatory and behavioral effects of stress, which may underpin its capacity to impart a stress resilient phenotype.

Title: Immunoregulatory effects of mycobacterium vaccae are dependent on the route of application

Authors: *S. O. REBER[1], M. AMOROSO[1], T. ELESLAMBOULY[1], M. DANDAMUDI[1], E. KEMPTER[1], C. A. LOWRY[2], D. LANGGARTNER[1]
[1]Lab. for Mol. Psychosomatics, Univ. Clin. Ulm, Ulm, Germany; [2]Dept. of Integrative Physiol. and Ctr. for Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Immunodysregulation and subsequent chronic low-grade inflammation are risk factors for the development of stress-related somatic and psychiatric disorders, including inflammatory bowel disease (IBD) and posttraumatic stress disorder (PTSD). Thus, immunoregulatory approaches that counterbalance basal and/or stress-induced immune activation are expected to be protective in this context. In support of this hypothesis, we recently demonstrated that repeated subcutaneous preimmunization with a heat-killed preparation of immunoregulatory *Mycobacterium vaccae* (*M. vaccae; NCTC 11659*) protected mice against stress-induced general anxiety, social anxiety, spontaneous colitis, and aggravation of dextran sulfate sodium (DSS)-induced colitis in a mouse model of PTSD. To induce a PTSD-like phenotype, the chronic subordinate colony housing (CSC) paradigm, which is based on the repeated psychosocial traumatization (i.e., social defeat) in combination with chronic subordination of four male CSC mice towards a dominant resident male conspecific, was used. In the current study we employed

the CSC paradigm (start Day 1) to test whether 0.1 mg/ mouse/ week *M. vaccae* has protective effects in CSC and/or respective single housed control (SHC) mice when administered repeatedly via the intragastric (i.g.) or intranasal (i.n.) route prior to CSC on Days -21, -14 and -7. Thus, we assessed the coping behaviour during (Days 1, 8, 15) and anxiety-related behaviour at the end (Day 19: elevated plus-maze; Day 20: open-field/novel object; Day 21: social preference avoidance test) of CSC exposure. Moreover, inflammatory parameters following 7 days (Days 21-28) of DSS treatment were measured. Interestingly, while both repeated i.n. and i.g. administration of *M. vaccae* affected stress coping during CSC, only repeated i.g. administration of *M. vaccae* had colitis protective effects in SHC mice and ameliorated CSC-induced aggravation of DSS colitis. Both repeated i.g. and i.n. administrations increased anxiety-related behaviour in SHC and/or CSC mice. Currently, we are testing if i.g. administration of *M. vaccae* also has protective effects when applied during stressor exposure. Taken together, these data broaden the framework for developing bioimmunoregulatory approaches based on microorganisms known as 'Old Friends' for the treatment and/or prevention of stress-related disorders.

Title: Oral exposure to a neuroactive bacterial strain leads to acute activation of specific brain regions and modulates chronic social stress-induced behavioural deficits

Authors: *A. BHARWANI[1], K. CHAMPAGNE-JORGENSEN[1], F. M. MIAN[1], M. G. SURETTE[2], J. BIENENSTOCK[3], P. FORSYTHE[2]
[2]Med., [3]Pathology & Mol. Med., [1]McMaster Univ., Hamilton, ON, Canada

Abstract: The gut microbiota and the brain are engaged in persistent bidirectional interplay—a phenomenon that influences host neural function and behaviour. Indeed, administration of a neuroactive bacterial strain reduces anxiety- and depression-like behaviours, while exposure to chronic social stress causes complex structural changes in the gut microbial community.

However, it is currently unclear whether the microbiota influences stress-associated behavioural and neural changes, and the candidate brain regions that respond to bacterial signals remain unknown. Using a neuroactive bacterial strain, *Lactobacillus rhamnosus* JB-1^{TM}, we investigated whether gut-brain signalling modulates the behavioural changes induced by chronic social stress, and mapped JB-1 induced c-fos immunoreactivity in select brain regions.
Male C57BL/6 mice were orally administered 10^9 colony-forming units (CFU) of JB-1 for 28 days and were subjected to chronic social defeat stress during the final ten days of treatment. Mice were assessed for alterations in social, exploratory, and anxiety-like behaviours using multiple behavioural assays. 16S rRNA sequencing was used to analyze structural changes in the microbiota community. In a second set of experiments, stress-naïve male Balb/c mice, which exhibit behavioural changes following long-term bacteria administration, were administered a single dose of 10^9 CFU of JB-1 before being sacrificed two hours later to map acute JB-1-induced c-fos expression.
Chronic stress induced various behavioural deficits—reduced sociability and exploration, and increased anxiety-like behaviour—that were partially corrected with bacteria administration. Stress exposure induced complex alterations in the microbiota profile, none of which were prevented by treatment. We also present immunofluorescence data of quantified c-fos expression in various brain regions at two hours following JB-1 administration.
These findings demonstrate the ability of bacteria to modulate gut-brain signalling independently of structural changes in the microbiota, and to correct specific behavioural deficits induced by chronic stress. Additionally, these data identify candidate brain regions that respond to bacteria-derived signals and which may be of further interest for functional analysis. Collectively, these results reveal further evidence of gut-brain signalling, and a potential role for microbe-based adjuncts or therapies as a novel strategy in the treatment of psychiatric conditions.

Abstract: Social stressors, such as aggression are major risk factors for neuropsychiatric disorders, including major depressive disorder (MDD). While it is well established that chronic social stress leads to profound changes in the immune system (e.g. increased levels of pro-inflammatory cytokines), which elicit behavioral changes relevant to MDD, the detailed mechanisms of how the peripheral immune system acts on the brain (and *vice versa*) remains to be elucidated. The present project aims to characterize the different immune cell populations in both blood and brain, and investigate the role of blood-brain barrier endothelial cells as an important interface between these two compartments in the murine chronic social defeat (CSD) model. Using mass cytometry (CyTOF), we performed single cell, high-dimensional analysis of blood in stress susceptible, resilient and unstressed control mice. We show that CSD leads to a significant stress effect, altering leukocyte subpopulation frequencies of both the myeloid and lymphoid lineage. Interestingly, stress susceptible and resilient mice show similar peripheral changes, suggesting that there may be cell intrinsic differences in leukocyte subpopulations or in the way in which inflammatory signals access the brain circuitry to affect depression-like behaviors. Investigating the mechanisms underlying interactions between the peripheral immune and central nervous systems in a mouse model relevant to MDD will yield important insights into the etio-pathophysiology of MDD and may lead to potential novel therapeutic targets.

Abstract: Retrospective human studies show that early life adversity is associated with elevated plasma C-reactive protein (CRP) levels and other markers indicative of immune dysregulation, which appear to increase risk of mental and physical illness later in life. Animal models demonstrate that stressors experienced very early in life result in elevated systemic immune markers in adulthood, associated with psychological and cognitive disruptions. However, whether chronic stress restricted to adolescence has long-lasting effects on basal or stress-induced peripheral and central immune makers is not as well understood. Adolescent social defeat is an animal model of social stress that replicates many of the aspects of peer bullying during a critical period of brain and behavior maturation. Adolescent social defeat in male rats results in learning/memory deficits and enhanced drug seeking in adulthood along with disruptions to cortical and accumbal dopamine function. Here we applied the same model to examine immune markers in basal and stress-challenged conditions in previously defeated male rats. Adolescent rats (postnatal day [P]35-39) were exposed to daily social defeat or control handling and were allowed to develop to adulthood (P60+) undisturbed. Brains and plasma were collected from adult rats immediately following either 20 minutes of restraint stress or in the absence of stress (n = 10-12 per group). Plasma corticosterone, CRP and cytokine levels were determined by ELISA while hippocampal proinflammatory cytokine mRNA was quantified. Main effects of adolescent defeat or restraint stress were observed such that restraint stress increased plasma cortisol levels equally in defeated and control rats, but CRP levels were increased by adolescent social defeat irrespective of restraint stress. Findings suggest long-lasting effects of adolescent social stress on basal immune markers that have been directly implicated in poorer psychological and physical health outcomes in later life.

Title: The effect of IL-1βin the BLA on enhanced fear memory

Authors: *A. KULP[1], B. LOWDEN[1], J. KRZOSKA[1], M. HAUCK[1], M. RUSS[1], D. MEHTA[1], D. BARNARD[2], J. D. JOHNSON[3]
[1]Biomed. Sci., [3]Biol Sci. Dept, [2]Kent State Univ., Kent, OH

Abstract: Following a traumatic event, individuals have an enhanced memory of the context of the event (location, people, etc.). This is evolutionary advantageous since it allows the individual to avoid the dangerous environment in the future; however, some individuals have too strong of a memory to a fearful event and is debilitating. Currently, it is unclear what causes the enhanced memory at the molecular level. The leading mechanism proposed is through the activation of the stress response, particularly the sympathetic nervous system (SNS). When stressed, the SNS utilizes norepinephrine binding to its receptor, beta-adrenergic receptors (βAR). Following, there is an influx of interleukin-1β (IL-1 β), a proinflammatory cytokine, which has evidence to be a sufficient molecule for inducing the enhanced fear memory: 1) Rodents given repeated stress show enhanced IL-1 β production in the amygdala; 2) Low levels of IL-1β added through intracerebroventricular injection facilitate memory processes; 3) Rodents with a stressful past have enhanced fear memories. Therefore, it is reasonable to hypothesize that IL-1β facilitates the enhanced fear memory following chronic stress.To answer this question, male rats were administered 0.5 µL of IL-1β in the basolateral amygdala, a brain region important for fear memory association:1) 0.0 ng/ µL; 2) 0.01 ng/ µL; 3) 0.1 ng/ µL; 4) 1.0 ng/ µL after the fear training. Surprisingly, the data suggest IL-1β dampens fear memory in a dose dependent manner. Future studies will investigate whether blocking IL-1 β enhances fear memory.

Title: Gender-specific gene expression profiling of the prefrontal cortices of social defeat stress model mice

Authors: *M. SAKAI
Dept. of Disaster Psychiatry, Grad. Sch. of Med. ,tohoku Univ., Sendai, Japan

Abstract: The prevalence of depression is higher among female population, and some of clinical features of depression is known to be gender-relevant. Although molecular mechanisms underlying the pathogeneses of depression have been intensively investigated utilizing the postmortem brains from depressed patients and multiple animal models of depression, gender

difference has rarely been taken into account. Since functional imaging and postmortem brain studies suggested the prefrontal cortex (PFC) abnormalities in patients with depression, gender difference in microarray-based gene expression profiling of PFC was evaluated utilizing the social defeat stress mouse model, which is widely used as an animal model for depression in neuroscience researches. Gene ontology analyses were used to investigate molecular and cellular pathways potentially involved in depression-linked behavior. Mitochondrion-associated genes were significantly enriched among the differentially expressed genes in the PFC between male mice susceptible to social defeat stress and control male mice, whereas nucleus-associated genes were significantly enriched among differentially expressed genes in the PFC between susceptible and control female mice. Besides, two hormonal molecules were extremely increased only in social defeat-susceptible female mice, whereas they were decreased in social defeat-susceptible male mice. The findings was validated by real-time PCR studies. The data suggests that these gender-specific gene expression profiling can underlie the pathogenesis of depression.

Abstract: Previous studies in our laboratory demonstrate that a heat-killed preparation of the immunoregulatory and anti-inflammatory environmental bacterium *Mycobacterium vaccae NCTC* 11659 is a potentially useful countermeasure that protects against negative outcomes of chronic psychosocial stress. These protective effects included ameliorations of stress-induced decreases in alpha (phylogenetic) diversity and increases in beta diversity of the gut microbiome, chemically induced colitis in a model of inflammatory bowel disease, anti-CD3-stimulated release of proinflammatory cytokines from freshly isolated mesenteric lymph node cells *ex vivo*, and anxiety-like behavior. Here we utilized a 2 x 2 experimental design in 3 cohorts of juvenile male C57BL/6N mice (postnatal day (pnd) 28; $N = 45$) to determine if immunization with *M. vaccae* is an effective countermeasure in a murine model of chronic circadian disruption (CDR). Mice were implanted on pnd 36 with telemetric recording devices for monitoring 24-h rhythms of core body temperature and locomotor activity (LA). We immunized (3 x weekly immunizations beginning on pnd 43) adolescent male mice with a heat-killed preparation of *M. vaccae* or vehicle and evaluated the gut microbiome and fecal metabolome using 16S rRNA gene sequencing and untargeted LC/MS/MS, respectively, before and during 8 weeks of CDR (pnd 42, 56, 91, and 105). Briefly, CDR consisted of weekly 12-h light reversals of the normal 12:12h light:dark cycle every 7 days for 8 weeks (pnd 64-120). Single-housed mice immunized with vehicle and maintained on a non-manipulated 12-h light:dark cycle (lights on at ZT0 = 7:00am, lights off at ZT12 = 7:00pm) for 8 weeks were used as controls. Immunization with *M. vaccae* increased LA measures during the active dark phase prior to the onset of CDR. Gut microbiome diversity and community structure were remarkably consistent within individuals across time. Neither *M. vaccae* immunization ($F = 1.3799$, $p = 0.152$, 121 residuals, PERMANOVA; pnd 56-105) nor CDR ($F = 1.2045$, $p = 0.26$, 82 residuals, PERMANOVA; pnd 91-105) altered alpha- or beta-diversity of the gut microbiome. We show instead that differences in microbial community structures in inbred mice are highly dependent on the cohort of mice received from the commercial vendor ($F = 16.495$, $p < 0.001$, 120 residuals, PERMANOVA; pnd 42-105) and cluster differently in measures of centroid dispersion ($F = 3.4056$, $p = 0.029$, 81 residuals). Analysis of the fecal metabolome is ongoing. These findings demonstrate the importance of using animal models that are not only genetically identical, but also housed in identical conditions from birth for use in -omics studies.

Title: Effects of a nootropic and immunomodulator drug in a mice model of social isolation

Authors: *D. C. MELO MAGALHÃES[1,2,3], M. MAMPAY[3], G. SHERIDAN[3], C. A. VALENTE[1,2], A. M. SEBASTIÃO[1,2]
[1]Ana Sebastião Lab., Inst. de Medicina Mol., Lisbon, Portugal; [2]Inst. de Neurociências e Farmacologia, Faculdade de Medicina da Univ. de Lisboa, Lisbon, Portugal; [3]NeuroImmunology & NeuroTherapeutics Lab., Univ. of Brighton, Brighton, United Kingdom

Abstract: Social isolation (SI) has psychiatric outcomes, such as anxiety and depression. However, biomolecular mechanisms underlying how this negatively impacts health are poorly understood.In this work, we hypothesize that SI, as a psychological stressor, will activate neuroendocrine pathways and will ultimately lead to a chronic systemic inflammation. This can cause alterations in the crosstalk of the immune system and CNS. Subsequently, activation of neuroinflammatory pathways and learning/memory impairment causes a development and/or continuous anxiety- and depressive-like behavior. This work aimed to study if the modulation of the crosstalk between the systemic immune system and CNS enhances cognition in SI mice and ameliorates neuroinflammation. Thus, a mouse model of SI was used and the effect of Fingolimod (FTY720), a nootropic and an inhibitor of the peripheral immune cell trafficking, upon SI-induced anxiety-like behaviour was evaluated. Young and adult C57BL/J6 mice were divided into 4 groups. Two groups were SI for three weeks, with FTY720 treatment or DMSO (designated as control (CTL)). The remaining two groups were grouped house (GH) with 4-6 animals per cage, and submitted to the same two conditions. The treatment was given through drinking water *ad libitum*, since FTY720 is lipophilic. The number of animals in this first battery of tests ranged between 6-8. All statistical analyses were performed through two-way ANOVA, followed by Bonferroni's Comparison Test. First, behaviour was evaluated through appropriate tests. Depression was assessed through Forced Swim Test and anxiety by Open Field. Young mice SI-FTY720 showed a decrease in immobility time, when compared with CTL. Morris Water Maze was used to evaluate learning, during 8 trials, and spatial reference memory through a probe trial in the last day. However, neither SI nor FTY720 had an impact on learning and memory. Following the behavior tests, a molecular approached was performed, specifically

ELISA, to evaluate neuroinflammatory markers in this SI model. Protein levels of IL-1β in hippocampal tissue, showed a decrease with FTY720 in SI groups. However, only in adult mice, a statistical significance was obtained. In summary, in young mice FTY720 showed a significant improvement in anxiety- and depressive- behavior, as well as a tendency for decreased levels of IL-1β. These results point to a relevant role of FTY720 in SI young mice. However, further confirmation is required and a replication of this series must be conducted.

Title: How does the presence of exogenous opioids affect linear relationships between inflammatory cytokines and mu-opioid receptor availability?

Authors: *A. K. BAKER[1], A. V. BAKIAN[1], P. R. BURGHARDT[3], E. L. GARLAND[1], J.-K. ZUBIETA[1], T. LOVE[2,1]
[2]Psychiatry, [1]Univ. of Utah, Salt Lake City, UT; [3]Nutr. and Food Sci., Wayne State Univ., Detroit, MI

Abstract: Objective. Chronic pain is one of the most prevalent and pernicious health problems in the US. Opioids are the frontline treatment for chronic pain, contributing to alarmingly high and rapidly increasing rates of opioid misuse. Opioids alter pain through numerous pathways, including inflammatory cytokine signaling in the immune system and μ-opioid neurotransmission in the endogenous opioid system—pathways also implicated in the reward circuitry undergirding addiction. In examining the downward spiral from chronic pain to opioid misuse, it is prudent to examine relationships between these systems. **Methods**. This secondary analysis examined data obtained from a sample of chronic non-neuropathic back pain (CNBP) patients (N=66) and healthy controls (N=28). We examined bivariate relationships between CRP, IL-8, IL-18, & IL-1RA and μ-opioid binding potential (BP) in the amygdala (AMG), hippocampus (HIP) and nucleus accumbens (NAc), at baseline and during acute pain. **Results**. **Baseline.** Among controls, CRP was significantly negatively correlated with μ-opioid receptor BP in each region of interest (L AMG: r = -.83, p < .05; R AMG: r = -.87, p < .05; L HIP: r = -.91, p < .01; R HIP: r = -.78, p < .05; L NAc: r = -.88, p < .01, R NAc: r = -.94, p < .01). There were no significant correlations between cytokines and μ-opioid BP in any region in the CNBP

group. **Pain Challenge.** Among controls, there were no significant correlations between cytokines and change in μ-opioid BP during experimental pain. Among CNBP patients, IL-8 and IL-18 were correlated with ΔBP in the right NAc (r = .68, p < .05 and r = .80, p < .01, respectively), and IL-1RA was correlated with ΔBP in the left AMG (r = .55, p < .05) and bilateral HIP (L: r = .57, p < .05; R: r = .62, p < .05). **Opioids vs. No Opioids: Baseline.** Among those without exogenous opioids in urine, CRP was correlated with μ-opioid BP in the bilateral NAc (L: r = -.70, p < .01; R: r = -.56, p < .05). Patients with exogenous opioids in urine exhibited correlations between IL-8 and μ-opioid BP in the right AMG (r = .91, p < .05) and between IL-18 and μ-opioid BP in the right AMG (r = .92, p < .05) and bilateral HIP (L: r =.88, p < .05; R: r = .96, p < .01). **Opioids vs. No Opioids: Pain Challenge.** Among patients without exogenous opioids, IL-1RA was correlated with ΔBP in the left AMG (r = .73, p < .01) and left HIP (r =.60, p < .05). Those with exogenous opioids exhibited no significant correlations between cytokines and change in μ-opioid BP. **Discussion.** Results suggest the presence of relationships between inflammatory markers and the endogenous opioid system. Also, that exogenous opioids alter the manner in which the immune and nervous systems interact in the context of persistent pain.

Title: Developing a radiation biodosimeter using exosomal miRNA isolated from murine brain tissue

Authors: *F. OYEFESO[1], N. NISHIYAMA[1], A. GONDA[2], N. WALL[2], M. PECAUT[1]
[1]Basic Sciences, Biomed. Engin. Sci., [2]Basic Sciences, Biochem., Loma Linda Univ., Loma Linda, CA

Abstract: Exosomes are small vesicles (30-150 nm) released from the cell by exocytosis during normal cell function. They have been reported to carry proteins, viral components, and nucleic acids. Further, they may have functionally diverse roles including cell-cell communication, disease transfer, and cell waste management. Still, much is unknown about the specific function

of exosomes and isolating exosome from excised tissue is a relatively new research approach compared to traditional techniques. We are investigating the possibility of using the content of exosomes as a dose-specific radiodosimeter, focusing specifically on exosomal miRNA of brain tissue. We will compare the exosomal miRNA signature found in brain tissue with a similar profile characterized in the blood. We believe this will ultimately allow us to quickly assess any potential risks for radiation-induced neural tissue damage due exposure during cancer treatment, combat situations, or nuclear disasters (e.g. Fukushima & Chernobyl). Our parameters for this research are sex (male and female), whole-body gamma-radiation dose (0, 2, and 4 Gy), and time after exposure (4 and 48 hours).
As a first step, we are testing two independent methods for isolating exosomes from brain tissue to determine which will give us a higher yield and greater sample purity. We begin by homogenizing tissue from a mouse hemi-brain and using step-wise centrifugation to remove large cell components. Using one protocol, this step is followed by ultracentrifugation to pellet exosomes. The ultracentrifugation steps require a sucrose gradient (layered 2.5 M, 1.3 M, and 0.6) to purify exosomes apart from cell debris and other extracellular vesicles (Vella et al., 2018). Following the alternative protocol, the step-wise centrifugation is also followed by ultracentrifugation. This protocol requires a sucrose gradient with six layered 2-ml solutions starting from 0.25 M sucrose in 0.35 M increments (Perez-Gonzalez et al., 2012). After resuspending the exosome pellets, we have compared the isolation methods by quantifying exosome size, quantity, and purity using Nanoparticle Tracking Analysis (Malvern Panalytical). The research is ongoing, following completion of exosome isolation we will proceed to isolating total RNA to characterize miRNA type and quantity.

Title: The effects of early life stress on adult depressive-like behaviour, intestinal and blood-brain barrier permeability, and brain-immune interactions

Authors: *J. SZYSZKOWICZ[1,2], S. BARNETT BURNS[1,2], I. KIM[2], M.-C. AUDET[3], G. TURECKI[2,1], G. N. LUHESHI[2,1]

[1]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [2]Dept. of Psychiatry, McGill Univ., Montreal, QC, Canada; [3]Sch. of Nutritional Sci., Ottawa Univ., Ottawa, ON, Canada

Abstract: Background & Hypothesis: Early life stress (ELS) significantly increases the risk for adult psychopathology, including depression and suicide; however, the mechanisms of this vulnerability remain unclear. The gut microbiome (the bacteria, viruses, and eukaryotes that reside in our intestinal tract) may be a key player in this regard as it regulates many physiological processes related to depression including, hypothalamic-pituitary-adrenal (HPA) axis homeostasis and brain-immune interactions.
Hypothesis: ELS confers long-lasting changes in gut microbiome composition, intestinal and blood-brain-barrier permeability, and promotes pro-inflammatory brain-immune interactions, ultimately resulting in an increased risk for depression.
Methods: We are using male and female C57Bl/6J mice exposed to early life (P2-P9) limited bedding in which we are assessing depressive-like behaviours, HPA axis homeostasis, intestinal and blood-brain barrier permeability, brain-immune interactions, and gut microbiome composition. Concurrently, we are collecting post-mortem intestinal tissue from depressed suicides or controls in which we will repeat relevant measures of intestinal permeability, cytokine expression, and gut microbiome composition.
Results & Significance: Preliminary results from our animal studies suggest that early life limited bedding produces sex-specific deficits in social behaviour along with decreased hypothalamic expression of corticotrophin releasing hormone (CRH) along with decreased expression of claudin-5 in both the hypothalamus and colon of these animals, suggesting altered HPA axis and blood-brain and intestinal barrier disruption respectively. These early observations are indicative of important changes in the multiple systems (brain, immune, gut) targeted for analysis as part of our studies and add support to our hypothesis that ELS triggers an integrative response that may be initiated by fundamental alterations in the microbiome.

Title: Phenotypic features of glucocorticoid receptor-deficient microglia in a mouse model exposed to chronic stress

Authors: *K. PICARD[1], K. BISHT[1], K. P. SHARMA[1], C. LIMATOLA[2], L. MAGGI[2], I. BRANCHI[3], M.-E. TREMBLAY[1]
[1]Dept. of Mol. Med., Univ. Laval, Quebec, QC, Canada; [2]Dept. of Physiol. and Pharmacol., Sapienza Univ. of Rome, Rome, Italy; [3]Dept. of Cell Biol. and Neurosciences, Inst. Superiore di Sanità, Rome, Italy

Abstract: Microglia, the resident immune cells of the brain, are active participants in the plastic remodeling of neuronal circuits. They are also very sensitive to changes in their environment, notably resulting from the exposure to chronic stress, well-known for predisposing to neuropsychiatric disorders and neurodegenerative diseases. Upon stress exposure, corticosterone released by the adrenal gland binds to glucocorticoids receptors (GR), throughout the body, and mainly within the hippocampus, amygdala and prefrontal cortex among the brain. Corticosterone in physiological concentrations promotes the formation of dendritic spines, while in high concentrations, it rather induces their elimination. GR receptors are abundantly expressed by microglia, but their roles are not well known. We hypothesize that deletion of microglial GR in adult mice exposed to chronic unpredictable stress would alter the homeostatic functions of microglia, particularly at synapses.
We generated mice in which microglia are selectively deficient in GR. In particular, CX3CR1-CreER mice were crossed with GR-floxed mice. The resulting mice (microglial GR-KO) received tamoxifen at adulthood. We evaluated their behavior using the Intellicage system, which randomly exposes mice to different stressors in addition to monitoring their behavior. The mice were housed 12 per cage (6 controls and 6 microglial GR-KO). They were habituated to the cages for two weeks, then exposed to chronic stress or left undisturbed for another two weeks. The stress paradigm revealed a greater vulnerability to stress in the microglial GR-KO mice. These mice were then perfused with aldehydes. Brains were cut using a vibratome and sections containing the hippocampus were immunolabeled with the marker Iba1, expressed by myeloid cells, and Tmem119, which is specific to microglia, thus allowing to differentiate microglia from peripheral myeloid cells. Using confocal analyzes, we observed no changes in the density and distribution of microglia in the hippocampus of microglial GR-KO mice and their controls, whether exposed to stress or not. There were also no changes in the infiltration of peripheral myeloid cells. Analyzes are in progress to evaluate possible changes in microglial morphology. Complementary observations will be made by electron microscopy, to analyze the ultrastructure of microglia and characterize their interactions with synapses.
Our study will provide novel insights into the specific contribution of microglial GRs in the adaptation of the brain and behavior to chronic stress. This understanding could ultimately lead to the development of treatments reducing the negative effects of stress.

Title: Early life stress effects on mast cell degranulation and blood-brain barrier function depend on the severity and chronicity of stress

Authors: *A. I. SAULSBERY[1], C. E. PAGE[2], L. H. NELSON[2], C. M. DODSON[2], K. M. LENZ[1]
[1]Psychology, [2]Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Early-life adversity in humans has been associated with vulnerability to adult mood and anxiety disorders. The causes of this vulnerability are not fully understood. In adult rats, chronic stress compromises blood-brain barrier (BBB) integrity and promotes depression- and anxiety-like behavior (Menard et al., 2017; Weber, Godbout, & Sheridan, 2017). We seek to determine whether stress increases BBB permeability in the developing brain via mast cell activity, and whether sex differences in BBB function exist at baseline or in response to early life stress. Mast cells are innate immune cells that colonize the developing brain and release vasodilators, histamine, serotonin, and proteases through a constitutive process called degranulation. Mast cells also regulate vascular permeability in the periphery and secrete cytokines and prostaglandins independent of degranulation during inflammogenic insults. Male and female Sprague-Dawley rats underwent one of several stressors: acute maternal separation stress (MSS) on postnatal day (P) 2; brief (15 min) daily MSS (e.g., handling) from P4-11, 3hrs/day of MSS from P1-7, or no stress. Brains from the acute MSS and brief daily MSS experiments were sectioned and stained with toluidine blue at stressor completion to visualize mast cells. Mast cells were counted and classified as granulated or degranulated. The proportion of degranulated mast cells did not differ between acutely stressed and control rats, although acute stress reduced the number of degranulated mast cells relative to control. Brief daily MSS increased total mast cells (but not degranulated mast cells) in the hippocampus relative to control. Regardless of stress, females in this experiment had a lower proportion of degranulated mast cells than males. Rat pups subjected to 3hrs/day of MSS were killed on P7. Hippocampi and hypothalamuses were rapidly dissected from these rats. In ongoing experiments, we are assessing expression of BBB protein genes and mast cell-related genes across stress conditions.

We predict that 3hr/day MSS during the first week of life will decrease expression of BBB protein genes, such as those for claudin-5, occludin, and tight junction proteins. Increased BBB permeability could alter brain development and increase vulnerability to depression- and anxiety-like behavior by facilitating trafficking of pro-inflammatory cytokines and peripheral immune cells into the brain. This work will help determine how early life stress creates vulnerability to adult psychological disorders, possibly enhancing early intervention efforts following early-life adversity.

Title: Altered photoperiod exposure induces a neuroinflammatory response in mice

Authors: *M. A. KWIATKOWSKI[1], Z. A. COPE[3], J. DESLAURIERS[4], J. W. YOUNG[2]
[1]Dept. of Psychiatry, UCSD, San Diego, CA; [2]Dept Psychiatry, UCSD, La Jolla, CA; [3]Dept. of Psychiatry, [4]Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: BACKGROUND: Seasonal variations in daylight can influence switching between mania and depression in patients with bipolar disorder (BD), i.e., more frequent depression episodes in the fall/winter vs. mania episodes in the spring/summer. Exposure to a winter-like short active (SA) photoperiod induces depression-like behavior plus elevated corticosterone levels (glucocorticoid hormone involved in stress response). Exposure to a summer-like long active (LA) photoperiod induces a risk-prone behavioral profile. Stress can regulate inflammation and certain cytokines can directly influence and alter brain structures important in emotional regulation. The current study assessed whether similarly altered photoperiod exposure induced neuroinflammatory changes in mice.
METHODS: Female C57BL/6J mice were exposed to either: 1) normal active (NA; 12:12 L:D; n=5), 2) short active (SA; 19:5 L:D; n=6), or 3) long active (LA; 5:19 L:D; n=4) photoperiod for two weeks. On day 14, brains and trunk blood were collected to analyze cytokine levels by enzyme-linked immunosorbent assay (ELISA). Cytokines assessed include interleukin (IL)-1β, IL-6, tumor necrosis factor alpha (TNFα), IL-1 receptor antagonist (IL-1Ra), and IL-10. C-

reactive protein (CRP) levels were also assessed.
RESULTS: A main effect of photoperiod for plasma IL-10 levels ($F_{(2,10)} = 6.9$, $p<0.05$) was observed, with elevated levels in LA-exposed mice vs. NA- and SA-exposed mice. No other significant group differences were seen in plasma cytokine or CRP levels. There were no significant group differences in brain cytokine levels or brain CRP levels; however, nonsignificant elevations in brain IL-6, TNFα, and IL-1Ra were observed.
DISCUSSION: Two weeks of altered photoperiod exposure induces elevations in proinflammatory cytokines in the mouse brain. While SA- and LA-induced increases in brain IL-6 and TNFα were not significant, elevated proinflammatory cytokines can disrupt neurotransmitter systems (e.g. serotonin, dopamine). Brain regions involved in emotional regulation, including the anterior cingulate cortex, hippocampus, and amygdala, are also particularly affected by proinflammatory cytokines. Neuroinflammatory changes, therefore, may contribute to the behavioral profiles observed in mice after altered photoperiod exposure. Finally, IL-1Ra levels tend to increase after IL-1 levels to terminate an inflammatory response. Assessing neuroinflammation at the beginning of altered photoperiod exposure will determine whether the current data represent the termination of a greater initial photoperiod-induced neuroinflammatory response.

Title: Chronic social defeat in male mice elicits long-lasting changes to intestinal barrier integrity and pro-inflammatory cytokine activation

Authors: A. D. SANTOS[1,2], N. D. OSBORNE[2,3], M. SEDRAK[1], H. ANISMAN[1,2], *M.-C. AUDET[4,1,2,3]
[1]Neurosci., Carleton Univ., Ottawa, ON, Canada; [2]Inst. of Mental Hlth. Res., The Royal Ottawa Mental Hlth. Ctr., Ottawa, ON, Canada; [3]Cell. and Mol. Med., [4]Sch. of Nutr. Sci., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Pro-inflammatory activation resulting from socially stressful experiences or immune insults has been associated with the pathogenesis of depressive illnesses. In mouse models, social stressors known to elicit depressive- and anxiety-like behaviours also increase circulating and

brain expression of pro-inflammatory cytokines, which has been suggested to stem from perturbations of gut microbiota composition and intestinal membrane integrity. The aim of the current study was to examine, in male mice, the long-lasting effects of a chronic social stressor on intestinal barrier integrity and pro-inflammatory cytokine expression along the gut-brain axis. Male C57BL/6 mice experienced a social defeat stressor (10-minute exposure to an aggressive resident mouse, followed by sensory contact for 24 hours) or a control condition (sensory contact with a non-aggressive resident for 24 hours) for 10 consecutive days. Five weeks later, blood, intestinal tissue from the jejunum, and brain tissue from the hippocampus were collected to determine plasma corticosterone levels and mRNA expression of the pro-inflammatory cytokines interleukin (IL)-6, IL-1β, and tumor necrosis factor (TNF)-α, the tight junction proteins occludin-1, zonula occluden-1, claudin-2, and the neurotrophin brain-derived neurotrophic factor (BDNF). Compared to non-stressed mice, chronically defeated mice had increased mRNA expression of IL-6, IL-1β, and TNF-α in the jejunum, but comparable expression of these cytokines in the hippocampus. Jejunal occludin-1 expression was reduced in mice that had been chronically defeated whereas the other tight junction proteins were unaffected. Finally, BDNF expression in socially stressed mice was decreased in the hippocampus. These findings demonstrate that chronic social defeat elicits long-lasting inflammatory activation and changes to barrier integrity in the jejunum. Perturbations of the intestinal membrane may increase the likelihood of microbial translocation into the intestinal mucosa and circulation, which may then drive pro-inflammatory activation along the gut-brain axis.

Title: Regional examination of glucocorticoid receptors and endogenous opioid signaling genes in self injurious behavior

Authors: *M. JACKSON[1], B. FORET[3], J. FONTENOT[4], E. ROMERO[4], J. SMITH[4], D. HASSELSCHWERT[4], F. VILLINGER[4], K. M. SMITH[2]
[1]Biol., [2]Univ. of Louisiana At Lafayette, Lafayette, LA; [3]Univ. of Louisiana Lafayette, Lafayette, LA; [4]New Iberia Res. Ctr., New Iberia, LA

Abstract: Abstract
The DSM-V defines Non-suicidal self-injury (NSSI) as the deliberate infliction of physical harm to one's own body without suicidal intent. While NSSI is by definition, not an attempt at suicide,

it is strongly associated with future suicide ideation. Self-injurious behavior (SIB) occurs in approximately 1-4% of the adult human population, with higher rates of incidence in the adolescent and institutionalized populations. With such a prevalent impact on our society, it is important to understand the underlying mechanisms that may lead a person to self-harm. Disruptions in endogenous opioid signaling and stress regulation have been proposed as potential contributing factors in NSSI and SIB. SIB also occurs in a low percentage of captive monkeys; it is an endogenously occurring model of SIB in humans in the context of captive animals. Rhesus Macaque monkeys are evolutionarily and physiologically similar to humans, share 93% of their DNA with humans. To study SIB, we used 8 sex-matched pairs of rhesus macaques, eight who exhibited self-injurious behavior (SIB) and eight controls, to examine alterations in gene expression. We examined genes in the endogenous opioid pathway as well as the glucocorticoid and mineralocorticoid receptors. The brain regions chosen are those closely linked to reward reinforcement and stress adaptation. Thus far, our findings suggest no uniform changes in gene expression of the mu-opioid receptor, mineralocorticoid receptor, glucocorticoid receptor, β-endorphin precursor molecule proopiomelanocortin (POMC), or the dynorphin A and B precursor prodynorphin in the regions tested. We did observe that females with SIB had reduced amounts of mu-opioid receptor in the amygdala ($p<0.001$), and a trend towards decreased prodynorphin in the Orbitofrontal cortex ($p=0.083$). Males with SIB had a significant increase in glucocorticoid receptor expression in the amygdala ($p<0.05$), whereas females with SIB had a significant decrease in mineralocorticoid receptors in the amygdala ($p<0.01$) and a significant decrease in glucocorticoid receptors in the hippocampus ($p<0.01$). It is our aim to expand these studies with six additional macaque brains from males with SIB that have been collected for mRNA extraction. Our data provides further evidence that regulation of stress responses, particularly in the amygdala, is playing a role in the behavioral expression of SIB. Previous studies have also identified reactive changes in astrocytes of animals exhibiting SIB. We have therefore collected brains from 13 additional rhesus macaques, 10 who exhibited SIB, to examine morphological changes in astrocytes via immunohistochemistry.

Title: Relationship between microbiome convergence and stress susceptibility

Authors: *J. GIANUZZI[1], M. LAMPETER[1], L. YUAN[2]
[2]Dept. of Physiol. and Pharmacol., [1]Des Moines Univ., Des Moines, IA

Abstract: JG and ML contributed equally.
Stress and stress-related disorders have been linked to both genetic and environmental factors. The gut microbiome has been suggested to exert influence on physiology and stress-related behaviors in humans, termed the gut-brain axis. This investigation aims to quantify the relationship between stress susceptibility/resilience and microbiome changes. Both cognitive and microbiome changes are experienced by individuals subject to new stressors. The association between microbiome states and stress resilience is of great current interest. We evaluate the relationship between cognitive resilience and microbiome convergence over time in newly matriculated medical students (n=31) who are subjected to novel stressors during their first semester of medical school. Using both subjective (Patient Health Questionaire-9, PHQ9, and Cohen's Perceived Stress Survey, PSS) and objective (Cortisol Level) assessments, participants were divided into stress susceptible and resilient groups. Their fecal samples were collected at different time points. Bacterial genomic DNA was extracted and amplicons representing the V4 region of 16s rRNA genes were amplified and sequenced. We use QIIME2 and PiCRUST for taxonomic and functional comparisons, respectively. Those include comparison of microbiome percent observed convergence (POC) between stressor resilient vs. susceptible groups. Our goal is to test whether specific microbiome changes are associated with stress resilient or susceptible groups Thorough understanding of intricacies of the gut-brain axis have potential to influence treatment of stress-related disorders and uncover new directions for genomic analyses of gut microbiota in parallel with human genomic analysis.

Title: Glutamatergic neuronal IL-1R1 is necessary for paired fighting stress-induced social withdrawal and working memory deficits

Authors: *D. J. DISABATO[1,2], D. NEMETH[2], X. LIU[2], B. OLIVER[3], J. GODBOUT[1,3], N. QUAN[2,3]

Abstract: Chronic stress is associated with an increase in prevalence of mental health complications such as anxiety and depression. We have previously reported that chronic social stress causes microglial activation, monocyte infiltration into the brain, and increased interleukin-1β (IL-1β) signaling in association with prolonged anxiety-like behavior. We hypothesized that IL-1β signaling in the brain was the key player in this stress-mood disorder interaction. In the present study, we used a modified paired fighting (PF) social stress paradigm to induce social stress. To examine the significance of IL-1 signaling in these processes, we used a global IL-1 receptor 1 (IL-1R1) reporter mouse (IL-1R1$^{GR/GR}$) and a global IL-1R1 knockout, the IL-1 receptor restore model (IL-1R1$^{r/r}$). Following exposure to six days of PF, both IL-1R1$^{GR/GR}$ mice and IL-1R1$^{r/r}$ mice had increases in neutrophils and Ly6C^{hi} reactive monocytes in circulation, but only IL-1R1$^{GR/GR}$ mice had an increased percentage of peripherally-derived leukocytes in the brain after PF. IL-1R1$^{GR/GR}$ mice alone displayed general withdrawal in a social interactivity test with juvenile C57BL/6 mice, and a percent decrease in spontaneous alternations in the Y-maze, a measure of functional working memory. IL-1R1$^{r/r}$ mice did not display these changes. Because of the importance for glutamatergic signaling in working memory tasks, we repeated the PF protocol with vGlu2Cre-IL-1R1$^{f/f}$ mice in which IL-1R1 has been deleted only on glutamatergic neurons. Following PF, vGlu2Cre-IL-1R1$^{f/f}$ mice show increased leukocytes in circulation, monocyte infiltration, and microglial morphological alterations similar to Cre^{-} WT controls. However, vGlu2Cre-IL-1R1$^{f/f}$ mice do not display behavioral changes after PF. Taken together, these results show that PF-induced social withdrawal and working memory deficits are dependent upon glutamatergic neuronal IL-1R1 signaling.

Abstract: IL-1R1 signaling is important for the pathogenesis for almost all CNS diseases. Here, we demonstrate the cell-type specific IL-1R1 expression patterns in the brain using a knockin reporter. The functions of IL-1R1 are then investigated by selective reciprocal deletion or expression of IL-1R1 on specific cell types. Endothelial IL-1R1 is found to mediate sickness behavior, leukocyte recruitment, impaired neurogenesis, and inflammatory microglial activation, whereas ventricular IL-1R1 is found critical for monocyte recruitment and non-inflammatory microglial activation. In contrast, the astrocytic IL-1R1 signaling dampens inflammatory cytokines, while neuronal IL-1R1 can promote microglial activation. In addition, IL-1 stimulates its own production in microglia indirectly through endothelial IL-1R1. Collectively, these findings describe the structural and functional cytoarchitecture of the brain IL-1R1 expressing system and lay a foundation for the dissection and identification of IL-1R1 signaling pathways in the pathogenesis of numerous CNS diseases.

Abstract: Social stress is an important trigger for neuropsychiatric disease. The pro-inflammatory cytokine interleukin 6 (IL-6) has been positively correlated with the onset of numerous stress-triggered neuropsychiatric conditions including schizophrenic psychoses and depression. This study sought to assess the IL-6 dependence of behavioral changes elicited by

social stress. To investigate this issue, we compared the behavior of wild type animals (WT) with that of genetically modified mice in which IL-6 central trans-signaling was blocked by overexpression of a soluble version of the IL-6 transducer glycoprotein 130 by the promoter of the astrocytic marker Glial Fibrillary Acidic Protein (GFAP-sgp130Fc, TG). C57BL/6 mice where submitted to a well-established chronic Social Defeat (SD) protocol, consistent in a 10 min exposure every day during 10 days to a preselected aggressive CD1 mouse. Four experimental groups were used for the experiments: control WT, SD-exposed WT, control TG, and SD-exposed TG mice. Both WT and TG SD-exposed animals were further divided into SD-resilient (R) and SD-sensitive mice (S), according to their response to a peculiar Open Field test measuring the Corner Preference, an index of sensitivity to SD. SD greatly reduced the time in the zone of contact with the CD1 mouse, and increased the time in the corner and corner preference in the Open Field test, equally in WT and TG animals. WT and TG animals displayed similar frequency of R vs. S animals (32% for WT, vs. 41% TG), suggesting that functional IL-6 central trans-signaling is not necessary for SD effectiveness in the induction of the fear response. On the contrary, SD decreased time in the center and time in the closed arms in the Plus Maze test, as well as the sucrose preference and the Porsolt forced swim time-to-immobility, only in WT but not in TG mice. Our results suggest that while central IL-6 trans-signaling may not be not necessary for the induction of the fear response, it may be selectively involved in other emotional behaviors like anxiety, depression, and anhedonia.

Title: Revealing repair roles for inflammatory monocytes in neurovascular dysfunction caused by chronic social defeat

Authors: *M. L. LEHMANN[1], C. CROSSEN[2], S. L. KIGAR[3], M. HERKENHAM[4]
[1]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD; [2]NIMH, NIH, Fairfax, VA; [3]Section on Functional Neuroanatomy, Natl. Inst. of Mental Hlth., Bethesda, MD; [4]Section on Functional Neuroanatomy, NIMH, NIMH, Bethesda, MD

Abstract: Psychosocial stressors, which contribute to the development of affective disorders in humans, induce central and peripheral immune pathway signaling that is increasingly thought to be relevant to the pathophysiology of depression. Previously we showed that 14 days of chronic social defeat (CSD), a model of psychosocial stress, triggered a change in blood-brain barrier (BBB) permeability coupled with the leakage of intravascular substances into brain parenchyma, i.e., microhemorrhages. Peripheral monocyte subtypes that express chemokine receptor CCR2 have been implicated in the pathogenesis of several different disease processes, including vascular permeability and numerous neuropathologies associated with inflammation and microhemorrhage. We wanted to understand how $CCR2^+$ cells contribute to BBB pathologies that occur in response to CSD. We found that CSD induced pronounced declines in behavioral tests of sociability coupled with scattered microhemorrhages in brain, but it had no effect on either the anatomical distribution or density of $CCR2^+$ monocytes adhered to vasculature. However, a substantial elevation in numbers of adhered $CCR2^+$ cells was detected if mice were given seven days to recover from CSD stress in the homecage environment. Next, we asked if microglia influence $CCR2^+$ cell trafficking to brain vasculature during or after CSD. Microglia were ablated by oral administration of the CSF-1R inhibitor PLX5622. Mice treated with PLX5562 and then exposed to CSD showed substantially elevated numbers of $CCR2^+$ cells associated with the vasculature; however, there was no apparent anatomical specificity. In contrast, animals that had undergone CSD stress with intact microglia showed no elevated recruitment. The inability of stress to increase $CCR2^+$ cell recruitment to brain diminishes the likelihood that monocytes play a causal role in the induction of neurovascular pathology during CSD. However, the elevation in $CCR2^+$ cell recruitment during recovery from stress highlights a potential role for monocyte/macrophages in mediating neurovascular repair. Lastly, the global trafficking pattern suggests that events causing $CCR2^+$ cell recruitment are not causally related to regional neuronal or microglia activation. Phenotyping of $CCR2^+$ cells is ongoing. Further investigation will examine peripheral factors responsible for BBB pathology in stressed mice.

Title: Microglia are extrinsically primed by the aged microenvironment

Authors: *S. M. O'NEIL, K. G. WITCHER, D. B. MCKIM, J. P. GODBOUT
The Ohio State Univ., Columbus, OH

Abstract: Microglia, the resident innate immune cells of the CNS, are responsible for propagating inflammatory signals from the periphery to the brain, where they drive the behavioral sickness response. With normal aging, these cells develop a pro-inflammatory, "primed" profile with increased expression of inflammatory mediators. Moreover, secondary immune challenge causes an exaggerated and prolonged neuroinflammatory response mediated by primed microglia in the aged brain. A critical question is if this age-associated profile can be reversed. Recent studies show CSF1R antagonism results in profound elimination of microglia in adult mice. Therefore, we hypothesized CSF1R antagonist-mediated depletion of microglia in the aged brain would result in repopulation of new, unprimed microglia. Here we provide novel evidence that microglia in the brain of adult and aged mice were robustly eliminated following 3-week oral administration of CSF1R antagonist PLX5622. When the CSF1R antagonism was stopped, microglia repopulated the adult and aged brain at the same rate and efficiency with new cells no longer burdened with lipofuscin, the hallmark lipid debris of aging. FAC-sorting and RNA-Seq analysis of microglia revealed these new microglia took on the same primed mRNA profile as the cells they replaced. Moreover, RNA-Seq analysis of the brain provided evidence of reactive astrogliosis in aged mice independent of microglial depletion/repopulation. Lastly, peripheral innate immune challenge still caused an exaggerated microglial inflammatory response in the aged brain with prolonged behavioral deficits. These data indicate the local microenvironment of the aged brain significantly influences the profile of repopulating microglia. Taken together, aged microglia can proliferate and repopulate the CNS, but the resulting "new" microglia still adopt a pro-inflammatory profile characteristic of aging.

Title: Social defeat of female mice recapitulates neuroimmune and behavioral responses detected in males

Authors: *W. YIN, D. B. MCKIM, N. R. GALLAGHER, Y. WANG, J. P. GODBOUT, J. F. SHERIDAN
The Ohio State Univ., Columbus, OH

Abstract: Repeated Social Defeat (RSD) has been used extensively to study the biological and behavioral responses to chronic psychosocial stress in pre-clinical rodent models. In this model, an aggressive intruder is introduced into a cage of resident mice with an established dominance hierarchy, and subsequently attacks and defeats the residents. RSD in mice successfully recapitulates key immunologic findings from humans with anxiety or mood disorders, including increased circulating IL-6 and proinflammatory monocytes. However, studies using RSD generally exclude female mice due to difficulty eliciting aggression among female cohorts. The inclusion of females in murine studies of chronic psychosocial stress is an important consideration because anxiety and mood disorders are highly prevalent among the human female population. Here, we used a modified aggressor, an estrogen receptor α (Esr1)-Cre mouse injected with a conditional Gq-DREADD expressed in the ventrolateral part of the ventromedial hypothalamus (VMHvl), to socially defeat female mice. Upon injection of a designer drug, the ER+ neurons in the VMHvl are activated, producing indiscriminate aggression. Male Esr1-Cre (DREADD) aggressors attacked female C57BL/6 mice and elicited subordinate behaviors. Following six consecutive days of defeat by DREADD aggressors, female mice exhibited anxiety-like behavior and social avoidance. Social defeat in females activated neurons and microglia in regions of the brain associated with threat appraisal, including the amygdala, prelimbic cortex, and hippocampus. Social defeat also caused a peripheral immune response characterized by enhanced myelopoiesis, monocyte release and trafficking to the spleen and brain, and elevated plasma IL-6. Social defeat also increased IL-1β expression in the brain. These findings resemble previous studies conducted in male mice, suggesting that the peripheral immune response to defeat stress is similar across both sexes. Modified DREADD aggressors may be an important means to include female mice in future studies using repeated social defeat stress.

Title: Novel photoreceptors entrain the circadian clock and modulate uv light-evoked behaviors in *Drosophila*

Authors: *L. BAIK[1], J. NI[2], Y. RECINOS[1], J. A. CHEVEZ[1], C. MONTELL[3], T. C. HOLMES[1]
[1]Universtiy of California Irvine, Irvine, CA; [2]Cell Biol., Harvard Med. Sch., Boston, MA; [3]MCDB Dept., UC Santa Barbara, Santa Barbara, CA

Abstract: Animals' ability to anticipate and adapt to daily changes in the environment through their internal circadian clock is crucial for survival. The circadian clock is entrained by daily oscillation of day/night cycles of light. In *Drosophila*, three distinct phototransduction pathways entrain the circadian clock: 1) CRYPTOCHROME (CRY) and 2) internal opsin-based RHODOPSIN7 (RH7) and 3) external opsin-based photoreceptors. We show that while mutation of either CRY or RH7 induces minor defects, loss of both CRY and RH7 leads to severe impairment in photoentrainment. We show that CRY and RH7 are expressed in a subset of the brain circadian neurons including the pigment dispersing factor (PDF)-positive lateral ventral neurons (LNv). CRY and RH7 mediate electrophysiological response to different spectral peaks of short wavelength light in large-LNvs (l-LNv). Reciprocally, the circadian clock regulates UV light-evoked attraction/avoidance behavior. Rhythmic UV light avoidance is crucial for avoiding potentially harmful environment conditions and may prevent desiccation. Here we show that the circadian clock and circuit modulates the valence and time-of-day dependent rhythm of UV light avoidance/attraction behavior. Flies lacking CRY or RH7-based phototransduction have attenuated UV light avoidance. Circadian mutant flies lacking core clock genes lack time-of-day dependent changes in UV light avoidance behavior. Non-genetic environmental disruption of the circadian clock by constant UV light exposure leads to complete loss of rhythmic UV light avoidance behavior. Flies with ablated or electrically silenced LNvs have attenuated avoidance response to UV light. We conclude that core circadian proteins, photoreceptors, and the pacemaker lateral ventral neurons regulate both the timing and the valence of UV light avoidance/attraction. Circadian modulated sensory responses contribute adaptively to behaviors in *Drosophila* to limit risk of environmental exposure during the hottest part of the day.

Title: Temperature entrainment of two different circadian rhythms in the flesh fly

Authors: *R. RAGSDALE, K. JOPLIN, D. MOORE
Biol. Sci., East Tennessee State Univ., Johnson City, TN

Abstract: It is well known that 24-hour day-night (light-dark) cycles can entrain the circadian rhythms of most species possessing circadian clocks. However, much less understood are other environmental cycles that may synchronize (entrain) the internal clock with the outside world. Potential non-photic time cues (zeitgebers) include daily cycles of temperature, food availability, and social signals. The goal of this project is to evaluate the efficacy of temperature cycles administered during the pupal and adult stages, ranging from 1°C to 10°C in amplitude, as potential zeitgebers for two different circadian rhythms, eclosion and locomotor activity, in the flesh fly (*Sarcophaga crassipalpis*). Both rhythms were monitored in male and female flies, using infrared motion detectors, under precisely controlled 24-h temperature cycles (12 h thermophase, 12 h cryophase) in constant darkness. In both sexes, our results show clear entrainment of eclosion (a once-in-a-lifetime event) and locomotor activity (reflecting daily sleep-wake rhythms) in response to temperature cycles at amplitudes of 2.5 (n= 28), 5 (n= 54), and 10^{o} C (n= 102). Both rhythms adopted a fixed phase position of acrophase (peak of the rhythm) within 1-2 h after the onset of thermophase. However, at 1^{o} C amplitudes (n= 26), the phase position occurred several hours earlier, during mid-cryophase, suggesting a continued influence of a light-dark cycle experienced two weeks prior to eclosion during the larval phase. Thus, the 1^{o} C amplitude cycles may be near the threshold for detection by the entrainment pathways communicating with the circadian clock. Interestingly, the entrainment profiles are remarkably different for light and temperature cycles, suggesting that these two zeitgebers activate different behavioral programs. Finally, the endogenous free-running periods under different constant temperatures yield a Q_{10} of 0.989, indicating an exceptionally precise level of temperature compensation. Our results provide conclusive evidence that temperature is a strong circadian zeitgeber in flesh flies, thereby expanding the known repertoire of environmental cues these organisms use to sync their internal clock with the world around them. These findings also set the stage for future experiments designed to explore the interactions between light and temperature entrainment mechanisms - these zeitgeber interactions almost certainly occur in nature but have received little or no attention.

Title: Social jet lag evokes *Drosophila* circadian neural network desynchrony

Authors: *C. E. NAVE[1], L. ROBERTS[2], J. D. ESTRELLA[2], N. PERVOLARAKIS[3], P. J. SHAW[4], T. L. LEISE[5], T. C. HOLMES[2]

Abstract: Weekly weekday-to-weekend shifts in sleep-wake cycles produce social jet lag (SJL), driven by artificial photic cues which shift our biological clocks in a manner similar to travel across time zones. We compared whole circadian circuit responses to un-shifted day/night and SJL-shifted cycling at single cell-resolution in cultured adult *Drosophila* brains for 11-days using real-time bioluminescence recordings of *per* gene cycling. Un-shifted circadian circuits show highly synchronous oscillation. In contrast, 3hr SJL weekend shifts significantly dampens oscillator synchrony and rhythmicity in most circadian circuit neurons for multiple days during and after shifts, while a small circadian subset robustly increase synchrony in response to 3hr SJL shifts. SJL shifts cause transient defects in memory and learning and sleep stability between 5-6 days of the week. Similarities in animal circadian biology suggest that SJL-induced defects are likely applicable to humans.

Title: Social and environmental influences in circadian rhythmicity of electric behavior

Authors: *A. MIGLIARO[1,3], D. SIMON[2], A. SILVA[2,4]
[2]Lab. de Neurociencias, [1]Facultad de Ciencias, Univ. de La Republica, Montevideo, Uruguay;

[3]Unidad Bases Neurales de la Conducta, [4]Inst. de Investigaciones Biológicas Clemente Estable, Montevideo, Uruguay

Abstract: Animal behavior is synchronized with environmental clues resulting in the synchronization of conspecifics activity. As biological rhythms are part of the integrative control of the brain, it is fundamental to explore its interaction with environmental and social influences. Nocturnal arousal in pulse type gymnotiform fish is associated to an increase in the basal rate of the electric organ discharge (EOD-BR). This characteristic electric behavior is modulated by social context through the neuropeptide arginine-vasotocin (AVT). Environmental influences on rhythmic behavior are tightly related to the melatonin system throughout vertebrates. In *Gymnotus omarorum*, isolated animals in laboratory settings, with a 12:12 light-darkness photoperiod, show a melatonin dependent-AVT independent early nocturnal increase in EOD-BR. In nature, nocturnal EOD-BR doubles its daily values decaying towards sunrise, despite the constant darkness registered under water. Wild animals are synchronized in their circadian rhythm, a trait that is lost when field individuals are recorded in isolation. With the aim of understanding the joint action of environmental and social influences on the nocturnal increase in electric behavior, isolated animals were independently treated with intraperitoneal melatonin (n=6, 1µg/g) and AVT (n=6, 1µg/g) during daytime. Both neurohormones increase the discharge rate, albeit differently, with no effects of their respective blockers (Luzindole, Manning Compound). Melatonin exerts a greater longer lasting effect; whereas AVT mediated increase is transient and mild. This AVTergic effect mimics an AVT mediated increment in the discharge rate of the central pacemaker nucleus commanding EOD-BR. Field experiments were performed to assess the role of Melatonin and AVT regulation when animals are under the influence of natural environmental and social stimuli. Animals in social context (n=6) maintain a circadian rhythmicity of EOD-BR even when treated with the melatonin antangonist Luzindole (n=4, ip, 2µg/g) known to successfully interfere with the nocturnal increase in EOD-BR of isolated lab setting recorded fish. Treated animals also show greater synchronization than isolated animals further supporting the importance of social stimuli as a timing signal.

Biol., Univ. of Illinois at Urbana-Champaign, Champaign, IL

Abstract: The endogenous circadian timekeeping system synchronizes rhythmic physiology and behavior with the environment. In mammals, this system is controlled by the suprachiasmatic nucleus (SCN). Exogenous factors, such as light at night and shift work, can modulate circadian rhythms. Circadian disruption (CD) by exposure to these exogenous factors influences outputs of the circadian system, including behavior, and the underlying physiology of the SCN. In this study, we assessed the impacts of two models of CD on locomotor activity, estrous cyclicity, and SCN clock gene expression in male and female Long-Evans rats. After an initial training period, animals performed the Five-Choice Serial Reaction Time Task, a cognitively demanding task, for 21 days. Animals were tested under one of three conditions: 4-hours after lights-off with no exposure to ambient light (Control), 4-hours after lights-off and exposure to ambient light during testing (Light at night [LAN] model), and 4-hours after lights-on during the animal's resting phase (Shift Work model). Animals were individually housed, and locomotor activity was quantified using automated infrared activity monitors. Estrous cyclicity was monitored daily using non-invasive vaginal lavage. Following testing, the SCN was removed for qPCR analysis at four different time points: 4 and 8 hours after lights-on (i.e. Zeitgeber Time [ZT] 4 and ZT8), and 4 and 8 hours after lights-off (i.e. ZT16 and ZT20). After 3 days of testing, Shift Work females exhibited reduced total activity, but as testing progressed they maintained similar total activity patterns as controls. Interestingly, males from both CD groups exhibited reduced total activity for the duration of testing compared to controls. Beginning after 12 days of testing, Shift Work males and females and LAN males had reduced anticipatory locomotor activity in the 3-hours before the task when compared to controls. Additionally, beginning 3 days after testing, Shift Work males and females exhibited decreased nocturnal activity, exhibiting more than 50% of their total locomotor activity during the light phase. In females, estrous cycle length was similar across groups, however both CD groups exhibited increased time spent in the estrus stage and decreased time spent in metestrus and proestrus stages. Circadian clock gene expression of *Bmal1*, *Clock*, *Per1*, *Per2*, *Cry1*, *Cry2*, *Avp*, and *Rorα* was analyzed at all four ZTs. We found effects in clock gene expression in a sex-, time point-, and gene-specific manner in both CD models compared to control. Together, these data suggest that two models of CD can differentially impact outputs and physiology of the circadian timekeeping system.

Title: DNA methylation modulates period aftereffects of light entrainment without affecting transient phase shifts

Authors: *S. KIM, D. G. MCMAHON
Neurosci. Grad. Program, Vanderbilt Univ., Nashville, TN

Abstract: Light signals can induce acute changes in the phase and enduring changes in intrinsic period (i.e. cycle length) of the circadian clock in the mammalian brain, as short- and long-term plasticity respectively. Although phase shifts are known to arise by transient photic induction of the Period genes, the mechanism underlying how light can drive long-lasting changes in the circadian clock remains elusive. A previous study showed that DNA methylation mediates the period aftereffects of entrainment to non-24 hour light cycles (i.e. T-cycles; Azzi et al., 2014, Nature Neuroscience 17, 377-382.) To determine if DNA methylation is a fundamental mechanism for driving light entrainment, we further tested whether DNA methylation is involved in the circadian clock resetting by single light pulses in constant darkness. We found that pharmacological inhibition of DNA methyltranferases with RG108 prior to and during the light pulse did not alter the phase shift of the endogenous locomotor activity rhythm but did attenuate the light-driven period aftereffects of these single pulses. Our findings suggest that DNA methylation is not necessary for acutely phase shifting the circadian clock, but is critical for driving enduring period aftereffects of photoperiodic light entrainment.

Title: An animal model of social jetlag: The role of endogenous oscillators on hippocampal-dependent learning and memory

Authors: J. M. CLEARY, L. M. LEWIS, K. B. VIGUERS, K. A. JONES, A. W. NEWMAN, T. T. S. CASSELL, D. M. SKINNER, *C. M. THORPE

Abstract: Students tend to shift their weekend sleep onset and wakeup times, resulting in differences between weekday and weekend sleep schedules, or “social jetlag.” Social jetlag disrupts the light-entrainable oscillator (LEO). Animal models have previously shown that photoperiod shifting in rodents elicits circadian arrhythmia similar to human shift workers. However, there is a dearth of research examining social jetlag in animal models as is experienced by students. The current study investigated the interaction between the LEO and the food-entrianable oscillator (FEO) by implementing a novel animal model of social jetlag, the “student light manipulation (SLM).” To determine the impact of social jetlag on learning and memory, both retention and acquisition were investigated. First, while receiving one meal (FEO access) or many meals (no FEO access) per day, rats were trained on both hippocampal-dependent (HD) and hippocampal-independent (HI) tasks under a 12:12 light-dark cycle, and then exposed to a period of SLM. There were no retention differences between SLM and control rats, yet rats with FEO access retained the HD tasks better than rats without FEO access. Next, while receiving one meal or many meals per day, rats were exposed to the SLM while being trained on both HD and HI tasks. There were no differences in acquisition between SLM and control rats. However, rats with FEO access acquired the HD task faster than rats without FEO access. Currently, there is little known about the anatomical location of the FEO. Such findings are indicative of the need to further investigate the role of the FEO in learning and memory, and its independence from the SCN.

Title: Recurring circadian disruption alters circadian clock sensitivity to resetting

Authors: *M. E. HARRINGTON[1], T. L. LEISE[3], A. GOLDBERG[3], J. MICHAEL[3], G. MONTOYA[3], S. SOLOW[3], P. MOLYNEUX[2], C. B. SAPER[4], R. VETRIVELAN[5]

Abstract: Modern life can involve repeated disruptions to daily light cycles. We have shown that one phase advance of the light:dark (LD) cycle can temporarily disrupt synchrony of the suprachiasmatic nucleus (SCN) neural circadian rhythm. Persistent disruption to the circadian system through light at night and phase resetting can be modeled by exposure to a 20 h light cycle, a day length that mice are unable to entrain to. We examined brain and peripheral tissues in mice exposed to more than a month of a repeating 20h light cycle (LD10:10). Control animals were housed under LD12:12. We measured locomotor activity and body temperature rhythms *in vivo*, and rhythms of PER2::LUC bioluminescence in tissues cultured *ex vivo*. Housing in LD10:10 induced disruptions to rhythms in response to recurrent exposure to light in subjective night. Bioluminescent measures *ex vivo* showed results that varied across tissues. Rhythm phase was strongly reset by dissection in SCN tissue from mice housed under LD10:10, while smaller phase shifts were observed in SCN from control LD12:12 mice. White adipose tissue (abdominal, mesenteric, inguinal fats) was reset by dissection regardless of light pre-treatment. Diet (high fat vs normal chow) and age (3-7 mos vs 19-22 mos) did not appear to moderate these effects. We conclude that exposure to circadian disruption might desynchronize SCN neurons, increasing network sensitivity to disruption. Dissection can induce large (as in fat tissues) or small (as in SCN) effects on phase even in mice from LD12:12. We interpret these results as suggesting that tissues from highly synchronized SCN networks, as, for example, with increased daily exercise or after short photoperiod exposure, would be less sensitive to these resetting effects, and tissue with weakened coupling, as, for example, with disruption of neuronal VIP signaling, will show larger resetting effects. Exposure to occasional light at night on a recurring weekly basis disrupts circadian rhythms and alters sensitivity of resetting.

Title: Effect of circadian synchronization to a hedonic stimulus on the sleep pattern and memory of the adult rat

Authors: *C. PEÑA-ESCUDERO[1], S. PRIEGO-FERNÁNDEZ[1], A. A. CORONA-MORALES[2], F. GARCÍA-GARCÍA[1]
[1]Inst. de Ciencias de la Salud, Univ. Veracruzana, Xalapa-Enriquez, Mexico; [2]Facultad de Nutrición, Univ. Veracruzana, Xalapa, Mexico

Abstract: Sleep is a circadian behavior/phenomenon entrained by the light-dark cycle, which is the best characterized synchronizer. Other signals, such as periodic food intake, can also entrain molecular, physiological and behavioral circadian rhythms. Adult rats that receive a single palatable meal (PM, such as a chocolate bar) restricted to a specific time each day, develop an increased arousal and locomotor activity prior to scheduled presentation of the PM, called anticipatory behavior (AA). The entrainment by this hedonic stimulus during the animal resting period could lead to disruption of the wake-sleep cycle. The objective of the present study was to determine whether PM entrainment modifies the sleep pattern and consequently it affects the declarative memory in Wistar rats. For this purpose, eight adult male Wistar rats (300-400 g) were implanted with electrodes for sleep conventional recording. Then rats were housed in individual cages under light/dark cycle (12/12; lights on at 16:00 h, defined as zeitgeber time 0 [ZT0]) with free access to food and water. After 7-10 days of recovery, basal recording of the sleep-wake cycle was measured with free access to food and water. Then, rats had access to a PM (chocolate bar, 5 g) at ZT 6 for eight days, with continuous sleep recordings and food and water *ad libitum*. We defined AA when wakefulness time 15 minutes prior to PM time was statistically higher than the same period in *ad libitum* conditions, at least in two consecutive days. After 9 days of PM entrainment, rats were evaluated in the object recognition test to measure declarative memory. For this test, eight additional rats not entrained to PM were included as control group. The results showed that at day 8, there was an increase in wakefulness time and a decrease in NREM time 45 minutes prior to PM, compared to the basal recordings. Animals expressing AA also showed lower REM sleep time one hour before PM. Wakefulness and NREMS times showed fluctuations in the first half of the active period of the rat, although total REM time did in a 24-h cycle did not change. EEG power spectral during NREM sleep and declarative memory did not show significant differences between control and PM groups.In conclusion, our results suggest that PM induces the presence of a timing system that leads the subject to eat during their resting period without altering the homeostatic components of the sleep-wake cycle, so that the cognitive process, such as declarative memory, is not affected.

Title: Photoperiodic encoding in the SCN: Interaction between cycle length and photoperiod in altering circadian properties

Authors: *M. TACKENBERG[1], D. G. MCMAHON[2]
[1]Neurosci., [2]Dept of Biol. Sci., Vanderbilt Univ., Nashville, TN

Abstract: Photoperiod is a factor in mood disorders and other non-communicable diseases, encouraging investigation of neural response to seasonal light exposure. These responses include changes to circadian properties such as phase angle of entrainment and free-running period of locomotor behavior and clock gene rhythms. Many of these changes outlast the photoperiod itself, indicating that photoperiodic information is encoded within the brain. While the mammalian master clock, the suprachiasmatic nucleus (SCN), is likely a primary site of photoperiodic encoding, how that encoding is induced remains poorly understood. We have examined the mechanisms of induction of photoperiodic encoding in the SCN by differentiating the after-effects of sustained exposure to non-equinox photoperiods and non-24-hour day lengths on *ex vivo* SCN PER2::LUC rhythms and locomotor behavior. We use an unsupervised clustering method for image analysis to explore underlying subregional changes to the phase and period of the SCN in these altered light conditions. Additionally, we examined the effects of pharmacological manipulation of $GABA_A$ signaling on free-running period *ex vivo* and have employed VIP-driven channelrhodopsin to explore the sufficiency of activity within these neurons in inducing photoperiodic after-effects. We found that while both T cycle duration and photoperiod length have significant influences on the free-running period and locomotor behavior duration (alpha) in DD, period changes are predominantly influenced by T cycle length and alpha changes are predominantly influenced by photoperiod length. In T24, bicuculline alters the period of the PER2::LUC rhythm in short and long photoperiod SCN slices, and extended activation of VIPergic SCN neurons by optogenetic stimulation induces a long photoperiod phenotype in short photoperiod mice *in vivo*. Our results so far indicate that photoperiod and T cycle have influence over persistent period and alpha changes, with photoperiod-induced changes being sensitive to $GABA_A$ blockade and inducible by VIPergic neuron stimulation.

These experiments aim to improve our understanding of how continued exposure to a particular photoperiod induces changes within the SCN, as well as how those changes may be altered.

Title: The central clock synchronizes the liver under ad lib feeding conditions

Authors: *M. P. BUTLER[1,2], A. KUKINO[2], X. XIE[3], A. M. BERMAN[2], H. E. CALCAGNO[2]
[1]Oregon Inst. of Occup. Hlth. Sci., [2]Oregon Hlth. & Sci. Univ., Portland, OR; [3]Guangzhou Med. Univ., Guangzhou, China

Abstract: Objective and rationale. Time-restricted food synchronizes circadian clocks in peripheral organs, but the synchronizing role of natural eating behavior is not known. Therefore, we tested whether naturalistic patterns of food intake, without long fasting intervals, were sufficient to phase shift and entrain the liver clock. Methods. PER2::LUC mice (B6.129S6-*Per2*^{tm1Jt}/J, Jackson Laboratory; n=11-12 adult males) were housed individually in cages with custom automatic feeders that dropped 20 mg pellets (S0163, Bio-Serv, Flemington, NJ) either when a pellet was removed from the trough (Ad Lib) or on a specified schedule. Circadian rhythm phase was measured longitudinally in the liver and submandibular gland by in vivo imaging 6 times in 24h under isoflurane anesthesia. An average feeding profile across the day was first obtained under Ad Lib feeding; this pattern was then imposed on mice by presenting food every 90 min and varying the meal size. In experiment 1, liver phase was assessed under this imposed schedule in a light-dark cycle, then after shifting the food schedule by 12h, and finally after restricting food availability to the light phase. In experiment 2, mice were acclimated to the imposed schedule and then released into constant darkness with the same feeding schedule. Circadian phase was measured every 2-3 weeks thereafter and assessed as a function of imposed meal schedule and as a function of the free-running circadian locomotor activity rhythm. Results. In experiment 1, peak PER2::LUC bioluminescence in the liver occurred 8h into the dark phase in both Ad Lib and imposed feeding conditions. Reversing the feeding schedule caused a significant but small 2h advance, suggesting that the liver is principally entrained by light under these conditions. In experiment 2, liver phase in constant darkness was best predicted by feeding schedule in half of the mice and best predicted by locomotor activity patterns in the other half. Conclusions. Natural patterns of eating are a weak zeitgeber for the

liver; under natural patterns of food intake, the central circadian clock retains its ability to entrain peripheral organs.

Title: Neural mechanisms linking hypernatremia and hyperthermia to circadian time

Authors: *C. GIZOWSKI[1], C. A. ZAELZER[2], C. W. BOURQUE[3]
[2]Neurol., [1]McGill Univ. Hlth. Ctr., Montreal, QC, Canada; [3]McGill Univ., Montreal, QC, Canada

Abstract: Our brain encloses an inner clock, the suprachiasmatic nucleus (SCN), which optimizes physiological functions according to the body's differing needs at various times of day (e.g. during wake vs sleep). When clock timing goes awry (e.g. due to age, jet lag, or shift work), this can result in significant health issues such as an increase the risk of cancer, mental illness and cardiovascular disease. Clock time is encoded by the action potential firing rate of vasopressin neurons in the SCN and my previous work in mice showed that this activity can activate thirst neurons to promote anticipatory water intake that protects against dehydration during sleep. While clock time is normally adjusted by daylight onset, it can also be regulated by non-photic stimuli through unknown mechanisms. In this project, I examined if hypernatremia and hyperthermia can acutely regulate clock time. The organum vasculosum lamina terminalis (OVLT) is a preoptic nucleus that contains neurons capable of detecting these conditions via the osmo- and heat-sensitive transduction channel dn-Trpv1. I therefore examined if OVLT neurons can modulate SCN clock neurons. Histological and tracing experiments showed that dehydration-activated dn-Trpv1 OVLT neurons project to the SCN. Moreover, single cell RT-PCR experiments showed these cells express GAD65, a marker of GABAergic neurons. Preliminary results suggest GABA excites SCN vasopressin (VP) neurons during wake time, when SCN electrical activity is low. Electrophysiological analysis in slices further revealed that a hypernatremic stimulus delivered to the OVLT significantly increases the frequency of spontaneous GABA synaptic currents and triggers an anticipatory shift in the onset of electrical activity in SCN clock neurons. These data show that the SCN not only drives circadian rhythms, but also receives important physiological signals that can mediate non-photic adjustments in clock time and possibly adapt organisms to dynamic environments.

Title: The effect of photoperiod on the estrous cycle length and stability in the C57 mice

Authors: *M. ORTEGA VILLEGAS[1], M. FUENTES-CANO[2], P. DURAN[3]
[1]Lab. de Biología Animal y Exptl., Fac. of Sciences, Univ. Nacional Autónoma, Ciudad de México, Mexico; [2]Facultad De Ciencias, UNAM, Mexico City, Mexico; [3]LBAE, Biología Celular, Facultad De Ciencias, UNAM, Ciudad de Mexico, Mexico

Abstract: The master clock in mammals, located in suprachiasmatic nucleus, impose phase and period to peripheral oscillators. This hypothalamic structure is part of reproductive axis, were entrain every structure of the axis to generate the physiological responses that require a temporal signal to give continuity to the estrous cycle on female. This process is regulated by many signals, and some of them can be modified by photoperiod. The most important signal for photoperiodic response is driven by melatonin, which code the night length that changes along the year. Previously we observed that, in Mongolian gerbil (a model that presents seasonal reproduction), the photoperiod alters estrous cycle regularity, both under short day, lengthening diestrous, and under long day, lengthening diestrous and estrous phases. The aim of the present study is to analyse if photoperiod alters estrous cycle regularity in a model that does not show seasonal reproduction. Female mice C57 were exposed to 14:10, 8:16 and 16:8 photoperiods. The estrous cycle was monitored by cytology via vaginal smears between ZT4 and ZT5, for 15 days. Under 14:10 photoperiod cycles were regular with an average length of five days, meanwhile under 16:8 photoperiod average length was 5.8 days and under 8:16 average length was 7.5 days, in both short and long days photoperiods estrous phase was lengthened. It has been reported prolonged exposition to light increase estrogens levels and secretion, promoting the vaginal estrous stands by more than a day, but it cannot explain the estrous lengthening under 8:16 photoperiod. Estrous cycle irregularity decreases fertilization chances and is related to an increase of abnormalities in early embryonic development, chromosomal aberrations, failure of implantation and embryonic death, that reflects the desynchronization in the central and peripheral events that are regulating endocrine and reproductive function in females, in this case is generated by photoperiod, and is not limited to models with seasonal reproduction. Next step is to register circadian locomotor activity that has been shown a correlation to estrous cycle under each photoperiod, in order to see a possible effect at hypothalamic level.

Title: Maternal malnutrition impact entrainment in adult offspring for water intake and locomotor activity rhythms

Authors: D. J. BUSTAMANTE-VALDEZ[1], J. S. GONZALEZ-RUANO[1], M. FUENTES-CANO[2], *P. DURAN[1]
[1]LBAE, Biología Celular, Facultad de Ciencias, UNAM, Ciudad de Mexico, Mexico; [2]Facultad de Ciencias, UNAM, Mexico City, Mexico

Abstract: Malnutrition is a widely health problem, it impacts not only developmental countries but higher economies, hypercaloric-hipoproteinic diets as the “cafeteria diet” are been linked to overweight, metabolic syndrome, diabetes and other metabolic disruptions from childhood to adulthood. However, there is limited research about its effect on the intrauterine environment and the critical periods of brain development, Hypoproteinic maternal malnutrition has been reported to diminish brain cells, produce cognitive deficits, and trigger irreversible physiological or metabolic changes; mainly the circadian expression for sleep-wake, water intake and locomotor activity rhythms, have been linked to a neuro-anatomo-functional alteration on the hypothalamic suprachiasmatic nuclei (SCN), the circadian clock on most physiological and behavioral responses. The coordination for circadian biological rhythms energy utilization, and storage is physiologically linked to a healthy food homeostasis in mammals. In this study, the juvenile offspring of dams under a “cafeteria diet” protocol during gestation and lactation was recorded, to analyze the water intake and locomotor activity circadian rhythms entrainment and incidentally the SCN integrity. Sprague-Dawley adult female rats were randomly divided in 2 nutritional protocols: control (CO) given rodent lab diet (5001 purina Chow 4.15kcal) and Cafeteria diet (CD-6.32kcal) maintained under 12/12 light-dark cycle, temperature room 22-24°C and food and water *ad libitum* three weeks before mating, during gestation and lactation. After weaning all offspring was sexed and maintained under rodent lab diet, and water and food ad libitum Postnatal body weight and size were recorded. At 7 weeks of age, the circadian protocol started as follows: 3 weeks under 12:12 Light-Dark (LD) cycle, 3 weeks constant darkness (DD) and 3 weeks re-entrainment to LD. Water intake and locomotor activity were recorded using a infrared sensors system. Food and water intake were monitored trhought the protocol. circadian parameters as amplitude, period, mesor, % of rhythm, transitory days to reintraiment were analized. The results showed, that malnourished female offspring present

lower body weight but same size as controls, Food intake for males diminished during constant darkness. For both locomotor and water intake rhythms the CD group displayed difficulty to re-entrain, more transitory days were required, period was reduced and the activity increased just before the lights on. At the end of the recordings, a 12 h cycle seems to appear, suggesting a splitting, as reported for hypoproteinic malnourished rats in other study.

Title: Use of excitatory and inhibitory DREADDs to evaluate the role of raphe nuclei-to-infralimbic cortex projections in the circadian regulation of the infralimbic cortex

Authors: *H. K. STRNAD, J. RAVENEL, A. E. CONCHA, S. P. SHARMA, M. J. HARTSOCK, R. L. SPENCER
Behavioral Neurosci., Univ. of Colorado At Boulder, Boulder, CO

Abstract: Circadian rhythms drive biological functions in a manner that parallels the roughly 24-hour cycle of light and dark on Earth. The suprachiasmatic nucleus (SCN) synchronizes its clock gene oscillatory expression with the environmental light/dark cycle. This rhythm is then communicated throughout the rest of the brain and periphery to optimize physiological functioning at appropriate times of day. Rhythmic clock gene expression outside of the SCN has been established, and that expression requires an intact SCN. However, not much is known about the specific mechanism by which the SCN communicates to extra-SCN cells. We have found that appropriately timed daily circadian patterns of corticosterone (CORT) hormone secretion are necessary for normal rhythmic clock gene expression in the infralimbic cortex (IL; Woodruff et al. Endo 157:1522-34, 2016). However, those studies suggest that CORT is not the sole entrainment factor. Serotonergic neurons from the raphe nuclei (RN) have been shown to contribute non-photic regulation of circadian rhythms via innervation of the SCN, demonstrating the capacity to directly regulate expression of clock genes. RN neurons have a wide range of projections throughout the brain including the prefrontal cortex. The current project utilized Designer Receptors Exclusively Activated by Designer Drugs (DREADD) to characterize DRN projections to the IL and their role in circadian regulation of the IL. A dual virus intersectional approach was used to express excitatory DREADDs in only RN neurons that project to the IL.

All rats underwent stereotaxic surgery for infusion of (retro)AAV-pmSyn1-EBFP-CRE into the IL. One week later AAV8-hSyn-DIO-hM3Dq was infused into the RN. After allowing one week for recovery from surgical procedures, rats were injected with Clozapine-*N*-Oxide (CNO) to activate the DREADD receptors and were perfused 1.5 hours later. Cells in the dorsal, ventrolateral, and ventromedial regions of the RN show successful DREADD expression as indicated by an mCherry reporter fusion protein. Some expression was also seen in the intermediate and median nuclei. FOS immunoreactivity was used to assess the ability of CNO to activate neurons expressing the DREADD as well as increases in cell activity at the IL projection site. Ongoing studies will use the same intersectional approach utilizing an inhibitory virus (AAV-hSyn-DIO-hM3Di) and then examine the extent to which activation or inhibition of this pathway at different times of day modulates diurnal variation in IL neural activity.

Title: Mixed mood state behaviors and circadian dysfunction following homocysteic acid treatment: Potential animal model for bipolar disorder

Authors: L. EVERT[1], G. MOYA[1], G. FOGO[2], N. ROZEMA[1], R. FELTON[1], S. PLOWMAN[1], T. STAUB[1], L. A. CHASE[1], *A. J. GALL[3]

Abstract: Bipolar disorder is a neuropsychiatric disease characterized by cyclical fluctuations of mood states between states between mania and depression. Circadian rhythm abnormalities and inconsistent sleep patterns are two common symptoms of bipolar disorder (Millar, Epsie, & Scott, 2004). Elevated levels of homocysteine, or hyperhomocysteinemia, in the blood or cerebrospinal fluid commonly occurs in patients with neuropsychiatric illnesses, including bipolar disorder (Bell et al., 1992; Boushey, Beresford, Omenn, & Motulsky, 1995). Homocysteic acid (HCA), an endogenous metabolite of homocysteine, has been implicated as a harmful neurotoxin and agonist of NMDA receptors. We have previously shown that postnatal administration of HCA (from postnatal day 3 to 21) in Sprague Dawley rats results in both

mania-like and depressive-like behaviors, suggesting that this may serve as a novel animal for bipolar disorder. The purpose of the present study was to characterize any circadian abnormalities that may be present in HCA-treated rats, as sleep and circadian dysfunction are common symptoms of bipolar disorder. In addition, we also characterized the developmental onset of the mania-like and depressive-like behaviors in this model. Prior to puberty, we found that HCA-treated rats exhibited no manic-like behaviors and only a trend toward depressive-like behaviors. After puberty, however, HCA-treated rats presented a mixed mood-state of both manic-like and depressive-like behaviors, along with significant dysfunction in the circadian clock. Specifically, both the free-running period and the amplitude of the rhythm were significantly reduced following HCA treatment. We are currently using microarray analyses to determine differences in circadian gene expression levels between HCA treated animals and controls. Additionally, we are examining the therapeutic role of lithium for reversing the circadian disruptions exhibited by the HCA treated animals. Altogether, the findings of the present study provide strong evidence in support of the HCA model's face validity for bipolar disorder, allowing us to better understand the mechanisms underlying the development of this disease.

Abstract: One of the most frequent neurocognitive entities in pediatric population is Autistic Spectrum Disorder (ASD). Because this entity becomes apparent since the early childhood, it is necessary to diagnose and establish therapeutic measures as soon as it is detected. Epidemiological studies have shown a high prevalence of ASD but there is a lack of adequate tools for the diagnosis. ASD is a complex entity that includes alterations in sleep, circadian rhythms and cognition, and there is a great need for biological models that fulfill most of the human alterations, in order to understand the biological basis of this disorder. Some murine models have been developed, among them the c58/j strain that shows repetitive behaviors, no other studies have been validated this model for ASD. The goal of this work was study the locomotor circadian rhythm of c58/j strain in order to validate it as an ASD murine model. We recorded locomotor activity in individual cages under 12:12 LD cycles during three weeks of continuous recordings then they were submitted to continuous darkness (DD) for 3 more weeks. We analyzed locomotor activity by means of cosinor with which we found differences between the control and the c58/j strains. In 12:12. In the 12:12 L/O scheme we found that in the c58/j strain the amplitude is greater than in the control strain, while the acrophase is smaller, no notable changes were observed regarding the mesor. During the continous dark, the strain c/58j showed higher values in the mesor and amplitude, while the acrophase still maintains lower values in comparison to the control strain. Our data suggest that there is a difference in the expression of the rhythm of locomotor activity, which may be comparable to the human condition.

Title: Evaluation of the circadian system in a VPA-induced model of autism spectrum disorder

Authors: *S. FERRARO, N. DE ZAVALIA, S. AMIR
Ctr. for Studies in Behavioural Neurosci., Concordia Univ., Montreal, QC, Canada

Abstract: Autism Spectrum Disorder (ASD) is a pervasive developmental disorder characterized by restrictive patterns of behaviour and deficits in social interaction and communication. Often

accompanied by co-morbid disorders, a staggering number of juvenile ASD patients exhibit sleep-wake cycle disturbances. Research has shown that these irregular sleep-wake cycles exacerbate ASD symptomology and further impair social performance. Although irregular sleep-wake cycles have been identified in ASD individuals, little has been done to assess the contribution of the circadian system to these findings. The objective of this study is to phenotypically characterize the circadian system in an animal model of autism. Valproic acid (VPA), a commonly prescribed anti-epileptic drug, administered on day 12.5 of gestation results in offspring which exhibit ASD-like behaviours. Male offspring are introduced to running-wheel apparatuses post-weaning and undergo various circadian challenges, including baseline 12:12 light-dark (LD) cycles, constant dark, constant light and phase advance/delay protocols. Baseline activity analysis revealed a significant increase in the total amount of activity bouts during the light phase in VPA-treated animals compared to controls (control: 1.1 ± 0.1795, VPA: 1.917 ± 0.2865 $p < 0.05$). Moreover, VPA-treated animals show greater distribution of wheel-running behaviour between light and dark phases, while controls show greater confinement of this activity to the dark phase (control: 0.07550 ± 0.01609, VPA: 0.1724 ± 0.01506. $p < 0.0001$). Further investigation revealed a later running-activity offset in VPA-animals ($p < 0.0005$). Constant light analysis revealed a greater amount of running activity in VPA animals ($p < 0.05$) , and an increase in the number of days to reach arrhythmicity (control: 12.89 ± 0.5638, VPA: 23.93 ± 2.069. $p < 0.0005$). Together, these results suggest differential light perception in VPA-treated animals, and suggest alterations in the entrainment capacity of the SCN. Moreover, these results lend to the validity of the VPA-induced model of ASD, as these findings recapitulate what is seen in human populations.

Title: Environmental light influences small intestine microbiota and metabolism through immune system

Authors: *I.-C. LEE, S.-K. CHEN
Life Sci., NTU, Taipei, Taiwan

Abstract: Recently, external light effect on mammalian circadian clock through ipRGCs in retina, which is also influence peripheral circadian oscillation and regulate several physiological hormone homeostasis. In previous studies, while absence of light-dark cycle might cause to the obesity, insulin resistance and gut microbiota oscillation abnormally change in mouse model.

However, how does environmental light influence the gut microbiota and its mechanism still unknown. In this study, we determined the transcriptome expression in mouse intestine tissue under dim light at night (LAN) and investigated what kind of genes would be involved in this pathway and how's its function within external light. In our preliminary results, we found that LAN group mice expressed lower nuclear receptor subfamily 1(Nr1d1) which involved in toll-like receptor 4(TLR4) signal pathway and impact the immune regulation compare to the mice with regular normal light-dark cycle.

Title: Light at night exacerbates metabolic dysfunction in a polygenic mouse model of type 2 diabetes mellitus

Authors: *K. L. RUSSART[1], S. CHBEIR[1], R. J. NELSON[3], U. MAGALANG[2]
[1]Neurosci., [2]Ohio State Univ., Columbus, OH; [3]West Virginia Univ., Morgantown, WV

Abstract: Electric lighting is beneficial for modern society; however, in recent years it is becoming apparent that light at night is not without biological consequences. Several studies have reported deleterious effects on health and behavior in humans and nonhuman animals. Exposure of nondiabetic mice to dim light at night (dLAN) impairs glucose tolerance, whereas a return to dark nights (LD) reverses this impairment. Reduced glucose tolerance is a characteristic of type 2 diabetes mellitus (T2DM); thus, we predicted that exposure to dLAN will exacerbate the metabolic abnormalities in a mouse model of T2DM. We exposed male TALLYHO/JngJ (TH) mice, a polygenic mouse model of T2DM, to LD or dLAN (40 lux) in 2 separate experiments. After 8 weeks, intraperitoneal glucose tolerance testing (ipGTT) was performed, and following recovery, we conducted intraperitoneal insulin tolerance testing (ipITT). In Experiment 1, all mice were then returned to dark nights for 4 weeks, and the ipITT was repeated. In Experiment 2, tissues were collected for analysis after recovery from the ipITT. TH mice housed in dLAN had increased body weight, impaired glucose tolerance, and higher insulin resistance than mice housed in LD. Insulin resistance was improved when mice were returned to LD for 4 weeks. Additionally, more mice developed T2DM and survival rate decreased when

housed in dLAN. dLAN worsens the metabolic abnormalities in a polygenic rodent model of T2DM and these effects were reversed upon return to dark nights. The decreased survival in the TH mice exposed to dLAN is an unexpected result that requires further investigation. Limiting light at night may be a simple intervention that could benefit humans with T2DM, but would require additional studies.

Title: Disruption of endogenous circadian rhythms by exposure to light at night accelerates pancreatic tumor growth in mice

Authors: *S. CHBEIR[1], K. L. G. RUSSAT[1], W. H. WALKER, II[1], D. M. PROCA[2], A. C. DEVRIES[3], R. J. NELSON[4]
[1]Neurosci., [2]Pathology, The Ohio State Univ., Columbus, OH; [3]Med., [4]Behavioral Med. and Psychiatry, West Virginia Univ., Morgantown, WV

Abstract: Intact circadian rhythms are critical for optimal physiological and behavioral functions. The widespread adoption of electric lighting world-wide has led to significant exposure to artificial light at night (LAN), which results in disruption of circadian rhythms. Exposure to LAN is strongly correlated with increased prevalence of obesity, metabolic disorders, and certain types of cancer. Pancreatic ductal adenocarcinoma (PDAC) is among the most aggressive cancers with poor prognosis and short post diagnosis survival rates in which K-Ras mutations account for ~90-95% of cases. The objective of this study was to explore whether dysregulation of circadian rhythms by LAN accelerates PDAC development in high-risk patients using a PDAC mouse model bearing K-Ras-G12D and P53−R270H mutation alleles (KPC). We hypothesized that exposure to LAN accelerates tumorigenesis by dampening the expression of the circadian gene Period-2 (*Per2*) in the pancreas, thereby disinhibiting cellular proliferation and exacerbating inflammatory responses to tumor formation. Six week old male KPC mice and littermate controls were randomly assigned to either dark nights (LD group: 14 h light-150 lux/10 h dark-0 lux) or a LAN group (14 h light-150 lux/10 dim white light-40 lux) for 8 weeks (n=10-11 per group). KPC mice had significantly increased body weight, pancreas mass, and elevated rates of neoplastic transformation resulting in increased incidence of solid tumors. More than 80% of the LAN group had both pancreatic intraepithelial neoplasia (PanIN) grade 3

lesions, and invasive ductal adenocarcinoma, whereas only 30% of the LD group had detectable tumor growth. These results were accompanied by reduced expression of *Per2* in the hippocampus and pancreas of KPC and WT mice in LAN, as well as increased expression of the cell cycle gene *Cyclin D* in the pancreas of KPC mice. Furthermore, LAN exacerbated the inflammatory responses to tumor growth in KPC LAN mice by increasing serum IL6 and pancreatic gene expression of *IL-6*, *TNFα*, and *NFkB*. In conclusion, LAN induces disruption of circadian clock function resulting in a sequence of events that promote cell proliferation and elevated inflammation, leading to a feed-forward process that enhances tumorigenesis, tumor growth, and early onset PDAC.

Title: The loss of melatonin circadian rhythm promotes tumor growth and angiogenesis

Authors: *S. CÁRDENAS ROMERO[1], L. HERNÁNDEZ-TORRES[1], N. BOTELLO-ARAUJO[1], O. RAMÍREZ-PLASCENCIA[1], C. B. ESCOBAR[2], R. SALGADO-DELGADO[1], N. SADERI[1]
[1]Facultad de Ciencias, Univ. Autónoma de San Luis Potosí, San Luis Potosi, Mexico; [2]Fac de Medicina UNAM, Mexico DF, Mexico

Abstract: The development of new blood vessels is essential to sustain the metabolic demand of tumor cells and it is associated to the increases expression of several pro-angiogenic genes, including *VEFG*, *EGF*, *PDGF*, *TNF-α*, *ANG-1*. Previous studies performed in our laboratory showed that, in rats inoculated with glioblastoma C6 cells (tumor bearing, TB), the Circadian Desynchronization (CD) induced by constant light (LL) promotes tumor growth and increases tumor vascularization, in comparison to non-desynchronized (LD) rats, suggesting that CD enhances the pathological process. To investigate the mechanisms that underlie this outcome, we focused on melatonin, which is a hormone released in a circadian fashion, whose rhythm is flattened by exposure to LL and which physiologically participates to the regulation of cell cycle and angiogenesis. We found that tumor growth and angiogenesis did not increase when TB

animals and under LL were administered with a daily dose of exogenous melatonin, which suggests that this hormone might have an inhibitory effect over endothelial proliferation. To investigate the role of CD and melatonin in cancer development, we compared the hepatic mRNA expression of cell cycle-regulating genes (*p53*, *p21*, *Cyclin E*), clock genes (*Per2*, *Bmal1*, *Rorα*, *Rev-erbα*) and pro-angiogenic genes (*VEFG*, *EGF*, *PDGF*, *TNF-α*, *ANG-1*) of following groups of rats: (1) LD; (2) LD-TB; (3) LL; (4) LL-TB; (5) LL-TB + melatonin. Results showed that the rhythms of p53, p21, Cyclin E and Per2 mRNAs were lost in all the groups under LL, and only *Per2* recovered rhythmicity after melatonin administration. VEGF displayed a phase delay of ~12 h in LL-TB, and ~18 h in both LL and LD-TB, with respect to the LD controls. LL and LL-TB showed increased levels of TNFα, while LL-TB also presented higher levels of ANG-1 in comparison with animals under LD. In the cancer tissue extracted by animals that were injected with C6 cell, neither the rhythm nor the levels of p53, Cyclin E and Per2 mRNAs were affected by LL, while melatonin administration decreased their concentration. Interestingly, VEGF y PDGF mRNAs were down-regulated by LL exposure and normal levels restored in melatonin-administered animals. All this evidence indicates that the loss of melatonin rhythm that has been reported in murine models and individuals exposed to CD might enhance tumor growth by promoting the loss of control over the cell cycle and pro-angiogenic genes expression.

Title: Temporal control of metabolism in proliferative glioblastoma cancer cells with differential time-regulated chemotherapy susceptibility

Authors: *M. E. GUIDO[1], P. M. WAGNER[1], L. G. SOSA-ALDERETE[2]
[1]Quimica Biologica, Univ. Nacional Córdoba- CONICET, Cordoba, Argentina; [2]Mol. Biol., Univ. Nacional de Rio Cuarto (UNRC), CONICET, Rio Cuarto, Argentina

Abstract: Circadian clocks driving transcriptional/translational rhythms in gene expression are even present in immortalized cell lines whereas metabolic rhythms conducted by an ancestral metabolic/redox clock can persist in enucleated cells or in the absence of transcription. Disruption of circadian rhythms by modern life (continuous illumination, shift work, jet lag, etc.) may cause metabolic disorders and higher cancer risk; however, little is known about clock functioning in tumor cells. Here we evaluated expression of clock and clock-controlled genes, redox metabolisms (reactive oxygen species (ROS), and levels and peroxiredoxin cycles) and cell susceptibility to the chemotherapeutic treatment of bortezomib in cultures of glioblastoma T98G cells. For this, cells were kept under proliferation (with serum), synchronized with dexamethasone (100 nM) (time 0) and collected at different times. In these cells, mRNA expression for clock- (*Bmal1, Per1, Rev-erbα)* and glycerophospholipid synthesizing enzyme-genes did not display circadian rhythmicity or fluctuated with a shortened period (τ=16 h) whereas the redox metabolism exhibited a 12 h- rhythm in ROS levels and longer peroxiredoxin oxidation cycles (τ=30 h). Moreover, cell viability significantly changed over time after bortezomib (500 nM) chemotherapy. Cell viability and redox state rhythms were altered when *Bmal1* expression was knocked down by CRISPR/Cas 9 technology showing different amplitudes, phases or periods than wild type cells. Nevertheless, observations indicate that an intrinsic metabolic clock continues to function in proliferating cells, controlling diverse metabolisms and highlighting differential states of tumor suitability for more efficient, time-dependent chemotherapy. Also, we may infer that cross-talk between the oscillators takes place in tumor cells to ensure tumor growth and survival over time. Furthermore, regardless of the precise nature of the link between them, molecular and metabolic oscillators work in unison to maintain cellular homeostasis.

Title: Quantification of Ox2R mRNA during baseline, oral nicotine, and withdrawal conditions

Authors: S. AHMAD[1], H. L. MATHEWS[2,1], *J. A. STITZEL[3]
[1]Univ. of Colorado, Boulder, CO; [2]Psychology & Neurosci., [3]Inst. Behav Genet., Univ. of Colorado Boulder, Boulder, CO

Abstract: Nicotine and withdrawal from chronic nicotine induce changes in reported and observed sleep quantity and architecture. The mechanisms responsible for the changes are not well characterized. The literature suggests a role of the wake-promoting orexinergic neurons of the lateral (LH) and dorsal medial (DMH) hypothalamus. The orexins (A & B) have widespread projections throughout the brain and act on two receptors (OX1R & OX2R). OX2R appears to be the primary receptor mediating the effects of arousal. The present study utilized a mouse model of forced oral nicotine to characterize the effects of nicotine consumption and withdrawal on the expression of OX2R throughout the brain during three conditions: baseline (BL), nicotine day one (N1), and withdrawal day one (WD1). Adult female C57BL/6J mice were individually house and maintained on a 12 hr light/12 hr dark cycle with ad libitum access to food and a 0.2% saccharin drinking solution. In a preliminary experiment, samples were collected at ZT8 (3PM). Pre-nicotine BL samples were collected one week after placement in individual cages. In a separate cohort of animals 200µg/ml of nicotine was added to the .2% saccharin water to produce nicotine dependence. N1 samples were collected at 32 hours after the introduction of nicotine. In a final cohort of animals, nicotine exposure persisted for 14 days and withdrawal was induced by excluding the nicotine from the drinking solution. WD1 samples were collected 32 hours after the removal of nicotine. Samples were coronally sliced at 14µm and a [α-35S]-labeled riboprobe specific to OxR2 was hybridized to the sections. Sections were exposed to phosphor screens for a period of one week and images were captured using a Cyclone phosphorimager. For individual brain regions 2-4 representative samples from consecutive slides were identified and quantified (cpm) using Optiquant software. Preliminary analysis indicates that relative to BL, the N1 and WD1 conditions show a trend towards increased OX2R in the olfactory tubercle (Tu), ventral pallidum (VP), and medial septal nucleus (MS). Additional samples are being collected at ZT0 and ZT12 for analysis to determine if there is diurnal variation in OX2R expression and whether the effect of nicotine and/or withdrawal on OX2R expression is time of day dependent.

Title: Alcohol-drinking behaviour and preference in striatal Bmal1 knock-out mice

Authors: *N. DE ZAVALIA, P. SOLIS, S. FERRARO, K. SCHÖTTNER, M. BUTTON, J. GOLDSMITH, M. VALYEAR, N. CHAUDHRI, S. AMIR
Concordia Univ., Montreal, QC, Canada

Abstract: The neural and molecular mechanisms that mediate chronic alcohol consumption and alcohol use disorders are not well understood. Alcohol exposure affects brain pathways and neuronal circuits related to reward, stress, habit formation, and decision-making, ultimately leading to alcohol dependence/addiction. Specifically, the dorsal striatum is implicated in addiction, it is involved in ethanol drinking and it is the site of ethanol neuroadaptations. However, the molecular and cellular mechanisms that mediate alcohol-induced striatal neuroplasticity and neuroadaptation remain to be defined. Persistent disruption to the circadian environment, regardless of whether the disruption is genetic or environmental, can affect alcohol intake. Genetic polymorphisms of clock genes involved in the generation of circadian rhythms are associated with a pattern of social drinking and alcohol abuse. The aim of this work was to study ethanol consumption in mice containing a functional mutation in Bmal1 gene in the striatum. We created a conditional Bmal1 knock-out mouse using the Cre-loxP system. *Bmal1*$^{lox/lox}$ mice were crossed to *Gpr88-Cre* mice to specifically knock out Bmal1 in Gpr88 expressing striatal medium spiny projection neurons. 12-18 week old WT, Knock-out (KO) and Heterozygote (HET) male and female mice were tested in: (A) 24 h intermittent ethanol (15% v/v) access protocol; (B) 24 h intermittent ethanol access protocol with ascending concentrations of ethanol (5-45% v/v); (C) 3 days of sucrose (2% m/v) access protocol. Selective depletion of Bmal1 mRNA and protein was observed in the striatum of KO mice compared with WT mice. No significant differences in the expression levels of Bmal1 was observed in the suprachiasmatic nucleus (the master circadian clock) or hippocampus of KO compared with WT mice. Bmal1 KO male mice drink significantly more alcohol and have a higher alcohol preference than WT mice (n=10/group, $P < 0.05$). Bmal1 KO female mice drink less alcohol and have a lower alcohol preference than WT mice (n=10/group, $P < 0.05$). No significant differences in alcohol consumption and alcohol preference between HET and WT male and female mice were observed. No significant differences in sucrose consumption and sucrose preference were observed between any of the genotypes studied. These preliminary results suggest a sex based difference in alcohol-related Bmal1 function in the striatum. A protective role of Bmal1 against alcohol intake was observed only in male and not in female mice. Further studies are being carried out to determine the mechanisms that explain how Bmal1 exerts its protective function and to understand the sex differences observed in this study.

Title: Extended photoperiod alters the circadian rhythm and expression of synaptic plasticity-associated genes. The impact of blue-enriched light

Authors: *A. R. MARTI[1], S. SKREDE[1,2], J. MRDALJ[1], T. T. PEDERSEN[1], L. H. BJERRUM[1], J. WASLANDER[1,3], V. LYSNE[1], K. M. ERSLAND[1,4], T. E. G. HENRIKSEN[1,5], C. R. BRAMHAM[1], J. GRØNLI[1]

Abstract: Light affects regulation of circadian rhythmicity and cognition through the blue-light sensitive intrinsically photosensitive retinal ganglion cells (ipRGCs). Here we use a model of extended photoperiod (20h light, 4h dark; 20:4 LD) with two different spectral qualities (white and blue-enriched light) to examine effects on the circadian rhythm of body temperature (BT), and expression of synaptic plasticity markers in the rat brain. For recording of BT rhythm, male rats (n=6/group) were housed in standard 12:12 LD condition, followed by exposure to 7 days of extended photoperiod (20:4 LD) in either white or blue-enriched light conditions, and 14 days recovery in standard 12:12 LD condition. Tissue from a separate set of animals (n=10/group) was collected on exposure day 7 (E7), and recovery day 3 (R3), from anterior cingulate cortex (ACC) and prefrontal cortex (PFC). Tissue samples were analyzed with qPCR to examine expression of immediate early response genes, including brain-derived neurotropic factor (BDNF), the activity-regulated cytoskeleton-associated (Arc) protein, Krueppel-like factor 10 (KLF10) and Neuronal PAS domain protein 4 (NPAS4). Two-tailed student's t-test was used for statistical comparison to 12:12 LD time-matched controls ($p<.05$). The rhythm of BT maintained a 24h period in both blue-enriched and white light conditions during 20:4 LD, although the acrophase was shifted to co-occur with the dark phase. Upon return to 12:12 LD, decreased amplitude and no clear 24h period was observed for several days. At E7, the extended photoperiod, independently of spectral quality, decreased expression of Arc (ACC and PFC; $t's_{(15\text{-}18)}>-3.74$, $p's<.002$) and KLF10 (ACC; $t's_{(17\text{-}18)}>-2.51$, $p's<.02$). NPAS4 was decreased in the blue-light condition only (PFC; $t_{(15)=}-3.53$, $p=.003$). The expression of BDNF was not

significantly changed at E7, but increased at R3 in the blue-light condition only (PFC; $t_{(14)}$=3.80, p=.002). No significant differences in expression of Arc, KLF10 or NPAS4 were observed at R3 compared to controls.The return from extended photoperiod disturbed the circadian rhythm of body temperature. In addition, extended photoperiod affected several markers of synaptic plasticity in brain regions important for mood and cognitive performance. The effect also appears to depend on the spectral quality of light and brain region.

Title: Gene expression in the SCN is altered during timed restricted feeding

Authors: *T. D. NIEPOKNY[1], A. RASTOGI[2], E. M. MINTZ[3]
[2]Dept. of Biol. Sci., [3]Dept. of Biol. Sciences, Sch. of Biomed. Sci., [1]Kent State Univ., Kent, OH

Abstract: The suprachiasmatic nucleus (SCN) of the hypothalamus regulates circadian rhythms of physiology and behavior in mammals. The circadian clock mechanism in the SCN is normally entrained by the daily light/dark (LD) cycle. This regular activity rhythm can be modulated by regular, nonphotic events. In particular, animals respond to periods of restricted food access during the daytime by showing a period of food anticipatory activity, which is thought to represent signaling from a food entrainable oscillator. The response of the circadian clock in the SCN to restricted feeding appears to be both species and strain-specific. In mice, some inbred strains can entrain locomotor activity to normocaloric restricted feeding cycles in constant darkness, while others, such as the C57BL/6J strain, rarely do so. Previous research suggests that C57BL/6J mice do not experience a shift in clock gene expression in the SCN during normocaloric timed restricted feeding, while other brain regions do show changes in clock gene expression. However, such studies were limited and primarily looked at period gene expression. In this series of studies, we sought to measure expression levels of both period and neuropeptide genes in the SCN of C57BL/6J mice on a 4-hour daytime restricted feeding schedule. In addition, clock and neuropeptide genes will be examined in hypothalamic nuclei involved in feeding or reproduction, including the arcuate, dorsomedial, and ventromedial nuclei. In a preliminary experiment, male and female mice were housed in 12:12 LD cycle for two weeks with ad libitum food access. Half of the mice then had food restricted to four hours in the middle of the light phase (ZT 6 to ZT 10), and the other half continued with ad libitum feeding, both for

a period of 10 days. The mice were euthanized at ZT 7 and the brains removed and stored at -80ºC. The SCN was punched out and RNA was extracted. Real-time quantitative PCR was used to analyze expression levels of per1, per2, avp, vip, grp and prok2. To our surprise, preliminary analysis of the data reveals that during restricted feeding at ZT 7 there is an increase in the expression levels of Per1 and Per2 in restricted feeding compared with ad libitum fed controls. No changes were detected in neuropeptide expression, however, a power analysis showed insufficient sample size. A larger, second experiment is examining expression in multiple brain regions across a full 24-hour time course. Changes in the quantities of Per1 and Per2 in the SCN from restricted feeding are contrary to the current conventional wisdom that the SCN in C57BL/6J mice is unaffected by restricted feeding, and may represent changes in amplitude rather than phase.

Title: Identifying novel genes that regulate the circadian timing of sleep

Authors: *K. PARK[1], S. S. LEE[1], Q. LIU[2], I. D. BLUM[1], M. N. WU[1,2]
[1]Dept. of Neurol., [2]Dept. of Neurosci., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The circadian clock is an evolutionarily conserved biochemical oscillator that rhythmically modulates physiology and behavior. Investigations conducted in model organisms have unraveled the molecular circadian oscillator, but the output mechanisms by which this clock regulates physiology and behaviors are poorly understood. We previously identified *wide awake* (WAKE), a novel gene important for the circadian regulation of sleep in *Drosophila melanogaster*, and found that the mouse homolog is enriched in the mammalian pacemaker, the suprachiasmatic nucleus (SCN) (Liu et. al, 2014). Therefore, we hypothesize that other molecules critical for circadian output might be expressed in the mammalian SCN and have orthologs in *Drosophila*. To quickly identify these genes in mammals, we conceived of a top-down approach generating a list of candidates based on mammalian SCN expression profiling and then screening behavioral rhythmicity using genetic knockdown in fruit flies.
Using RNA-seq data from mouse SCN, we performed read alignment to quantify gene

transcription levels and identified the 3,230 most highly expressed genes in this data set for further screening. We further expanded this list by culling a list of candidates from the literature, using publicly available microarray and RNA-seq datasets collected at different time points. This initial list of ~4,000 gene candidates was further refined by visually examining mRNA expression using *in situ* hybridization data from the Allen Brain Atlas. Each candidate gene was then categorized based on restricted expression patterns, focusing primarily on genes that were enriched in the SCN but expressed relatively sparsely in the rest of the brain. From these 900 SCN-enriched genes, 700 *Drosophila* homologs were identified.
We are currently performing an RNAi screen of the fly homologs, focusing on phenotypes related to the circadian timing of sleep. So far, 54 out of the 510 genes from the primary screening have been identified as potential candidates whose knockdown affects various aspects of the circadian timing of sleep. Details of the results of this screen and implications for the circadian regulation of sleep in mammals will be discussed.

Title: The importance of diurnal corticosterone rhythms in regulating mood

Authors: *D. M. MEHTA[1], A. KULP[1], D. F. BARNARD[2], J. D. JOHNSON[3]
[1]Biomed. Sci., [3]Biol Sci. Dept, [2]Kent State Univ., Kent, OH

Abstract: Corticosterone (CORT) is primarily known for controlling glucose metabolism and is released by the adrenal cortex. An intrinsic circadian rhythm of CORT is established due to the increased need for glucose during an animal's active phase than its rest phase. This results in higher levels of CORT during the active phase and lower levels during the resting phase. CORT has also been shown to entrain the rhythm of certain circadian genes to optimize function during specific times of the day. Circadian genes appear to be expressed by the neurons in the limbic brain areas that control emotional responses. Therefore, our hypothesis states that removal of the circadian rhythm of CORT can flatten the circadian gene expression in these limbic brain areas, resulting in disruption of emotional behavior. To test our hypothesis, the first step was to find a dose of CORT that can be administered in an osmotic mini-pump that mimics low basal diurnal levels of CORT. For this, we had four groups (n=3 each): 1) No pump (control); 2) 0.2ug/hr; 3)

1.0ug/hr; 4) 2.0ug/hr dose of CORT. Treatment groups underwent adrenalectomy and pump implant while the control group underwent sham surgery. Blood samples were collected one week after the surgery and an assay will be performed to measure CORT. The next step will be to examine the emotional behavior following the flattening of the diurnal CORT rhythm. For this, we plan to conduct sucrose-preference and forced swim tests during the active phase.

Title: The Na^+/H^+-exchanger NHE1 regulates extracellular and intracellular pH and $[Ca^{2+}]_i$ in the the rat suprachiasmatic nucleus

Authors: Y.-S. CHEN[1], P.-C. CHENG[1], H.-Y. LIN[1], R.-C. CHENG[1], *R.-C. HUANG[2]

Abstract: The master circadian clock in the suprachiasmatic nucleus (SCN) is densely packed with neurons and has higher metabolic activity than extra-SCN areas in the anterior hypothalamus. In this study we tested the hypothesis that H^+ produced during energy metabolism may be extruded by the Na^+/H^+ exchanger (NHE) to maintain a more alkaline intracellular pH (pHi) and cause a more acidic extracellular pH (pHe) in the SCN in hypothalamic slices. We used ion-selective electrodes to measure the pHe values in hypothalamic slices containing the SCN and ratiometric pH imaging to investigate the pHi in reduced (mini-slice) SCN preparations. In hypothalamic slices bathed in 10 mM HEPES-buffered solution a standing acidification of ~0.3 pH units was recorded with pH-sensitive microelectrodes in the SCN but not extra-SCN areas. The NHE blocker amiloride alkalinized the pHe with an IC_{50} of 30 µM. Results obtained between day and night revealed similar levels of standing extracellular acidification and similar changes in the pHe evoked by 100 µM amiloride. RT-PCR showed the expression of mRNA for plasmalemmal-type NHE1, NHE4, and NHE5 isoforms in the SCN. The NHE1-specific antagonist cariporide alkalinized the pHe with an IC_{50} ~0.1 µM and at 1 µM acidified the pHi, suggesting that constitutive activation of NHE1 extrudes H^+ to maintain a more alkaline pHi and cause a more acidic pHe in the SCN. To determine the possible role of NHE1 in the regulation of $[Ca^{2+}]_i$, ratiometric Ca^{2+} imaging was employed to investigate the

effect of cariporide on glutamate-evoked Ca^{2+} responses in the SCN neurons. The results indicated that cariporide had mixed inhibitory and stimulatory effects on the basal $[Ca^{2+}]_i$ but inhibited glutamate-evoked Ca^{2+} rise. Real-time PCR and western blotting showed no day-night variation in NHE1 mRNA and protein levels. Immunofluorescent staining revealed punctated immunoreactivity for NHE1 around the soma and in neuropil, with moderate levels of colocalization with markers for afferent inputs, serotonin transporter and neuropeptide Y. Together the results indicate that constitutive activation of NHE1 extrudes H^+ to regulate both pHi and pHe and may play a role in the regulation of glutamatergic signaling in the rat SCN.

Title: Characterizing clock gene expression in the substantia nigra pars compacta

Authors: *L. GOODE[1], H. H. HUYNH[2], S. BOAS[2], J. R. PAUL[3], R. M. COWELL[4], K. L. GAMBLE[5]
[1]Grad. Biomed. Sci., [2]Univ. of Alabama Birmingham, Birmingham, AL; [3]Dept. of Psychiatry and Behavioral Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL; [4]Southern Res., Birmingham, AL; [5]Psychiatry, UAB Med. Ctr., Birmingham, AL

Abstract: Though the expression of the core circadian molecular clock genes has been well characterized in the central circadian oscillator, the suprachiasmatic nucleus, less is known about clock gene expression in other brain regions and cell populations. One such brain region is the substantia nigra pars compacta (SNc). In particular, very little is known regarding clock gene expression within the dopaminergic neurons of the SNc. These neurons of the SNc release dopamine onto striatal neurons important for coordinating normal movement. Additionally, they exhibit pace-making properties thought to be responsible for the tonic release of dopamine. The molecular clock regulates the intrinsic firing of action potentials in the pace-making neurons of the suprachiasmatic nucleus, and thus, exploring the molecular clock within dopaminergic neurons of the SNc may provide insight into regulation of their pace-making activity. Real-time imaging of organotypic brain slice cultures containing SNc taken from Per2-Luciferase reporter mice reveals strong PER2::LUC expression rhythms that persist for several circadian cycles. Detection and visualization of individual neurons in these organotypic cultures show that

PER2::LUC oscillates at the single-cell level. Moreover, we used RNAScope single-molecule fluorescent in-situ hybridization, and found that Per2 mRNA expression in tyrosine hydroxylase-containing neurons in the SNc changes over 12hr light:12hr dark cycle, peaking in the early night. Future research aims to elucidate the role of the molecular clock in regulating these neurons' normal physiology and function. Given that dopaminergic SNc neurons are vulnerable to metabolic dysfunction and neurodegeneration, these studies are important for understanding underlying mechanisms of Parkinson's disease, which also show circadian variation in symptomology.

Title: Somatostatin regulates photoperiodic changes in circadian behavior and master clock function

Authors: *D. A. MAY[1], M. ARZBECKER[2], T. INDA[2], E. HERFF[2], J. A. EVANS[2]
[2]Biomed. Sci., [1]Marquette Univ., Milwaukee, WI

Abstract: Seasonal changes in the environment modulate daily rhythms of behavior and physiology, but the neural mechanisms that underlie these adaptations remain unclear. Previous research has found that seasonal lighting conditions influence somatostatin expression in the hypothalamus, which has been postulated to be driven by changes in the master clock of the suprachiasmatic nucleus (SCN). Here we test that long days increase somatostatin (SST) neurons in the SCN and that SST signaling regulates circadian clock function. Using a genetic labeling approach, we find evidence that long days activate *de novo* somatostatin transcription in a reserve pool of SCN neurons. Similar effects are observed in the paraventricular and periventricular nuclei. Further, we find that loss of somatostatin alters circadian behavioral responses to long day photoperiods and other environmental lighting conditions. Last, we find that inhibition of somatostatin signaling disrupts coupling among SCN neurons that have been reorganized into a polarized network state by long days. Collectively, these results suggest that somatostatin signaling contributes to light-driven plasticity of circadian behavior and master clock function.

Title: *In vivo* physiology of the perihabenular nucleus

Authors: *L. LAZZERINI OSPRI[1], H. ZHAO[1], S. HATTAR[2]
[1]Johns Hopkins Univ., Baltimore, MD; [2]Natl. Inst. of Mental Hlth., Natl. Inst. of Hlth., Bethesda, MD

Abstract: Light can affect mood independently of circadian and sleep alterations. A newly-discovered circadian oscillator in the dorsal thalamus, the perihabenular nucleus (PHb), mediates these direct effects of light. As its physiology was entirely unknown, we set out to characterize the PHb's activity in mice in vivo. PHb neurons were transfected with the fluorescent Ca^{2+} sensor GCaMP6. Specificity of transfection to the PHb was ensured by conditional expression of the GCaMP6 vector based on connectivity. An optical fiber was implanted above the PHb to deliver excitation light and collect emitted fluorescence, in a photometry setup where the test mouse could move and behave freely in its cage for multiple-day recordings.
In a standard equinoctial light cycle (T24), we found that the PHb responded to out-of-phase light presentation: Light pulses at night elicited biphasic Ca^{2+} transients, characterized by short (90 ms) onset latency, a 2 s plateau phase followed by more intense activity, and a slow decline back to baseline over a variable interval lasting 5-30 s. The PHb also detected the regularly-scheduled lights-on event (daybreak) at ZT00, which elicited a similar biphasic response, but of smaller amplitude and with faster decay. The PHb also responded to the regular lights-off event at ZT12 with a modest, slow Ca^{2+} transient with onset 1 s after nightfall and peak within 5 s. "Spontaneous" (i.e. photic-stimulus-independent) activity was also evident with sporadic, low-amplitude peaks occurring throughout the day and night. Median GCaMP fluorescence exhibited a daily rhythm, with the peak in the photophase. After an animal was switched to an aberrant light cycle, LD 3.5:3.5 (T7), known to cause depression-like behavior, the PHb showed a generalized activity elevation, with Ca^{2+} transients after the light-to-dark and dark-to-light transitions, and a progressive disruption of its daily rhythm. We conclude that the PHb seems to be especially suited to encode information about dawn and dusk timing, consistent with a role in photoperiod calculation, and that depressogenic light regimens can stimulate its activity.

This is the first physiological characterization of a newly-discovered thalamic nucleus involved in mood regulation by light exposure.

Title: vasopressin modulates circadian behavior by setting phase and period of scn neurons

Authors: *K. E. ROHR, J. EVANS
Marquette Univ., Milwaukee, WI

Abstract: The suprachiasmatic nucleus (SCN) is a neuronal network that programs daily rhythms in behavior and physiology. Intercellular signaling among SCN neurons is required to maintain daily rhythms in behavior and adjust them to the environment. A subset of SCN neurons produces arginine vasopressin (AVP), which typically viewed as an important SCN output. In addition, the SCN expresses receptors for AVP, but whether AVP modulates SCN function remains unclear. Here, we tested the influence of AVP signaling on SCN function and circadian behavior. To test the role of AVP signaling on SCN clock function, we examined the molecular rhythms of SCN neurons using real-time bioluminescence imaging. To manipulate AVP signaling, we used a pharmacological blockade of AVP receptor signaling (V1 antagonism).
Whereas the SCN under typical conditions displays molecular rhythms that are close to 24 h, V1 antagonism increased SCN period by at least 1 h. Additionally, V1 antagonism caused SCN neurons to display similar times of peak protein expression, which increased homogeneity of molecular timing across the network. The magnitude of response to V1 antagonism varied across the anteroposterior SCN and neurochemically distinct subregions of the network, suggesting that AVP signaling differentially modulates the molecular clock of neuronal subgroups. Consistent with pharmacological results in vitro, AVP knockdown mice display longer free-running period and differences in the plasticity of circadian waveform under constant darkness. Together, these results indicate that AVP signaling modulates the period and phase relationships of SCN neurons, which has functional consequences for how the master clock communicates time of day to downstream tissues and responds to environmental changes.

Title: Circadian regulation of phosphoprotein enriched in astrocytes (PEA-15) expression and function within the mouse suprachiasmatic nucleus

Authors: K. WHEATON[1], S. ATEN[2], L. S. QUEIROZ[1], K. SULLIVAN[2], J. OBERDICK[2], K. OBRIETAN[2], *K. R. HOYT[1]
[1]Pharmacol., [2]Neurosci., Ohio State Univ., Columbus, OH

Abstract: Disruption of the circadian timing system has profound detrimental effects on health and cognition and has been linked to an array of human pathologies. The suprachiasmatic nucleus (SCN) of the hypothalamus (often referred to as the 'master clock') generates timing cues that coordinate cellular oscillator populations throughout the brain as well as peripheral organ systems. This phasing is tightly controlled by photic input signals from the retina and resetting of the clock by photic input is regulated by the p44/42 mitogen-activated protein kinase (MAPK) pathway. Here, we investigated cellular mechanisms that regulate ERK (the key effector kinase of the MAPK pathway) phosphorylation and its cellular localization within the SCN. To this end, we examined the expression and function of phosphoprotein enriched in astrocytes (PEA-15), a scaffold protein that regulates both the activation state of ERK and its subcellular localization. Using immunohistochemical labeling and Western analysis, we found that PEA-15 is highly enriched within the mouse SCN and PEA-15 expression oscillates with a circadian rhythm. Notably, the peak in PEA-15 expression was antiphase to the well-characterized circadian oscillation in ERK activity. PEA-15 phosphorylation at serine-104 was induced by photic stimulation. This phosphorylation event triggers the dissociation of ERK from PEA-15 and the translocation of ERK to the nucleus. We confirmed both PEA-15 binding to ERK and the dissociation of ERK from PEA-15 upon photic stimulation via co-immunoprecipitation experiments in SCN lysates. In total, these studies reveal PEA-15 to be neuronally enriched, clock-gated and light responsive in the SCN. Given its high expression in the SCN, coupled with its role as a critical regulator of MAPK signaling, PEA-15 may be well positioned to contribute to the functional fidelity of signaling networks that regulate SCN clock timing and entrainment. Current work is focused on the examination of clock timing in PEA-15 null mice.

Title: Microglia dynamics in the suprachiasmatic nucleus across circadian time

Authors: *L. G. CHASTAIN, K. A. HALTER, R. A. PROSSER
Biochem. & Cell and Mol. Biol. Dept., Univ. of Tennessee Knoxville, Knoxville, TN

Abstract: Microglia, the brain's resident immune cells, have been shown to play important non-immune roles in regulating synapses and maintaining neuronal function. Circadian rhythms are regulated by the suprachiasmatic nucleus (SCN) of the hypothalamus, but specific mechanisms underlying circadian clock regulation are not completely understood. Data on the role of microglia in circadian rhythms are scarce, but a few studies have shown significant time of day differences in microglial immune response, and microglia show circadian rhythms in pro-inflammatory factor expression, suggesting that microglia undergo circadian changes in function. Our studies aim to investigate whether microglia undergo changes in phenotype in the SCN as a function of endogenous circadian rhythms. To address this issue, we used immunohistochemical characterization of microglia cells in the SCN of adult male C57Bl/6 mice at three distinct circadian times: Zeitgeber Time (ZT) 6, ZT 16, and ZT 23 (where ZT 0 corresponds to lights on and ZT12 corresponds to lights off). Hypothalamic blocks of mouse brain tissue (n=3) were collected at the three timepoints, sectioned at 25 µm thickness and stained for IBA-1 (a microglia-specific marker) using immunofluorescence. Slides were imaged on an immunofluorescent microscope to assess fluorescent intensity, microglia cell number, and microglia cell phenotype in the SCN region at the three times. As microglia transition from a quiescent to an active state, their morphology changes from a ramified state (small cell body and many filopodial extensions) to an amoeboid state (larger cell body, less extensions). We characterized microglia in the SCN as either amoeboid, partially amoeboid, ramified, or partially ramified according to the number and complexity of their processes. Differences between timepoints were analyzed by one-way ANOVA followed by Newman-Keuls post-tests. There was no significant difference in microglia number in the SCN across circadian time, but there was a significant increase in partially ramified microglia at ZT 16 and ZT 23 compared to ZT 6. In addition, there was a trend for increased partially amoeboid microglia in the SCN at ZT 6 compared to ZT 16 and ZT 23. Finally, there was an increase in IBA-1 immunofluorescence in the SCN at ZT 23 as compared to ZT 6 in the SCN. Thus, microglia undergo morphological

changes in the SCN as a function of circadian time, and these changes may indicate dynamic alterations in function or activation. Follow up studies are addressing whether microglial interactions with SCN neurons are altered across circadian time and whether microglia play a role in modulating SCN neuronal regulation of circadian rhythm.

Title: Calcium-binding protein calreticulin is co-expressed with neurogenesis marker SOX2 in the adult mouse suprachiasmatic nucleus

Authors: T. M. BIRKHOLZ, D. H. BELIGALA, A. DE, *M. E. GEUSZ
Dept. of Biol. Sci., Bowling Green State Univ., Bowling Green, OH

Abstract: The role of multiple calcium-binding proteins such as calbindin and calretinin in the hypothalamic suprachiasmatic nucleus (SCN) has been frequently examined. Here we describe the expression pattern of the multifunctional calcium-binding protein calreticulin (calregulin or calreg) that is known to buffer endoplasmic reticulum (ER) Ca^{2+}. Cytosolic Ca^{2+} mobilization driven by Ca^{2+} release from ryanodine-sensitive internal stores has been shown to modify gene transcription in the SCN and shift the phase of the circadian clock. Calreg is a major regulator of ER Ca^{2+} levels and has been shown to interact with ryanodine receptors of the ER to influence Ca^{2+} release, yet its function within the SCN is largely unknown. To identify calreg protein distribution in the SCN we performed immunocytochemistry and confocal microscopy of mouse brain sections. Imaging revealed positive calreg expression within both shell and core SCN sub-regions with relatively higher expression in the ventral SCN. A large number of calreg-positive cells (85%) showed co-localization with SOX2 protein, a regulator of embryonic and adult neurogenesis that is known to be expressed in the SCN. The SCN expresses several proteins that are more often found in stem cells or during neurogenesis, and confirming this we identified stem cell marker OCT4 in 53% of SCN cells. Neural stem cells have been shown to express integrins that are known to serve in cell-cell communication and cell adhesion with the extracellular matrix. Overexpression of calreg has been shown to influence integrin-mediated epithelial-mesenchymal transition, suggesting that it also contributes to morphological changes and stemness in the SCN. Furthermore, co-localization of calreg with SOX2 indicates that calreg may have a unique function in SCN stem-like cells. Localization of calreg with neuronal marker NeuN indicated that some of the calreg expression was in SCN neurons. Calreg expression was primarily within the ventral SCN where retinal axons project to SCN neurons, suggesting that

calreg could serve in this pathway of light signals to the clock that maintains its entrainment to the daily rhythms of the external environment.

Title: Circadian timekeeping in the brainstem: Ticking and talking in the area postrema and nucleus of the solitary tract

Authors: *L. CHROBOK[1], R. C. NORTHEAST[2], H. D. PIGGINS[2]
[2]Fac. of Life Sci., [1]Univ. of Manchester, Manchester, United Kingdom

Abstract: Major components of energy balance exhibit circadian variation. In the brainstem, the area postrema (AP) is a sensory circumventricular organ which plays well documented roles in cardiovascular and visceral reflexes. Immediately adjacent to the AP is the nucleus of the solitary tract (NTS), a key relay structure for enteroceptive signals. Together these nuclei create a complex which acts a powerful gateway for homeostatic signals through the brainstem. Here, using single cell bioluminescent imaging, we report our novel findings of clear circadian rhythmicity and spatiotemporal patterning of *Per2*, a core canonical clock gene, in the AP and NTS. To monitor cyclic changes in PER2 *ex vivo*, bioluminescence signals were recorded from brain slice explant cultures obtained from male mPER2::LUC mice. Highly robust single cell oscillations were readily detected in both the AP and adjacent NTS. Spatiotemporal analysis revealed higher amplitude oscillations in the cell-dense AP compared with the NTS, where rhythmic cells were more sparsely distributed. At the whole tissue level, the peak in the NTS rhythm was delayed by approximately 2 hours compared to that of the AP (n=9). Rhythmic bioluminescence was sustained for up to 7 days in culture and could be resynchronised and prolonged for up to a further 14 days by forskolin. Single cell analysis demonstrated that individual rhythmic cells in the NTS were more robust than corresponding cells in the AP, but the phase dispersal of rhythmic NTS cells was broader than that of rhythmic AP cells. To gain insight into the role of signalling between the AP and the NTS in maintenance of oscillations, we mechanically disconnected these two nuclei (n=3) which led to an increased phase dispersion of rhythmic NTS cells. This indicates that the phase coupling of NTS cells is dependent on intact neural connectivity to the AP. Additionally, the application of 0.5 μM TTX resulted in

pronounced phase desynchronization of single cell oscillators in both structures throughout the pharmacological blockage of action potential-dependent neuronal communication. This diminished the rhythmicity of the AP/NTS at the whole tissue level, which recovered on removal of TTX from the media. This study is the first to demonstrate self-sustained single cell oscillations in PER2 bioluminescence in the AP and the NTS with evidence of neuronal interplay between the structures in the maintenance of these rhythms. When compared to other extra-suprachiasmatic nucleus oscillators, the AP/NTS complex exhibit highly robust rhythmicity, therefore our findings place it as a potentially important component of an extended neural circadian system.

Title: Robust cycling of circadian clock genes in the area postrema/nucleus of the solitary tact complex accompanies daily changes in permeability to blood-borne signals

Authors: R. C. NORTHEAST[1], L. CHROBOK[2], *H. PIGGINS[3]
[1]Fac. of Biology, Medicine, and Hlth., Univ. of Manchester, University of Manchester, United Kingdom; [2]Fac. of Biology, Medicine, and Hlth., Univ. of Manchester, Manchester, United Kingdom; [3]Univ. Manchester, Manchester, United Kingdom

Abstract: The area postrema (AP) is a sensory circumventricular organ (CVO) located in the brainstem that senses blood-borne chemical signals. Although the AP lacks a blood-brain barrier (BBB), a specialized cellular barrier between the AP and the adjacent nucleus of the solitary tract (NTS) regulates the entry of circulating substances into the brain. This barrier is composed of vimentin/GFAP+ve glial processes connected by tight junction proteins including zona occludens-1 and occludin. Little is known about the role of the intrinsic circadian clock in the AP/NTS complex and how it might regulate their key functions. Here we investigated rhythmic gene expression in these areas as well as the possibility of daily changes in the permeability of the NTS to blood-borne signals. In brainstem slice cultures obtained from mPER2::LUC mice, we detected sustained PER2 bioluminescence oscillations at the level of single cells in both the AP and NTS (n=6). Confocal imaging of fixed brain sections from *Per1::*Venus mice (n=3) showed *Per1* expression in numerous cells of the AP/NTS complex. Moreover, circadian qPCR

measurements from AP and NTS sections (CT0, CT6, CT12 and CT18; n=4-5) indicated robust *Per2* cycling, peaking at CT12, with *Bmal1* oscillation reversed in phase in both structures. Intra-cardiac perfusions with Evans Blue dye (EB; does not penetrate a functionally healthy BBB) were performed at two time points, early day (ZT1; n=5) and early night (ZT13; n=4). Surprisingly, at ZT13, EB staining was found not only in the BBB-lacking AP, but also penetrating into the adjacent NTS (particularly its medial subregion); whereas at ZT1, all EB staining was restricted to AP only. Further immunohistochemical staining against glial markers in the AP/NTS border showed decreased density of GFAP-positive but not vimentin-positive processes in the early subjective night (CT13, n=5) compared to early subjective day (CT1, n=4). Additionally, *zona occludens-1* in the AP demonstrated circadian variation across 4 time points (CT0, CT6, CT12, CT18; qPCR) with the lowest expression at CT12. As expected, EB was contained in the other sensory CVOs, the subfornical organ and vascular organ of lamina terminalis, and with no accompanying circadian change in glial markers unlike the AP/NTS. Taken together these results reveal novel temporal control unique to the glial border in the AP/NTS complex. This study is the first to demonstrate robust circadian rhythmicity of the core molecular clock in the AP/NTS complex *ex vivo*. We also highlight a potential role for the local circadian clock in shaping daily changes in the permeability of the brainstem to blood-borne signals.

Title: A Bmal1-ablation macaque monkey model for circadian-related disorders

Authors: *H.-C. CHANG[1], Y.-C. TANG[2]
[1]Inst. of Neurosci., Shanghai city, China; [2]Shanghai Inst. for Biol. Sci., Shanghai City, China

Abstract: Circadian dysfunction has long been recognized as a risk factor causing metabolic abnormalities, psychiatric disorders and aging. To investigate the circadian-related disorders in a physiological comparable manner to humans, we generated a circadian disrupted non-human primate model to monitor the associations to clinic findings. By ablating BMAL1, a crucial circadian transcription factor, with CRISPR/Cas9 editing in cynomolgus monkeys, we obtained monkeys showing higher nocturnal activities and depression phenotypes at preadolescent age. Deterioration of internal circadian program in the mutants was revealed by arrhythmic hormonal

levels and a sensitized response to constant illuminating regimen. Ablation of BMAL1 led to transcriptional programs elevated toward inflammatory and stress responses. Further transcription network analysis revealed significant correlations clustered to human sleep deprivation, major depressive disorder and aging data, suggested the *Bmal1* model is valuable in examining circadian disturbed outcomes in a collective manner. The new model offered a perspective option to circadian-oriented interventions for psychological and chronic diseases.

Title: Connectome of the mouse SCN: New insight into the relation of the peptides VIP to AVP

Authors: *S. VARADARAJAN[1], M. TAJIRI[1], R. JAIN[1], R. HOLT[1], Q. AHMED[1], J. LESAUTER[1], R. SILVER[2]
[1]Barnard Col., New York, NY; [2]Psychology, Columbia Univ., New York City, NY

Abstract: A brain clock, constituted of ~20,000 peptidergically heterogeneous neurons, is located in the hypothalamic suprachiasmatic nucleus (SCN). While many peptidergic phenotypes have been identified, little is known about the connections among these neurons in mice. We first sought to identify contacts among major peptidergic cell types in SCN using triple-label fluorescent immunocytochemistry. To this end, contacts among VIP, gastrin-releasing peptide (GRP), and calretinin (CALR) cells of the core, and arginine vasopressin (AVP) and met-enkephalin (ENK) cells of the shell were analyzed. While reciprocal connections are made among the other phenotypes tested, VIP fibers make many appositions with AVP neurons, but contacts in the reverse direction are sparse. To better understand the impact of VIP-to-AVP communication, we next explored the SCN in VIP deficient mice (VIP-KO). In these animals, AVP expression is markedly reduced in the SCN, but it is not altered in the paraventricular and supraoptic nuclei. Surprisingly, in VIP-KO mice, the number of AVP appositions onto other peptidergic phenotypes is not reduced. Colchicine administration restored numbers of AVP neurons to that of wild-type littermates. The results support the hypothesis that AVP synthesis is reduced in neurons of VIP-KO animals. In summary, the various SCN peptidergic phenotypes of the SCN core and shell make largely reciprocal connections. The results highlight a unique mostly unidirectional core-to-shell communication by VIP-to-AVP. Furthermore, the results point to an important role for VIP in AVP regulation, in a manner specific to the SCN.

Title: Adenosine receptors and recovery sleep in *C. elegans*

Authors: *B. MAHAMA, A. C. HART
Neurosci., Brown Univ., Providence, RI

Abstract: The purpose of this study was to investigate the role of adenosine receptor, *ador-1*, signaling on recovery sleep in *C. elegans*. Poorly understood homeostatic mechanisms drive recovery sleep after extended wakefulness, altering the next sleep period. Studies with humans and mice implicate adenosine buildup and adenosine receptor signaling in this recovery sleep. However, *Drosophila* and other mouse studies suggest adenosine receptor signaling is not needed for recovery sleep. I propose to examine this conflict by studying the consequence of *ador-1* loss of function in *C. elegans* recovery sleep. I developed a simple system that perturbs sleep during L4/A lethargus and showed that recovery sleep in this system is dependent on daf-16, as reported in the literature (PMID: 23477722, PMID: 25474127, PMID: 29523076). Compared to wildtype animals that increase their total sleep after deprivation, preliminary data suggests *ador-1* loss of function animals decreased their total sleep after deprivation. These results imply that adenosine receptor signaling in *C. elegans* may be important for their ability to respond to disrupted sleep. In the future, I will probe specifics of the signaling pathway by testing the effects of caffeine, a known adenosine receptor antagonist. Then, I will determine which neurons require *ador-1* function for recovery sleep. These studies will help us understand how animals recover after sleep loss.

Abstract: Abstract
Histone activity has been described as a key element in epigenetic mechanisms. Moreover, histone methyltransferases and demethylases have been identified as contributing factors in the development of multiple health disturbances, especially cancer. However, the neurobiological role of histone demethylases in behaviors, such as sleep, remains unknown. Thus, we investigated the effects of the systemic administration of histone demethylation inhibitor GSK-J1 or the histone methylation inhibitor DZNep in sleep-wake cycle during the lights-on or the lights-off period of rats. We found that systemic injection of GSK-1 (5, 10 or 20mg/Kg, i.p.) when injected at the beginning of the lights-on period induced no statistical changes in total time of W, SWS or REMS. However, if administered at the beginning of the lights-off period, GSK-J1 decreased wakefulness (W) and enhanced slow wave sleep (SWS) as well as rapid eye

movement sleep (REMS). In opposition, DZNep (5, 10 or 20mg/Kg, i.p.) exerted a dose-dependent increase in W as well as a decrease in SWS and REMS during the lights-off period with no changes observed in lights-on period. Thus, histone demethylation inhibition provoked sleep whereas histone methylation inhibition induced alertness. Our study reports by the very first time the role of epigentical elements such as histones in sleep modulation.

Title: Sleep deprivation induces alterations in RNA splicing and changes in gene expression within the hippocampus

Authors: *M. E. GAINE[1], S. CHATTERJEE[1], E. BAHL[2], J. J. MICHAELSON[2], L. C. LYONS[3], T. ABEL[1]
[1]Mol. Physiol. and Biophysics, [2]Psychiatry, Biomed. Engineering, Communication Sci. and Disorders, Univ. of Iowa, Iowa City, IA; [3]Dept. of Biol. Science, Program in Neurosci., Florida State Univ., Tallahassee, FL

Abstract: Sleep deprivation has become a common problem in modern society due to work demands, the use of personal electronics and lifestyle choices. Sleep deprivation results in numerous adverse health issues including the exacerbation of mood disorders and neurodegenerative diseases. We and others have shown that sleep deprivation causes deficits in cognitive function and performance, with hippocampus-dependent memory particularly susceptible to the effects of sleep deprivation. Previously, we found that a single 5 hour period of sleep deprivation impacted hippocampal gene expression (Vecsey et al., 2012). However, little is known about the effects of sleep deprivation on mRNA processing and splicing. The current research furthers our understanding of this question using genome-wide deep RNA sequencing to identify the impact of sleep deprivation on gene expression and mRNA splicing. Wildtype

C57BL/6J male mice were sleep deprived using a gentle handling method that has previously been shown to disrupt sleep without inducing stress effects (Vecsey et al., 2013). Immediately after sleep deprivation (or at the same circadian time point for non-sleep deprived controls), the hippocampus was removed, flash frozen and RNA extracted. Following rRNA depletion with the Ribo-Zero kit (Illumina), RNA libraries were prepared using the TruSeq Stranded Total RNA Library Prep Gold kit (Illumina). Sequencing was performed on a HiSeq4000 with 150bp paired-end reads. Differential RNA expression between the sleep deprived (n=4) and control (n=4) groups was computed with statistical models accounting for unwanted sources of variation. Gene set enrichment analysis was performed on gene ontology terms and KEGG pathways. Differential expression of genes of interest following sleep deprivation was verified in independent biological replicates using Q-PCR. Consistent with previous research (Vecsey et al, 2012; Wang et al 2010), we found that sleep deprivation significantly affected gene expression of *Rbm3*, an RNA binding protein. Specifically, we found that sleep deprivation significantly increased the abundance of the long isoform of *Rbm3* and significantly decreased levels of the short *Rbm3* transcripts. Furthermore, we found genes in two pathways related to regulation of mRNA splicing up-regulated following sleep deprivation ($P = 8.3 \times 10^{-4}$). These results strongly suggest that sleep deprivation affects RNA splicing as well as overall gene expression. This study sets the stage for future work investigating the role of sleep in RNA processing and understanding of the molecular consequences of acute sleep deprivation.

Title: Sleep- related electrophysiological activity of cortical cultures on MEA

Authors: *I. COLOMBI[1,3], M. PACE[1], V. TUCCI[1], M. CHIAPPALONE[2]
[1]Neurosci. and Brain Technol., [2]Rehab Technologies, Inst. Italiano di Tecnologia, Genova, Italy; [3]Univ. degli Studi di Genova, Genova, Italy

Abstract: Over the last few years, it has been proposed that electrophysiological markers for sleep cycles can be also derived from in vitro neuronal networks, similar to those present in vivo. To this end, a lot of efforts in current sleep science aims at understanding to which extent an in vitro system can recapitulate the essential features of a sleeping brain. In this context, cortical cultures coupled to Micro-Electrode Arrays (MEAs) can represent a simplified and easily accessible in vitro model used for studying principles of neurodynamics and neural coding.

Although neuronal assemblies plated on MEAs show spontaneously synchronized, low frequency firing patterns, which could resemble the slow wave oscillations that characterize non-REM (NREM) sleep in vivo, the lack of the awake state counterpart limited the investigation of the main physiological aspects of sleep. To this end, in a previous work we stimulated our in vitro neuronal networks using the cholinergic agonist Carbachol (CCh, 20 µM) to suppress the sleep features. We observed for the first time that CCh treatment affected both the high and the low frequency components of the signal, causing a suppression of the classical sleep-like properties of activity. Starting from this finding, we were then interested in understanding how the electrophysiological signal changed in pathologies that affect sleep. Prader-Willi syndrome (PWS) is a rare neurodevelopmental disorder that is associated with a paternally-expressed genomic imprinting defects within the human chromosome region 15q11-13. One of the candidate genes is the small nucleolar ribonucleic acid-116 (SNORD116). PWS patients are often affected by sleep-wake disturbance associated with alteration during REM sleep, including abnormalities in theta waves. The same identical sleep/EEG defects were found using mutant mice (PWS) carrying a deletion of Snord116 at the orthologous locus. Then we wanted to answer one main question: can our model recapitulate the essential features in a pathological model of sleep? More specifically, is it possible to observe the same abnormalities in a simplified and accessible model in vitro? We performed preliminary experiments using cortical cultures of PWS mice and we applied Carbachol (CCh, 20 µM) to suppress the sleep waves. We found the same difference in the theta waves upon CCh administration, suggesting the idea that our model can be used to study and manipulate sleep properties in a very controlled way. MEA recordings coupled to cortical cultures seem to represent a possible model to investigate the essential features of sleep in both physiological and pathological conditions.

Abstract: *Cannabis sativa* is a plant that contains more than 500 components, of which the most studied are Δ^9-tetrahydrocannabinol (Δ^9-THC) and cannabidiol (CBD). Several studies have indicated that CBD displays neurobiological effects, including wake promotion. In this regard, experimental evidence shows that injections of CBD enhance wake-related compounds, such as monoamines (dopamine, serotonin, epinephrine, and norepinephrine). Despite that CBD modulates several neurochemicals linked with wakefulness modulation, no clear evidence is available regarding the effects of CBD on additional wake-related compound such as acetylcholine (ACh). Here, we determine that systemic injections of CBD (0, 5, 10 or 30mg/Kg, i.p.) at the beginning of the lights-on period, increased the extracellular levels of ACh measured by microdialysis and HPLC means. These findings indicate that CBD promotes ACh accumulation in the basal forebrain, a brain region related to wake control.

Abstract: Narcolepsy is a sleep disorder characterized by excessive daytime sleepiness (EDS), fragmented sleep/wake and cataplexy (C), the emotionally-triggered loss of muscle tone. Pitolisant (PIT), an inverse agonist at histamine H3 receptors that was approved by the EMA as a narcolepsy therapeutic in 2016, has been reported to decrease both EDS and C symptoms. Here, we tested its effects compared to the selective H3 inverse agonist irdabisant (IRD) and to the wake-promoting drug modafinil (MOD) in a conditional mouse narcolepsy model, *orexin/tTA; Tet-O diphtheria toxin A* mice (DTA mice), where hypocretin/orexin neurons are ablated in the absence of doxycycline in the diet.

PIT (10, 20 and 40 mg/kg), IRD (3, 10 and 30 mg/kg), and MOD (32, 64 and 128 mg/kg) were administered IP to DTA mice during the dark period at ZT18. C, sleep/wake parameters, core body temperature (T_b), and locomotor activity (LMA) were compared to vehicle treatment (0.5% methylcellulose /0.2% Tween 80 in deionized water). EEG, EMG, T_b, LMA were recorded via telemetry along with video recordings of behavior and assessed for 6 h post-injection. EEG and EMG recordings were scored in 10 s epochs for waking (W), rapid eye movement sleep (REM), non-rapid eye movement sleep (NR) and C.

Although both PIT and IRD had strong wake-promoting effects and all 3 compounds increased W in a dose-related manner, only PIT at 40 mg/kg significantly decreased C across the 6 h recording period. Both PIT and IRD significantly decreased NR and REM; MOD effects were limited to decreased NR. Sleep/wake consolidation measures revealed that the increase in W following PIT occurred via an increase in W bout duration and a decrease in the number of W bouts, indicative of a highly consolidated W periods. The increased W following IRD and MOD occurred via increases in both W bout duration and the number of W bouts. EEG power analysis revealed different spectral profiles during W for the 3 compounds. PIT at 40 mg/kg produced large variations across the power spectrum: power within the delta range and from ~21-40 Hz increased while power between ~5-19 Hz and ~42-100 Hz decreased. These effects gradually attenuated but were still evident during the last recording h. In addition, PIT caused abnormal EEG synchrony in 5 of 8 mice. The high dose of IRD resulted in a large increase in power between 30-60 Hz which lasted for ~4 h. MOD had very little effect on the W power spectrum. Our data show that PIT increased W and, at the highest dose, reduced C in a mouse model of narcolepsy. However, since the selective H3 receptor inverse agonist IRD only increased W, the PIT-mediated effects on C may occur through a non-H3 mechanism.

Title: Brain state dependent modulation of neuronal firing and membrane potential dynamics in the somatosensory thalamus during natural sleep

Authors: *N. L. URBAIN[1], N. FOURCAUD-TROCMÉ[2], P. SALIN[2], L. GENTET[2]
[1]CRNL INSERM U1028, CNRS UMR 5292, Lyon, France; [2]CRNL INSERM U1028, Lyon, France

Abstract: Slow rhythms and spindle oscillations form the hallmarks of non-rapid eye movement sleep (NREMs). The thalamus plays a central role in sleep rhythms in the mammalian brain yet, surprisingly little is known about its function and interaction with local cortical oscillations during NREMs. To uncover the functioning of the thalamocortical loop in naturally-sleeping animals, simultaneous measurements of thalamic and local cortical activity are required. Focusing on the mouse somatosensory system, we investigated during natural NREMs the neuronal correlates of cortical barrel activity in its two corresponding thalamic nuclei, the ventral posterior medial (VPM) and the posterior medial (Pom) nuclei.
We performed extra- and intra-cellular recordings of thalamic relay cells combined with S1 local field potential (S1-LFP) while simultaneously measuring the electroencephalogram and the electromyogram. These recordings allowed us to investigate the dynamics of thalamic subthreshold and spiking activity coupled with cortical oscillations across episodes of NREMs in non-anesthetized mice.
Our data reveal 1) that spindle features evolve throughout NREMs episodes and vary according to the post-NREMs state, 2) distinct modulations of VPM and Pom activity throughout NREMs episodes, 3) a thalamic nucleus-specific phase-locking to cortical slow and spindle waves, and 4) cell-specific subthreshold spindle oscillations in VPM neurons that only partially overlap with cortical spindles.
Taken together, our results suggest that, during natural sleep, the barrel cortex exerts a leading role in the generation and transfer of slow rhythms to the thalamus and reciprocally for spindle oscillations.

Title: Pontine neural ensemble dynamics during p-waves in mice

Authors: *T. TSUNEMATSU[1,2], S. SAKATA[3]
[1]Tohoku Univ., Sendai, Japan; [2]Univ. of Strathclyde, Glasgow, United Kingdom; [3]SIPBS, Univ. of Strathclyde, Glasgow, United Kingdom

Abstract: Rapid eye movement (REM) sleep is characterized by hippocampal theta waves and phasic sub-second waves in the brainstem, so-called ponto-geniculo-occipital (PGO) waves in cats or pontine (P) waves in rodents. Although the sub-second pontine wave during REM sleep was originally described in 1960s, the underlying mechanism of P-wave genesis during REM sleep is still not fully understood. Using in vivo electrophysiological approaches in mice, we investigated the temporal evolution of P-waves and accompanied neural ensemble dynamics in the pontine. First, to examine how P-waves appear during the sleep-wake cycle, bipolar electrodes were implanted into the medial parabrachial nucleus (MPB) of head-fixed mice. The density of P-waves was maximum at ~ 0.8 Hz during REM sleep, consistent with that in cats and rats. Second, to monitor neural ensemble dynamics during P-wave genesis, we inserted a 4-shank silicon probe, which could cover multiple pontine nuclei simultaneously. While a rich structure of neural activity was apparent across pontine nuclei, we found that P-waves during REM sleep were associated with highly synchronous burst firing across nuclei. In conclusion, our findings suggest that coordinated firing across pontine neurons plays an important role in P-waves as well as REM sleep regulation.

Title: Subcortical Sox14 neurons are required for sleep-wake regulation

Authors: *Ç. GELEGEN VAN EIJL[1], O. BROCK[2], P. JAGER[2], S. BRICKLEY[3], G. MOORE[3], A. DELOGU[2]
[1]Dept. of Basic and Clin. Neurosci., [2]Basic and Clin. Neurosci., King's Col. London, London, United Kingdom; [3]Life Sci., Imperial Col. London, London, United Kingdom

Abstract: ***Background***: Sleep is a universal behavior and its disruption is associated with a broad spectrum of mental disorders. Despite recent progress, our understanding of sleep regulation remains limited. Sox14 is a transcription factor that controls neuronal differentiation and maturation in the subcortical brain. We previously showed that Sox14 expression is required to drive development of a network that ensures entrained circadian rhythmicity. More recently, we have mapped the distribution of Sox14 neurons and identified their presence in areas implicated in the regulation of sleep-wake cycles.
Aim: To determine whether subcortical neurons that are defined by the Sox14 marker are implicated in sleep-wake regulation. For this, we investigated sleep architecture in adult Sox14 mutant mice.
Methods: High resolution imaging of whole brains by 2-photon confocal tomography revealed the global distribution of Sox14 neurons in control ($Sox14^{Gfp/+}$) and mutant ($Sox14^{Gfp/Gfp}$) brains. Electroencephalography and electromyography electrodes were implanted in 4-6 months old control and mutant mice (n=16 total). Sleep recording was performed and recordings were analyzed using SleepPro software (Pinnacle Technology, USA). Behavioral tests assessed alterations in cognitive performance of Sox14 mutant mice.
Results: Hypnograms of Sox14 mutant mice indicated a significant increase in time spent in WAKE and a concomitant decrease in NREM and REM vigilance states. REM in particular was dramatically reduced. Increased fragmentation characterized sleep in the Sox14 mutant mice. In agreement with the reduction in sleep time, Sox14 mutant mice failed in a hippocampal-dependent memory task.
Conclusion: Mice deleted for the *Sox14* transcription factor gene show a difference in both macro and micro architecture of their sleep. The Sox14 mutant mice will be a useful tool to study the impact of sleep disruption on brain function (e.g. memory consolidation) and general physiology. The availability of $Sox14^{cre}$ mice will allow for more targeted manipulations of Sox14 neurons to dissect out their relative contribution they make to the observed sleep phenotype.

Title: The effects of sleep deprivation and caffeine on the rodent psychomotor vigilance task (rPVT)

Authors: *M. CREWE, D. HOLT, J. DYCHE
Psychology, James Madison Univ., Harrisonburg, VA

Abstract: The relationship between sleep deprivation and performance on the Psychomotor Vigilance Task (PVT) and the effects of caffeine to mediate this relationship have been well documented in the human literature. Recently, a version of the PVT that is analogous to the human PVT has been developed for use with rodent models (rPVT). Several studies have measured the effects of sleep deprivation (SD) on rPVT performance, but no studies to date have examined the effect of caffeine to mediate the effects of sleep deprivation as seen in the human literature. The goal of the current study is to determine the effects of sleep deprivation and subsequent caffeine administration on rPVT performance in Wistar rats (N=7). We hypothesized that 6hr/day sleep deprivation would produce significant impairment in rPVT performance, and 10mg/kg i.p. caffeine would be sufficient to mediate the effects of SD on performance. After meeting baseline criterion, animals experienced three conditions for one week each: 6hr/day SD in forced exercise wheels with no caffeine, 10mg/kg i.p. of caffeine (no SD), and 6hr/day SD immediately followed by 10mg/kg i.p. of caffeine. Sleep deprivation and caffeine only conditions were counterbalanced to control for carry-over effects. Performance on the rPVT was measured daily at 15:00. A series of repeated measures ANOVAs were conducted to analyze the effects of each condition on both the primary (mean IRT, percent lapses, & percent of omissions) and secondary (percent correct & percent incorrect) measurements of rPVT performance. Significant ANOVAs were followed-up by pairwise t-tests using a Bonferroni correction. Significant omnibus results were found for mean IRT, percent lapses, percent correct responses, and percent incorrect responses. In general, 6hr/day SD was effective for decreasing performance on the rPVT, but 10mg/kg caffeine was not sufficient to increase performance over baseline or to mediate the effects of sleep deprivation. These results support the hypothesis that 6hr/day will produce significant impairment on the rPVT, but do not support the hypothesis that 10mg/kg i.p. will be sufficient to mediate this effect. These results also do not match patterns observed in the human literature that suggest a caffeine dosage equivalent to two cups of coffee is sufficient to mediate the effects of chronic partial sleep deprivation on PVT performance. Future research in this area will explore dose-response effects of caffeine on rPVT performance following SD as well as the effects of selective adenosine antagonists such as cyclo-pentyl-theophylline.

Title: Activation of adenosine A_{2A} receptors in the olfactory tubercle promotes sleep

Authors: *R. LI[1,2], Y.-Q. WANG[1,2], M.-Q. ZHANG[1,2], W.-Y. LIU[1,2], Y. CHERASSE[3], S. N. SCHIFFMANN[5], A. DE KERCHOVE D'EXAERDE[6], M. LAZARUS[4], Z.-L. HUANG[1,2]

Inst. for Integrative Sleep Med., Univ. of Tsukuba, Tsukuba, Japan; [5]Univ. Libre de Bruxelles (ULB), Brussels, Belgium; [6]Univ. Libre de Bruxelles, Brussels, Belgium

Abstract: Adenosine A_{2A} receptors (A_{2A}Rs) play a major role in adenosine induced-sleep. Studies find that A_{2A}Rs are abundantly expressed in the caudate putamen (CPu), nucleus accumbens (NAc), and olfactory tubercle (OT). Given that A_{2A}Rs in the CPu and NAc regulate sleep, we hypothesized that A_{2A}Rs in the OT might also regulate sleep. First, the role of A_{2A}Rs in the OT was pharmacologically probed by implanting cannulae in bilateral OT and EEG/EMG electrodes in rats (male, SD, 280-320 g), delivering a selective A_{2A}R agonist, antagonist or vehicle, and assessing sleep-wake behaviors. Second, the function of A_{2A}R expressing neurons in the OT ($OT^{A_{2A}R}$ neurons) was chemogenetically determined by expressing hM3Dq in the $OT^{A_{2A}R}$ neurons of mice (male, A_{2A}R-Cre, 22-28 g), giving CNO (i.p., 3 mg/kg), and assessing sleep-wake behaviors. Thirdly, projection sites of $OT^{A_{2A}R}$ neurons were studied by unilaterally

injecting viruses that conditional express hrGFP under the presence of A_{2A}Rs into the OT of A_{2A}R-Cre mice. Finally, properties of connections between $OT^{A_{2A}R}$ neurons and other brain regions were tested by expressing ChR2 in the $OT^{A_{2A}R}$ neurons with the help of *in vitro* electrophysiology. Application of a selective A_{2A}R agonist CGS21680 (0.6 nmol/side) into the OT of rats at 21:00 increased amounts of hourly NREM sleep for five hours compared with the vehicle-treated group, whereas application of a selective A_{2A}R antagonist KW6002 (15.6 nmol/side) at 9:00 increased sleep latency and decreased NREM sleep amounts. A_{2A}R-Cre mice expressing hM3Dq in the $OT^{A_{2A}R}$ neurons treated with CNO at 21:00 showed an increase in hourly NREM sleep amount for three hours. Terminals of $OT^{A_{2A}R}$ neurons were found abundantly in the ventral pallidum (VP) with few scattered in the lateral hypothalamus (LH). Photostimulation (5-ms 473-nm light pulse at 1 Hz) of terminals of $OT^{A_{2A}R}$ neurons at the VP and LH was blocked by the application of a GABA antagonist. Our exploratory research demonstrated that activation of A_{2A}Rs in the OT or $OT^{A_{2A}R}$ neurons increased NREM sleep, probably through inhibitory innervations to the VP and LH. That the OT as one component in the olfactory system regulated sleep may advance the understanding of and encourage new therapies for neurological disorders where sleep disturbances and olfactory dysfunctions are comorbidities. In conclusion, the OT promoted NREM sleep via activation of A_{2A}Rs.

Title: *In vitro* model for the study of the role of the mesopontine region in rapid eye movement (REM) sleep and wakefulness

Authors: *E. PINO[1], H. KUNIZAWA[1], J. YAMUY[2], M. BORDE[1]
[1]Fisiología - Lab. de Neurofisiología Celular y Sináptica, Facultad de Medicina - Univ. de la República, Montevideo, Uruguay; [2]VA Greater Los Angeles Healthcare System; UCLA Sch. of Med., Los Angeles, CA

Abstract: The ponto-mesencephalic junction in the brainstem contains the neuronal circuits that are necessary for the generation of rapid eye movement sleep (REM-S). The latero-dorsal and pedunculo-pontine tegmental nuclei (LDT/PPT), and the nucleus pontis oralis (PnO), have been

proposed to be responsible for the orchestration of the physiologic processes that result in the expression of REM-S, although cellular and synaptic processes that promote the expression of this state remain poorly understood. We carried out the morphological and functional characterization of a slice preparation of rat brainstem containing the LDT/PPT, PnO and the trigeminal motor nucleus (MV). We obtained whole-cell patch clamp recordings from visually (DIC-IR) identified PnO neurons (n=45) that showed input resistances (R_{in}) of 292.17 ± 22.41 MOhm. A 47% of neurons exhibited low-threshold Ca^{2+} spikes (LTS neurons). Both LTS and Non-LTS neurons exhibited electrophysiological responses suggesting the presence of A-type K^+ and I_h-type cationic currents. The existence of a direct functional connection between LDT/PPT and PnO neurons in our slice model was demonstrated using morphological, electrophysiological and pharmacological techniques. A population of ipsilateral LDT/PPT neurons were retrograde labeled after iontophoretic injection of Neurobiotin into the PnO (n=6 slices). Immunodetection of choline acetyltransferase (ChAT) in these cells, revealed the presence of ChAT-positive and ChAT-negative retrograde labeled neurons. Electrical LDT/PPT stimulation elicited mixed (excitatory-inhibitory) short latency synaptic responses in PnO neurons (n=45). Inhibitory and excitatory post-synaptic currents where selectively blocked by 100 μM *picrotoxin* and 50 μM *kynurenic acid*, respectively. Pharmacological activation of LDT/PPT neurons by local application of *Carbachol* (CCh, 1 mM, n=2) and *Glutamate* (10 mM, n=3) resulted in short latency transient increases (2-15 Hz) in the firing rate of PnO neurons. Two out of 30 LDT/PPT neurons exhibited short latency antidromic action potentials in response to electrical stimuli delivered to the PnO. As observed *in vivo*, microvolumes of CCh (1 mM) applied to the PnO resulted in a transient reduction of MV neurons excitability with a decrease in R_{in} as occurs during motor suppression of REM-S. Application of $GABA_A$ agonists (*muscimol*, 10 μM, n=3) had the opposite effect. The above data indicate that connectivity and functionality of the mechanisms that are responsible for the generation and execution of the motor suppression that is typical of REM-S are intact in our mesopontine rat slice preparation.

Title: Maternal-placental-fetal disruptions with acute prenatal sleep deprivation: Relating stress and placental immune responses to kynurenine pathway metabolism

Authors: *A. BARATTA[1], N. KANYUCH[1], J. DESLAURIERS[2], A. POCIVAVSEK[1]
[1]Maryland Psychiatric Res. Ctr., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: The kynurenine pathway (KP) is the dominant pathway for tryptophan degradation in the mammalian body and recent studies suggest that alterations in KP metabolism during pregnancy, including increases in the neuroactive metabolite kynurenic acid (KYNA), may negatively impact fetal neurodevelopment. As levels of KYNA, an endogenous astrocyte-derived antagonist of α7 nicotinic acetylcholine (α7nACh) and NMDA receptors, are elevated in the cerebrospinal fluid and post-mortem brain tissue from patients with schizophrenia, it appears that the KP may play a role in psychiatric illnesses with neurodevelopmental origin. Emerging evidence suggests that acute episodes of sleep deprivation (SD) disrupt KP metabolism (Baratta et al. *Scientific Reports*, 2018). With pregnancy being a critical period during which several factors, such as sleep disruptions, could lead to a higher risk for psychiatric illness in the offspring, we explored the relationship between maternal SD and KP and immune pathways in the maternal, placenta, and fetal tissues. Pregnant Wistar rat dams were sleep deprived by gentle handling for 5 h from zeitgeber time (ZT) 0 to ZT 5. Experimental cohorts included: A) one session of SD on embryonic (ED) 18 or B) three sessions of SD on ED 16 to ED 18. Maternal (plasma, brain), placental and fetal (plasma, brain) tissues were collected immediately after the last session of SD or after 24 h of recovery from SD. Maternal (plasma, brain) and fetal (placenta, plasma, brain) tissues were collected immediately after the last session of SD or after 24 h of recovery from SD. Respective controls were euthanized at ZT 5 on ED 18 and ED 19. Maternal plasma corticosterone, tryptophan and kynurenine levels, as well as fetal brain KYNA, were significantly elevated only after one session of SD on ED 18. Importantly, plasma corticosterone and tryptophan levels correlated significantly with fetal brain KYNA levels. In addition, placental levels of the pro-inflammatory cytokines IL-1beta and IL-6 were altered following maternal SD, suggesting a relationship between placental immune response to SD and fetal brain KYNA accumulation. Collectively, our results demonstrate that sleep loss during pregnancy can adversely impact maternal kynurenine pathway metabolism, placental immune function, and fetal brain KYNA levels. We introduce KYNA as a novel molecular target influenced by sleep loss during pregnancy. Future experiments are designed to unravel the contribution of changes in kynurenine and immune pathways during maternal sleep loss on long-lasting biochemical and behavioral outcomes in developing offspring.

Title: Ascending projections from parafacial zone to the medial parabrachial neurons

Authors: R. DE LUCA[1], P. M. FULLER[2], *E. ARRIGONI[3]
[1]Neurol., Beth Israel Deaconess Med. Ctr. - Harvard Med., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]Dept Neurol., Harvard Med. Sch. Dept. of Neurol., Boston, MA

Abstract: The parafacial zone (PZ) of the rostral medulla is an important region for the generation of non-REM sleep (NREM). It contains GABAergic neurons that are active in NREM sleep and chemogenetic activation of these neurons rapidly induces sustained periods of NREM sleep with high EEG delta power. We previously found that optogenetic stimulation of PZ projections inhibits neurons of the lateral parabrachial (lPB) that project to the basal forebrain (BF). We proposed that the PZ -> lPB -> BF is the circuit through which the PZ neurons promote NREM sleep. Recent studies however have found that while the lPB is important in producing arousals in response to hypercapnia or pain, it might not be involved in promoting spontaneous waking as lesions or deletions of the glutamatergic signal in lPB do not increase NREM sleep or EEG delta power. Conversely, deletion of the glutamatergic signaling in the medial PB (mPB) produces a significant reduction in the total amount of wakefulness suggesting that glutamatergic mPB neurons are necessary for spontaneous arousal. We have found that the PZ heavily innervates the mPB, suggesting that the PZ might promote NREM sleep by inhibiting the mPB. In this study we used an AAV-based channelrhodopsin2 (ChR2)-assisted circuit mapping (CRACM) in brain slices to investigate the functional synaptic connectivity between the PZ and mPB neurons. **Methods.** We stereotaxically injected the PZ region of *Vgat-IRES-cre* mice with a cre-dependent AAV-ChR2-mCherry. We then performed whole-cell recordings in mPB neurons while photostimulating the PZ input that express ChR2. **Results:** Optogenetic-stimulation of the input from PZ Vgat neurons evoked inhibitory postsynaptic currents (oIPSCs) in 21 out of 29 mPB neurons. We have previously found in lPB neurons that optogenetic stimulation of PZ projections evoked oIPSCs that were solely mediated by $GABA_A$ signaling. In this study bath application of the $GABA_A$ antagonist bicuculline only partially reduced the oIPSCs in mPB neurons. The oIPSCs in mPB neurons were abolished only when bicuculine and the glycine antagonist strychnine were co-applied. **Conclusions:** Our results suggest that PZ neurons project to both the lPB and the mPB. They inhibit the lPB neurons by GABA release and they inhibit the mPB neurons through the release of GABA and glycine. Our hypothesis is that the PZ promote NREM sleep by inhibiting the mPB.

Title: Chemogenetic silencing of corticotropin releasing hormone neurons in the paraventricular nucleus attenuates acute stress related sleep disturbance in mice

Authors: I. GVILIA[1], S. KUMAR[2], D. MCGINTY[2], *R. S. SZYMUSIAK[3]
[1]V.A. Greater Los Angeles Healthcare Syst., Los Angeles, CA; [2]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [3]Res. Service, UCLA/VA Greater Los Angeles, Los Angeles, CA

Abstract: Introduction: We have previously shown that acute elevation of Corticotropin Releasing Factor (CRF) in rats results in exacerbation of stress-induced sleep disturbance. In the present study in mice we (1) assessed sleep-disturbing effect of an acute stressor, exposure to the dirty cage of a male rat, and (2) examined the effect of chemogenetic silencing of CRF neurons in the hypothalamic paraventricular nucleus (PVN) on sleep occurring after the exposure to this stressor. Methods: First, 9 male mice were implanted with EEG/EMG electrodes and housed individually. Two weeks after surgery, at ZT1, five mice were transferred to the dirty cage of a male rat and recorded continuously for 24-hr. Four control mice were transferred to clean cages. In a second study, 4 male CRF-ires-Cre mice received bilateral injections of AAV-hSyn-DIO-hM4Di-mCherry targeting the PVN and were implanted with EEG/EMG electrodes. Four weeks after surgery, the mice were subjected to intraperitoneal (IP) administration of vehicle or clozapine-n-oxide (CNO; 3 mg/kg) at ZT1, transferred to dirty cages from male rats, and recorded for a 24-hr wake-sleep. Results: In the first study, mice were awake for most of the first 1h period (98.6±1.9%) after being transferred to dirty cages. During the following three hours, mice placed in dirty cage versus clean cage exhibited high percentages of time spent in wakefulness (second hour, 78.6±10.8% vs. 25.9±6.9%; third hour, 47.6±16.2% vs. 35.6±8.3%; fourth hour, 38.8±5.7 vs. 20.7±5.3). In the second study, IP CNO versus saline, resulted in a significant decrease of sleep onset latency, decrease of time spent in wakefulness (first hour, 71.4±17.2 vs. 98.4±1.6, second hour, 35.4±9.5**%** vs. 80.4±35.4**%;** third hour, 44.9±13.6% vs. 66.2±19.6**%;** fourth hour, 61.7±14.6 vs. 66.9±16), and increase in non-rapid eye movement (NREM) sleep time (22.4±12.9% vs. 1.6±1.0%; 62.6**%**±8.1 vs. 15.1 ± 10.9**%;** 54.2±13.7% vs. 29.5±17.0**%;** 39.1±15.4 vs. 31.4±10.1). CNO-treated mice exhibited longer episodes of NREM sleep, compared to saline controls (first hour, 131.3±80.4sec vs. 19±1.9sec; second hour, 437.6±85.7sec vs. 77.8±45.4sec; third hour, 467.5±142.8sec vs. 142±82.7sec; fourth hour,

230.3±86.6sec vs. 194±74.9sec).Conclusion: Chemogenetic silencing of CRF neurons in the PVN attenuates acute stress-induced sleep disturbance in mice.

Sch., West Roxbury, MA

Abstract: Understanding the cellular/molecular mechanisms which regulate non-rapid-eye-movement sleep (NREM) delta oscillations (1-4Hz) is of considerable importance due to their association with synaptic homeostasis, cellular energy regulation and clearance of toxic metabolites. Cortical delta-oscillations are generated by intrinsic delta-frequency burst discharge of thalamocortical (TC) neurons whose main inhibitory input is from GABAergic thalamic reticular nucleus (TRN) neurons, the majority of which contain the calcium-binding protein, parvalbumin (PV). TRN-neurons themselves are regulated by extrinsic GABAergic inputs from wake-active neurons acting on alpha3-subunit containing $GABA_A$ receptors ($GABA_AR$). Based on this model, and findings that tonic optogenetic stimulation of TRN-neurons promotes delta-

power, we hypothesize that knockdown of alpha3-GABAAR on TRN-neurons increases NREM-delta.
We used clustered-regularly-interspersed-short-palindromic-repeats (CRISPR) gene-editing to selectively knock-down (KD) alpha-3 GABAARs in a region-specific (TRN) and cell-type specific (GABA-PV) manner in vivo. An adeno-associated viral (AAV) vector encoding three single-guide-RNAs targeting the alpha-3 subunit was injected into TRN of PV-Cre/Cas9 transgenic mice, to disrupt local expression of synaptic $GABA_A$Rs, in TRN-PV neurons. We measured electroencephalography (EEG) and electromyography to determine NREM, REM and wakefulness in freely moving mice before and after AAV induced CRISPR-Cas9 mediated KD of alpha-3 subunits locally in TRN. We validated the effectiveness of the KD by in vitro recordings of inhibitory post synaptic currents.
In the light period, NREM time was increased (9.9±1.7%, p=0.001) with longer bouts (22%±8.7, p=0.02) in mice (N=5) after alpha-3 KD in TRN-PV neurons. Normalized delta-power was higher (light-period:43.9±31.01%, p=0.05, dark-period:38.7±17, p=0.02) after alpha-3 KD in TRN-PV neurons. sIPSCs frequency was reduced in alpha-3 KD TRN-PV-neurons (1.01±0.53, N=5) vs. control PV-tdTomato-neurons (3.47±0.75, N=6, p=0.03).
This is the first use of cell-type and brain-region localized CRISPR-Cas9 technology to study sleep or EEG in vivo. Our data suggests that in the absence of alpha-3-$GABA_A$Rs the TRN-PV neuronal activity is upregulated, leading to the potentiation of NREM sleep and delta activity. This might explain how hypnotics which potentiate alpha-3-$GABA_A$Rs suppress delta-oscillations while promoting sleep.

Title: Circuit deconstruction of the arousal-promoting ventral lateral hypothalamic GABA neurons

Authors: *A. VENNER[1,2], R. DELUCA[1,2], E. ARRIGONI[1,2], P. M. FULLER[1,2]
[1]Dept. of Neurol., Harvard Med. Sch., Boston, MA; [2]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: The inhibitory GABAergic neurons of the ventral lateral hypothalamus (vLH^{GABA} neurons) have recently been characterized as potently wake-promoting. Here, we utilize a battery of molecular-genetic techniques to characterize the inputs to this cellular population, uncover the downstream effector pathways through which these neurons promote wakefulness and determine under what physiological conditions these neurons are activated *in vivo*. We first employed the VGAT-cre mouse line, in combination with stereotaxically injected cre-dependent viral vectors, to gain genetic access to vLH^{GABA} neurons. For conditional retrograde tracing, we injected the helper viruses, AAV8-EF1α-FLEX-TVA-mCherry and AAV8-CAG-FLEX-RG, then 4 weeks later injected the pseudoyped modified rabies virus (EnvA-ΔG-eGFP) into the vLH. Intriguingly, retrogradely labelled eGFP-containing neurons from the vLH were found in brain areas involved in arousal state control (the ventrolateral preoptic nucleus (VLPO), supramammillary nucleus) and stress (paraventricular nucleus of the hypothalamus, amygdala and bed nucleus of the stria terminalis). To determine through what effector pathways vLH^{GABA} neurons elicit arousal we injected AAV10-FLEX-ChR2-eYFP unilaterally into the vLH of VGAT-cre mice and implanted optical fibers over the ipsilateral lateral preoptic area (LPO). During sleep, we delivered 473 nm light via the optical fibre while monitoring electroencephalogram/electromyogram (EEG/EMG) activity to determine arousal state. Optogenetic stimulation of vLH^{GABA} terminals in the LPO induced rapid transitions to wake from NREM sleep, but not from REM sleep. Functional connectivity between vLH GABA neurons and putative sleep-promoting galaninergic neurons in the VLPO was confirmed using ChR2-assisted circuit mapping combined with single cell PCR from recorded neurons. We next expressed the genetically-encoded fluorescent Ca^{2+} indicator, GCaMP6s (AAV10-hSyn-FLEX-GCaMP6s) in vLH^{GABA} neurons and surgically implanted these mice with an optical fibre directed immediately above vLH^{GABA} axons terminals in the LPO. The population Ca^{2+} signal from vLH^{GABA} terminals in the LPO and EEG/EMG activity were acquired simultaneously over multiple sleep-wake cycles. Surprisingly, increases in Ca^{2+} activity did not precede transitions to wake although Ca^{2+} activity during wake was high and progressively decreased as mice transitioned into NREM and REM sleep. Together the data suggest a role for vLH^{GABA} neurons in promoting arousal under behaviorally relevant conditions (for example, stress), through their inhibition of galaninergic neurons in the sleep-promoting VLPO.

Title: Synaptic regulation of dorsal raphe neurons by prefrontal cortex in narcoleptic mice

Authors: *N. E. MOLINA, E. A. BERRY, M. ISHIBASHI, C. S. LEONARD
Physiol., New York Med. Col., Valhalla, NY

Abstract: Narcolepsy is a sleep disorder that is characterized by excessive daytime sleepiness, fragmented sleep-wake states and bouts of cataplexy. The disorder results from the loss of orexin/hypocretin (OX) neuropeptide neurons in the lateral hypothalamus (LH) and this phenotype is reproduced in animals by the loss of OX signaling. Serotonergic dorsal raphe (5-HT DR) neurons, which receive excitatory input from LH OX neurons, regulate numerous brain functions including sleep-wake states, circadian phase, reward and mood. Recent findings suggest 5-HT DR neurons also play a key role in suppressing cataplexy, since re-expression of OX receptors (OXR) in 5-HT DR neurons of narcoleptic OXR-null mice rescues the cataplexy component of narcolepsy. 5-HT DR neurons project to several regions involved in regulating emotional responses and cataplexy including the amygdala (AMG) and prefrontal cortex (PFC). PFC neurons project to numerous areas, including the AMG, LH, and DR; but it is not known whether PFC synaptic inputs to these areas are altered in narcolepsy or whether these inputs regulate the expression of cataplexy. We have begun investigating PFC inputs to the DR, where we hypothesize that activation of PFC inputs to DR will increase cataplexy in OX-null mice by decreasing 5-HT neuron outflow to the AMG. To test this using an optogenetic approach, we are expressing light-activated ion channels (Chronos) in PFC neurons, which enables optical excitation of their synaptic terminals in the DR. Injections of AAV-Chronos-GFP into PFC produced robust expression in prelimbic, infralimbic and anterior cingulate cortex that resulted in extensive terminal labeling in the DR and other expected areas. In brain slice experiments, we confirmed that optical stimulation of PFC terminals produces monosynaptic EPSCs and di-synaptic IPSCs in both putative 5-HT and GABA DR neurons. Moreover, preliminary findings indicate monosynaptic EPSCs in DR neurons from Ox-null mice are smaller in amplitude compared with EPSCs in WT controls. In behavioral experiments, we have begun examining the effect of PFC terminal stimulation in the DR in WT and OX-null mice on open field locomotion and anxiety-behaviors and reward encoding, using marble burying and conditioned place preference paradigms. We are also studying stimulation effects on bout frequency and duration

of cataplexy-like events. Preliminary findings suggest that PFC terminal stimulation in DR has no effect on mouse locomotion and may increase bouts of immobility in narcoleptic mice. Collectively, these finding suggest that PFC input to DR is an important node regulating emotion-linked behaviors.

Title: Estradiol action modulates adenosinergic sleep pressure

Authors: *P. C. SMITH[1], S. VIECHWEG[2], S. BUCK[2], A. POCIVAVSEK[3], J. A. MONG[2]
[1]Univ. of Maryland SOM, Ellicott City, MD; [3]Maryland Psychiatric Res. Center, Dept of Psychiatry, [2]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Primary sleep disorders are among the most common medical conditions, and clinical data show women are far more likely to experience sleep disorders over their lifespan. This increased risk emerges at puberty and has been associated with fluctuations in ovarian steroids, particularly estrogens such as estradiol (E2), suggesting that gonadal steroids and biological sex are significant risk factors for sleep disruptions. Using adult female Sprague-Dawley rats, studies consistently demonstrate that sleep time is significantly reduced when endogenous ovarian steroids or exogenous E2 are elevated in females. This effect is mediated through the inhibition of sleep-active neurons in the median preoptic nucleus (MnPN). Moreover, E2 is capable of marked suppression of sleep under sleep deprivation, when homeostatic sleep need, also known as sleep pressure, is increased. The nucleoside adenosine is a known mediator of sleep pressure, with established actions at the MnPN and a closely related (but non-E2 sensitive) nucleus, the ventral lateral preoptic (VLPO). We thus employed female rats to test the hypothesis that E2 attenuates the ability of adenosine signaling to stimulate sleep behavior. Our data show that E2 attenuates the action of adenosine signaling at the sleep-promoting A2A receptor, resulting in reduced sleep duration. Female animals were oophorectomized and implanted with a pump containing controlled-release E2 (at a low dose calculated to mimic overall average E2 load, rather than peak proestrus levels) or oil vehicle. One week later, animals received injections of 24nmol of the adenosine 2A receptor agonist CGS21680, a dose shown sufficient to induce additional sleep in male animals, or DMSO vehicle, with animals receiving the opposite

treatment three days later. Sleep behavior was then analyzed for six hours following each injection. In the oil treated animals, the infusion of agonist led to a decrease in wake time as expected. The lower-dose E2 infusion did not decrease wake time on its own. However, in the E2 group, the effect of the agonist on wake time was significantly attenuated ($p<.04$). These data suggest that there is an interplay between estrogen and adenosine which modulates the ability of adenosine to generate sleep pressure, and thus the effect of E2 on wake may be mediated through the adenosinergic system.

Title: Effect of suvorexant on sleep in rats exposed to chronic intermittent ethanol vapor and protracted withdrawal

Authors: *M. SANCHEZ-ALAVEZ, J. BENEDICT, D. N. WILLS, C. L. EHLERS
Neurosci., Scripps Res. Inst., LA Jolla, CA

Abstract: Insomnia is a prominent complaint of alcoholic patients, that can fail to resolve over the course of recovery, and is a leading cause of their relapse to drinking. Despite the importance of sleep in the maintenance of sobriety, treatment options for sleep disturbance in recovering alcoholic patients are currently limited. Literature supports a prominent role of the hypothalamic peptide hypocretin/orexin (Hct/OX) system as a master regulator of the sleep wake cycle. The objective of the present study was to evaluate the effects of suvorexant, a selective, dual Hct/OX receptor antagonist, on chronic ethanol-induced sleep pathology in an animal model. Methods: 44 adult Wistar rats were exposed to 8 weeks of chronic intermittent ethanol [CIE] vapor or control conditions and then withdrawn (blood ethanol [EtOH] concentrations averaged 182.3 ± 6.9 mg/dl). Five hours of sleep electroencephalograms were collected and evaluated at baseline prior to CIE exposure and 24 hours following EtOH withdrawal. Four weeks following EtOH withdrawal, the effects of vehicle and 2 doses of suvorexant (10, 30 mg/kg) on sleep EEGs were evaluated. Results: CIE exposure in the rat was found to reduce the mean duration of SWS episodes 24 hours following EtOH withdrawal as compared to controls ($F=16.7$, $p<0.001$). Band power significantly decreased in delta (1-4 Hz, $F=8.0$, $p=0.008$) and increased in beta (16-32 Hz, $F=4.2$, $p=0.05$) in the parietal cortex and increased in the beta in the frontal cortex ($F=5.9$,

p=0.02) following EtOH withdrawal, as compared to baseline. Four weeks following EtOH withdrawal, during the vehicle treatment, the mean duration of SWS in the EtOH exposed group was found to be no different from the controls. However band power significantly increased in delta in the frontal cortex in the ethanol exposed animals (F=4.1, p=0.05). Administration of suvorexant produced a significant reduction in the latency to, and mean duration of SWS, in both the EtOH exposed and control groups. Additionally, in the EtOH exposed group, the 30 mg/kg dose of suvorexant was found to produce a significant increase in the number of SWS episodes (F=6.2, p=0.018) with no significant effects seen on SWS duration. In addition, both the 10 and 30 mg/kg suvorexant dose were found to reduce delta power in the frontal cortex, when compared to controls, in the EtOH exposed group. Conclusions: Taken together, these studies suggest that an hypocretin/orexin receptor antagonist, suvorexant, has overall sleep-promoting effects, and it can also reverse some aspects of alcohol-induced sleep and EEG pathology.

Title: Intermittent hypoxia induces a fate switch in hippocampal neuroprogenitor cells

Authors: *S. SULLERE[1], T. NALLAMOTHU[3], M. A. KHUU[3], A. J. GARCIA, III[2]
[1]Committee on Neurobio., [2]Emergency Med., The Univ. of Chicago, Chicago, IL; [3]Univ. of Chicago, Chicago, IL

Abstract: Patients with sleep apnea commonly experience intermittent hypoxia (IH) and exhibit cognitive decline that coincides with changes in the hippocampal formation. However, the basis for these IH-related changes remains poorly defined. The subgranular zone of the hippocampus is a well-established site for adult neurogenesis—a process hypothesized to support the physiology of this brain structure. Our study uses a mouse model to investigate how IH affects hippocampal adult neurogenesis. Immunohistological analysis indicates that IH stimulates the proliferation of $SOX2^+$ progenitor cells. This coincides with an increase in the number of $SOX2^+$ cells residing in hypoxic niches of the subgranular zone. However, IH reduces the proportion of granule neurons produced by adult neurogenesis. Preliminary experiments suggest that the reduction in neuronal number is due to asymmetric division of neuroprogenitor cells favoring the generation of the Type-β cell phenotype ($SOX2^+/S100\beta^+$) over the Type-α cell phenotype

($SOX2^+/S100\beta^-$). We are currently investigating the potential mechanistic role that IH-dependent HIF1α signaling plays in mediating this fate switch. Our findings suggest that IH may have a diminishing effect on the multipotent neuroprogenitor population contributing to the pathophysiology associated with sleep apnea.

Title: changes in human salivary proteome after six hours of sleep deprivation at night

Authors: *A. A. BJORKUM[1], I. FRICH MELING[1,2], B. KLUGE[2], K. ROSENDAHL[3]
[1]Dept. of Biomed. Lab. Sci. Chem. Engineering, Fac. of En, Western Norway Univ. of Applied Sci., Bergen, Norway; [2]Med. Res. Ctr., [3]Dept. of Radiology, Paediatric section, Haukeland Univ. Hosp., Univ. of Bergen, Bergen, Norway

Abstract: Sleep deprivation (SD) might lead to cellular stress. We subjected humans (n=11) to 6 hours of SD from 22h until 4h in the morning and sampled saliva during a 48h period day and night. Saliva samples was collected after approved protocols and informed consent. A label-free Velos Orbitrap Pro mass spectrometer (LC-MS/MS) was used to analyse the samples. The differently expressed proteins has been analysed using systems biological databases as MetaCore, QuickGO and WebGestalt to discover the changed processes, biological pathways and networks.
Earlier we analysed saliva with a sIgA-kit (Salimetrics) and found a reduction after 3 h of SD also the levels of alpha-amylase (Salimetrics) was found reduced after 6 h of SD.
Out of the 222 identified proteins, 7 proteins were upregulated. These differently expressed proteins after 6 h SD were BPI fold-containing family A member 2 (BPIA2 and Q96DR5, Protein name and SwissProt ID respectively), Carbonic anhydrase 6 (CAH6 and P23280), Cystatin-D (CYTD and P28325), Metalloproteinase inhibitor 1 (TIMP1 and P01033), Cystatin-S (CYTS and P01036), Cystatin-SA (P09228 and CYTT) and SPARC-like protein 1 (SPRL1 and Q14515). These proteins where analysed by QuickGO and classified into three main categories, biological process, molecular function and subcellular localization. «Interactome»-analysis («Interactions by protein function») and enrichment»-analysis was done in MetaCore to look for affected Process Networks and Pathway Maps. The BPIAT2 protein plays a part in hospital infections by inhibitory effect on the growth of *Pseudomonas aeruginosa* also known to play a part in serious hospital infections (Prokopovic et al. 2014 and Schøyen, Josephsen, 2011). Others have also found changes in alpha-amylase after sleep deprivation (Seugnet et al. 2006, Thimgan

et al. 2011, Wilson and Wright 2014).
Preliminary findings of the salivary changed proteome profile indicate compromised immune system and a reduction in cell repair and regeneration after 6 h of SD at night.

Abstract: Overweight and obesity has become one of the most serious global health issues due to the high rates of prevalence that presents in different populations. It has been described that the unbalanced diet with high caloric content, genetic factors and decreased physical activity are the main associated factors. However, it has been shown that sleep plays a fundamental role in the endocrine regulation of the hormones involved in lipid and glucose metabolism. Several studies have proposed that a reduction in the total sleep time (TST) is a risk factor for the development of overweight and obesity. However, little is known about the physiological and molecular mechanisms that could be involved in this alteration. It has been suggested that a Peroxisome Proliferator Active Receptors (PPARs) is involved with circadian clock control, manly in the regulation of homeostasis and sleep architecture such as metabolism of lipids and glucose. The aim of the present study was to investigate associations between TST and mRNA expression levels of PPAR alpha and gamma, in the population with the normal weight, overweight and with obesity. For the analysis of molecular parameters (qPCR), a blood sample was taken. For these purpose, 90 participants of Universidad Veracruzana (18-25 years) participated. The study was conducted in according to standards established by the declaration of

Helsinki as well as their applied the informed consent. All subjects completed a questionnaire Pittsburgh scale for measuring the quality and quantity of sleep. Results showed that subjects who have a reduced sleep time (less 7 hours) increase body mass index (Pearson's correlation r = -.222 P = .162) compared to those who have adequate sleep time (more 7 hours). On the other hand, the analysis of body mass index showed a positive and statistically significant association with the parameters of body fat percentage (r = .377, P = .015), hip waist ratio (r = .771, P = .000) and visceral fat level (r = 709, *P* = .0001) with TST. Gene expression no showed differences in the levels of both genes in the groups with decreased sleep. In conclusion It is necessary more studies to analyze the relation between TST and circadian gene expression with overweight and obesity.

Title: Redundant control of water intake by type-1 cannabinoid receptors

Authors: *Z. ZHAO[1,2], E. SORIA[1,2], M. VARILH[1,2], A. DUVEAU[1,2], A. CASTIGLIONE[1,2], A. CANNICH[1,2], L. BELLOCCHIO[1,2], A. BUSQUETS-GARCIA[1,2], G. MARSICANO[1,2]
[1]INSERM 1215, Bordeaux cedex, France; [2]Univ. of Bordeaux, Bordeaux, France

Abstract: The cannabinoid receptor type-1 (CB1) is a G protein-coupled receptor abundantly expressed in different cell types of the central and peripheral nervous system. It is mainly a presynaptic receptor, which is activated by exogenous cannabinoids and endogenous lipid-based retrograde neurotransmitters. Stimulation of CB1 causes the inhibition of synaptic transmission and contributes to the regulation of a variety of brain functions (e.g. memory, learning, analgesia, feeding etc.). However, the role of CB1 in the control of water intake and the underlying mechanisms are scantly known. Several brain regions known to be involved in the regulation of drinking behavior contain CB1 mRNA expression. Therefore, we hypothesize that CB1 is involved in drinking behavior by regulating specific brain circuits. We found that constitutive genetic deletion and systemic pharmacological blockade of CB1 decreases water intake in different experimental conditions. Interestingly, using genetic deletion and rescue approaches,

we observed that conditional deletion of CB1 in several brain cell types does not impact water intake. However, specific genetic re-expression of CB1 in cortical glutamatergic neurons or in the anterior cingulate cortex fully rescues drinking behavior in mice lacking the CB1 protein elsewhere. These data indicate that general CB1 signaling is necessary and sufficient to promote water intake. CB1 expression in cortical glutamatergic neurons plays a sufficient but not necessary role in controlling water intake. These results strongly indicate that CB1 receptor signaling is redundantly involved in water intake in mice. Currently performed experiments aim at identifying additional brain regions and cell types where CB1 receptors contribute to the central regulation of water intake.

Abstract: Astrocytes uptake glucose from brain blood circulation to produce usable energetic substrates, thereby determining neuronal activity and neurotransmitter signaling. In turn, astrocytes respond to neurotransmitters through specific receptors. However, whether activation

of astroglial neurotransmitter receptors can directly regulate cellular glucose metabolism to eventually modulate behavioral responses is not known. Here, we show that specific activation of type-1 cannabinoid receptors located in astroglial mitochondria ($mtCB_1$) impairs social behavior by altering brain glucose and lactate metabolism. By modulation of the phosphorylation of specific Complex I subunits, activation of astroglial $mtCB_1$ receptors inhibits stability and activity of complex I to attenuate reactive oxygen species levels, leading to reduced glycolytic lactate production. Conditional deletion of astroglial CB_1 receptors, genetic inhibition of cannabinoid effects on phosphorylation of Complex I subunits and brain lactate supplementation reversed cannabinoid-induced behavioral deficits in mice. These results reveal that mitochondrial neurotransmitter receptor signaling can directly regulate brain glucose metabolism to modulate high order behavioral responses.

Title: The endocannabinoid system controls olfactory processes in the anterior Piriform Cortex

Authors: *G. TERRAL[1], M. VARILH[1], A. CANNICH[1], L. BELLOCCHIO[1], A. PANATIER[1], F. MASSA[1], E. SORIA-GOMEZ[1], A. BUSQUETS-GARCIA[1], G. FERREIRA[2], G. MARSICANO[1]

Abstract: The ability to perceive and retrieve sensory information is crucial for survival and appropriate behavioral responses. In particular, olfactory perception regulates many behavioral functions in animals and human.
However, the mechanisms behind the modulation of integrative olfactory processing such as odor perception and odor memory are not fully understood. Here, we show that type-1 cannabinoid receptors (CB1) in the anterior Piriform Cortex (aPC) regulate olfactory processes

by modulating synaptic transmission and plasticity. By combining immunostaining and double fluorescent *in situ* hybridation, we observed that CB1 receptors are mainly expressed in GABAergic interneurons projecting to the principal neurons layer of the aPC. Local injections of the CB1 receptor antagonist AM251 into the aPC improved odor perception by increasing odor detection but impaired odor retrieval of odor-dependent memory. *Ex vivo* whole-cell patch clamp experiments of principal neurons revealed that CB1 receptor agonists reduce GABAergic transmission and that a layer-dependent endocannabinoid-ediated long-term plasticity exists in the aPC. These findings show that the endocannabinoid system is present in the aPC, where its physiological activation is involved in the control of inhibitory synaptic transmission and plasticity, eventually modulating olfactory sensory processing and memory.

Title: Role of the endocannabinoid system in wheel-running preference/motivation

Authors: *B. REDON[1,2], C. MUGURUZA[1,2,3], G. MARSICANO[1,2], F. CHAOULOFF[1,2]
[1]Neurocentre Magendie, INSERM U1215, BORDEAUX CEDEX, France; [2]Univ. de Bordeaux, Bordeaux, France; [3]Dept. of Pharmacol., Univ. of the Basque Country UPV/EHU, Leioa, Bizkaia, Spain

Abstract: Sedentarity and physical inactivity rest mainly on the lack of intrinsic motivation to engage and persist in physical exercise. The identification of the neurobiological bases of exercise motivation is thus mandatory to improve health. Based on wheel-running performance and/or after-running conditioned preference tests, animal studies have suggested candidate systems, among which the opiate, the leptin and the endocannabinoid system. However, none of these studies has been able (i) to provide direct evidence for their role in running motivation, and (ii) to discriminate between the different dimensions of such a process, i.e. appetitive motivation and consummatory motivation. The goal of this study was to examine the role of the main cannabinoid receptor in the brain, namely type-1 (CB1) receptor, on wheel-running motivation. We thus used CB1 receptor mouse mutants and CB1 receptor antagonist/agonist and examined their respective influences on the behaviors of mice tested in a T-maze while choosing between

one free running wheel and one locked running wheel located at two extremities of the maze. Pretreatment with the CB1 receptor antagonist/inverse agonist SR141716 decreased the preference for the free wheel over the locked wheel, the running duration per sequence and the number of entries into the free wheels, doing so without affecting total arm entries, an index of locomotion. Pretreatment with the main psychoactive component of cannabis, namely delta9-tetrahydrocannabinol, a CB1/CB2 receptor agonist, did not alter the preference for the free wheel. Full deletion of CB1 receptors promoted behavioral changes similar to those measured after SR141716 administration, including an increase in the initial latency to run. These results show that CB1 receptors exert a tonic control on the preference/motivation for wheel-running. In order to further define the role of CB1 receptors on running motivation, on-going experiments test constitutive and conditional CB1 receptor mutants on the behaviors of mice undergoing an operant conditioning procedure where wheel-running is used as a positive reinforcer.

Title: Exercise-induced activation of the hypothalamic-pituitary-adrenal axis in male and female rats

Authors: *J. DAVIS, J. JAIME, M. K. TANNER, E. C. LOETZ, R. M. FORIGHT, B. N. GREENWOOD
Psychology, Univ. of Colorado Denver, Denver, CO

Abstract: Chronic exercise can produce resistance against the deleterious effects of future non-exercise stressors on mental and physical health, including attenuation of the hypothalamic-pituitary-adrenal-axis (HPA) response to mild stressors. Exercise can constrain the HPA response to future stressors despite itself recruiting neuroendocrine components of the stress response. In male rats, the HPA response to acute bouts of voluntary exercise quickly habituates during repeated daily exercise. This habituation of the HPA response to chronic exercise in males could generalize to non-exercise stressors, a phenomenon known as cross-stressor habituation. Female rats typically have exaggerated HPA responses to non-exercise stressors, but the HPA response to chronic voluntary exercise has not been characterized in females. Adult, male and female, Long-Evans rats were housed with either locked or mobile running wheels for

4 days or 4 weeks. Estrus phase was monitored daily by vaginal lavage and males were handled for an equivalent period of time. After either 4 days or 4 weeks, thymus, adrenals, spleen and trunk blood were collected 30 min after the start of the active (dark) cycle, during which time rats with mobile wheels were allowed voluntarily access to their wheels. Running distance was observed to be sexually dimorphic. Females ran more than males regardless of estrus phase, but females ran the greatest distance during pro-estrus compared to other phases of the estrus cycle. There was no effect of exercise on organ weights in either males or females. Corticosterone is currently being analyzed with ELISA. Results will indicate whether the HPA response to acute and chronic exercise differs between the sexes.

Title: Sex- and duration- dependent neural circuit control of voluntary exercise behavior

Authors: *M. K. TANNER[1], N. HADDAD[3], J. JAIME[2], J. K. P. DAVIS[2], E. C. LOETZ[2], N. A. MOYA[2], B. N. GREENWOOD[2]

Abstract: Despite the ability of exercise to increase resistance against stress-related psychiatric disorders, participation in regular exercise is decreasing. Identifying the neural circuits that control exercise could lead to novel strategies to promote exercise participation, as well as reveal mechanisms underlying exercise-induced stress resistance. Rats given running wheels demonstrate robust voluntary exercise behavior that follows distinct phases of acquisition, during which wheel running escalates, and maintenance, during which nightly running reaches a steady state. Although dopamine (DA) and the dorsal striatum are critical for movement, the specific DA-striatal circuits used to control the phases of voluntary exercise are unknown. The goal of the current studies was to identify the DA-striatal circuits controlling exercise in adult, male and female, Long-Evans rats. In males, exercise during the acquisition phase recruits midbrain DA neurons projecting to the dorsomedial striatum (DMS), a region important for goal-directed learning. Once in the maintenance phase; however, an acute bout of running no longer recruits DMS-projecting midbrain DA neurons. Even so, chronic exercise produces neural adaptations in

the DMS consistent with stress-resistance and a hyperdopaminergic state. These changes are not observed in the dorsolateral striatum (DLS), a region supporting habitual behavior. Temporary inactivation of the DMS reduces voluntary exercise during the acquisition phase, but not the maintenance phase. In contrast, whereas temporary inactivation of the DLS has no effect on running during the acquisition phase, DLS inactivation reduces running during the maintenance phase, suggesting that wheel running becomes habitual during the maintenance phase. Together, these data suggest that "goal-directed" DA-DMS circuits control the acquisition of voluntary exercise and plasticity in this circuit could contribute to exercise-induced stress resistance, which is robust in males. In contrast, females acquire wheel running behavior faster than males and run more than males, regardless of estrous stage. This rapid acquisition of exercise resembles the more rapid development of other habitual behaviors, such as drug taking, in females relative to males. Although adaptations in response to exercise in DMS and DLS circuits have not been characterized in females, these data suggest that females rely on the habit DA-DLS circuit to control exercise. We are currently assessing the roles of the DMS and DLS to control the acquisition and maintenance of exercise in females.

Title: Lesions of ventrolateral striatum eliminates lose-shift but not win-stay behaviour in rats

Authors: *R. THAPA[1], A. J. GRUBER[2]
[2]Neurosci., [1]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Animals tend to repeat actions that are associated with reward delivery, whereas they tend to shift responses to alternate choices following reward omission. These so-called win-stay and lose-shift responses are employed by a wide range of animals in a variety of decision-making scenarios, and these proximal effects of reinforcement often overshadow optimal actions based on the utility of choice options. These response strategies depend on dissociated regions of the striatum. Specifically, lose-shift responding is impaired by extensive excitotoxic lesions of the lateral striatum. Here we used focal lesions to assess whether dorsal and ventral regions of the lateral striatum contribute differently to this effect. We found that damage to ventrolateral striatum reduced lose-shift responding without impairing win-stay, motoric, or motivational

aspects of behaviour in the task, whereas lesions confined to the dorsolateral striatum significantly impaired the ability of rats to complete trials of the task. Moreover, lesions to the dorsomedial striatum had no effect on either lose-shift or win-stay responding. Together, these data suggest a novel role of the ventral portion of the lateral striatum in driving lose-shift decisions.

Title: Identifying the threshold of habitual responding in female long evans rats

Authors: *H. SCHOENBERG, E. X. SOLA, C. WINN, D. J. TOUFEXIS
Psychological Sci., Univ. of Vermont, Burlington, VT

Abstract: Our previous results show that although male rats are sensitive to lithium chloride-induced reward-devaluation after 240 reinforcer-outcome pairings, devalued female rats continue to respond like non-devalued control females at this same level of training. Thus, females exhibit an earlier onset of habitual responding than do males. In order to further investigate the mechanisms controlling habit formation in both sexes, it is first necessary to identify the narrow range of training within which male and female rats transition from goal-directed to habitual behavior. Identifying this threshold range will allow us to test a variety of manipulations that might accelerate or attenuate the progression from goal-directed to habitual behavior and how these may differ due to sex. To begin this endeavor, we trained female rats on a variable interval 30-s schedule to nose-poke for sucrose with decreasing response-reinforcer pairings starting at 200 reinforcer exposures. We found that female rats show habitual behavior down to 140 response-reinforcer pairings, but remain goal-directed at 120 reinforcer pairings. Thus, the habit-threshold range in females is between these two levels of reinforcer exposure. Based on this information we are currently using viral vectors to selectively enhance activation of particular pathways within the habit-mediating portion of the basal ganglia, the dorsolateral striatum (DLS), in female rats. Data is as of yet inconclusive, however we hypothesize that enhanced activation of the direct pathway at the habit sub-threshold range of 120 reinforcer pairings will accelerate habit formation, and enhanced indirect pathway activation will offset the development of habitual behavior at the habit super-threshold level of 150 reinforcers.

Title: Stress recruits dopamine in the ventrolateral striatum to promote goal-directed behaviors

Authors: *C. STELLY[1], G. HAUG[2], Y. RAFATI[2], M. WANAT[2]
[1]Neurosciences Inst., Univ. of Texas At San Antonio, San Antonio, TX; [2]Univ. of Texas at San Antonio, San Antonio, TX

Abstract: The mesolimbic dopamine system is a critical locus for controlling motivated behavior. Behavioral studies examining dopamine's role in the ventral striatum have largely focused on dopamine's action in the ventral medial striatum (VMS), while neglecting the contribution of dopamine transmission in the ventral lateral striatum (VLS). The dopamine neurons projecting to the VLS undergo rapid changes in excitatory synaptic strength after exposure to stress, suggesting the VLS dopamine projection could mediate the influence of stress on motivated behavior. Here, we utilized fast-scanning cyclic voltammetry to monitor dopamine release in the VMS and VLS. We found that a single exposure to acute stress elicited a persistent enhancement in conditioned responding toward food-paired cues, which was mediated by an elevated cue-evoked dopamine response in the VLS. Using a negative reinforcement behavioral paradigm, our preliminary data suggests the VMS dopamine response reflects the negative valence of stress-predictive cues, whereas the VLS dopamine response reflects the salience of these cues. These findings suggest that dopamine in the VLS confers enhanced cue reactivity during and after stressful circumstances. Therefore, the dopamine projection to the VLS could be a putative site of dysfunction in stress-associated pathologies such as post-traumatic stress disorder and depression.

Title: Neuronal correlates of reward vs. fear memory discrimination in the prelimbic cortex

Authors: *J. A. FERNANDEZ-LEON, D. S. ENGELKE, M. NAIM-RASHEED, A. B. TERZIAN, F. H. DO MONTE
Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr., Houston, TX

Abstract: The brain ability to identify and discriminate cues associated with reward and aversive stimuli allows an organism to select the most appropriate response. Neurons in the prelimbic prefrontal cortex (PL) can discriminate between cues that anticipate imminent rewards and threats, implicating this region in decision-making under states of certainty. Because PL neurons are critical for the retrieval of reward and fear-associated memories, we speculated that these neurons would also discriminate reward and fear cues under states of uncertainty, when decision-making depends entirely on the associated memories. To address this question, male Long-Evans rats previously implanted with single-unit recording electrodes in PL were trained to learn that each lever press during a cue tone delivered a sucrose pellet in a nearby dish. After training, animals were fear conditioned by pairing a neutral odor with electrical foot shocks. Rats were then tested in a rectangular arena (60cm x 26cm x 40cm) comprising two different zones: a hidden zone and a foraging zone where the lever and the dish were located. The test session was separated in three different phases: only tone cues (reward), only odor cues (fear), or both at the same time (decision-making). To search for food during the decision-making phase, animals had to leave the hidden zone and confront the conditioned odor presented in the foraging zone. During the reward phase, animals pressed the lever in 95% of the tone cue presentations with an average latency to press of 5.3s. During the fear phase, animals showed stronger defensive behaviors characterized by a reduction in time exploring the foraging zone (17% vs. 62% in the reward phase, $p<0.001$) and an increase in time spent in the hidden zone (77% vs. 35% in the reward phase, $p=0.001$). During the decision-making phase, animals showed 66% of reduction in lever presses, with an increase of 49% in the average latency to press. Recordings from PL neurons during the reward phase revealed two distinct populations of responsive neurons that changed their firing rates during the tone cues (Z-score > 2.54 for excitatory and < -1.96 for inhibitory responses, first bin of 300ms). Neurons showing excitatory tone responses during the reward phase continued to respond during the decision-making phase. Interestingly, neurons showing inhibitory tone responses during the reward phase did not respond to the cues during the decision-making phase. Together, our findings suggest that PL inhibitory responses to reward cues are involved in action selection during competing behavioral alternatives (searching for food vs. avoiding potential threats) that depend on previously associated memories.

Title: Balancing food seeking with the risk of predation recruits the paraventricular thalamus

Authors: *D. S. ENGELKE, J. A. FERNANDEZ-LEON, A. L. TERZIAN, M. NAIM-RASHEED, F. H. DO MONTE
Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr., Houston, TX

Abstract: The ability to survive in nature depends on a balance between foraging and the risk of being attacked by a predator. Although the brain mechanisms modulating food seeking and fear have been extensively studied apart, it remains unknown which neural circuits integrate both behaviors. Neurons in the paraventricular thalamus (PVT) change their activities during the presentation of both food and fear-associated cues, making this region a strong candidate to regulate reward and fear responses. To investigate whether PVT is involved in the competition between fear and food-seeking behavior, male and female Long-Evans adult rats were initially trained to press a bar for sucrose in the presence of cues (reward cues). Cat saliva was used to induce innate fear responses (predator odor). Rats exposed to predator odor alone showed stronger defensive behaviors characterized by increased freezing and avoidance responses, when compared to neutral odor controls (Freezing, neutral= 1.8% vs. predator odor= 38.1%, $p<0.001$; Avoidance, neutral= 36.5% vs. predator odor= 75.7%, p= 0.007, Unpaired *Student's* t-test). Predator odor exposure also increased the expression of the neural activity marker cFos in the anterior portion of PVT (aPVT), when compared to neutral odor (neutral= 59.7 cells/mm^2 vs. predator odor= 102cells/mm^2, p= 0.039). Single-unit recordings from aPVT neurons revealed two distinct populations of neurons that changed their firing rate in response to either predator odor or reward cues, compared to baseline (Z-score > 2.54 for excitatory and < -1.96 for inhibitory responses). During a competition test, when predator odor and reward cues were simultaneously presented, excitatory responses observed during the reward cues were abolished. This neuronal change was associated with a dramatic reduction in food-seeking behavior (presses/min: neutral= 19.1 vs. predator odor= 1.5, $p<0.001$). Inactivation of aPVT with the GABA(A) agonist muscimol increased time approaching the food area (Vehicle= 11.36%, Muscimol= 35.19%, p= 0.038) and reduced the percentage of time avoiding the predator odor area during the competition test (Vehicle= 75.6%, Muscimol= 48%, p= 0.04). Notably, inactivation of aPVT had no effect when the predator odor or the food-seeking tasks were carried

out independently. We have previously reported that photoactivation of aPVT induces aversion and food-seeking suppression. Together, the present results suggest that aPVT activity is necessary to balance food seeking in face of an aversive stimulus. We are currently investigating which aPVT projections and cellular subtypes are involved in the integration of reward and fear responses.

Abstract: The paraventricular nucleus of the thalamus (PVT) regulates behavioral responses under emotionally arousing conditions. Photoactivation of anterior PVT (aPVT) neurons abolishes sucrose seeking and induces aversive behaviors in rodents. However, the specific aPVT neuronal subpopulation regulating these functions remains unknown. The stress neuropeptide corticotropin-releasing factor (CRF) has been shown to reduce food intake and induce anxiety-like behavior in different species. Interestingly, a recent neuroanatomical study demonstrated that CRF neurons are present in the aPVT, but their physiological functions have never been explored. To assess the role of aPVT-CRF neurons during sucrose seeking, adult male Long-Evans rats were infused with a mixture of viral vectors (AAV-CRF-Cre and AAV-

ChR2-DIO-eYFP) to express channelrhodopsin in aPVT-CRF neurons. Animals were trained in a reward conditioning task, where each bar press during a 30s cue tone delivered a sugar pellet in a nearby dish. High-frequency photoactivation of aPVT CRF neurons (20 Hz, 5ms pulse width, 10 mW) during the cue tone reduced bar presses when compared to the eYFP-Control group (aPVT-CRF-ChR2, presses/min: Laser OFF: 14.5±1.4, Laser ON: 4.2±1.1; eYFP-Control, presses/min: Laser OFF: 17.5±1.1, Laser ON: 18.8±1.2, $p<0.05$). In contrast, 5Hz low-frequency photoactivation of aPVT-CRF neurons had no effect (aPVT-CRF-ChR2, presses/min: Laser OFF: 17.2±0.9, Laser ON: 14.88±1.6, $p=0.20$). Photoactivation of aPVT-CRF neurons also reduced the time spent on the side of the chamber paired with 20Hz laser stimulation in a real-time place preference task, indicating that stimulation of aPVT-CRF neurons is aversive (Laser OFF side: 80.7%, Laser ON side: 19.2%, $p<0.05$). Neuroanatomical investigation of aPVT-CRF efferents revealed dense projections to the nucleus accumbens shell (NAc-shell); moderate projections to the nucleus accumbens core, lateral region of the bed nucleus of the stria terminalis, lateral subnuclei of the central nucleus of the amygdala and suprachiasmatic nucleus; and relatively weak projections to the infralimbic/prelimbic cortex, basolateral nucleus of the amygdala, and medial regions of the hypothalamus. Slice recordings from NAc-shell neurons demonstrated that photoactivation of aPVT-CRF fibers in the NAc-shell elicits large excitatory postsynaptic responses, which are blocked by AMPA and NMDA receptor antagonists. Our results demonstrate the existence of a defined glutamatergic-CRF-expressing subpopulation of neurons in aPVT that is sufficient to mediate anorexigenic and aversive effects in rats.

Title: Predictive coding by neural ensembles in the amygdala

Authors: L. K. QUINN*[1], V. H. MINCES*[1], I. M. RUSSELL[3], *A. A. CHIBA[2]
[1]Cognitive Sci., UCSD, La Jolla, CA; [2]Cognitive Sci. and Program in Neurosci., UCSD, LA Jolla, CA; [3]Sch. of Med., Stanford Univ., Stanford, CA

Abstract: Animals rely on the associative history of stimuli in their environments to guide their choices and to develop a behavioral repertoire that is adaptive to survival. Learning theory asserts that a given stimulus in the environment holds the value of its prior associations, indicating a shared code for the stimulus and its reinforcers. Given its rich interconnectivity with sensory and associative areas of the brain, the amygdala is anatomically situated to play a role in building such associations. To date, a large body of literature supports this view, including studies demonstrating that the same neurons respond to a stimulus and its associated punishment (Baroh et al., 2008; Grewe et al., 2017). We devised a novel associative learning task for rats, in order to assess the neurophysiology of the basolateral amygdala complex (BLA) in associating visual stimuli with specific food punishments or reinforcers, ranging from aversive to highly appetitive. The resultant data demonstrated that, as expected, individual amygdala neurons differentially responded to relevant stimuli (Lego objects) and their outcomes (aversive and appetitive). Additionally, a population-based neural decoder revealed that the network activity in the amygdala can accurately encode sensory stimuli (objects) and outcomes (aversive and appetitive food pellets). Finally, the neural decoder revealed that the population activity during the object presentation accurately predicted the identity of the subsequent outcome. This provides evidence for neurophysiological populations in the amygdala that hold a shared code for a stimulus and its outcome, a theoretical necessity of evaluative conditioning. These findings solidify a role for network properties of the amygdala in coordinating a salience map of the environment, allowing an animal to advantageously interact with the environment.

Title: Amygdala-cortical circuitry in reward-expectation guided behavior

Authors: *N. T. LICHTENBERG[1], L. SEPE-FORREST[1], Z. T. PENNINGTON[1], S. M. HOLLEY[2], V. Y. GREENFIELD[1], C. CEPEDA[2], M. S. LEVINE[2,3], K. M. WASSUM[1,3]

Abstract: Reward-seeking behaviors are heavily influenced by expectations about future potential rewards and their value. These expectations are often generated by using stimuli in the environment to retrieve detailed memories of associated rewards. Little is known about the neural circuits supporting such processes. Using tract tracing, we identified distinct reciprocal connections between the basolateral amygdala (BLA) and both the lateral (lOFC) and medial (mOFC) orbitofrontal cortex subdivisions. Using chemogenetics, we evaluated the unique function of each pathway in expectation-guided behavior. Inactivation of BLA to lOFC projections was found to disrupt the influence of cue-triggered reward expectations over both reward-seeking decisions and adaptive conditional goal-approach responding following a value shift. Inactivation of BL to mOFC disrupted only the latter, leaving cue-directed decision making intact. lOF to BLA projections were found to be unnecessary for either behavior, whereas inactivation of mOFC to BLA projections attenuated the influence of cue-triggered expectations over decisions and adaptive conditional responding. Our working hypothesis, which is undergoing further investigation, is that both lOFC and mOFC to BLA projections enable the retrieval of detailed stimulus-reward memories, whereas BLA to mOFC projections mediate access to the current value of specific cue-predicted rewards. The cognitive symptoms underlying many psychiatric diseases, such as addiction, result from a failure to appropriately anticipate potential future events. These data, therefore, provide insight into potential dysfunction that might underlie these conditions.

Title: An intersectional approach to investigate the roles of central amygdala Htr2a-positive neurons in appetitive behaviors

Authors: *F. FERMANI[1], P. L. ALCALA MORALES[2], R. KLEIN[3]
[1]Max Planck Neurobio., Martinsried, Munich, Germany; [2]Molecules - Signaling - Develop., Max Planck Neurobio., Munich, Germany; [3]Max-Planck Inst. Neurobiol, Martinsried, Germany

Abstract: The amygdala is an integrative brain center for emotions and motivation and plays an essential role in processing both fearful and rewarding environmental stimuli. Recent studies have focused on the role of different amygdala neuron subpopulations in appetitive behaviors. Central amygdala (CeA) protein kinase C delta (PKCδ)-positive neurons were shown to mediate

the anorexigenic effects of malaise and satiety signals, in part via local inhibitory connections within the CeA (Cai et al., Nat. Neurosci., 2014). Other subpopulations within the lateral (CeL) and medial (CeM) subdivisions of the CeA were shown to drive appetitive behaviors in self-stimulation experiments (Kim*, Zhang* et al., Neuron, 2017).
Recently in the lab, a subpopulation of CeA PKCδ-negative neurons that express the serotonin receptor 2a (Htr2a) (Isosaka et al., 2015) was shown to promote feeding and reward-related behaviors (Douglass*, Kucukdereli*, Ponserre*, et al., Nat. Neurosci., 2017). These findings suggest that within the CeA there are genetically-defined GABAergic cell types with functional antagonism that process signals of opposite valence.Taking advantage of intersectional genetic tools we are investigating the specific roles of CeA^{Htr2a} neurons located in either the CeL or CeM subdivisions, in a series of rewarding behaviors.
To do so, we have generated a novel transgenic mouse line that expresses on optimized and Tamoxifen-inducible version of the Flp recombinase under regulatory elements of the Wfs1 gene (*Wfs1-FlpoER* mouse line). In this mouse line FlpoER is expressed specifically in the majority of neurons of the CeL (not CeM). The crossing between *Htr2a-Cre* and *Wfs1-FlpoER* mice generates double transgenic intersectional mice (*Wfs1-FlpoER;Htr2a-Cre*) in which CeL^{Htr2a} cells are positive for both Cre and Flp, while CeM^{Htr2a} cells are positive for Cre only. We are currently independently and functionally manipulating the Htr2a subpopulations of the different CeA subdivisions with the help of specific intersectional viruses, addressing the question of how they independently contribute to the different rewarding behaviors.

Title: A synthetic orexin agonist improves inflammation-induced immobility through activating the medullary raphe nucleus

Authors: *S. UCHIDA, Y. IRUKAYAMA-TOMOBE, Y. OGAWA, T. YAMAGUCHI, Y. ISHIKAWA, K. SAKURAI, S. SOYA, T. SAITO, H. NAGASE, M. YANAGISAWA, T. SAKURAI

Abstract: Hospitalization in an intensive care unit (ICU) can be associated with a perilous functional decline. Patients can develop impairments in mobility, cognition, and ability to perform daily living activity. Immobility due to prolonged bed rest in the ICU play a major role in the development of ICU-acquired weakness. However, there has been no means to evoke early mobilization of patients. Recently, we found peripherally administered orexin rescues mice with endotoxin shock. Furthermore, our group developed a non-peptide orexin type-2 receptor selective agonist, YNT-185, which penetrates through the blood-brain barrier. The purpose of this study is to examine whether an orexin agonist could improve inflammation-induced immobility state in mice. We found that intraperitoneal administration of YNT-185 accelerates horizontal activity and wheel running after LPS challenge in wild type mice, but not in in orexin type-2 receptor knockout mice. This effect is mimicked by ICV injection of orexin, or transgene-driven overexpression of orexin in mice. Immunohistochemistry using anti-Fos antibody suggested that serotonergic neurons in the medullary raphe nucleus are activated after administration of YNT-185 in LPS-challenged mice. By anterograde tracing study, we found that these neurons send projections to the dorsal raphe nuclei, the ventral tegmental area, nucleus of the solitary tract, and the rostral ventrolateral medulla, regions involved in the regulation of sleep/wakefulness states and autonomic function. Furthermore, chemogenetic activation of the raphe nuclei also promotes recovery from immobility after LPS challenge. These findings demonstrate that orexin accelerate recovery from inflammation through the raphe nuclei and this effect may be due to activation of the serotonergic neurons that regulate the autonomic nervous system.

Title: Activation of NMDA receptors in the insular cortex alters aversive-appetitive stimuli association

Authors: *M. J. OLVERA-CALTZONTZIN[1], M.-I. MIRANDA[2]
[1]Neurobiología Conductual y Cognitiva, Univ. Nacional Autonoma de Mexico, Queretaro, Mexico; [2]Inst. Neurobiologia-UNAM, Queretaro, Qro., Mexico

Abstract: During conditioned taste aversion or inhibitory avoidance (IA), an inherently appetitive or pleasant stimulus carries positive valence that changes during association with another stimulus, which is inherently aversive and has negative valence. In these tasks, taste or context is learned under negative or aversive consequences and the insular cortex (IC) is significantly involved in the association. However, few studies have evaluated the behavior and cortical function when stimuli, with opposite valence, compete during taste and context association. Thus, the purpose of this research was to assess, in male Wistar rats, the involvement of NMDA receptors (NMDAr) in the IC, when two stimuli with opposite valences, e.g., sweet taste and aversive context, were associated simultaneously. Accordingly, a modified IA task was used; at the end of the dark compartment (DC), a graduated bottle with sugar was placed (positive valence) and then competed with a mild foot shock (negative valence) administered before rats drank. Three parameters were obtained during acquisition and test retrieval: 1) the entry latency to DC to evaluate the response to the context; 2) the latency of sugar consumption (hedonic response); 3) ml liquid consumption, to evaluate the appetitive or aversive response. Five minutes before the IA acquisition, rats received NMDA (1 µg/µl) bilateral injection in the IC. The results showed that IC-NMDAr activation disrupted IA, since entry latency to DC decreased, regardless of the presence of water or sugar at the end of DC. However, NMDAr activation significantly increased sugar consumption, even though no difference was observed in liquid consumption latency between groups. These results indicate the increment in NMDA receptors activity in the IC during association of novel stimuli with opposite valence, significantly strengthened the appetitive memory formation. These results suggest that glutamatergic activity in the IC might be modulating the appetitive valence when two opposite stimuli are competing for an association.

Title: Chemogenetic evidence for the protein synthesis requirement during memory consolidation

Authors: *P. SHRESTHA[1], P. AYATA[2], P. M. H. VIDAL[1], A. GASTONE[1], N. HEINTZ[3], E. KLANN[4]

Abstract: Studies over the last several decades have established that *de novo* protein synthesis is a requirement for the conversion of short to long term memories. However the widespread use of broad antibiotics, such as anisomycin, in neurobehavioral studies for blocking protein synthesis has been considered problematic due to their lack of specificity including activation of cellular stress pathways aside from their intended action on translation. We have developed a novel chemogenetic strategy, cre-conditional drug-inducible protein synthesis inhibitor (ciPSI)- to address the need for a highly selective and inducible translation inhibiting agent. The ciPSI knock-in mouse line comprises transgenic cre-dependent expression of a drug activatable kinase, iPKRkd, for eukaryotic translation initiation factor eIF2α that has been rendered inducible by an NS3/4 protease site tailored within the kinase. NS3/4 protease, also expressed transgenically, binds to and inhibits iPKRkd at steady state but upon administration of NS3/4 protease inhibitor, we are able to disinhibit iPKRkd to mediate its action on protein synthesis. Phosphorylation of eIF2α is a physiologically relevant molecular event for consolidation of long term threat memories. While phosphorylation of eIF2α at Serine 51 blocks translation initiation by limiting the abundance of eIF2 ternary complex, dephosphorylation of eIF2α at the same residue has been shown to be a crucial molecular event for the switch from short to long term plasticity and memory in classical fear conditioning paradigms. We have applied the ciPSI strategy in Nestin.iPKRkd animals to interrogate whether *de novo* translation is necessary for consolidation of long term threat memories. Our data indicates that there is a sensitive time period following threat conditioning for *de novo* translation initiation during which consolidation of long term threat memories, lasting over 24h, is vulnerable to disruption. Further, we have found that bidirectionally switching the phosphorylation status of eIF2α in CamK2α principal neurons in the lateral amygdala causes a robust change in the defensive state exhibited by animals 24h following threat conditioning. The ciPSI strategy is also engineered to express EGFP-tagged ribosomal protein L10, making the system amenable to translating ribosome affinity purification (TRAP)-seq. Overall, we have generated a tripartite chemogenetic protein synthesis inhibitor that allows us to interrogate various memory systems in healthy and diseased brain states.

Title: Sex differences and neural correlates of safety learning

Authors: *A. R. FOILB, G. SANSARICQ, K. FERNANDO, J. P. CHRISTIANSON
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Distinguishing between safety and danger is critical to survival and is impaired in individuals with post-traumatic stress disorder (PTSD). More females are diagnosed with PTSD than males and women with PTSD display difficulty inhibiting fear responses. To investigate sex differences in the neural correlates of safety learning, intact male and normally cycling female adult Sprague-Dawley rats received discrimination conditioning with a danger signal (CS+) co-terminating with a mild footshock and a safety signal (CS-) indicating the absence of shock and were perfused one hour later for brain wide c-Fos quantification. Females displayed less freezing, an index of fear, to the CS- and greater discrimination between the CS+ and CS- compared to males. This pattern suggests sex differences exist within the neural circuits that encode and recall safety information, which is the focus of ongoing study. In addition to comparing regions activated in discrimination in males and females, we are also comparing animals that underwent discrimination training to rats exposed to danger conditioning only (CS+ only), or to a control treatment (CS only). The activation of prefrontal cortex, amygdala nuclei, and plasma levels of stress-related hormones are under current investigation. Together, these components will lead to a better understanding of the neural mechanisms that underlie improved safety learning and discrimination in females compared to males.

Title: Vitamin D attenuates retention of conditioned fear in low startle rats

Authors: L. W. AYERS[1], J. SCHULKIN[2], *J. B. ROSEN[3]
[1]Psychology Dept., Widener Univ., Chester, PA; [2]Dept. of Neurosci., Georgetown Univ., San Rafael, CA; [3]Psychological and Brain Sci., Univ. Delaware, Newark, DE

Abstract: Calcitriol (1,25-dihydroxycholecalciferol or 1α,25-$(OH)_2D_3$) is the biologically active form of vitamin D3 best known for its role in calcium regulation. The Vitamin D Receptor (VDR) is found in notable concentrations within brain areas associated with autonomic-

neuroendocrine function and fear/anxiety. Namely, it is found in high densities within the paraventricular nucleus of the hypothalamus (PVN), the intermedolateral nucleus of the spinal cord, the bed nucleus of the stria terminalis (BNST), the central nucleus of the amygdala, and the hippocampus (Stumpf & Privette, 1991). Recent evidence from Ithier et al, (2018) also suggests that Calcitriol activity may suppress corticotrophin-releasing hormone (CRH), a key signal used in the neuroendocrine stress response and a mediator of fear/anxiety behavior.
We hypothesize that Calcitriol may be an important mediator of fear and anxiety, possibly through its regulation of CRH in amygdala, BNST and/or PVN. To test this, a 1, 10 or 100 µg/kg dose of Calcitriol was given subcutaneously to male Sprague-Dawley rats 6 hours prior to contextual fear conditioning. Subjects were then tested for fear retention 24 hours later. Calcitriol had no effect on conditioned fear acquisition, but fear retention was reduced by the 10 µg/kg dose in a subset of subjects classified as having low baseline startle. Subjects with high baseline startle were unaffected by the compound. This finding is important given the previously described associations between baseline startle responding and the expression of learned fear in both rodents and humans (Bush, Sotres-Bayon, & LeDoux, 2007; Holmes & Singewald, 2013; Russo & Parsons, 2017), and suggests trait-anxiety might be a factor in vitamin D's ability to reduce the retention of conditioned fear. Follow-up studies are planned which will examine the effects of Calcitriol on CRH gene expression within the amygdala, BNST, and PVN.

Title: Amygdala lesions impaired fear conditioning under dexmedetomidine-induced anesthesia in rats

Authors: *H.-Y. HSIAO, D.-Y. CHEN
Dept. of Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Anesthesia may interfere with brain and cognitive function, but animals and human still be able to perform certain learning and memory under general anesthesia. These evidences indicate that fully conscious state may be not necessary for all cognitive functions. Previously, we have demonstrated that rats could learn a modified inhibitory avoidance (IA) task when they were anesthetized by dexmedetomidine (DEX). This paradigm provides an animal model to study the neural mechanism of fear conditioning under anesthesia. The present study examined

whether the amygdala play an important role in this learning task. In Experiment 1, rats received bilateral ibotenic acid lesions of the amygdala or a sham surgical procedure about one week before the training sessions. On Day 1, rats were allowed to shortly explore the entire apparatus. On Day 2~4, rats were anesthetized by DEX (60 μg/kg, s.c.) and placed into the light component of the apparatus for 5 minutes (light exposure phase). Then, they would be waked up by atipamezole (0.84 mg/kg, s.c.) that reversed the effect of DEX, and returned their home cage. After 6 hours, rats were anesthetized again. They received ten foot-shocks (1.2 mA, 2 s, ITI: 30 s) in the dark component under anesthesia (dark-shock pairing phase). Rats were wake up after the training sessions. On Day 5, they were placed into light component for a memory retention test. In contrast to the sham control group, rats with lesions in the amygdala had significant shorter latencies stepping into the dark component. This result indicated that the amygdala play an important role in the learning of IA task under anesthesia. In Experiment 2, we further examined the importance of the basolateral amygdala (BLA) in learning under anesthesia. Rats received bilateral ibotenic acid lesions of the BLA. After one week of recovery, they received the same training procedure in Experiment 1. In the retention test, the BLA-lesioned group also showed impaired memory. In summary, the present findings suggested that learning of fear conditioning under anesthesia required the amygdala, and the BLA might be critical. Further experiments are required to examine whether other nuclei in the amygdala are also important in learning under anesthesia.

Title: Functional connectivity between the mediodorsal thalamic nucleus and frontal cortex accounts for the variability in fear memory acquired under dexmedetomidine

Authors: *K.-H. CHEN[1,2], D.-Y. CHEN[3], K. LIANG[2]
[1]Ministry of Sci. and Technol., Res. Inst. for the Humanities and Social S, Taipei, Taiwan; [2]Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [3]Dept Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: In search of the neural change altered by learning, we trained male Wistar rats under dexmedetomidine (0.1 mg/kg/hr, s.c) to associate a visual CS with a nociceptive US and concurrently obtained functional images with a 7T Bruker Biospec scanner. A within-subject paradigm was adopted by arranging the functional scans of CS-only, US-only, and CS-US association trials in separate blocks interleaved with resting state fMRI scans. The memory was probed by a fear potentiated startle (FPS) task on awake and drug-free rats in the next day. As huge variability in memory performance was found, rats were categorized into the good and poor learners for further analyses based on their FPS scores. The diversity in the memory scores could be attributed to variability of the subject in several aspects, such as sensitivity of detecting external stimulus or state of the brain when learning was initiated. The first possibility was excluded as no difference was found in the sensory stimulus-evoked BOLD signal. Concerning the initial state during learning, we focused on the signal synchronization between the thalamus and cortices as the former is involved in arousal and acts as a hub to regulate cortical connectivity. Before any sensory stimulation or learning experiences, the functional connectivity between the mediodorsal thalamic nucleus (MDN) and the frontal cortex positively correlated with the FPS scores (MDN-S1, r = .598; MDN-ACC, r= .497), but that between the MDN and the posterior parietal cortex (V1 and V2/RSC) did not. This indicated that a certain kind of thalamo-cortical activity coherence may play a critical role for learning to occur under sedation, and the initial state of the MDN-frontal cortex connectivity is critical. Additionally, the good and poor learners showed an opposite pattern in the MDN-S1 connectivity, either after the sensory stimulation or after the CS-US association session, and the changes in both phases significantly correlated with the behavioral outcome. Findings of this connectivity analysis could be viewed as interaction between the general brain state and task-evoked specific activity contributing to the individual difference in fear learning under sedation.

Title: Bidirectional communication between the prelimbic cortex and the basolateral amygdala modulates the acquisition of trace fear memory

Authors: *A. J. KIRRY, M. R. HERBST, K. LEPAK, R. C. TWINING, M. R. GILMARTIN
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: The association of a neutral conditional stimulus (CS) and aversive footshock unconditional stimulus (UCS) in fear conditioning critically depends on the amygdala. However, if the CS and UCS are separated by several seconds as in trace fear conditioning, additional brain areas are needed, including the prelimbic area (PL) of the medial prefrontal cortex. A subset of PL cells exhibit sustained firing in response to the CS and prefrontal activity during the trace interval between the cue and shock is necessary for learning (Gilmartin & McEchron, 2005; Gilmartin et al., 2013). This suggests that the PL may provide a bridging signal to link the CS and UCS in memory, but it is unclear whether and how this activity is directly integrated in the basolateral amygdala (BLA) to support fear learning. Here we selectively manipulated PL inputs to the amygdala using projection-targeting optogenetics during training. The PL-BLA connection was either silenced or stimulated during the trace interval by delivering laser light to opsin-expressing terminals in the BLA during training. Memory retention was tested the following day in the absence of laser illumination. Memory formation was largely unaffected by inhibition or stimulation restricted to the trace interval. However, analysis of fiber placement revealed a correlation between impaired cued fear and anterior fiber placement, suggesting a rostral-caudal gradient in the function of PL inputs to the BLA. A similar gradient was observed in response to PL-BLA stimulation during fear extinction. ChR2-mediated stimulation of PL terminals in the BLA increased the expression of freezing to the CS, which was mediated by PL inputs to the anterior, but not posterior, BLA. These results suggest a functional rostral-caudal organization of PL input to the BLA in the acquisition and expression of cued fear. In a separate set of studies, an intersectional chemogenetic approach was used to silence communication between the PL and BLA in both directions and during the entire training session. Inhibition of PL to BLA slowed the acquisition of cued but not contextual fear memory and inhibition of BLA to PL impaired memory formation, leading to reduced fear to the CS at test. Together, these studies support a role for direct communication between the PL and BLA in the formation of cued, but not contextual, fear memories. To determine whether BLA input to the PL is necessary for CS or trace interval encoding, we are currently testing the consequence of BLA inactivation on PL neuronal firing during trace fear conditioning.

Title: Conditioned inhibition training results in reduced intracellular calcium signals in Hermissenda type B photoreceptors

Authors: *J. FARLEY[1], J. CAVALLO[2], J. B. ANDERSON[2]
[2]Neurosci., [1]Indiana Univ. Bloomington, Bloomington, IN

Abstract: Previous research has demonstrated that induction of bidirectional learning-produced changes in photoresponses, excitability, and somatic K^+ currents of *Hermissenda* Type B photoreceptors, by either paired or explicitly-unpaired (EU) presentations of light and rotation, are calcium-dependent phenomena. The changes are prevented if B cells are first injected with a Ca^{2+}-chelator prior to either training protocol (paired vs EU). Several Ca^{2+}-dependent signaling pathways have been implicated in these changes: PKC and PTKs for pairings, and PP1/PP2B and AA/12-LOX metabolites for EU training. Enhanced light-evoked $[Ca^{2+}]_i$ -transients have also been reported for B cells on days following paired training, suggesting that learning may also alter the rules of $[Ca^{2+}]_i$ -signaling in B cells. To determine if EU training also produces persistent alterations in B cell $[Ca^{2+}]_i$-signaling, we undertook measurements of both resting and light-evoked $[Ca^{2+}]$i in B cells from animals exposed to either EU or control training conditions. Following ionophoresis of fura-2 into single B cells, measurement of light-evoked generator potentials and spike frequencies and input resistances (which confirmed previously described EU-produced reductions in photoresponses and excitability), ratiometric dye fluorescence was measured using dual-wavelength (340/380 nm) microphotometry. B cells were repetitively illuminated for 30 sec periods (9 min ISIs) using an incandescent epi-illumination source (~300 $uW \cdot cm^{-2}$) similar to that used in behavioral/neurophysiology experiments. In standard (10 mM Ca^{2+}) ASW, baseline $[Ca^{2+}]_i$ of dark-adapted control B cells (n=13) averaged 91.1 ± 14 nM. Light evoked large increases in sustained $[Ca^{2+}]_i$ (209 nM) that remained elevated for ~ 3-4 min following light offset and then dipped below the pre-light level for 2-3 min before recovering to the original baseline. In contrast, dark-adapted B cells (n=3) from EU-animals had significantly lower baseline $[Ca^{2+}]_i$,levels of 43.0 ± 8 nM. Light-evoked sustained $[Ca^{2+}]_i$ levels (104.7 nM) in these cells were ~50% of control cell values, but showed similar kinetics as control cells and exhibited the same dip below baseline ~ 4 min post light. Thus, paired and EU-training produce opposing metaplasticity within the Ca^{2+}-signaling system(s) of B cells. We suggest that the enhanced $[Ca^{2+}]_i$ in paired B cells contributes to extinction-produced reversal of original pairing-produced excitability, while reduced light-evoked $[Ca^{2+}]_i$ levels in EU-trained B cells are insufficient to support normal PKC activation by pairings, and thus contribute to retarded acquisition of paired (excitatory) conditioning.

Title: Aversive learning strengthens episodic memory in adolescents and adults

Authors: *A. O. COHEN, N. G. MATESE, A. FILIMONTSEVA, C. A. HARTLEY
New York Univ., New York, NY

Abstract: Adolescence is often filled with emotional experiences that may change how individuals remember and respond to stimuli in their environment. Recent studies in adults have shown that learned aversive associations can generalize across a category of stimuli and lead to enhanced memory for the reinforced category of trial-unique exemplars. The present study tests whether learned aversive associations similarly lead to better memory and generalization across a category of stimuli in adolescents. Participants complete a pavlovian category conditioning task where one of two categories is partially reinforced with an aversive odor, and return 24 hours later to complete a surprise recognition memory test. Preliminary data analyses including 30 individuals ages 13 to 25 (half of our planned sample) show better corrected recognition memory for the reinforced than the unreinforced category of exemplars in both adults and adolescents. Further analysis reveals that enhanced recognition memory is driven by better memory for the reinforced exemplars in both age groups. Thus, while we do not presently observe category conditioning effects in either adolescents or adults, we do see enhanced memory for the items with an acquired aversive association in both adults and adolescents. These findings build on previous work in adolescent and adult humans and rodents showing similar acquisition of aversive pavlovian conditioning using simple stimuli across age groups. Analyses in the full sample will examine age continuously to test for age-related changes in memory across adolescence.

Title: Phosphorylation of mitogen-activated protein kinase in the medial prefrontal cortex is associated with individual variation in extinction recall in rats

Authors: *A. S. RUSSO[1], R. G. PARSONS[2]
[1]Psychology, [2]Stony Brook Univ., Stony Brook, NY

Abstract: Although most individuals are exposed to a traumatic event at some point, only a small portion of individuals develops posttraumatic stress disorder (PTSD), suggesting there are individual differences rendering some people more susceptible to PTSD-development than others. Pavlovian fear conditioning involves the pairing of an aversive, unconditioned stimulus (US) with a neutral stimulus (CS) such that presentation of the CS alone comes to yield a conditioned fear response (CR). Decrease in the CR after repeated presentations of the CS alone is referred to as extinction. It has been shown that individuals with PTSD have a poor ability to extinguish CRs, suggesting that studying individual variation in extinction learning using rodent models may inform our understanding of the neurobiological basis of PTSD. However, the neural mechanisms underlying variation in extinction have been investigated sparsely. To understand whether altered activity in brain areas known to be involved in extinction corresponds to expression of extinction learning and recall, we assessed levels of phosphorylated mitogen-activated protein kinase (p-MAPK) in the amygdala and medial prefrontal cortex (mPFC) of rats with good and poor extinction learning and recall. Phosphorylation of MAPK is a key event underlying many forms of neural plasticity and is known to be crucial for formation of long-term fear and extinction memories. Rats were exposed to a Pavlovian fear conditioning paradigm with conditioning consisting of two combinations of tone and foot-shock, extinction training consisting of 20 presentations of the tone alone, and extinction recall testing consisting of 8 presentations of the tone alone. Rats were sacrificed either after extinction training or extinction recall sessions, and all brains were saved for western blotting. We found that there was significantly less p-MAPK in the mPFC of rats which had poor extinction recall than rats which had good extinction recall following an extinction recall session. There was no significant difference in p-MAPK between rats with poor and good extinction recall in the amygdala, nor were there significant differences in p-MAPK between rats with good and poor extinction learning in the mPFC or amygdala. These data suggest that the inability to extinguish learned fear is the result of aberrant neural plasticity in the mPFC. Future investigation will seek to delineate the role of specific projections from areas like the basolateral amygdala (BLA) and paraventricular nucleus of the thalamus (PVT) to the mPFC.

Title: Manipulating the strength of initial fear learning does not affect the extent to which subsequent fear learning is facilitated

Authors: *K. COLE[1], J. LEE[1], R. G. PARSONS[2]
[1]Psychology, [2]Stony Brook Univ., Stony Brook, NY

Abstract: Prior experience can have a profound effect on memory formation. Therefore, it is important to study the conditions whereby an initial learning event can affect subsequent learning. A recent study from our laboratory showed that learning of a weak fear conditioning trial was enhanced by prior auditory fear conditioning when the two training events were spaced 24 hours apart. Interestingly, a correlation between fear levels for the two training events was observed such that the rats that learned the initial auditory fear conditioning well, showed poor facilitation to the second single light-shock trial. Conversely, rats that showed weaker learning of the initial auditory fear conditioning showed good facilitation to the subsequent light-shock trial. These data suggest that the strong learning to the initial learning event somehow occludes subsequent learning. If that is the case, then altering the strength of the initial learning by changing the number of trials should dictate whether or not the subsequent learning is facilitated. Here, we manipulated the strength of the auditory fear conditioning event by varying the number of tone-shock pairings. Rats received either one, two, six, eight tone-shock pairings followed by a single light-shock pairing 24 hours later. Long-term memory for both cues was assessed in separate test sessions. We report that there was facilitation of learning to the subsequent event in all groups. Therefore, while weak learning is facilitated by prior auditory fear conditioning, manipulating the amount of shocks during auditory conditioning does not affect the extent of facilitation to subsequent learning. These findings suggest that the mechanism that primes future learning is engaged regardless of the strength of initial learning.

Title: Activation of the Mitogen-Activated Protein Kinase in female rats during the expression and extinction of fear

Authors: *M. VOULO[1], R. G. PARSONS[2]
[1]Psychology, [2]Stony Brook Univ., Stony Brook, NY

Abstract: Activation of the Mitogen-Activated Protein Kinase in female rats during the expression and extinction of fear.
Women are more than twice as likely as men to develop post-traumatic stress disorder (PTSD), which is associated with impaired retention of fear extinction. Despite this, the majority of basic research regarding fear extinction has been conducted using males as subjects. Studies of fear conditioning and extinction learning have begun to include female animals, but results have been mixed with respect to sex differences. Most studies only use one measure of fear – freezing behavior. However, it has been suggested that females show more active fear responses than males, and therefore measures of fear susceptible to differences in locomotor activity, such as freezing, may not be ideal. Our lab recently found a response-specific sex difference in fear extinction such that females show impaired extinction when measuring fear-potentiated startle (FPS), but not when measuring freezing behavior, however the neural basis of this difference between males and females is unknown. To begin to address this question, we examined phosphorylation of the mitogen activated protein kinase (pMAPK) in female rats following a test for the expression of fear memory and following an extinction retention test. There were two test groups, one that underwent fear conditioning and the next day was exposed to a test session to reactivate the memory for acquisition. The second group underwent fear conditioning, followed by extinction training the next day, and the final day received an extinction retention test. Rats in both groups were sacrificed 30 minutes following the final test session, allowing us to look at pMAPK activity during fear expression after acquisition and extinction memory expression. We compared MAPK activity in these two groups to that in naive controls. Our results show that rats that underwent only fear conditioning before the test showed enhanced activity in both the infralimbic (IL) and prelimbic (PL) areas of the prefrontal cortex compared to the other two groups. Surprisingly, there was no increase in PL or IL activity in the group that underwent extinction training prior to the test day. We are currently analyzing pMAPK in the periaqueductal grey and the amygdala to determine if there are other differences between the groups. In addition, we are beginning to compare brain activity in males and females undergoing

FPS extinction to understand any sex differences in the brain mechanisms underlying this behavioral effect.

Title: Chemogenetic inhibition of excitatory neurons in the basolateral amygdala disrupts the facilitation of subsequent fear learning

Authors: *R. G. PARSONS, J. LEE
Stony Brook Univ., Stony Brook, NY

Abstract: Memory permits adaptation to future experience. In the laboratory we can study this essential property of memory by assessing how an initial learning experience can alter subsequent learning. We have previously shown that while a single weak fear conditioning trial is insufficient to support long-term memory, it alters the capacity for future learning such that another trial delivered within a protracted time window results in robust memory. In this set of experiments, we sought to determine whether or not manipulating neural activity in the basolateral amygdala (BLA) using designer receptors exclusively activated by designer drugs (DREADDs) during the initial learning trial affected the facilitation of subsequent learning. Male rats were either given injections of AAV8-hM4Di under the control of the neuron specific promoter (hSYN), AAV8-hM4Di under the control of the CaMKII promoter, or AAV8-eGFP. Rats were then trained with two fear conditioning trials spaced 24 hours apart. One hour prior to the first trial rats received systemic injections of the DREADD ligand, clozapine N-oxide (CNO; 5mg/kg). An additional control group of rats was included that were given the CaMKII expressing inhibitory DREADD into the BLA, but given vehicle injections prior to training. During the initial training trial, there were no differences between groups in activity levels or in reactivity to the shock. Memory was tested 48 hours later by presenting rats with the cue that had predicted shock and fear-potentiated startle was measured. Preliminary results indicate a promoter specific effect on learning, such that rats infected AAV-hM4Di-CAMKII exhibited a deficit in fear-potentiated startle compared to rats expressing AAV8-hSYN-hM4Di, rats infected with AAV-eGFP, or controls given vehicle injections. We are currently testing if different doses of CNO produce the same pattern of results. These findings indicate that 1) the blocking neural activity in the BLA during an initial fear conditioning trial prevents the mechanism responsible

for facilitating subsequent learning and 2) that this effect requires that expression of the inhibitory DREADD receptor be restricted to excitatory neurons in the BLA.

Title: Projection specific mechanisms of auditory sensitivity that contribute to enhanced fear after traumatic brain injury

Authors: *A. N. HOFFMAN[1,2], E. HSIEH[1], Z. T. PENNINGTON[1], S. WATSON[2,1], D. A. HOVDA[2,3,4], C. C. GIZA[2,3,7], M. S. FANSELOW[1,5,6]

Abstract: Traumatic brain injury (TBI) increases the risk for post traumatic stress disorder (PTSD), however the underlying neurobiology of this comorbidity is unknown. Sensory sensitivity is common following TBI, and changes in sensory processing might influence the encoding of traumatic events in the wake of injury. The lateral amygdala (LA) receives direct sensory cortical and thalamic inputs necessary for the formation of auditory fear memories, and may be vulnerable to TBI. We have shown enhanced contextual fear after lateral fluid percussion injury (FPI) in rats following fear conditioning when white noise, but not when low frequency tones signal mild aversive footshocks. Altered sensitivity to white noise might reflect phonophobia after FPI and underlie increased fear after injury when used in fear conditioning. We hypothesized that FPI enhances contextual fear to white noise-signaled conditioning due to altered sensory-emotional network processing. In this study we show that when rats are exposed to 75dB white noise alone prior to fear conditioning, FPI rats demonstrate robust defensive

behavior and show increased context fear after white noise-signaled fear conditioning relative to sham. We also show increased neuronal activity within the ipsilateral LA in FPI rats during white noise exposure relative to noise-exposed shams and quiet FPI controls with Arc immunohistochemistry. Finally, to determine functional activity in sensory projections to LA, we bilaterally infused retrograde tracer cholera toxin B (CTB) three weeks before FPI and measured c-Fos expression in CTB+ cells during white noise exposure. In this experiment we demonstrate that the increased activity in the ipsilateral LA is driven by increased activity in neurons projecting from ipsilateral auditory thalamus (medial geniculate nucleus, MGN) to LA as measured by more c-Fos in CTB+ MGN neurons during white noise exposure. This effect was specific to the MGN and not secondary auditory cortex (Te3)-LA projections, indicating the specificity of the inputs that drive increased plasticity and corresponding defensive behavior. These data provide implications for the vulnerability of the thalamo-amygdala pathway underlying phonophobia and altered sensory processing after TBI, where otherwise neutral stimuli may adopt aversive properties and impact encoding of traumatic memories contributing to psychiatric comorbidities.

Title: Dissociation in effective treatment and behavioral phenotype between stress-enhanced fear learning and learned helplessness

Authors: *M. A. CONOSCENTI[1], T. U. NGUYEN[1], J.-P. WOLLAM[2], V. L. TUTAJ[1], M. S. FANSELOW[3]
[1]Psychology, [2]Neurosci., [3]Dept Psychol, UCLA, Los Angeles, CA

Abstract: An acute traumatic event can lead to life-long changes in stress susceptibility and result in psychiatric disease, such as Post-Traumatic Stress Disorder (PTSD). Despite the relatively high prevalence of PTSD, limited progress has been made in identifying practical interventions to stress-induced psychopathology. Historically, two animal models of PTSD that use unpredictable and uncontrollable shock have been used to examine the underlying mechanisms of stress-induced maladaptive behavior: learned helplessness (LH) and stress-enhanced fear learning (SEFL). An interesting disparity between LH and SEFL behavior is the relatively brief window of time in which LH persists compared to SEFL's apparent persistence. Despite many differences, the two models share one physiological mechanism. Post-stress elevations in glucocorticoid concentrations are necessary for phenotypic induction in both LH and SEFL. We have previously shown that access to a concentrated glucose solution after trauma decreased stress-related pathology in LH. Furthermore, it appears that post-stress glucose consumption decreases peripheral concentrations of free corticosterone, suggesting that the treatment may also work in eliminating SEFL. Our first experiment tested the hypothesis that exposing rats to glucose following exposure to the standard SEFL protocol of 15 footshocks would inhibit expression of the SEFL phenotype. We exposed 32 Long-Evans rats to 15, 1mA footshocks, or context exposure without shock. Rats in each condition had 18-hours access to a 40% glucose solution or water immediately following termination of the session. 24-hours later, we measured freezing in a novel context that shared the same olfactory cues as the previous context. The following day, all rats were exposed to 1, 1mA footshock in a novel context and were tested for freezing in that same context 24-hours later. Our second experiment examined the effect of shock number on the induction of SEFL behavior. We exposed 24 male Sprague-Dawley rats to 100 tail shocks (1 mA, an LH protocol), 15 tail shocks (1 mA, SEFL protocol), or simple restraint. One week later, rats received 1, .5 mA footshock in a novel environment and were tested for freezing in that same context 24-hours later. We found that glucose ingestion did not eliminate SEFL, but did decrease freezing in the context that shared olfactory cues with the acute-stress context. Number of shocks appeared to have a small, but significant effect on SEFL. These data suggest many elements of dissociation between the two models of PTSD. Future studies examining shared mechanisms between LH and SEFL may open the door for the development of potent PTSD interventions.

Title: Differential modulation of fear behaviors in female mice with deletion of PAC1 receptors from the ventral intercalated cells and the basolateral amygdala

Authors: *A. K. RAJBHANDARI[1,2], J. CHAVEZ[1], L. NGUYEN[1], N. KECES[1], J. A. WASCHEK[3], M. S. FANSELOW[1,2,3]

Abstract: Fear responses are critical for survival. However, exposure to extremely traumatic stimuli can cause fear regulation via certain brain regions to go awry leading some individuals to develop anxiety-related disorders like post-traumatic stress disorder (PTSD). Various brain regions, particularly the amygdala, govern fear. The amygdala microcircuitry containing the intercalated cells (ICCs) that lie in the interface of basolateral (BLA) and central amygdala are important modulators of fear behavior. Several neuropeptide systems are part of the amygdala microcircuitry including the neuropeptide PACAP (pituitary adenylyl cyclase-activating peptide) and its G-protein coupled receptor PAC1. In this regard, it was reported that the PACAP and PAC1 receptors are linked to PTSD symptom severity at both genetic and epigenetic levels, and this link was stronger in females with PTSD. We investigated whether deletion of PAC1 receptors from the ventral ICCs or BLA of female mice alters fear acquisition, generalization, retention or extinction. We infused AAV-driven Cre-recombinase or a GFP control into the vICCs or BLA of female mice with a floxed PAC1 gene. After viral expression, mice went through a contextual fear acquisition protocol (1 trial/day for 5 days) in which 4-minute after being placed into a conditioning context they received a 0.65 mA, 1-second shock. We found that mice with PAC1 deletion in the vICCs showed decreased fear acquisition, but deletion in the BLA led to normal fear acquisition. No differences were found in fear generalization, which was measured by placing the mice in a novel context for four minutes. Mice with PAC1 receptor deletion in the BLA showed decreased fear retention, which was measured in the acquisition context for four minutes. Lastly, deletion of PAC1 receptors from the BLA, but not vICCs, led to decreased fear extinction, which was carried out by placing them in the acquisition context for 30 minutes every day for five days and freezing measured during the first 4 minutes of the session. Our previous results showed that deletion of PAC1 receptors from the vICCs of male mice enhances fear generalization, but deletion from the BLA decreases acquisition of fear. Overall, the current behavioral findings in female mice with PAC1 deletion, when combined with the results from male mice with the same manipulation, indicate that PACAP/PAC1 system is poised to modulate fear in a dynamic manner via the amygdala microciruitry. This dynamic balance is significantly different in males and females. It will be interesting to determine the physiological properties of these PACAP/PAC1 neural networks within the amygdala sub-regions.

Title: Blockade of corticotropin-releasing factor type 1 receptors in the basolateral amygdala decreases post-shock freezing but does not prevent stress-enhanced fear learning

Authors: *S. GONZALEZ, A. K. RAJBHANDARI, J. CHAVEZ, L. NGUYEN, N. KECES, M. S. FANSELOW
Psychology, Univ. of California Los Angeles, Los Angeles, CA

Abstract: Post-traumatic stress disorder (PTSD) is an anxiety disorder that develops after exposure to traumatic events and can involve an exaggerated fear response to stimuli that are reminiscent of the original stressor. Our laboratory has developed a rodent model of PTSD that captures this symptom termed stress-enhanced fear learning (SEFL). In this model, exposure to a traumatic stressor (15 unsignalled footshocks) in one context sensitizes fear learning to a mild stressor (1 unsignalled footshock) in a second context. However, the stress-induced changes in the fear learning circuitry that support this enhancement are not fully understood. The neuropeptide corticotropin-releasing factor (CRF) plays a key role in the stress response and blockade of CRF activity has been shown to impair fear learning. In this study we investigated whether CRF activity in the basolateral amygdala (BLA) during the traumatic stressor is necessary for the SEFL phenotype. Rats received an infusion of either a CRF1 receptor antagonist (CP-376395) or vehicle into the BLA immediately prior to the traumatic stressor. We found that blockade of CRF1 receptors decreased post-shock freezing during the traumatic stressor, but did not prevent stress-enhanced fear learning to the mild stressor. These findings suggest that while CRF activity in the BLA does play an important role in the fear response, blockade of these receptors is insufficient to prevent development of the SEFL phenotype.

Abstract: The ability to respond to biologically relevant stimuli is critical for adaptive behavior. These responses are likely shaped by associative learning that provides initially neutral cues with predictive value signaling impending threat or safety. Disturbances in fear and safety learning are of high clinical relevance in anxiety and pain-related disorders, both with increased prevalence in women. Brain imaging studies support distinct processing of learned emotional responses in networks involving amygdala, hippocampus and prefrontal cortex (PFC). However, evidence is missing on sex differences in the activity and connectivity within networks supporting threat versus safety learning, particularly in visceral pain. We therefore aimed to discern the structural and functional mechanisms underlying learned emotional responses in healthy women and men. For this re-analysis, data of 75 volunteers (38 women, 37 men; mean age 28.9 y) from two 3T MRI studies were pooled. Participants underwent differential fear conditioning during which an experimental visceral pain stimulus was repeatedly paired with a visual cue (CS^+) while a second cue (CS^-) was presented unpaired. CS valence was assessed on visual analogue scales before and after conditioning. Group differences were assessed on the behavioral and neural level in response to threat and safety cues and analyzed regarding brain structure-function associations. Overall, participants rated the CS^+ as significantly more unpleasant and the CS^- as more pleasant

after conditioning without evidence of sex differences. On a neural level, an amygdala-hippocampus network was found for both cues that further encompassed dorsal anterior cingulate for CS^+ only. This network correlated negatively with parahippocampal volume in men. For women, a network including nucleus accumbens correlated positively with CS^- valence. Women also revealed higher functional connectivity between amygdala, dorsolateral PFC, mid-cingulum and precuneus in response to the CS^+. In conclusion, the amygdala-hippocampus network seems of pivotal relevance in both, visceral, pain-related fear and safety learning, yet with highly diverging mechanisms. While for men, fear learning was associated with regional volume change, women showed a stronger discrimination between fear and safety learning as evidenced by increased processing of the rewarding safety cue and stronger amygdala coupling in response to threat. Together, these results shed light on the neural circuitry possibly underlying the high female prevalence in anxiety and pain-related disorders and call for future studies extending sex-specific effects in fear conditioning.

Abstract: Fear expression is one of the fundamental emotions of human beings and is crucial for living organisms and adapting to the environment. The understanding of the formation and extinction of fear emotions can promote the non-drug treatment of mental disorders, such as post-traumatic stress disorder. Numerous animal studies have demonstrated that fear expression and extinction relies on the coordinated activity of dorsal medial prefrontal cortex (dmPFC) and amygdala and 4Hz oscillations specific to fear expression supports this long-range synchronization. However, it remains unclear whether this circuit and brain rhythm can be

generalized to human fear expression. In addition to dmPFC, few studies have addressed the roles of ventral medial prefrontal cortex in fear acquisition. This study aims to investigate the roles of dorsal/ventral prefrontal cortex and amygdala in conditioned fear acquisition using human intracranial EEG recordings.Seventeen patients with pharmacologically refractory epilepsy (five female and twelve male) participated in this study. SEEG electrodes were surgically implanted in the medial prefrontal cortex and medial temporal lobe, including amygdala and hippocampus, under a clinical protocol. Implantation sites were chosen solely on the basis of clinical criteria. In the experiment, each patient performed a classical fear-conditioning task. This task consisted of two different color-coded squares, each of which was assigned randomly to CS+ or CS− across patients. The US was electric shock (0.15s duration before the termination of 4s CS+, 50% of CS+ trials were paired with US). The shock level was manipulated according to the individual pain rating. The interval between CS trials varied from 8 to10s.Skin conductor response recorded from eight patient confirmed successful acquisition of fear conditioning. Patients who failed to show fear acquisition were eliminated from further analysis. We found that during fear acquisition, amygdala and ventral/dorsal medial PFC cortex showed an increased power of theta-band (2-8Hz) activity, and the theta synchronization between amygdala and medial prefrontal cortex were significantly enhanced for CS+ condition. Single-trial dynamic analysis on power and coherence revealed neural mechanisms of fear acquisition processing. The preliminary results indicated that the formation of human fear acquisition invoked medial prefrontal cortex-amygdala circuit that communicated through theta-band oscillation. Notably, the ventral medial prefrontal cortex also played critical roles in fear acquisition, which challenged the findings from previous animal and human studies.

Title: Contribution of CRF and 5-HT in the anterodorsal BNST to phasic and sustained fear in freely behaving mice

Authors: *T. SEIDENBECHER, M. HESSEL
Inst. for Physiol. I, Muenster, Germany

Abstract: Sustained fear paradigms in rodents have been developed to model clinical situations in patients suffering from long-lasting anxiety disorders. Rodent data suggest that short-lasting (phasic) fear responses rely on the central amygdala, whereas more long-lasting (sustained) fear responses critically depend on the bed nucleus of the stria terminalis (BNST). Conditioned fear can be mediated by the amygdala via corticotropin-releasing factor (CRF), a stress hormone that acts on receptors in the BNST. CRF-containing cell bodies and CRF receptors were found in high concentrations in the BNST and CRF neurons co-localize with 5-HT (Serotonin) terminals in this brain region. Therefore, in this study we used a pharmacological approach combined with fear behavioral protocols in an established phasic/sustained fear mouse model to reveal the critical involvement of CRF and 5-HT in the anterodorsal (ad)BNST to modulate phasic and sustained fear.
Bilateral local application of a CRF1-receptor agonist (Stressin I) before fear memory retrieval, 24h after predictable CS-US training, induced sustained fear (maintained freezing) indicating the critical contribution of the CRF1-receptor during sustained states of conditioned fear. Application of saline (control) revealed only phasic fear 24 hours after predictable CS-US pairing as expected. Bilateral local application of a 5-HT2A-receptor antagonist (R-96544) either before unpredictable CS-US training or before fear memory retrieval, 24 hours after unpredictable conditioning, blocked the sustained component of fear while phasic fear component was not affected, indicating the critical contribution of serotonergic transmission mediated by the 5-HT2A-receptor during sustained states of conditioned fear. Saline application as control revealed sustained fear 24 hours after unpredictable CS-US pairing. Further, data also revealed that 5-HT1A– and 5-HT1B-receptor in the adBNST critically contribute to the modulation of phasic and sustained fear.
In summary, here we show the critical contribution of CRF and 5-HT in the adBNST to phasic and sustained fear in freely behaving mice. This study will advance the understanding of clinical anxiety and its treatment strategies and will thus provide a putative perspective for pharmacological treatments that specifically target the BNST.

Title: Connection from granular to dysgranular retrosplenial cortex is required for contextual fear memory retrieval

Authors: S. DE OLMOS[1], E. L. SGWALD[1], N. E. PONCE[1], E. A. BIGNANTE[1], *A. G. LORENZO[2]
[1]Inst. de Investigación Médica Mercedes y Martín Ferreyra, INIMEC-CONICET-Universidad Nacional de Córdoba, Cordoba, Argentina; [2]INIMEC-CONICET-UNC, Cordoba, Argentina

Abstract: The retrosplenial cortex (RSC) is divided in dysgranular (A30) and granular (A29) subregions. However, the functional role of each RSC subdivision in episodic memory processing remains poorly understood. In recent years, the participation of the RSC in contextual fear memory (CFM) has gained increased attention; nevertheless these studies have regarded the RSC as a uniform structure. The aim of this work was to reveal functional differences of RSC subdivisions in CFM processing. We used male rats and assessment of c-Fos and Egr-1 expression to infer neuronal activity during contextual fear conditioning. Data showed that during training and test, expression of Egr-1 dropped in A29 while Egr-1 and c-Fos rose in A30. Repeated measures ANOVA ($F(5,37)= 83.967$, $p=0.0000$) confirmed significant difference between RSC subdivisions, suggesting distinct or complementary roles for each area. Further analysis and statistical comparisons showed that similar to A29, reduced Egr-1 expression during training and test also occurred in caudomedial entorhinal cortex (CEnt). Contrarily, increases in c-Fos and Egr-1 in A30 during training and test were coincidental with medial entorhinal cortex (MEnt), dorsal CA1 field of hippocampus (CA1), central (CeA) and basolateral (BLA) nucleus of the amygdala (ANOVA ($F(12,108)=75.006$, $p=0.0000$), suggesting that A30 and these limbic structures are coupled into a distributed network supporting CFM encoding and retrieval. We later used systemic applications of MK801 to induce a non-invasive and selective elimination of neurons in layers IV-Va of A29 ($A29^{MK801}$ neurons). Loss of $A29^{MK801}$ neurons after CFM consolidation did not affect activation of limbic structures during test, but significantly impaired activation of A30 (ANOVA ($F(18,144)=5.7599$, $p=0.0000$) and the expression of freezing during test (ANOVA $F(2,12)=34.168$, $p=0.00001$). This observation indicates that during test, $A29^{MK801}$ neurons are critically required for coupling activity of A30 with limbic structures and the retrieval of CFM. By using silver staining, immunolabeling and track-tracing methods we showed that $A29^{MK801}$ are typical pyramidal neurons (likely excitatory) projecting to superficial layers of A30, and confirmed that GABAergic neurons in A29 were not affected by MK801. Collectively, our results indicate that $A29^{MK801}$ neurons play a critical role coupling activation of A30 with limbic structures during fear memory recall, which is required for CFM retrieval and expression of adaptive freezing behavior.

Title: Effects on fear versus safety discrimination by the partial NMDAR agonist D-cycloserine

Authors: *A. ESCOBEDO[1], E. M. SOWINSKI[2], R. HERAKOVICH[2], S. SANGHA[3]
[1]Psychological Sci., [3]Dept. of Psychological Sci., [2]Purdue Univ., West Lafayette, IN

Abstract: Learning to inhibit fear and maintain reduced fear levels to non-threatening environmental cues is a constant challenge for individuals suffering from posttraumatic stress disorder (PTSD). PTSD individuals have difficulty maintaining reduced fear levels after extinction-based therapies, and are also impaired in learning to inhibit fear to explicit safety cues trained under conditioned inhibition paradigms. Prior research has shown the beneficial effects of exposure therapy in reducing fear can be facilitated by the partial NMDA receptor agonist, D-Cycloserine (DCS). However, it is unclear if DCS is facilitating fear versus safety discrimination or if it is promoting non-specific fear reduction. Thus, the present study examined the effects of DCS in adult male Long Evans rats during a fear, safety, and reward cue discrimination conditioning task (DC) that is well-established in our laboratory. In this DC task, rats are exposed to pairings of a) a fear cue with shock, b) a safety cue with no shock, c) a reward cue with sucrose, and most importantly, d) a compound fear+safety cue with no shock. Adult male rats typically show significant inhibition of freezing to the compound fear+safety cue compared to the fear cue during the 3rd discrimination session. In this study, we hypothesized that DCS would facilitate discrimination learning between the fear cue and the fear+safety cue during earlier discrimination sessions, and that this improved discrimination may facilitate subsequent fear extinction under drug-free conditions. DCS (30.0 mg/kg i.p) was administered during the first three of four DC sessions. Saline was administered during the last DC session, to assess behavior under drug-free conditions, and subsequent extinction. As is typical, the saline group showed significant inhibition of fear during DC3, but preliminary data suggests the level of inhibition to the fear+safety cue versus the fear cue may be greater in DCS group. Based on our preliminary data it does not appear this improved fear versus fear+safety cue discrimination has any beneficial effects on subsequent fear extinction, as both saline and DCS groups showed similar fear extinction curves. This may suggest extinction and conditioned inhibition are mediated by different mechanisms.

Title: Oxytocin receptor activation in the basolateral complex of the amygdala facilitates discrimination between stimuli and promotes configural processing of stimuli

Authors: *J. FAM[1], N. M. HOLMES[1], A. J. DELANEY[2], J. W. CRANE[3], R. F. WESTBROOK[1]

Abstract: Oxytocin (OT) is a neuropeptide which influences the expression of social behaviour and regulates its distribution according to the social context - OT is associated with increased pro-social effects in the absence of social threat and defensive aggression when threats are present. However, this bi-directional effect of OT has not been demonstrated with stimuli outside the domain of social behaviour, and studies have yet to examine the learning mechanisms that underlie the effects of OT manipulations. The present experiments investigated the effects of OT beyond that of social behaviour by training rats in a Pavlovian fear conditioning protocol. In Experiment 1, an OT receptor agonist (TGOT) microinjected into the basolateral amygdala enhanced the discrimination between an auditory cue that was predictive of shock and another auditory cue that signalled the absence of shock. Experiment 2 replicated the TGOT-facilitated discrimination using compound cues that consisted of auditory and visual elements, and additionally demonstrated that the enhanced discrimination following TGOT administration was accompanied by a qualitative shift in the learning mechanisms underlying the discrimination. Specifically, rats given TGOT microinjections into the BLA engaged in configural (Pearce, 1987) processing of stimuli while rats given vehicle microinjections used an elemental strategy (Rescorla & Wagner, 1972).

Title: Fear and reward intersect in the ventral pallidum

Authors: *M. MOADDAB, H. JEON, M. A. MCDANNALD
Psychology Dept., Boston Col., Chestnut Hill, MA

Abstract: The ventral pallidum (VP) is integral to reward seeking and a variety of reinforcement-driven behaviors. However, little is known about the contribution of the VP to adaptive behavioral responses to threating stimuli. Here, we examined the role of the VP in multi-cue fear discrimination. To induce neurotoxic lesions, male Long Evans rats were injected with N-Methyl-D-aspartic acid (NMDA; 20 mg/ml; 0.3µl per side) into the VP (n = 8). For controls (n = 7), the needle was lowered to the VP, but no injection was made. Following recovery, rats were food deprived to 85% of their body weight and trained to nose poke in order to receive food pellets. In 16 sessions of fear discrimination, rats were presented with three 10-s auditory cues, each associated with a unique probability of foot shock; danger, p = 1.00; uncertainty, p = 0.25; and safety, p = 0.00. The schedule for rewarded nose poking was completely independent from auditory cue presentation and foot shock. Fear was measured using suppression of rewarded nose poking. Consistent with the demonstrated role for the VP in reward seeking, VP lesioned rats showed lower rewarded nose poking rates than their control counterparts. Controls acquired excellent discrimination: showing high fear to danger, intermediate to uncertainty and low to danger. VP lesioned rats readily acquired fear but were markedly impaired at reducing fear to uncertainty and safety. Elevated and excessive fear was demonstrated to these cues for the entirety of the 16 sessions of testing. These results reiterate that the VP is required for reward seeking but reveal a crucial role for VP in reducing fear in the face of uncertainty and safety. Studies are now underway to determine if information about reward, danger and safety are processed in overlapping or distinct neurons, revealing the nature of the intersection between fear and reward in the ventral pallidum.

Title: Optogenetic inhibition of caudal substantia nigra globally inflates fear in multi-cue Pavlovian discrimination

Authors: *K. M. WRIGHT, S. CIESLEWSKI, M. A. MCDANNALD
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Appropriate modulation of fear behavior in situations of potential threat is vital. Disruption in neural circuits that support this process are thought to underlie maladaptive fear responses observed in psychiatric disorders of stress and anxiety. The goal of the experiment was to demonstrate a causal role for the caudal substantia nigra (cSN), a region beyond currently identified fear circuitry,in fear modulation. Adult male, Long Evans rats received bilateral intra-cSNinfusions of either enhanced halorhodopsin (eNpHR: AAV-hSyn-eNpHR3.0-EYFP) or a control fluorophore (YFP: AAV-hSyn-EYFP), and bilateral optical ferrules dorsal to the cSN. Following recovery, all rats were trained to nose poke for a food reward, exposed to the to-be-conditioned cues, then given 8 sessions of Pavlovian fear discrimination. Discrimination consisted of three auditory cues, each associated with a unique foot shock probability: danger, p = 1.00; uncertainty, p = 0.25; and safety, p = 0.00. eNpHR and YFP rats achieved discrimination during these eight sessions: demonstrating high fear to danger, intermediate fear to uncertainty and low fear to safety. The remaining 10 sessions were broken down into 5, 2-session blocks. All rats were habituated to the optogenetic cables in the first 2-session block. For one group of rats [(eNpHR (n = 3), YFP (n = 4)], the next 8 sessions consisted of 2-session blocks of CUE illumination, NO illumination, ITI illumination and NO illumination. During CUE illumination sessions, 12.5 or 25 mW - 532 nm light was delivered bilaterally for the entirety of the 10-s cues. During ITI illumination sessions, light was delivered for 10-s ITI periods between cue trials. The NO illumination sessions provided measures of pre- and post-illumination fear behavior. A second group of rats [(eNpHR (n=6), YFP (n=6)] received the exact same procedure, only ITI stimulation was given first to counterbalance for potential order effects of CUE/ITI light stimulation. Optogenetic inhibition of the cSN during the cue inflated fear to danger, uncertainty and safety. That is, eNpHR - but not YFP - rats receiving CUE illumination showed inflated fear to all cues. ITI illumination had no effect on nose poking in either eNpHR or YFP rats, demonstrating that cSN optogenetic inhibition did not simply suppress nose poking. The cSN then normally acts to moderate overall fear levels, ensuring they are appropriate to the level of

threat. The results uncover a novel node in the fear circuit, and a possible contributor to dysfunction in psychiatric disorders of stress and anxiety that are characterized by excessive fear.

Title: Cholinergic regulation of individual differences in fear extinction in rats

Authors: *D. M. KELLIS[1], K. F. KAIGLER[1,2], E. J. WITHERSPOON[1], J. R. FADEL[1], M. A. WILSON[1,2]
[1]Dept. of Pharmacology, Physiology, and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC; [2]WJB Dorn VA Med. Ctr., Columbia, SC

Abstract: It has been demonstrated previously that outbred Long-Evans rats display individual differences in the ability to extinguish fear memories, an observation that mirrors human individual differences in resilience to traumatic stress and the development of post-traumatic stress disorder. Due to the cholinergic system's involvement in attending to environmental cues and heavy innervation to brain regions involved in conditioned fear behaviors in rodents, such as freezing and ultrasonic vocalizations (USVs), the role of cholinergic neurotransmission in cued fear extinction was investigated via numerous methods. We found that rats showing resistance to extinction in freezing behavior also vocalized more during fear acquisition and extinction trials. We administered the muscarinic cholinergic antagonist scopolamine (1 mg/kg, i.p.) before extinction learning and extinction recall to investigate the role of muscarinic receptors in individual differences in extinction learning and recall. Results suggested that muscarinic receptor activation was involved in some of the individual differences in freezing behavior and USVs during extinction, but that freezing and USVs were differentially regulated by muscarinic receptor activation. Further, we investigated plasma and brain acetylcholinesterase (ACHE) in relation to freezing behavior during fear conditioning and extinction. ACHE levels in plasma and the basolateral amygdala (BLA) assessed after extinction recall were negatively correlated with freezing behavior during fear extinction, such that extinction resistant rats showed lower ACHE levels compared to rats with normal extinction patterns; current studies are investigating if ACHE may serve as a biomarker for the extinction resistant phenotype. Finally, we utilized *in-vivo* microdialysis to examine acetylcholine (ACh) and glutamate (GLU) release in the BLA in relation to freezing behavior during fear recall and extinction. Preliminary results show increased

ACh efflux in the BLA during cue-conditioned fear recall and extinction learning. Overall, our data indicate that cholinergic neurotransmission plays a role in individual differences in cued fear extinction and may include differences in neurotransmitter release, degradation, and/or muscarinic receptor binding.

Title: Chronic alcohol intensifies fear memory generalization: A role for the medial prefrontal cortex

Authors: *M. SCARLATA, S. LEE, S. KANDIGIAN, K. LAWSON, I. SOLER, A. NG, J. BEZEK, H. BERGSTROM
Dept. of Psychological Sci., Vassar Col., Poughkeepsie, NY

Abstract: Post-traumatic stress disorder (PTSD) and alcohol use disorder (AUD) often co-occur. Drinking tends to increase following exposure to a traumatic event and has been associated with more severe trauma-related symptoms. This raises the question of whether alcohol changes how traumatic fear memories are expressed. The objective of this study is to determine the neurobehavioral impact of chronic alcohol (ethanol; EtOH) on the retrieval of fear conditioning. Male adult C57BL/6N mice underwent auditory cued fear conditioning and were then administered 2.5 g/kg EtOH (i.p.) once daily over 5 days. Following three EtOH-free days, the fear memory was reactivated using either the “target” conditioned stimulus (CS; 5-kHz) or a “non-target” novel tone frequency (3-kHz) to test cued discrimination and generalization. Results revealed greater freezing behavior in response to the novel tone in the EtOH group, indicating enhanced cued fear memory generalization. Importantly, there were no effects of alcohol on the retrieval of the “target” CS, a memory of weaker strength, or contextual fear memory, and the effects on generalization reversed with the passage of time. Further, no effects were uncovered with a lower EtOH dose (1.0 g/kg). Together, these results identify a highly selective effect of chronic alcohol on cued fear memory generalization. Next, using immunohistochemistry we visualized the activity-regulated cytoskeletal arg/Arc3.1 (*Arc*) protein in the medial prefrontal

cortex (mPFC) following retrieval of the novel stimulus (generalization test). Results revealed a significant reduction in *Arc* expression in the shallow layers of the infralimbic cortex (IL) that was associated with fear memory generalization. No effects were observed in IL deep or prelimbic cortical layers. Considering a role for the IL in inhibitory control over conditioned fear expression, these data lead to a model whereby EtOH-induced hypoactivity of the IL drives fear memory overgeneralization. Chemogenetic manipulations (excitatory DREADDs) are currently underway to determine a causal role for EtOH-induced mPFC neuroadaptation in fear memory overgeneralization.

Title: Increased feedforward inhibition to engram neurons required for precision of fear memory

Authors: *S. LEE, H.-Y. LEE, J.-H. KIM
Dept. of Life Sci., Pohang Univ. of Sci. and Technol., Pohang, Korea, Republic of

Abstract: Fear memory would be stored mainly in a specific population of neurons (engram neurons) that had been activated during fear learning. Excitatory inputs to fear engram neurons in the lateral amygdala is enhanced after fear learning, but it remains unknown whether or not inhibitory microcircuits for engram neurons are also altered. Here, we report that feedforward inhibition to fear engram neurons in the lateral amygdala was significantly increased after fear conditioning. Importantly, the increase in feedforward inhibition correlates with precision for expression of fear memory. The feedforward inhibition onto fear engram neurons in the lateral amygdala is likely to be a critical factor for keeping appropriate fidelity of fear memory.

Title: Involvement of adenosine A_{2A} receptors in enhanced fear learning following traumatic brain injury

Authors: Y.-L. NING[1], N. YANG[1], X. CHEN[1], F. LUO[1], Y.-W. XU[1], Y.-L. JIANG[1], H.-K. TIAN[2], *Y. ZHOU[1]
[1]Res. Inst. Surg and Daping Hospital, Army Med. Univ., Chongqing City, China; [2]Dept. of Trauma and Microsurgery, the PLA No. 324 Hosp., Chongqing, China

Abstract: Traumatic brain injury (TBI) usually causes lasting neuropsychological abnormalities such as cognitive and emotional dysfunction. However, the regulatory mechanisms are poorly understood and there is no treatment available. Adenosine A_{2A} ($A_{2A}R$) is one of the key modulators of neuropsychical function and brain injury in the central nervous system (CNS). We have demonstrated previously that inactivation of $A_{2A}R$ exerted neuroprotective effects against TBI-induced spatial memory impairment. Here we investigated whether TBI causes augmented fear and the roles of adenosine $A_{2A}R$ in contextual fear learning following TBI. Moderate controlled cortical impact (CCI) was used to perform TBI in adult male c57BL/6 mice. At 12h post TBI, mice were submitted to a contextual fear conditioning (FC) paradigm (n=12 per group). Fear learning was assessed at 24h post FC by quantifying freezing behavior. The results showed that the percentage of freezing time in TBI+FC group was significantly higher than that in FC group, indicating an enhanced contextual fear following TBI. Meanwhile, the immunofluorescent staining showed that $A_{2A}R$ level increased remarkably in CA1, CA3 and DG regions of dorsal hippocampus (dHP), as well as the basolateral amygdala (BLA). The effect of dHP- or BLA- specific $A_{2A}R$ deletion by local injection of AAV5-Cre into floxed-$A_{2A}R$ mice was also examined. The results demonstrated that both dHP and BLA $A_{2A}R$ deletion attenuated contextual fear conditioning, comparing with TBI+FC mice. Together, this study provides the evidence that TBI facilitates contextual fear conditioning and that inactivation of $A_{2A}R$ in dHP or BLA inhibits fear memory following TBI, suggesting a therapeutic rationale of brain region-specific $A_{2A}R$ for the treatment of TBI-induced cognitive and emotional impairment. Since these injuries enhances the risk for the development of neuropsychiatric disorders including post-traumatic stress disorder (PTSD), $A_{2A}R$ may also be a promising therapeutic target for PTSD.

Title: Roles for the nucleus accumbens core, and its Gad1 subpopulation, in adaptive scaling of fear

Authors: *M. H. RAY, A. N. RUSS, E. K. ENABULELE, E. LEE, M. A. MCDANNALD
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Environmental threats exist on a continuum from unlikely to certain. Adaptive behavior requires fear to scale to the level of threat. Such scaling would be maximally adaptive if observed rapidly following threatening encounters. In two experiments, we examined roles for the nucleus accumbens core (NAcc), and its Gad1 subpopulation, in adaptive scaling of fear. In experiment 1, male Long Evans rats received bilateral neurotoxic NAcc lesions, deleting all neuron types, or sham surgery, leaving NAcc intact. In experiment 2, male and female Gad1-cre rats received bilateral NAcc viral infusions of pAAV-flex-taCasp3-TEVp (Casp3), selectively deleting NAcc Gad1 neuron types, or AAV-EF1a-DIO-EYFP (YFP), leaving Gad1 neurons intact. Following recovery, rats received 16 days of fear discrimination in which three auditory cues were associated with unique foot shock probabilities: danger (p = 1.00), uncertainty (p = 0.25), and safety (p = 0.00). Fear was measured over the entire 10-s cue, or in 100-ms intervals during the first 2-s, using suppression of rewarded nose poking. In experiment 1, sham rats acquired excellent fear discrimination, showing high fear to danger, intermediate fear to uncertainty, and low fear to safety. NAcc lesioned rats failed to show the same degree of discrimination, exhibiting decreased fear to danger and increased fear to safety. This pattern was most evident when assessing fear in the first 2-s of cue onset. While shams showed evidence of discrimination in ~600 ms, such discrimination was not observed in NAcc rats until nearly 2-s. The NAcc is then necessary for adaptive scaling of fear on multiple timescales. In experiment 2, YFP and Casp3 rats acquired excellent fear discrimination. In YFP rats, discrimination emerged rapidly and adaptively scaled to shock probability. Casp3 rats demonstrated a similar rapid discrimination, however, fear was heightened to all three cues. The results demonstrate an integral role for the NAcc in adaptive scaling of fear. Further, the results suggest that distinct NAcc neuron types may underlie specific components of adaptive scaling. In particular, NAcc GAD1 neurons may be tuned to onset of threatening stimuli, permitting fear to rapidly scale to the level of threat.

Title: Network dynamics of PSD95 and nNOS interactions in acquisition of conditioned fear

Authors: *E. T. DUSTRUDE[1,2], L. LI[2,3], S. FITZ[1,2], A. I. MOLOSH[1,2], Y. Y. LAI[5,6,4], A. SHEKHAR[4,1,6,2,3]

Abstract: Formation of fear memories involves stimulation of N-methyl-D-aspartic acid receptors (NMDARs) that results in greater interaction between the post-synaptic density 95 (PSD95) and nitric oxide synthase (nNOS) which increases production of nitric oxide (NO) and facilitates synaptic plasticity and fear conditioning. We have demonstrated that disrupting this protein-protein interaction within the basolateral amygdala (BLA) reduces conditioned fear, but little is known about the dynamics of PSD95 and nNOS interactions within conditioned fear network or the effect of this protein-protein interaction on neural network properties during acquisition of conditioned fear. Utilizing co-immunoprecipitation, electrophysiology, behavioral paradigms, and RNA sequencing, we investigated the dynamics of as well as the synaptic and molecular effects of PSD95/nNOS binding in various brain regions critical for conditioned fear, utilizing a small molecule disruptor of PSD95-nNOS interaction, ZL006. Immediately following fear conditioning, association of PSD95 and nNOS is enhanced in the basolateral amygdala (BLA) and ventral hippocampus (vHP) but not in the medial prefrontal cortex (mPFC). Systemic and intra-BLA treatment with ZL006 significantly attenuated cue-induced fear consolidation. Utilizing whole tissue RNAseq, we found that fear conditioning altered expression of 81 genes in the BLA, with the only a small group of gene changes reversed by ZL006 treatment. Further studies are underway to elucidate the molecular and synaptic mechanisms underlying the role of PSD95-nNOS-NO in conditioned fear in both the BLA and vHP. These data suggest that PSD95-nNOS interaction at specific sites within the fear network is a key step in the acquisition of

conditioned fears and disrupting this protein-protein interaction is a viable strategy for treating fear related disorders.

Title: Chronic intermittent nicotine exposure attenuates conditioned fear: A therapeutic model of the nicotine patch

Authors: *W. A. CARLEZON, Jr[1], I. HOLLOWAY[2], M. A. ROBBLE[2], E. MELONI[2], R. DESAI[2]
[1]Dept Psychiat, Harvard Med. Sch./Mclean Hosp., Belmont, MA; [2]McLean Hospital, Harvard Med. Sch., Belmont, MA

Abstract: The use of nicotine products such as cigarettes and smokeless (chewing) tobacco in the military is highly prevalent, but it is not known how nicotine affects vulnerability to stress and stress-related conditions including post-traumatic stress disorder (PTSD). Previous work has demonstrated that nicotine can relieve stress while also enhancing cognitive function. These two broad actions may have opposing effects on vulnerability to stress-related illness such as PTSD, which is thought to involve learning and memory components. Preliminary studies from our lab suggest that intravenous self-administration (IVSA) of nicotine in rats can reduce the impact of a traumatic event, as reflected by decreased responsivity to a context previously associated with footshock in the fear-potentiated startle (FPS) paradigm. These findings suggest that nicotine use in soldiers might reduce pathological responses that occur in contexts that have similarities with those in which a trauma was experienced, whether in combat settings or after returning home. Here we examined if the putative beneficial effects of nicotine IVSA on contextual fear learning are retained when the drug is given by a different (safer) route of administration, using a model of the nicotine patch. Male Long-Evans rats were implanted with a subcutaneous iPRECIO$_{TM}$ programmable minipump. After 7 days of recovery, rats received 1, 10, or 21-day exposure to either 0.3 mg/kg (low) or 1.0 mg/kg (high) of nicotine or saline for a 12-hr on/12-hr off period;

doses were based on previous work showing that rats self-administer ~1.0 mg/kg in 12-hr sessions. Following exposure, rats were trained in the FPS paradigm, which provides an index trauma and enables quantification of exaggerated startle response, a characteristic observed in humans with PTSD. Context-potentiated startle (CPS) and FPS were determined in each subject in a test session 10 days after training. We found that a 10-day exposure to the high dose of nicotine leads to decreased responsiveness to trauma (footshock)-associated cues and contexts, similar to findings after nicotine IVSA. Notably, a 1-day exposure produces the opposite effect on CPS, suggesting that chronic exposure is an important factor for the potential therapeutic benefits of nicotine. We are currently evaluating the effects on fear conditioning when nicotine exposure is maintained during the 10 days between training and testing. Our findings suggest that passive administration of nicotine can impact physiological responses trauma-associated stimuli and contexts, raising the possibility that medical application of nicotine could reduce the psychological impact of trauma.

Title: Cannabinoid and chronic mild stress modulation of hippocampal fear conditioning in adolescent female rats

Authors: *L. J. BARON[1], C. G. REICH[2]
[1]Ramapo Col., Paramus, NJ; [2]SSHS/Psychology, Ramapo Col. of New Jersey, Mahwah, NJ

Abstract: Chronic-Mild-Unpredictable-Stress (CMUS), an animal model of depression, selectively enhances hippocampal-dependent trace fear conditioning in male adolescent rats. The CMUS-induced fear enhancement is relieved by administration of a cannabinoid type 1 (CB1) receptor agonist (Reich et al., 2013). CMUS also decreases CB1 in male rats while increasing receptor levels in females. Furthermore, hippocampal CB1 levels are lower in control female rats compared to male rats (Reich et al., 2009). These findings suggest that hippocampal CB1 receptors are organized to differentially respond to stress depending on sex. However, it is unclear how CB1 sex differences translate behaviorally; particularly there is a lack of female

data. We therefore investigated the effects of CMUS and CB1 activation on the acquisition, recall, and extinction of both hippocampal-dependent trace and contextual fear conditioning. Trace (auditory-cued) or contextual fear conditioning were performed in female adolescent (40-60 days old) Sprague-Dawley rats. The CB1 agonist, ACEA (1 µM), was administered to both stress and non-stress rats prior to acquisition or prior to a 24 hr recall/extinction session. This was done in a factorial fashion with sample sizes were greater than n=6, the size needed for 80% statistical power. Our findings indicate that the CMUS enhances fear behavior in trace (cued) but not contextual paradigms. This is similar to our previous results in male rats. CMUS did not affect extinction; however, exogenous CB1 activation prior to acquisition impaired both short-term and long-term extinction in non-stress animals. In stressed females, CB1 activation prior to acquisition and memory recall decreased trace fear memory recall compared to controls; although ACEA impaired short and long-term extinction in stressed rats. Our results demonstrate that chronic stress can enhance trace fear conditioning (a form of episodic memory) in both male and female rats. However, the observed CB1-mediated extinction impairments in both non-stressed and stressed females (CB1 activation in males reliably facilitates fear extinction) reveal how sex differences in CB1 signalling manifests behaviorally.

Title: A novel rodent model to assess resistance to risk of punishment during reward seeking suggests dopamine related sex differences

Authors: *D. S. JACOBS[1], M. C. ALLEN[2], B. MOGHADDAM[3]
[1]Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR; [2]Oregon Hlth. and Sci. Univ., Portland, OR; [3]Behavioral Neurosci., OHSU, Portland, OR

Abstract: The ability to adapt to the complex relationship between reward and risk of punishment is critical for optimal action selection. While there have been some recent advances

in assessing this relationship (e.g. Park & Moghaddam, 2017) the neuronal basis of how punishment risk probability influences reward processing remains poorly understood. Here we designed and characterized a novel behavioral model to assess how varying probabilities of punishment modifies reward seeking actions in rats. Male and female rats were trained to perform instrumental responses in a chained seek-take procedure for food reinforcement. After behavioral stability was achieved in the seek-take stage, a punishment contingency was introduced during the seek link where reward seeking responses were punished by mild foot shock with increasing probability. Both male and female rats reliably decreased total responding and increased their latency to perform the punished (reward seeking) response as the probability of punishment increased. Results indicate that males were more resistant to punishment than females. Both non-punished (reward taking) responding and reward retrieval were unaffected, suggesting that changes in reward seeking were not due to satiety or the general suppression of behavior. Furthermore, task performance remained stable over experimental sessions, indicating robust and reliable patterns of behavioral reinforcement and suppression for males and females. Pharmacological D2 receptor manipulation generally decreased resistance to punishment, though females qualitatively appear to be less sensitive to D2 agonism-induced changes on punishment resistance than males. Circuit-level manipulation and electrophysiological studies that assess the mechanistic underpinnings of these observations are currently underway.

Title: Deletion of the prion-like domain of CPEB2 impairs long-term memory of one-trial inhibitory avoidance

Authors: *M. L. HUFF[1], B. A. EBNER[3,5], K. SI[2,4]
[1]Si Lab., [2]Stowers Inst. for Med. Res., Kansas City, MO; [3]Univ. of Kansas Med. Ctr., Kansas City, KS; [4]Dept. of Mol. & Integrative Physiol., Univ. of Kansas Med. Ctr., Kansas City, MO; [5]Stowers Inst. for Med. Reserach, Kansas City, MO

Abstract: Memories can last for hours or even years in humans, yet the molecular basis of this memory stabilization is still not fully understood. Previous work in our lab has revealed that the neuronal RNA binding protein cytoplasmic polyadenylation element binding protein (CPEB) is required specifically for the persistence of memory in a drosophila and this stability relies on self-sustaining amyloidogenic (prion-like) properties. Structural maintenance is also proposed to lead to memory stabilization in mammals and the CPEB2 isoform has been linked to synaptic

plasticity and long-term memory. Therefore, we hypothesized that removal of CEPB2 in a mouse model would impair long-term memory and synaptic plasticity. Deletion of the first exon and the prion-like domain led to viable homozygous CPEB2 knockouts (KO) with no detectable physical defects. Tissue isolated from KOs show no detectable full length CPEB2 as either a monomer or oligomer. To assess the role of CPEB2 in learning and memory, wildtype (B6/J) and KO littermates were trained on one-trial inhibitory avoidance. On training day, mice received a single, inescapable footshock (0.5mA, 1s) upon fully crossing from the illuminated to the darkened compartment. Retention was tested 48h later and latency to cross from the illuminated to darkened "shock" compartment was measured. Long-term potentiation was measured in hippocampal slice preparations from animals at 1 and 6-months of age following 4 trains of 100 Hz high frequency stimulation. An open field test (30 min session) was used to examine any general anxiety deficits or locomotor changes. Sessions were recorded and analyzed using EthoVision software. During inhibitory avoidance testing, KO animals show reduced retention latencies compared to matched wild type when trained at 3 or 6 months of age. This impairment persisted when retention was tested up to 2 months after initial training. Long-term potentiation and paired-pulse facilitation was impaired in KO animals at one-month but not 6 months of age. KO animals travel significantly less during a 30 min open field test but show no preference in center vs. border regions. Together, these findings suggest that lack of the CPEB2 prion-like domain disrupts normal learning and memory. Future work will investigate the role of CPEB2 in short term memory across development as well as long term memory at earlier timepoints (i.e. 1 month) when synaptic potentiation is impaired.

Title: Shifting from fear to safety through reconsolidation memory updating: Deconditioning as a novel approach to eliminate traumatic memories

Authors: *L. O. ALVARES[1], B. POPIK[2]
[1]Federal Univ. Rio Grande do Sul, Porto Alegre, Brazil; [2]UFRGS, Porto Alegre, Brazil

Abstract: Traumatic memories are at the heart of psychiatric disorders such as post-traumatic stress disorder (PTSD) and lead to severe economic and social burden. Pharmacological or psychological treatments such as exposure therapy have limited efficacy and are transient,

because the traumatic memories reemerge with the passage of time. Here, we show a new approach that eliminate aversive memories in an effective and permanent way, transforming them into an innocuous memory. This method consists of "deconditioning" rats which have previously been trained to associate a sound with a strong foot-shock where the shock information is updated and replaced by an extremely low aversive/neutral stimulus during the plastic state induced by memory retrieval, resulting in a permanent reduction of fear responses in the presence of the sound. Our results indicate that deconditioning-update is effective in eliminating up to 80% of fear responses. Moreover, such effects are long-lasting, and insensitive to renewal and spontaneous recovery, suggesting a permanent update in fear memory. Remarkably, this new strategy overcame important boundary conditions, as it was effective in eliminating either a remote or a very strong traumatic memory. Furthermore, the same beneficial effect was also found in other type of fear-related memories (contextual memory and inhibitory avoidance.

Title: Infralimbic inputs to the basal forebrain regulate consolidation of extinction

Authors: *S. LEI[1], M. B. HARNOIS[2], E. LIKHTIK[3]
[1]CUNY Hunter Col., New York, NY; [2]Psychology, New York Univ., New York, NY; [3]Biol., Hunter Col., New York, NY

Abstract: The medial prefrontal cortex (mPFC) is an important region for regulating emotion, and its infralimbic (IL) subregion plays a crucial role in consolidation of fear extinction learning. The IL suppresses defensive responding after extinction by inhibiting amygdala output. However, it is not known whether this outcome is achieved only via direct IL-amygdala connectivity or with additional, indirect modulation of the amygdala by the IL. The basal forebrain (BF) may be one node on the indirect pathway from the IL-to-amygdala that plays a role in extinction. The BF receives IL input, sends GABAergic and cholinergic afferents to the amygdala, and is known to regulate attention to task relevant cues. We tested the contribution of IL-to-BF projections to consolidation of extinction by optogenetically inhibiting IL inputs to the

BF during Extinction Training and recording physiology across the IL-BF-basolateral amygdala (BLA) circuit. Male mice (C57B6J) were injected with either the inhibitory opsin archaerhodopsin (eArch3.0) or with eYFP into the IL, and optic fibers were placed above the BF to inhibit IL terminals. Mice underwent fear conditioning and then Extinction Training, when IL inputs to the BF were either inhibited (eArch3.0, n=13) or left undisturbed (eYFP, n=9). Extinction Recall was tested 24 hours later without the presence of light. Whereas same day acquisition of extinction in the eArch group was undisturbed, eArch animals showed significantly impaired recall the next day, suggesting that IL inputs to the BF during training are important for consolidation of extinction learning. Immunohistochemical analyses of cFos across the BF revealed that mice in the eArch group showed significantly more neural activity during Extinction Recall than the eYFP group. Quantification of cFos in choline acetyltransferase (ChAT+) expressing cells of the BF show that increased freezing during recall significantly correlates with cholinergic (ChAT+) cell activity in the ventral pallidum (VP) of the BF. Moreover, analyses of cFos in parvalbumin expressing (PV+) GABAergic cells and ChAT+ cholinergic cells after recall suggest that activity in these two cell groups is reciprocally modulated in the VP. Impaired Extinction Recall is associated with higher activation of cholinergic cells and dampened activity in PV+ cells, whereas successful Extinction Recall shows increased activity of PV+ cells and a concomitant decrease in cholinergic activation. We suggest that the IL projections we recently demonstrated in PV+ cells of the BF contribute to extinction consolidation by inhibiting cholinergic activity that is normally associated with recall of fearful cues.

Title: Differential connectivity between the infralimbic and prelimbic cortices with the basal forebrain - amygdala circuit

Authors: *R. ZHANG[1], M. LABKOVICH[1], N. BURNEY[1], D. GOLDER[1], E. LIKHTIK[1,2]
[1]Biol., Hunter College, CUNY, New York, NY; [2]The Grad. Center, CUNY, New York, NY

Abstract: To develop targeted treatments for anxiety disorders, we need a comprehensive understanding of the connectivity between regions involved in aversive memory formation and extinction in both sexes. Direct projections from the medial prefrontal cortex (mPFC) to the basolateral amygdala (BLA) are important for modulating aversive and extinction learning. However, we know much less about the indirect pathways from the mPFC to the BLA that may also be involved in modulating behavior. Here, we examine how the prelimbic (PL) and infralimbic (IL) sub-regions of the mPFC connect with the BLA via the basal forebrain (BF), a structure that sends cholinergic and GABAergic projections to the BLA, and modulates the signal-to-noise ratio in the BLA during aversive learning. To investigate this pathway, we injected retrograde tracers (Retrobeads, Lumafluor and Cholera Toxin B) in the BLA, and an AAV anterograde synaptic labeling vector (AAV8.2-hEF1α-DIO-synaptophysin-mCherry, Rachel Neve, MIT Viral Core) in either the IL or PL of the mPFC in male and female mice (C57BL6J/129SvEv F1 generation). We then examined the overlap in synaptophysin-labeled axon terminals and retrograde- labeled cell bodies across three nuclei of the BF: the ventral pallidum, the substantia innominata, and the horizontal limb of the diagonal band. In order to identify BF cholinergic and GABAergic cells, we counterstained the tissue with choline acetyl transferase (ChAT+), parvalbumin (PV+), and somatostatin (SOM+). Our analyses confirm previous findings in the rat, showing that whereas cholinergic and PV+ cells project to the BLA from all examined nuclei in the BF, projections from SOM+ cells are very rare. We then show that the IL contacts a significantly larger proportion of PV+ than cholinergic BLA projectors, whereas the PL contacts more cholinergic than PV+ BLA projectors. Our preliminary analyses also show that this dichotomy is even more pronounced in female mice. These findings suggest that the PL may promote BLA activation during fear expression by driving BF cholinergic inputs to the BLA. Conversely, the IL may contribute to consolidation of extinction learning by activating BF PV+ cells that would disfacilitate cholinergic input to the BLA on the one hand, and inhibit cells in the BLA directly on the other.

Title: Developing a safety learning paradigm as a therapeutic tool for high anxiety

Authors: *I. NAHMOUD[1], H. CHO[3], S. TALBOT[2], T. DENNIS-TIWARY[4], E. LIKHTIK[4]
[1]Chem. Dept., [2]Biol. Dept., Hunter Col., New York, NY; [4]Biol. Dept., [3]CUNY Grad. Ctr., New York, NY

Abstract: Post-Traumatic Stress Disorder (PTSD) is characterized by generalized fear, such as indiscriminate autonomic and defensive behavioral responses to cues that are unrelated to threat. Extinction has been the most successful behavioral therapy for these disorders. However, extinction is cue- and context- specific, and for a significant proportion of patients this approach doesn't alleviate generalized fear. Therefore, an expanded repertoire of behavioral therapeutic approaches is desirable to address the needs of a larger patient population. Previous work in wild type C57BL6J mice has shown that Safety Conditioning, where a conditioned stimulus (tone CS) explicitly signals the absence of an aversive unconditioned stimulus (shock US), also known as "Unpaired" (US//CS_T) training, the CS can become a conditioned inhibitor of fear in and outside of the training context. However, we show that in a high anxiety strain of mice (129SvEv, Taconic) the "Unpaired" Safety Conditioning doesn't result in conditioned inhibition of fear to the CS. To improve safety learning in high anxiety mice, we enhanced Safety Conditioning in two ways: (1) via increasing the salience of the CS ("Salient CS") where the CS signaling the absence of shock consisted of a tone and a houselight (CS_{TL}//US), and (2) by making the CS a "Feature Positive" stimulus that is paired with the onset of a neutral house light, whereas the US remained unpaired (US//CS_T-L). A fourth group of mice underwent paired fear conditioning training ("Paired", CS_T-US). We then assessed the degree of defensive freezing during CS presentation in the training context, and whether CS meaning can transfer to a new context by presenting the CS in a novel open field. We also tested whether the initial Safety or Fear Conditioning affects acquisition of discrimination learning on a new differential fear conditioning task learned 7 days later. Initial analyses show that Enhanced Safety Conditioning increases percent center time in the open field and improves discrimination learning in high anxiety mice. We propose that Enhanced Safety Conditioning increases attention to the "Salient" and the "Feature Positive" CS during training making it a better predictor of safety for high anxiety mice. Likewise, increased attention allocated to the "Salient" and the "Feature Positive" CS may teach animals to pay attention to "Feature Negative" (or unpaired) stimuli during subsequent learning, leading to better discrimination. These findings point to Enhanced Safety Conditioning as a potentially useful therapeutic approach to improve generalized anxiety and adaptive learning in patients with PTSD.

Title: Inhibition of protein synthesis in the dorsal hippocampus prevents reconsolidation of a covertly retrieved fear memory

Authors: *R. RESSLER, T. D. GOODE, S. KIM, S. MAREN
Psychological and Brain Sci. and Inst. for Neurosci., Texas A&M University, Col. Station, TX 77840, College Station, TX

Abstract: Memories enter a labile state after retrieval, and administration of protein synthesis inhibitors interferes with the reconsolidation of reactivated memories. After fear conditioning, infusion of protein synthesis inhibitors into the amygdala impairs the reconsolidation of fear to an auditory conditioned stimulus. However, it has been reported that indirectly reactivated memories (e.g., memories to a second-order conditioned stimulus, CS) are not sensitive to protein synthesis inhibition in the amygdala. Because the hippocampus is thought to play a role in the S-S associations that underlie higher order conditioning phenomena, we explored whether an indirectly retrieved context memory would be sensitive to protein synthesis inhibition in the hippocampus. It has previously been reported that backward conditioning, a procedure in which the unconditioned stimulus (US) directly precedes the CS, is mediated by contextual fear association (Chang et al. 2003). We tested whether the extinction of fear to the conditioning context selectively attenuates fear to a backward--conditioned CS. Accordingly, rats were conditioned using either forward (FW; CS-US) or backward (BW; US-CS) trials (context A). The following day animals underwent context extinction (context A) or novel context exposure (context B). Animals were then tested for fear to the CS in a third context (C). Results revealed that extinction of the conditioning context selectively reduced freezing in BW-conditioned but not FW-conditioned animals. In Exp. 2, rats were implanted with bilateral cannulae aimed at the DH. After recovery, FW or BW conditioning was conducted as in Exp. 1. Twenty-four hrs later, all rats received a single CS exposure in a familiar context (B), which we hypothesized would reactivate the memory of the conditioning context in BW-conditioned but not FW-conditioned rats. To target reconsolidation of the memory retrieved by the CS, we infused the protein synthesis inhibitor rapamycin (or vehicle) into the DH immediately followed the reactivation session. Two days later, we assessed freezing behavior in the original conditioning context (A)

during a 20-min test. In support of our hypothesis, intra-DH rapamycin infusion reduced contextual freezing in only rats conditioned with the BW CS. These results provide evidence that the backward, but not forward, CS reactivated a hippocampal representation of the original conditioning context, and that reconsolidation of this memory required hippocampal protein synthesis. This has important implications for novel therapeutic approaches to target and selectively erase traumatic memories.

Title: NMDA receptors in the BNST are necessary for learning to fear ambiguous threats

Authors: *T. D. GOODE, R. RESSLER, C. EVEMY, K. FRENCH, S. MAREN
Inst. for Neurosci. and Dept. of Psychology, Texas A&M Univ., College Station, TX

Abstract: We have recently shown that the bed nucleus of the stria terminalis (BNST) is critical for the expression of conditioned freezing to ambiguous threat signals in rats. In particular, BNST inactivation impairs freezing to a conditioned stimulus (CS) arranged to follow an aversive unconditioned stimulus (US) during conditioning (i.e., backward conditioning), but does not impair freezing to a CS that precedes the US (i.e., forward conditioning). Here we explored whether *N*-methyl-D-aspartate (NMDA) receptors in the BNST and the amygdala are necessary for backward fear conditioning. We hypothesized that NMDA receptor activity in the BNST is required for backward conditioning, whereas central amygdala (CeA) NMDA receptors are important for forward fear conditioning; basolateral amygdala (BLA) NMDA receptors were expected to mediate fear conditioning in both cases. Adult male and female Long-Evans rats were implanted with cannula aimed at the CeA, BLA, or BNST. Intracranial microinfusions (0.275 μl/hemisphere) of APV (10 μg/μl) or vehicle occurred immediately before fear conditioning in which an auditory CS (10 sec, 2 kHz, 80 dB tone) was presented with an aversive US (2 sec, 1 mA footshock). For half of the rats, the CS immediately preceded the US (forward conditioning), while the other rats experienced the US immediately before the CS (backward conditioning). Training consisted of twelve forward or backward trials in a distinct context.

Defensive immobility (freezing) served as the dependent variable. Forty-eight hrs after training, animals (drug-free) were placed in a novel context and tested to the CS (five trials). Twenty-four hrs later, animals were returned to the training context to assess levels of context fear. Interestingly, APV blocked the acquisition of conditioned freezing to the backward CS when infused into the BNST or CeA (but not BLA), while conditioned freezing to the forward CS was blocked by infusions of APV into CeA and BLA (but not BNST). Additionally, APV infusions in the BNST and BLA completely blocked fear acquisition to the conditioning context, whereas CeA infusions produced a partial impairment in contextual freezing. All animals acquired fear when retrained drug-free and similar effects were observed in males and females in all cases. Overall, these data reveal dissociable roles for the BLA, CeA, and BNST in fear conditioning to ambiguous and certain threats.

Title: Propranolol stabilizes shock-induced increases in spike firing in the basolateral amygdala: Implications for the immediate extinction deficit

Authors: *T. F. GIUSTINO[1], M. TOTTY[2], S. MAREN[2]
[2]Psychological and Brain Sci. and Inst. for Neurosci., [1]Texas A&M Univ., College Station, TX

Abstract: Early interventions, such as psychological debriefing and exposure therapy, after trauma exposure aim to reduce the development of trauma- and stressor-related disorders such as posttraumatic stress disorder (PTSD). Our lab and others have shown that when extinction learning occurs soon (i.e., minutes to hours) after fear conditioning that animals and humans show impaired extinction learning, a phenomenon termed the immediate extinction deficit (IED). We have recently shown that both systemic ß-adrenergic blockade with propranolol and local propranolol infusions into the basolateral amygdala (BLA) attenuate the IED. This suggests that stress-induced deficits in extinction learning might operate through noradrenergic signaling in the BLA. As a first step to testing this hypothesis, we recorded single-unit activity in the BLA

immediately after fear conditioning during a post-conditioning window that is associated with the IED, and examined the effects of systemic propranolol on shock-induced changes in BLA activity. Animals were implanted with a 16-channel microelectrode array targeting the BLA and after a 3 min stimulus free baseline period were injected with either vehicle or propranolol (10 mg/kg, i.p.). Twenty min after the injection animals underwent standard auditory fear conditioning procedures as previously described (Fitzgerald et al., 2015) and remained in the chamber for 60 min following the last shock. Twenty-four hours later, animals were placed in a novel context and were tested for fear memory retention. Neural and behavioral data were recorded continuously throughout the sessions. We found that fear conditioning resulted in a rapid and sustained increase in BLA spontaneous firing rates and this corresponded with high levels of post-shock freezing. Interestingly, propranolol treatment reduced both post-shock freezing and the shock-induced increases in BLA spike firing. During the fear recall test, controls animals showed high levels of tone-evoked freezing as well CS-induced increases in BLA spike firing. Prior propranolol treatment reduced both CS-evoked freezing and BLA spike firing. Overall, these data suggest that footshock produces rapid and sustained excitation in amygdala single-unit activity that are dependent, at least in part, on ß -adrenoceptors. Stress-induced increases in BLA noradrenergic activity may be a therapeutic target for trauma- and stressor-related disorders.

Title: Hormonal basis for state-dependent conditioned fear in naturally cycling female rats

Authors: N. WARREN[1], G. M. ACCA[2], B. TSAO[1], A. MATHEW[2], A. PHAN[2], N. CAYARD[1], J. JULIETTE[2], S. MAREN[2], *N. NAGAYA[2]

Abstract: Women are more susceptible than men to stress- and trauma-related disorders, suggesting that ovarian steroid hormones play a modulatory role in fear and anxiety. Indeed, in both humans and rodents, estrogen and progesterone (PROG) have been shown to influence various aspects of fear learning. We have recently found that allopregnanolone (ALLO), a neuroactive metabolite of PROG, can confer state dependence to contextual fear in adult male

rats when infused into the bed nucleus of the stria terminalis. Given that circulating ALLO levels mirror fluctuations in PROG across the estrous cycle in female rats, we hypothesized that PROG confers state dependence to contextual fear in naturally cycling females. To this end, we performed Pavlovian fear conditioning on gonadally intact, cycling female rats in high (late proestrus) or low (late diestrus) PROG states. Animals were conditioned with 5 tone (2 kHz, 10 s, 80 dB) - footshock (2 s, 1 mA) pairings and tested 3 to 6 days later for context-induced freezing behavior in the conditioning chamber (10 min). Conditioning and testing were timed such that rats were in either the same or different estrous cycle phase in a factorial design. Animals that were conditioned in diestrus and tested in proestrus displayed significantly lower levels of contextual freezing compared to those that were conditioned and tested in the same estrous cycle phase (either diestrus or proestrus), suggesting a state-dependent effect of estrous cycle phase and PROG level on fear learning. This state dependence was asymmetric, insofar as animals conditioned in proestrus and tested in diestrus displayed levels of freezing that were similar to those for which estrous cycle phase was matched during conditioning and testing. As a first step in exploring the role for ovarian steroids in this effect, we examined whether exogenously administered PROG would regulate fear expression in ovariectomized (OVX) animals. Following 1 week of recovery, OVX females were conditioned and tested in either the same or different hormonal state (induced by acute injection of either 4 mg/kg PROG or 1 ml/kg sesame oil vehicle, VEH, 1 hr prior to behavior) in a factorial design. PROG administration did not influence the acquisition or expression of contextual fear. However, we did observe lower levels of conditioned freezing to the tone in the VEH-PROG group compared to the VEH-VEH and PROG-PROG groups, indicating that some state dependence could be generated in this model. Together, these results suggest that natural fluctuations in PROG (and perhaps ALLO) levels can confer state-dependence such that hormonal state serves as an interoceptive contextual cue in conditioned fear.

Title: Does stress or event segmentation account for the immediate extinction deficit?

Authors: *M. TOTTY, S. MAREN
Psychological and Brain Sci. and Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: Research in both rodents and humans has demonstrated that when extinction training occurs soon after (15 min) fear conditioning it results in impaired long-term extinction memory, a phenomenon called the "immediate extinction deficit" (IED). Considerable data suggest that IED is caused by a stress-induced dysregulation of neural circuits, including the medial prefrontal cortex and amygdala, that are essential for extinction learning (Fitzgerald et al., 2015). However, a recent study in humans (Dunsmoor et al., 2018) suggests that a short break between conditioning and extinction produces an "event boundary" that segments these events, prioritizes consolidation of the fear memory, and interferes with extinction. By this view, a "continuous" (CONT) extinction procedure [in which extinction trials follow conditioning trials at identical inter-trial intervals (ITIs)] would not yield an IED relative to a procedure in which there is a 15-min break (BREAK) between conditioning and extinction. To test this hypothesis, animals underwent auditory fear conditioning consisting of five tone conditioned stimulus (CS; 10 sec, 80 dB, 2kHz)-shock unconditioned stimulus (US; 2 sec, 1.0 mA) pairings in a distinct context. Conditioning was followed by extinction training (in the same context) after either a 60-sec (CONT; extinction trials delivered at the same ITI used during conditioning) or a 15-min break (BREAK); a third group of animals did not receive extinction but remained in the chambers an equivalent period of time (NO-EXT). Time in the training context was equated for all animals and freezing served as the index of fear. During extinction training, animals in the CONT group exhibited greater within-session extinction of freezing relative to BREAK or NO-EXT animals. However, this difference did not persist to the retention test conducted 48 hrs later in the same context. As we have previously reported, animals receiving extinction trials within 15-min of conditioning (CONT and BREAK) exhibited levels of freezing to the CS during the test and were identical to the high levels of freezing exhibited by animals that were not extinguished; animals in the CONT and BREAK conditions did not differ from one another. Therefore, eliminating the event boundary with a continuous extinction procedure did not eliminate the IED. These results support the view that the the IED is caused by the stress associated with fear conditioning, which disrupts the brain circuits and neural mechanisms involved in extinction learning.

Title: Nucleus reuniens inactivation impairs the acquisition and expression of contextual fear conditioning in rats

Authors: *K. R. RAMANATHAN[1], R. L. RESSLER[2], J. JIN[2], S. MAREN[2]
[2]Inst. for neurosciences and Dept. of Psychological and brain sciences,, [1]Texas A&M Univ., College Station, TX

Abstract: The nucleus reuniens (RE) is a ventral midline thalamic nucleus that interconnects the medial prefrontal cortex (mPFC) and hippocampus (HPC). Recent data suggest that RE lesions or inactivation produce deficits in spatial and working memory, which depend on HPC-mPFC interactions. Contextual fear conditioning also requires HPC-mPFC circuitry, but it is unclear whether RE manipulations affect the acquisition or retrieval of these memories and, importantly, whether RE inactivation affects performance in a state-dependent manner. To test this hypothesis, we inactivated the RE with muscimol (MUS, 0.3 µl at 0.1µg/µl concentration) either before the acquisition or expression (or both) of fear conditioning in a 2 X 2 factorial design; saline (SAL) infusions served as a control. The design yielded four groups of animals: SAL-SAL, SAL-MUS, MUS-SAL, and MUS-MUS (where drug conditions during conditioning and retrieval testing are indicated). Fear conditioning was conducted with either signaled (10 sec, 80 dB, 2 kHz tone) or unsignaled footshock (2 sec, 1 mA) and freezing served as the index of fear. Twenty-four hours after conditioning, rats were again infused with MUS or SAL and contextual freezing was assessed in either the conditioning context or a novel context in counterbalanced tests. Inactivation of the RE produced a robust impairment in the acquisition of contextual freezing in MUS-SAL rats, however, this impairment was absent in animals that were both trained and tested after RE inactivation (MUS-MUS). Interestingly, RE inactivation alone (SAL-MUS) did not cause a state-dependent generalization decrements, but increased freezing in a novel context as has previously been reported; this effect was not simply due to a nonspecific increase in freezing. Inactivation of RE did not affect the acquisition or expression of auditory fear conditioning. Together, these data suggest that RE inactivation impairs contextual processing and reveal that alternate, elemental representations of context support conditioning when the RE is offline.

Title: Sex-specific effects of endocannabinoid action on cued fear conditioning and extinction

Authors: M. MEJDELL[1], A. LI[1], J. LAPETINA-COLOM[1], B. BROWN[1], I. SHURNAYTE[1], A. WINTER[1], S. BEGLEY[1], J. ABETTAN[1], *R. SHANSKY[2]

Abstract: Experiencing a traumatic event is twice as likely to cause post-traumatic stress disorder in women as it is in men. Despite this imbalance, most of what we know about the neural mechanisms that underlie PTSD comes from research in male animals. One especially under-studied area is the endocannabinoid (eCB) system, whose role in modulating the stress response is just beginning to be uncovered. A better understanding of sex differences in these processes is critical to progress in developing more personalized therapies for PTSD patients of both sexes. To explore the influence of eCB signaling on aversive learning and memory processes, we tested male and female rats in a standard cued fear conditioning and extinction paradigm after systemic administration of FAAH inhibitor URB597, CB1 receptor antagonist AM251, MAGL inhibitor MJN110, or vehicle. We measured both cue-elicited freezing and darting in all animals, finding that as we have previously reported, females are more likely than males to engage in darting behavior during fear conditioning. In addition, AM251 administered during fear conditioning increased context generalization in females, but not males. These data suggest that endocannabinoid systems may differentially affect learning and memory processes in males and females.

Title: A multifaceted approach for investigating sex-specific behavioral profiles during associative fear learning in rats

Authors: *A. LI, J. COLOM-LAPETINA, A. KIRUNDA, L. MILLER, R. SHANSKY
Behavioral Neurosci., Northeastern Univ., Boston, MA

Abstract: Classical Pavlovian fear conditioning has been widely used to study stress learning mechanisms. An animal's level of fear is typically evaluated by "freezing", but recent studies have identified a wide array of behaviors, suggesting that freezing is an incomplete measure of fear. Our previous work identified and characterized "darting", a sexually dimorphic active fear response predictive of improved extinction retention. In this study, we hypothesized that previous stress exposure biases fear behavior toward darting. One week before fear conditioning, male and female Sprague-Dawley rats underwent either a single sham surgery (n = 35) or five days of restraint stress (n = 30) to induce physiological stress or psychological stress, respectively. An additional control cohort (n = 31) was briefly handled. Five days after initial stress exposure, we used the tail flick test (TFT) to evaluate pain sensitivity. Then, the rats underwent fear conditioning on Day 1 via exposure to five unpaired tone presentations (CS) followed by seven footshock-paired tone presentations (CS-US). On Day 2, the animals underwent extinction with 20 unpaired CS presentations. Day 3 tested extinction retention with five unpaired CS presentations. Across the fear conditioning paradigm, velocity data were collected using EthoVision and analyzed with a set of custom Python scripts. Our high-throughput analysis method allows for efficient and accurate evaluation of a variety of behaviors, including darting, freezing, and general locomotion. Importantly, visualization of each animal's velocity across the entire paradigm allows us to dissect individual differences and predictive factors for these divergent behavior profiles.

Title: Social buffering in fear memory extinction

Authors: *T. GORKIEWICZ, E. KNAPSKA
Neurophysiol., Nencki Inst., Warsaw, Poland

Abstract: Social support during the exposure-based psychotherapy has been suggested to have an important influence on the course of exposure treatment; however the mechanisms of such influence remain unknown. The literature review indicates that group treatment for posttraumatic stress disorder (PTSD) is efficacious compared with no treatment; however, some randomized clinical trials show that individual therapy may be more effective than group therapy. To

compare neuronal correlates of individual and group exposure therapy, we have developed a rat model of socially modulated fear extinction. In this model pair-housed rats are separately fear conditioned to the tones and then subjected either to fear extinction or merely exposure to the experimental cage. Next, the rats are placed in the experimental cage and presented to conditioned tones in pairs or separately. We observed much lower freezing response in rats tested with a partner compared to rats tested separately. The magnitude of social buffering effect depended on familiarity. However, the effect was transient, when fear memory was measured on the next day there was little difference between rats exposed to the conditioned tones together or separately. Lower freezing level during exposure with a partner was associated with lower activation of the prefrontal cortex; with the dominant input to active neurons from the hippocampus, whereas the retrieval of fear memory was associated with greater amygdalar input. Taken together, these results suggest that the social buffering effects may partially rely on the same neuronal circuits as individual fear extinction but the social fear memory suppression is transient.

Title: Exposure to elevated levels of kynurenic acid impairs the extinction of conditioned fear: Implications for anxiety and stress disorders

Authors: C. H. PUSKAS, M. C. EDDY, N. E. DEANGELI, K. B. COCHRAN, *D. J. BUCCI
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Kynurenic acid (KYNA), a metabolite of tryptophan degradation, acts as an antagonist of both NMDA glutamate and alpha-7 nicotinic acetylcholine receptors. Prior work has shown that in rats with a compromised stress response system (e.g., adrenalectomy, ADX), subsequent exposure to a mild stressor increases the concentration of KYNA in the prefrontal cortex. Moreover, the increase in KYNA in ADX-rats following stress causes rats to generalize fear to otherwise innocuous stimuli. This has led us to propose that a stress-induced increase in KYNA may contribute to abnormal fear behavior in persons with a compromised stress response system, such as those with PTSD. If so, increased levels of KYNA may also impair fear extinction. Extinction is the basis for exposure-based therapy in humans and consists of repeated presentations of the fear-eliciting stimulus in the absence of aversive consequences, thereby

reducing the fear-provoking ability of the stimulus. Interestingly, extinction is often ineffective in persons with PTSD; in addition, a wealth of research in rodents and humans has revealed that the prefrontal cortex has a pivotal role in fear extinction. In the present study, rats underwent a standard fear conditioning procedure in Context A and received presentations of a tone followed by footshock. Extinction training began the next day and consisted of four daily sessions in which the tone was presented without shock in a new context (Context B). Two hours before each extinction session half of the rats were treated with 100mg/kg l-kynurenine (L-KYN; i.p.), the precursor of KYNA, which significantly elevates brain KYNA levels. The other half of the rats were treated with a vehicle solution. During the subsequent extinction test sessions, rats received presentations of the tone (no shock) in the original training context (A) and in the extinction context (B). No injections were made before the test sessions. Control rats exhibited low levels of fear to the tone during the Context B test session, while fear renewed (high levels) when the tone was presented in Context A, reflecting the normal context-dependency of fear extinction. However, rats that had been treated with L-KYN during extinction training exhibited high levels of fear to the tone in both contexts. A subsequent re-acquisition procedure showed that this effect was not simply due to an inability to discriminate between the two contexts. This suggests that increased levels of KYNA impair the extinction of conditioned fear, providing further support for the notion that increased levels of KYNA may contribute to impairments in fear learning and extinction associated with stress-related disorders.

Title: Diurnal examination of infralimbic prefrontal cortex neuronal activity: Encoding of distinct behaviors relevant to conditioned fear extinction learning

Authors: *M. J. HARTSOCK, J. R. RAVENEL, K. S. MCCONOMY, H. K. STRNAD, A. B. FAUSNAUGHT, M. P. SADDORIS, R. L. SPENCER
Univ. of Colorado Boulder, Boulder, CO

Abstract: Stress-related mental disorders are associated with circadian disruptions and with impairments in fear extinction learning. In rats, projections from the infralimbic prefrontal cortex

(IL) to the basomedial amygdala are believed to mediate extinction. We have shown recently that rats exhibit a diurnal rhythm in fear extinction recall that is abolished by disruption of the IL circadian system, raising the possibility that circadian disruptions in this pathway—such as those produced by stress—may lead to learning impairments similar to those observed in mental disorders. To determine whether diurnal rhythms in extinction are driven by diurnal rhythms of neuronal activity in the IL, we recorded IL neuronal activity during fear extinction in the daytime (inactive phase) or nighttime (active phase). Adult male Sprague-Dawley rats on a 12h:12h light:dark cycle were administered bilateral microinjections of CaMKII-promoter-driven channelrhodopsin-2 (ChR2) in the IL to enable photo-tagging of IL pyramidal neurons. One week later, an 8-channel electrode array surrounding an optical fiber was implanted in the IL in each hemisphere. After recovering from surgery, rats were trained and tested in a delayed fear conditioning protocol consisting of tone-shock pairing on Day 1, fear extinction on Day 2, and fear extinction recall on Day 3. Neurophysiological recording of IL neurons was conducted on Days 2 and 3, and 470nm blue light was used on Day 3 to stimulate ChR2 during extinction recall. We have identified changes in phasic activity corresponding to two different behaviorally relevant events: 1) cue presentation after tone-shock pairing and 2) behavioral responding (i.e. freezing or unfreezing) to the paired cue. Of neurons associated with behavioral responding, one subpopulation increased its firing rate for freezing onset and decreased its firing rate for freezing offset, while another subpopulation exhibited an opposite activation pattern. Photo-tagging demonstrated that some recorded cells were positive for ChR2, establishing proof of principle that recorded cells can be distinguished by phenotype and subsequently manipulated. This study is the first to record diurnal firing within the IL and to differentiate neuronal subpopulations within the IL associated with freezing onset versus freezing offset.

Title: The effects of pharmacological blockade of PPARs on formalin-evoked nociceptive behaviour, fear-conditioned analgesia and conditioned fear in the presence or absence of nociceptive tone

Authors: *J. C. GASPAR[1,2,3], B. OKINE[1,2,3], D. DINNEEN[1], A. LLORENTE-BERZAL[1,2,3], M. ROCHE[4,2,3], D. P. FINN[1,2,3]
[1]Natl. Univ. of Ireland Galway, Galway, Ireland; [2]Galway Neurosci. Ctr., Galway, Ireland; [3]Ctr. for Pain Res., Galway, Ireland; [4]Physiol., Natl. Univ. of Ireland, Galway, Ireland

Abstract: Introduction Peroxisome proliferator-activated receptors (PPARs) are nuclear receptors[1]. There is evidence for their involvement in pain[2], cognition[3], and anxiety[4]. However, their role in pain-fear interactions is unknown. The amygdala plays a key role in pain, conditioned fear and fear-conditioned analgesia (FCA). **Aims** Investigate the effects of systemic and intra-basolateral amygdala (BLA) and central amygdala (CeA) administration of PPARα, PPARβ/δ and PPARγ antagonists on nociceptive behaviour, fear-conditioned analgesia (FCA), and conditioned fear in presence or absence of nociceptive tone in rats. **Methods** Male Sprague-Dawley (SD) rats received footshock (FC) or no footshock (NFC) in a conditioning arena. 23.5h later, rats received intra-plantar injection of formalin and intra-peritoneal vehicle, PPARα (GW6471), PPARβ/δ (GSK0660) or PPARγ (GW9662) antagonists, before re-exposure to the arena for 15 minutes, and behaviour recorded. In subsequent experiments, rats underwent a similar protocol except PPAR antagonists or vehicle were microinjected intra-BLA or intra-CeA 15 minutes prior to formalin or saline administration. Pain- and fear-related behaviours were assessed for 30 minutes and amygdalar neurotransmitters/endocannabinoids were measured post-mortem. **Results** Systemic administration of all antagonists potentiated context-induced freezing in the presence of formalin-evoked nociceptive tone, with no effect on nociceptive behaviour. Intra-BLA administration of PPARα or PPARγ antagonists potentiated freezing in the presence of nociceptive tone in FC rats. Blockade of all PPARs in the BLA increased freezing and BLA dopamine levels in NFC rats in the absence of nociceptive tone. Administration of PPARα, PPARβ/δ or PPARγ antagonists intra-CeA did not affect freezing duration in FC rats in the presence of nociceptive tone. Formalin-injected FC rats receiving PPARα, PPARβ/δ and PPARγ antagonists systemically had lower levels of CeA dopamine, while those receiving intra-BLA PPARα and PPARγ antagonists had higher levels of dopamine in the BLA, compared with vehicle-treated counterparts. **Conclusions** PPARs, particularly PPARα and PPARγ, in the BLA play a role in expression or extinction of conditioned fear in the presence or absence of nociceptive tone. **References** [1]Blanquart C. et al. Title: Selective manipulation of ventral hippocampus projections to the prelimbic cortex selectively facilitates fear extinction generalization

Authors: *K.-C. LEONG, J. H. VASQUEZ, I. A. MUZZIO
Dept. of Biol., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Extinction is the mechanism through which an organism decreases fear responses to cues that no longer predict danger. A major characteristic of extinction memory is that it is context-dependent, in that extinction memories formed in one context is not necessarily recalled in a different context, leading to fear renewal. The ability to extinguish fear memories and generalize these extinction memories to multiple contexts provides therapeutic potential, but little is known about the specific mechanisms that mediate fear renewal and extinction generalization. Several studies point at the ventral hippocampus (VH) as a key brain region mediating contextual gating of emotional behavior, yet the functional role of VH projections remains unknown. VH cells project to the prelimbic (PL) region of the medial prefrontal cortex, an area that is primarily involved in fear expression. In this study, we examined the effect of pathway-specific chemogenetic manipulations on VH cells projecting to the PL to determine their effect on fear extinction and generalization. First animals underwent cued fear conditioning and extinction. By employing the use of intersectional DREADDs, we observed that targeted activation of projections from the VH to the PL during extinction memory retrieval was sufficient to attenuate fear renewal after extinction and generalize extinction behaviors across contexts. Furthermore, chemogenetic manipulation of this pathway during cued fear retrieval had no effect on fear expression of subsequent extinction memory, suggesting that other pathways are involved in mediating fear expression prior to extinction. These findings suggest that VH projections to the PL cortex may be critical to increase extinction generalization across contexts. Understanding the functional role of VH projections may contribute to determine the etiology of anxiety disorders and the role that contextual information plays in emotional memories.

Title: Extinction-paired vagus nerve stimulation reduces avoidance of a conditioned odor

Authors: *C. R. OLEKSIAK, M. N. TABET, S. ARORA, M. P. SRIVASTAV, R. R. SOUZA, C. K. MCINTYRE

Abstract: Vagus nerve stimulation (VNS) enhances extinction of auditory fear conditioning in a rat model of posttraumatic stress disorder (PTSD). Olfactory cues are described as powerful triggers of avoidance, panic attacks, and flashbacks in those with fear disorders. Here, we examined whether VNS paired with a conditioned olfactory cue could reduce avoidance and second order conditioning. To test this, adult male Sprague Dawley rats were implanted with a stimulation cuff around the vagus nerve. After recovery, the rats received two days of fear conditioning where the olfactory cue (CS; 100 µl of 10% amyl actetate) was paired with eight footshocks per day (US; 1-sec, 0.8 mA). Seventy-two hours later, the rats were given three days of sham (n=11) or VNS-paired extinction (5x 30-sec VNS at 0.4 mA/day; n=14). Finally, rats underwent an avoidance paradigm that consisted of habituation to a new context, an odor avoidance test, and a context avoidance test where approach, hiding time, and transits between the neutral chamber and the odor chamber were assessed. We found that sham- and VNS-treated rats did not differ in extinction acquisition or in the habituation to the avoidance chamber. However, VNS rats spent significantly more time approaching the odor source ($t=3.09$, $p=0.01$) and significantly less time hiding ($t=3.05$; $p=0.01$) than the sham-stimulated rats. These results suggest that VNS can be used to enhance extinction of conditioned fear to cues that span different sensory modalities. Neither group demonstrated second order conditioning. Further studies are needed to determine the optimal VNS parameters for enhancing extinction and possible VNS effects on extinction generalization across modalities.

Title: Impact of chronic early life adversity on fear extinction in juvenile and adolescent rats

Authors: *K. DRUMMOND[1,2], M. BLEWITT[3,2], G. FAULKNER[4,5], J. H. KIM[1,2]
[1]Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia; [2]The Univ. of Melbourne, Melbourne, Australia; [3]Walter and Eliza Hall Inst., Melbourne, Australia; [4]Translation Res. Inst., Brisbane, Australia; [5]Univ. of Queensland, Brisbane, Australia

Abstract: Early life is viewed as a developmental period in which adversity could cause long-term impairments in fear inhibition. Exposure to adversity in both the neonatal period (Postnatal Day (P) 2-13) and adolescence period (P21-42) has previously been shown to cause robust changes to anxiety and fear-related behaviors. We hypothesized that chronic adversity early in life would be deleterious to fear inhibition throughout development in male and female Sprague-Dawley rats. In Experiment 1: We subjected male and female neonatal rats to a limited bedding stress environment from P2-13. Five days later, animals underwent fear conditioning, extinction and were tested to see whether their fear would renew. In Experiment 2: We reared rats in social isolation from P21-42, at which they were either behaviorally tested or resocialized and then tested in adulthood at P70. All animals underwent fear conditioning, extinction and were tested for their extinction retrieval ability. In Experiment 1, we found that juvenile male rats exposed to a limited bedding stress environment displayed a robust relapse of fear following extinction compared to controls. However, juvenile female rats behaved no differently to controls as both groups displayed a relapse of fear. In Experiment 2, relative to group-housed controls, both male adolescent and resocialized adult rats displayed higher freezing at test. In contrast, female adolescent and resocialized adult rats displayed enhanced extinction acquisition compared to controls but showed similar levels of freezing at test. Overall, these results demonstrate that exposure to adversity during early post-natal and adolescence development impacts the ability of rats to inhibit fear. Future work will determine whether exposure to adverse environments during development led to alterations in the activity of transposons (particularly long interspersed nuclear elements) in the rat genome.

Title: Learning not to fear: Mindfulness meditation improves retention of fear extinction

Authors: *G. SEVINC[1], B. HOLZEL[2], T. GARD[3], J. GREENBERG[1], J. A. HASHMI[4], M. R. MILAD[5], S. W. LAZAR[1]
[1]Massachusetts Gen. Hosp., Charlestown, MA; [2]Tech. Univ. of Munich, Munich, Germany; [3]Univ. Zurich, Zurich, Switzerland; [4]Anesthesia, Pain Mangement and Perioperative Med., Dalhousie Univ., Halifax, NS, Canada; [5]Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Mindfulness based stress reduction (MBSR) programs have been widely utilized to ameliorate stress-related symptoms, however the neural mechanisms that underlie the improvements are still largely unknown. Mindfulness meditation involves refraining from cognitive avoidance and thus provides a basis for internal exposure to aversive stimuli. We hypothesized that mindfulness-based interventions create a context akin to behavioral exposure and thereby alter neurobiological responses to aversive stimuli. We tested this hypothesis in a randomized longitudinal study design using a 2-day fear conditioning and extinction protocol with skin conductance as the index of extinction retention. Meditation-naïve participants completed either an 8-week MBSR program (n=42), or a stress management education program (n=25), as an active control. Alterations in brain structure and function from pre to post were assessed using fMRI. Both interventions decreased stress levels, while MBSR resulted in further improvements in anxiety, emotion regulation, rumination, and self-compassion. Both interventions improved memory for extinguished stimuli. Compared to the control, MBSR resulted in enhanced activity in right supramarginal gyrus during retrieval of extinction memory, and neural activity within this cluster correlated with total practice time. Changes in emotion regulation were associated with the differential functional coupling of right supramarginal gyrus to ventral posterior parietal cortex during early phases of recall. An investigation of hippocampal coupling patterns further revealed enhanced connectivity between hippocampus and postcentral gyrus following MBSR. Changes in hippocampal structure further predicted the degree of functional connectivity between the hippocampus and dorsolateral prefrontal and retrosplenial cortices. The results suggest that MBSR improves extinction predominantly though enhancing neural activity in regions associated with attentional input to memory during extinction recall. Structural and functional changes in the hippocampus suggest a role for enhanced contextual

retrieval in stress reduction following MBSR. Enhanced activity and connectivity with regions associated with dynamic control of attention suggest that MBSR may enhance emotion regulation skills through modulating attention and memory interactions. Considering that the ability to recall that a stimulus is no longer associated with threat is critical for healthy emotional functioning, the results suggest the improvement in this ability may be a key mechanism through which mindfulness meditation ameliorates stress-related symptoms.

Title: Neural mechanisms underlying impaired extinction learning in a wild-type inbred mouse strain

Authors: *V. A. CAZARES[1], K. GORDON[3], G. G. MURPHY[2]
[1]Mol. and Behavioral Neurosci. Inst., [2]MBNI/Physiology, Univ. of Michigan, Ann Arbor, MI; [3]Biol., Kalamazoo Col., Kalamazoo, MI

Abstract: The ability to learn that neutral environmental stimuli can become predictive of an aversive outcome heightens an organism's chance for survival. Equally important for survival, is the ability to learn to diminish a fearful response (known as fear extinction) when stimuli no longer predict an aversive outcome. Deficits in extinction learning are often used to model maladaptive behavior in humans that are experiencing generalized anxiety or post-traumatic stress disorder. Previous work (Camp et al., 2009) has identified strong variations in the capability for fear extinction learning between *wild-type* inbred mouse strains. This work seeks to leverage deficits in the 129S1-inbred mouse strain, which is significantly impaired in extinction learning relative to the C57BL/6 mouse strain, to define neurophysiological substrates of fear suppression. Previous work has shown that distinct cell populations in the medial-prefrontal cortex (mPFC) respond to changes in the contingency between environmental stimuli and aversive outcomes. Our hypothesis is that instructive neural signals generated by mPFC to modulate downstream regions like the amygdala are degraded in 129S1 relative to C57BL/6. Impaired executive prefrontal neuromodulation in the 129S1 strain may account for deficits in fear extinction. To test this hypothesis, we first examined if neural activation in the mPFC between these mice strains differs depending on the amount of extinction training. For these

studies, we used the expression of *cfos,* an activity-dependent immediate-early gene as an indirect measure of neuronal activation. Consistent with prior results, we find that 129S1 mice are impaired in extinguishing freezing responses compared to the C57BL/6 strain. Moreover, using both immunolabeling and *cfos*-driven YFP expression our results show that for both strains of mice, reductions in fear responses are inversely correlated with the level of activation in the infralimbic subregion of the mPFC ($R = -0.5$, $p < 0.05$). Additionally, 129S1 mice also had reduced overall *cfos* expression in IL after three days of extinction training. Interestingly, we find that animals of the 129S strain while impaired in extinguishing fear responses can discriminate stimuli that was previously paired with an aversive outcome from neutral stimuli, suggesting that they possess a specific deficit in fear suppression. Based on this preliminary data, our current efforts deploy the use *in vivo* optical techniques to monitor neuronal activation in the mPFC during extinction learning to discern if changes in cell firing dynamics can account for the strain-specific behavioral phenotypes. <!--EndFragment-->

Abstract: Extinction therapy is the most commonly used clinical method to treat a variety of psychiatric conditions, such as addiction, trauma, and stress-related disorders. Importantly, fear extinction, the basis of exposure-based therapy, is a primary treatment strategy for anxiety disorders. However, extinction learning in clinical settings is conducted under exceptional internal states of the subjects, which, especially in patients suffering from psychiatric disorders, may hamper treatment success. Indeed, stress as well as internal feeling and emotional states have long been known to affect learning and memory performance. Since the posterior insular

cortex (pIC) is crucially involved in interoception and plays a prominent role in the detection and processing of feelings and emotions, we here addressed the role of the pIC in extinction learning. Using optogenetic activity manipulations we found an important role for the pIC in regulating extinction-learning abilities, which depended on the internal fear-state of the animal. Further, *in vivo* electrophysiological recordings revealed state-dependent processing of fear-related behaviors and cues in pIC neurons. These data suggest that the insula potently shapes fear extinction learning dependent on the internal state. To start addressing how internal state may affect the pIC's role in learning, ongoing research in the lab addresses the link between pIC-mediated interoception, vagal afferents carrying bodily signals to the brain, and fear extinction performance.

Title: Fear conditioning and exposure therapy benefit

Authors: *A. ZLOMUZICA, C. MERZ, D. ADOLPH, S. SCHNEIDER, J. MARGRAF, F. PREUSSER
Ruhr-Universität Bochum, Bochum, Germany

Abstract: Patients with anxiety disorders exhibit systematic changes in the acquisition and extinction of conditioned fear which might constitute a potential mechanism contributing to the development and maintenance of these debilitating disorders. Extinction learning has been increasingly acknowledged as a translational tool which can be used to refine current treatment options for anxiety disorders such as exposure-based therapies. Both, exposure-based therapy benefit and conditionability are individually variable. The present study sought to determine whether individual variability in fear acquisition and extinction predicts exposure therapy outcome in specific phobia. Participants with spider fear underwent a differential fear conditioning procedure before undergoing a standardized one session exposure therapy. In the differential fear conditioning task, skin conductance responses (SCR), subjective valence and contingency ratings of the CS were measured as dependent measures of conditionability. As a

measure of exposure therapy outcome, several variables were collected including reductions in self-reported fear, spider-phobic cognitions, as well as changes in behavioral avoidance (i.e. Behavioral Approach Test, BAT) from pre to post-treatment. Participants who successfully completed the exposure session showed more pronounced reductions in different self-reported fear measures relative to participants who did not master exposure. Most importantly, an association between the extinction learning rate and exposure success was found. Specifically, participants who benefited more from exposure showed superior extinction learning relative to participants who benefited less from exposure. Our findings indicate that individual differences in treatment benefit can be predicted on the basis of extinction learning performance.

Title: Neural and behavioural dynamics of pain learning

Authors: *O. ZIKA[1], B. CRITTENDEN[2], R. BOGACZ[2], K. WIECH[2]
[1]Functional Magnetic Resonance Imaging of the Brain Ctr., [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Introduction Aversive experiences such as pain are known to lead to fast associative learning but can be highly resistant to extinction. This asymmetric learning is discussed as a key psychological mechanism involved in the maintenance of chronic pain. We used functional magnetic resonance imaging together with computational modelling to examine differences between acquisition and extinction of pain-related associations in a reversal learning paradigm.
Methods 28 healthy volunteers (14 male; mean age: 25.75) were tested in a 3T MR scanner. On each trial, participants were presented with one of three visual cues which were either followed by pain on 75% of trials, on 25% of trials or with probability switching between 75% and 25%. Switching cue probabilities changed unbeknownst to the participant every 28 to 32 trials (270 trials total). Upon cue presentation, participants had to indicate the subjective probability of pain (0%-100%) prior to delivery or omission of a noxious electrical stimulus.
Results Our results show that learning occurred faster when stimulus delivery became more likely (25% to 75%; acquisition) than when it became less likely (75% to 25%; extinction).

Probability ratings consistently exceeded the true probability during extinction. This over-prediction of pain during extinction increased over the course of the experiment and was best characterised by a computational model with dynamic learning rate. Critically, over-prediction was more pronounced in low-anxious individuals. The over prediction in low-trait anxious participants was due to increasing learning from shocks while learning from shock omissions remained constant. In contrast, high trait anxious individuals kept learning from both outcomes in a similar fashion.
Our fMRI results identified several regions that showed an increase in outcome-related activity in the second compared to the first half. The signal level in the posterior insula, precuneus and left dorsolateral prefrontal cortex increased during learning from shocks while thalamic activity decreased over time.
Conclusion Our data suggest a time-dependent mechanism involved in aversive learning. While learning during acquisition remains high, learning during extinction becomes increasingly slower. This decrease in extinction learning is modulated by trait anxiety with high trait anxious individuals being better at following the environmental statistics.

Title: A possible role for perirhinal cortex in fear extinction learning

Authors: *N. POTTER, C. A. CALUB, S. C. FURTAK
Dept. of Psychology, California State University, Sacramento, Sacramento, CA

Abstract: Several studies suggest that the perirhinal cortex (PER) may function to unitize stimulus components across time or modalities (Kent & Brown, 2012). For example, multiple findings have supported the involvement of the PER in stimulus unitization during fear conditioning to discontinuous auditory stimuli, such as discontinuous tones and pre-recorded rodent ultrasonic vocalizations. However, the role of the PER in processing such stimuli during other aspects of fear learning, including fear extinction, have not been fully evaluated. The current study assessed the involvement of the PER during a fear extinction paradigm using a discontinuous or a continuous conditioned stimulus (CS). Based on the stimulus unitization hypothesis, we predicted that the PER would be necessary to support fear extinction to the discontinuous CS but not to the continuous CS. Sprague-Dawley derived male rats were

randomly assigned to one of four groups based on two factors: CS type (a continuous light versus a discontinuous light) and PER manipulation (Inactivation group or Control group). All rats were bilaterally implanted with cannulae targeting the PER. Upon surgical recovery, subjects were evaluated on a three-day fear extinction paradigm conducted in the same context. On Day 1, Fear Acquisition, rats received 5 presentations of the CS that co-terminated with a foot shock unconditioned stimulus (US). On Day 2, Extinction Training, rats were bilaterally infused with muscimol, a GABA agonist (Inactivation group), or a saline vehicle (Control group). Approximately 40 mins following infusions, rats received 20 CS-alone presentations. On Day 3, Extinction Recall, rats were presented with an additional 15 CS-alone presentations. Behavioral sessions were recorded digitally for offline analysis using customized software to assess the level of freezing, defined as no movement for at least 1 sec. In a subset of rats, infusions of fluorescently-conjugated muscimol were analyzed to assess the spread of inactivations. Rats in the Inactivation group displayed significantly more freezing than the Control group during Extinction Recall regardless of whether the CS was a continuous light or discontinuous light. A subset of these results was previously presented (discontinuous CS only; Calub et al., 2015). Possible interpretations of the results are discussed within the framework of the stimulus unitization hypothesis.

Title: Investigating the neural correlate of TMR-dependent fear extinction

Authors: *I. C. HUTCHISON[1], L. K. SHANAHAN[1], J. A. GOTTFRIED[1,2]
[1]Dept. of Neurol., Northwestern Univ., Chicago, IL; [2]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Sleep plays a crucial role in the consolidation and integration of memories, particularly those with emotional salience. Recent studies indicate that memories can be selectively targeted and reactivated in sleep via presentation of a sound or smell associated with the learning task in the prior wake state. Further, the reactivation of fear memories during sleep, in the absence of negative reinforcement, facilitates fear extinction (Hauner et al., 2013). In the current study we have used an olfactory contextual conditioning paradigm in which face images (conditioned stimuli; CS+) are paired with mild electric shocks (unconditioned stimuli; US) with

a 50% reinforcement rate in the presence of neutral background odors. During fMRI scanning, one of the odors (the target odor) was repeatedly delivered during non-REM sleep (measured using MR-compatible EEG recordings) in 16s intervals separated by 16s odor-free periods. This was followed by a second conditioning period with a reinforcement rate of 12.5%. Preliminary data suggest a selective reduction in response to target CS+ across sleep compared to the non-target CS+. In addition, analysis of functional MRI data in sleep indicates activity in limbic areas supportive of fear memory replay which appears to diminish with repeated cue exposures. We plan to use multivariate pattern analysis to further investigate how the representational content of odor-cued emotional memories develops as a function of contextual odor-cue delivery in sleep. In addition, we aim to assess to which degree this development relates to physiological extinction evidenced by skin conductance responses. We anticipate that our findings will yield important new insights into the plasticity of emotional memory storage that hold potential for future translational research in the area of psychiatric illness and pathological fear. Given the relative scarcity of effective therapeutic interventions, the use of smell cues in sleep represents a highly unique and innovative approach for tackling this problem.

Title: The role of mTOR signaling in enhanced fear extinction produced by acute, voluntary exercise

Authors: *N. A. MOYA[1], M. K. TANNER[2], J. JAIME[2], E. C. LOETZ[1], H. S. HAKE[2], B. N. GREENWOOD[1]
[1]Psychology, [2]Univ. of Colorado Denver, Denver, CO

Abstract: Exercise can benefit cognition, learning and memory, and mental health. In rats, beneficial effects of acute exercise include enhancing the extinction of traumatic memories, wherein a single bout of voluntary exercise after fear extinction training can enhance fear extinction memory and reduce relapse. Identifying mechanisms by which acute exercise augments fear extinction could reveal novel targets for the treatment of trauma-related disorders, such as Post-Traumatic-Stress Disorder (PTSD), the etiology of which depends on memories of traumatic events. The mechanisms by which acute exercise enhances fear extinction are unknown. One factor that could contribute to enhanced fear extinction memory following

exercise is the mammalian target of rapamycin (mTOR). mTOR is a translation regulator involved in synaptic plasticity, cell growth, and proliferation. mTOR signaling is sensitive to many exercise signals such as monoamines, growth factors, and metabolic signals, and is increased after chronic exercise in brain regions involved in learning and emotional behavior. mTOR is therefore a compelling potential facilitator of the memory-enhancing and overall beneficial effects of exercise on mental health. The goal of the current study was to test the hypothesis that mTOR signaling is critical for the enhancement of fear extinction memory produced by acute, voluntary exercise, in adult, male Long-Evans rats. We observed that, like chronic exercise, a single session of voluntary exercise increased mTOR signaling in extinction-related brain areas. Moreover, intracerebral-ventricular (ICV) administration of the mTOR inhibitor rapamycin reduced mTOR signaling and eliminated the enhancement of fear extinction memory produced by acute exercise, without reducing voluntary exercise behavior or altering fear extinction learning. These results suggest that mTOR signaling contributes to the memory-enhancing effects of acute exercise. Factors that increase mTOR signaling could be useful novel targets for the treatment of psychiatric disorders like PTSD.

Title: Effects of optogenetic activation on nucleus accumbens projecting ventral tegmental neurons during fear extinction on fear extinction memory and relapse

Authors: *J. WISEMAN[1], E. C. LOETZ[2], E. B. OLESON[2], B. N. GREENWOOD[2]
[1]Univ. of Colorado Denver, Lakewood, CO; [2]Psychology, Univ. of Colorado Denver, Denver, CO

Abstract: Exposure therapy relies on the process of fear extinction, which is learning that a prior conditioned fear stimulus no longer predicts danger. One limitation of exposure therapy is that fear extinction memory is labile, and fear often returns even after successful extinction. Identification of novel strategies to prevent fear relapse after extinction is of utmost importance to mental health. Manipulations that enhance dopamine (DA) signaling can strengthen fear extinction, but the specific DA pathways involved, and whether fear extinction enhanced by DA is resistant to relapse, remain unclear. Midbrain DA neurons originating in the ventral tegmental

area (VTA) and projecting to the nucleus accumbens (NAc) encode prediction error. Activation of these neurons during extinction could, therefore, facilitate extinction by enhancing the learning that the conditioned stimulus no longer predicts an aversive event. The goal of the current study was to test the hypothesis that activation, during fear extinction, of midbrain DA neurons that project to the NAc, can enhance fear extinction and reduce relapse. Adult, male Long-Evans rats received bilateral intra-NAc microinjections of either AAV2retro-Cre-eGFP or CAV-Cre. These viruses travel retrograde to midbrain cell bodies of origin and express the enzyme Cre-recombinase. A second virus (AAV-EF1a-DIO-hChR2(H134R)-EYFP) that expresses a light-sensitive ion channel (ChR2) in a Cre-dependent manner was then injected into the VTA, allowing the expression of ChR2 in VTA neurons projecting to the NAc. VTA neurons projecting to the NAc were then optogenetically stimulated during auditory fear extinction. Fear extinction memory and relapse were subsequently assessed in the absence of stimulation. Preliminary results indicate that optogenetic stimulation of NAc-projecting VTA neurons during fear extinction reduces the renewal of fear in a novel context. These data suggest that novel therapeutic strategies aimed at the mesolimbic DA circuit could be effective adjuncts to exposure therapy.

Title: 3,4-methylenedioxymethamphetamine (MDMA) impairs the extinction and reconsolidation of fear memory in rats

Authors: *R. R. WOOD[1], H. HAKE[1], A. SANCHEZ[1], E. C. LOETZ[1], M. OSTROVSKYY[1], E. B. OLESON[1], J. GRIGSBY[2], R. DOBLIN[3], B. N. GREENWOOD[1]
[1]Psychology, [2]Psychology and Med., Univ. of Colorado Denver, Denver, CO; [3]Multidisciplinary Assn. for Psychedelic Studies, Santa Barbara, CA

Abstract: 3,4-methylenedioxymethamphetamine (MDMA) paired with psychotherapy can reduce symptoms of post-traumatic stress disorder (PTSD) more effectively than psychotherapy or typical pharmacotherapy, either alone or in combination. However, the mechanisms by which MDMA might enhance psychotherapy remain unclear. Given that fear memories contribute to

PTSD symptomology, MDMA could augment psychotherapy by neurochemically targeting fear memories. We have investigated the effects of a single administration of MDMA on extinction and reconsolidation of fear memory in adult male Long-Evans rats. Our initial results indicate that low dose MDMA (1 or 2 mg/kg), administered 30 min before cued fear extinction, has no effect on fear extinction recall or fear renewal, whereas high dose MDMA (3 or 10 mg/kg) impairs cued fear extinction recall. In contrast, 5 mg/kg MDMA, but not 3 mg/kg MDMA, administered immediately after contextual fear memory reactivation, interferes with the reconsolidation of contextual fear memory. These data suggest that the therapeutic effects of MDMA could be mediated by a reconsolidation impairment, rather than an enhancement of fear extinction as previously suggested by studies in mice. However, it is unclear from these results whether the therapeutic effects of MDMA are specific to reconsolidation, or affect contextual fear memory in general. Our current studies are investigating the effects of 5 mg/kg MDMA (the dose previously observed to interfere with contextual fear memory reconsolidation) on contextual fear extinction and cued fear reconsolidation. Data collection is ongoing.

Title: Role of the dorsal striatum in fear extinction and relapse

Authors: *J. JAIME[1], M. K. TANNER[1], N. A. MOYA[1], J. DAVIS[1], E. C. LOETZ[2], B. N. GREENWOOD[2]
[2]Psychology, [1]Univ. of Colorado Denver, Denver, CO

Abstract: Fear extinction-based exposure therapy has poor long-term success for illnesses like PTSD. Previous work has shown that activation of substantia nigra dopamine (DA) neurons projecting to the dorsal striatum during cued fear extinction training enhances fear extinction recall and reduce relapse; however, the striatal circuits underlying enhanced extinction learning remain unknown. The striatum consists of two specific subregions; the dorsomedial striatum (DMS) and the dorsolateral striatum (DLS). The DMS supports “goal-directed” learning, while the DLS supports inflexible “habit learning”. The goal of this study is to investigate whether these dorsal striatum subregions differentially contribute to fear extinction learning and memory.

Following surgical implantation of bilateral cannulae into either the DMS or DLS, adult male Long-Evans rats were conditioned to fear a tone that terminated with a foot shock. After fear conditioning, rodents were injected with a $GABA_A/GABA_B$ agonist concoction (0.03 nmol Muscimol/0.3nmol Baclofen) to temporarily inactivate the DMS or DLS during fear extinction training. Preliminary data indicate that temporary inactivation of the DMS has no effect on extinction acquisition or recall, but reduces fear renewal in a novel context. In contrast, temporary inactivation of the DLS enhances fear extinction recall 24 h after extinction training, but has no effect on fear renewal. These results suggest that unique DA-striatal circuits could support different components of fear extinction. DLS inactivation could increase the DMS "goal-directed" contribution to extinction learning, resulting in an extinction memory strongly modulated by context. In contrast, DMS inactivation could increase the DLS "habit learning" contribution to extinction learning, rendering the extinction memory impervious to contextual modulation. These results have implications for novel strategies aimed at reducing the relapse of fear after extinction. <!--EndFragment-->

Title: OFC glutamate activity and reward processing: Implications for schizophrenia

Authors: *S. BARNES[1], J. W. YOUNG[1], D. RAMANATHAN[1,3], L. FAGET[1], D. DILLON[4], T. S. HNASKO[2], M. A. GEYER[1]

Abstract: Introduction: Reward deficits in schizophrenia are unresponsive to available medications and contribute significantly to poor functional outcome. A deeper understanding of the neural mechanisms underlying reward processing may identify novel therapeutic targets to improve reward function in schizophrenia. The ability to regularly update representations of reward value and use this information to guide decisions is necessary to maximize reward payoff. These processes can be quantified across species using the probabilistic reversal learning (PRL) task. The orbitofrontal cortex (OFC) is involved in detecting reward outcomes and is

disrupted in schizophrenia. Our aim was to determine how OFC glutamate neurons respond during PRL performance and identify how manipulation of OFC glutamate activity influences PRL performance.
Methods: Male Wistar rats were trained in the PRL task. In separate cohorts, AAV-CaMKIIa-GCaMP6f or AAV-CaMKIIa-ChR2-eYFP was injected into the medial OFC. Optic fibers were implanted dorsal to injection site to enable delivery of excitation light. Fiber photometry (FP) was used to record mOFC glutamate activity and optogenetics was used to activate mOFC glutamate neurons during PRL performance. PRL data was fitted to a Q-learning computational model according to $Qt+1 = Qt + \alpha \times PE$. α-Gain and α-Loss are learning parameters while β is a parameter in the softmax function that reflects choice behavior (exploratory or exploitative).
Results: FP revealed that mOFC glutamate neuron activity is suppressed when animals made a response that was rewarded. In contrast, no change in neural activity was observed when animals made a response that was punished. Optogenetic activation of mOFC glutamate neurons impaired PRL performance. When stimulation was delivered during accurate feedback presentation, animals completed fewer reversals, required more trials to complete the first reversal, and had a reduction in Win-Stay responding. Moreover, optogenetic stimulation elevated exploratory behavior (increased β) without affecting the ability to assign value to a stimulus (α-Gain or α-Loss).
Conclusions: These findings suggest that suppression of mOFC glutamate neuron activity is necessary for rewarding actions to be exploited. mOFC hyperactivity did not disrupt the ability to maintain accurate representations of value (indicated by normal learning parameters) but instead impaired the ability to appropriately use this information to guide choice behavior (reduced Win-Stay and increased β). These findings suggest that OFC hyperactivity in schizophrenia may contribute to impaired feedback-driven decision-making.

Title: Modulation of endocannabinoid-mediated plasticity within the orbitofrontal cortex by a palatable diet

Authors: *B. K. LAU, C. MURPHY-ROYAL, G. R. GORDON, J. S. BAINS, S. L. BORGLAND
Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: The orbitofrontal cortex (OFC) plays a key role in the cognitive and emotional processing of decision-making. It is well established that the endogenous cannabinoid (endocannabinoid) system in the brain is important for appetite regulation. However, it is unknown if endocannabinoid signalling in the OFC is altered by an obesogenic diet. Using in-vitro patch clamp electrophysiology, we show that inhibitory GABAergic synaptic inputs onto pyramidal neurons within layer II/III of the OFC are sensitive to endocannabinoids. Specifically, they exhibit endocannabinoid-mediated short-term depression (depolarization-induced suppression of inhibition, DSI) and long-term depression (iLTD, via theta-burst stimulation). We then examined whether consumption of a palatable, energy-dense cafeteria diet altered endocannabinoid signalling within the OFC. We found there was a reduction in GABAergic synaptic transmission onto OFC pyramidal neurons following extended access (24 hr), but not restricted access (1 hr) to a cafeteria diet. This suppression of inhibition was partly reversed by the neutral CB1 receptor antagonist, NESS-0327, indicating the presence of tonic levels of endocannnabinoids. Associated with this endocannabinoid tone was an impairment of iLTD. We further showed that these obesity-induced synaptic alterations were mediated by upstream activation of Group 1 metabotropic glutamate receptors (mGluRs). Specifically, mGluR-iLTD induced by the Group 1 mGluR agonist, DHPG was impaired in obese animals, while endocannabinoid tone was blocked in the presence of the mGluR5 antagonist, MTEP. Interestingly, the impairments in iLTD were rescued in obese animals by restoring glutamate homeostasis, via the cystine/glutamate exchanger and glutamate transporter 1 (GLT-1) in astrocytes. Together, our findings suggest that long-term exposure to a palatable diet alters astrocyte modulation of glutamate homeostasis within the OFC, resulting in enhanced endocannabinoid signalling and tone via Group 1 mGluR activation, which then leads to decreased GABAergic synaptic transmission.

Abstract: Heightened aggression is characteristic of multiple neuropsychiatric disorders and can have a wide variety of negative effects on patients, their families, and the public. Recent studies in humans and animals have implicated brain reward circuits in aggression and suggest that, in subsets of aggressive individuals, repeated domination of subordinate social targets is reinforcing. Here, we use a multidisciplinary approach to show that orexin neurons originating from the lateral hypothalamus activate a small population of GABAergic interneurons in the lateral habenula via orexin receptor 2 to promote aggression and conditioned preference for aggression-paired contexts. Our study suggests that the orexin system is a promising target for the development of novel therapies aimed at reducing aggressive behaviors and provides the first functional evidence of a local inhibitory circuit within the lateral habenula.

Title: Chemogenetic activation of the PRAM pathway prevents light deprivation-induced augmentation of orexin/hypocretin expressing neurons and depressive-like behavior

Authors: *H. E. BOWREY[1], M. H. JAMES[2], G. S. ASTON-JONES[1]
[1]Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ; [2]Brain Hlth. Inst., Piscataway, NJ

Abstract: ***Introduction:*** The 24 h light-dark (LD) cycle has a robust influence on behavior and mood. Deviations from this light cycle induce depression and depressive-like behavior, which can be ameliorated by artificially restoring normal light pattern information via phototherapy. We have recently demonstrated that the activation of a trisynaptic (retina->supra chiasmatic nucleus (SCN)->dorsomedial hypothalamus (DMH)->locus coeruleus (LC)) pathway, termed the PRAM (photic regulation of arousal and mood) pathway, prevents light deprivation-induced depression-like behavior. Previous research indicates that an orexin-dependent mechanism may underlie this depression-like behavior. As the DMH is a critical node in the PRAM pathway, we analyzed the expression of orexin in the DMH and the surrounding perifornical area (PF) and lateral hypothalamic (LH) orexin cell fields in animals that received PRAM stimulation during chronic light deprivation. ***Methods:*** Male Sprague Dawley rats received intraocular injections of an AAV encoding a Gq-linked designer receptor exclusively activated by designer drugs (DREADD: AAV2-hSyn-hM3D(Gq)-mCherry; *n*=12) or control virus (AAV2-hSyn-EGFP; *n*=10) . Rats were placed in continuous darkness for 8 wk, and those that received virus were concurrently subjected to daily i.p. injections of the DREADD agonist clozapine-*N*-oxide (CNO). A control group (*n*=10) received no virus and was maintained on a regular 12:12 light/dark cycle. Rats were then subjected to assays of mood (saccharin preference test, elevated plus maze and forced swim test) and vision (electroretinagram: ERG). Rats were perfused using 4% paraformaldehyde, and brains were cut into 40 µm thick cryosections. Hypothalamic tissue was immunohistochemically stained for orexin-A and c-Fos. ***Results:*** PRAM pathway stimulation enhanced retinal ERG signals and activated key PRAM pathway structures, including orexin neurons. Constant light deprivation induced a depression-like phenotype in control animals, which was augmented in DREADD animals given daily CNO. The abundance of orexin-A-immunoreactivity (IR) in DMH, LH and PF was affected by chronic light deprivation. Activation of the PRAM pathway prevented the light deprivation-induced reduction of orexin-A-IR in DMH, LH and PF. ***Conclusions:*** Dysfunctional orexinergic signaling may underlie light deprivation-induced depression-like behavior. PRAM pathway stimulation may prevent the augmentation of orexin-A-IR that occurs as a result of light deprivation. The PRAM pathway presents a novel circuit for the regulation of mood, and thus a possible new direction for the treatment of depression in humans.

Title: Signaling at the orexin/hypocretin-1 receptor mediates food motivation in female rats after excessive weight gain and binge-like eating

Authors: *S. LIU[1], M. H. JAMES[1,3], S. WALSH[1], H. E. BOWREY[1,4], N. T. BELLO[2], G. ASTON-JONES[1]
[1]Brain Hlth. Inst., Rutgers, The State Univ. of New Jersey, Piscataway, NJ; [2]Dept. of Animal Sci., Rutgers, The State Univ. of New Jersey, New Brunswick, NJ; [3]Florey Inst. of Neurosci. and Mental Hlth., Parkville, Australia; [4]Save Sight Inst., Sydney, Australia

Abstract: ***Introduction:*** Binge eating disorder (BED) is characterized by a progressive escalation of intake of highly palatable food and increased responsivity to food-associated cues that induce craving and overeating. In this way, many of the clinical characteristics of BED closely resemble symptoms of drug abuse disorders, pointing to possible commonalities in the neural circuitry underlying these disorders. We and others have reported that the hypothalamic orexin (hypocretin) system is critically involved in the expression of highly-motivated drug seeking behavior, however its role in compulsive food seeking is not well understood. Here, we tested the hypothesis that orexin-1 receptor signaling mediates food motivation in female rats with a history of binge-like eating. In addition, we examined the role of obesity on our outcomes. ***Methods*****:** Using a within subjects design, female Long-Evans rats were assessed for baseline economic demand for sucrose using a novel behavioral economics paradigm. Binge-like eating was induced by exposing rats to sweetened fat (vegetable shortening/10% sucrose) for 30 min, twice/wk for 4wk, before being re-assessed for sucrose demand and following injections of the orexin-1 receptor antagonist SB-334867 (0,10,30mg/kg, ip). Rats were then exposed to a high fat diet (HFD; 45% fat) for 8wk, and the experiment was repeated. Sweetened fat binge intake was measured following SB dosing. ***Results****:* Binge eating increased sucrose demand only after HFD-exposure, which was dose-dependently reversed by SB. Binge intake was not altered by HFD exposure. SB also dose-dependently decreased sweetened fat binge intake after HFD exposure. ***Conclusions****:* Our findings indicate an interaction between binge-like eating and excessive weight gain with respect to motivation for food. This effect was blocked by an orexin-1

antagonist, highlighting the orexin system as a potential novel target for pharmacotherapies for controlling overeating episodes in individuals with obesity. Ongoing studies are investigating the effect of excessive weight gain and binge-like eating on other properties of the orexin system.

Title: Variable episodic self-administration enhances economic demand for cocaine and sensitivity to the orexin/hypocretin receptor antagonist SB-334867

Authors: *M. H. JAMES[1,2], H. E. BOWREY[1,3], J. E. FRAGALE[1], G. ASTON-JONES[1]
[1]Brain Hlth. Inst., Rutgers, The State Univ. of New Jersey, Piscataway, NJ; [2]Florey Inst. for Neurosci. and Mental Hlth., Parkville, Australia; [3]Save Sight Inst., Sydney, Australia

Abstract: Introduction: Cocaine addicts rarely report using drug on a daily basis; in most cases, addicts use 3-4 times/week. This can be due to self-imposed abstinence, or related to issues that are difficult to predict, including drug supply, financial constraints or legal intervention. Despite this, models of cocaine self-administration typically involve giving animals access to drug on a highly predictable daily schedule 5-7d/week. Here, we tested whether introducing periods of abstinence of varying duration between self-administration sessions produces stronger addiction-like endophenotypes. We also tested the effect of the orexin-1 receptor antagonist SB334867 (SB) on the expression of these endophenotypes. **Methods:** Male Sprague-Dawley rats were assessed for 'baseline' economic demand for cocaine using our within-session threshold procedure (Bentzley et al., 2014). Rats were then given short (ShA; 1h) or intermittent (IntA; 5min access every 30min for 6h) access to cocaine on either a daily basis (14 sessions over 14 consecutive days) or a variable episodic basis (14 sessions over 28d, with 1-4d between sessions). Rats were then re-assessed for economic demand, as well as several other addiction endophenotypes. The effect of SB (0, 10, 30mg/kg) on demand and reinstatement behavior was assessed. **Results:** As per our recent studies (James et al., 2018), daily IntA was associated with greater escalation of intake, higher economic demand, higher compulsive responding and higher depression-like behavior compared to daily ShA. This IntA-induced multiphenotype was

exaggerated even further by variable episodic IntA. In contrast, variable episodic access did not affect the expression of addiction endophenotypes in ShA animals. SB was most effective at reducing demand and cued reinstatement behavior in variable episodic-IntA rats. **Conclusions:** These data indicate that IntA and variable episodic self-administration patterns interact to produce an exaggerated addiction-like phenotype, which is hyper-reliant on signaling at the orexin-1 receptor. Ongoing studies are investigating the effect of variable episodic self-administration patterns on orexin peptide expression in discrete subregions of the lateral hypothalamus, and orexinergic innervation of reward and stress centers.

Title: Intermittent access to fentanyl increases economic demand through an orexin/hypocretin mechanism

Authors: *J. E. FRAGALE[1], M. H. JAMES[1], V. BEHMAN[1], A. POLO[1], G. S. ASTON-JONES[2]
[2]Brain Hlth. Inst., [1]Rutgers Univ., Piscataway, NJ

Abstract: Our lab recently found that the intermittent access (IntA) self-administration model (Zimmer et al., 2012) produces a multifaceted addiction-like phenotype for cocaine that includes escalation of intake, increased motivation, greater cue-induced reinstatement, and a negative emotional state (James et al., 2018). While the IntA model has been successfully applied to the study of cocaine addiction, it has yet to be applied to opioids. Here, we extend the IntA model to the study of fentanyl self-administration. Rats were either given IntA (6 hr sessions with 5 min access to fentanyl every 30 mins) or short access (ShA; 1 hr) to the opioid fentanyl for 14 consecutive days. Following IntA or ShA, economic demand for fentanyl was assessed using a within-session behavioral economics procedure (Bentzley et al., 2012). IntA and ShA rats were also tested for a variety of other addiction-like behaviors. Like IntA to cocaine, we found that IntA to fentanyl produced a robust and persistent increase in motivation (decreased demand elasticity) without effecting hedonic set point (Q_o). IntA rats also showed increased cue-induced reinstatement of drug seeking and a depressive-like phenotype. We recently reported that IntA to

cocaine is associated with the persistent augmentation of lateral hypothalamic orexin/hypocretin function and that the addiction-like behaviors produced by IntA to cocaine are reversed by blocking orexin-1 receptor signaling (James et al., 2018). To determine the importance of the orexin system in the expression of addiction-like behaviors produced by IntA to fentanyl, IntA and ShA rats were treated with the orexin-1 receptor antagonist SB-334867(SB; 3, 10, and 30 mg/kg i.p.) 30 min prior to testing. We found that SB dose-dependently decreased motivation for fentanyl (increased demand elasticity) and blocked cue-induced reinstatement in IntA rats but not in ShA rats. Our results indicate that the IntA model can be extended to opioids and is a useful tool in the study of opioid addiction. Moreover, the data indicates that the orexin system is a potential target for the treatment of addiction across various drugs of abuse.

Title: Cocaine self-administration disrupts the diurnal fluctuation in orexin (hypocretin) cell number and activity

Authors: *A. CHANG[1], M. H. JAMES[1,2], H. E. BOWREY[1,3], K. PENG[1], S. L. O'CONNOR[1], J. E. FRAGALE[1], G. ASTON-JONES[1]
[1]Brain Hlth. Inst., Rutgers, The State Univ. Of New Jersey, Piscataway, NJ; [2]Florey Inst. for Neurosci. and Mental Hlth., Parkville, Australia; [3]Save Sight Inst., Sydney, Australia

Abstract: ***Introduction:*** Addiction is associated with disruptions in sleep and circadian rhythmicity, and several addiction-related behaviors exhibit clear circadian regulation. The brain systems underlying these phenomena remain poorly understood. We and others have demonstrated that the hypothalamic orexin (hypocretin) system is a critical regulator of drug-seeking behavior. Orexin neurons exhibit significant diurnal fluctuations in cell number and activity; both measures are significantly higher during the active period relative to the inactive period. Here, we tested whether these regular fluctuations in orexin function are disrupted by cocaine self-administration. ***Methods***: Male Sprague Dawley rats were trained to self-administer

cocaine on a fixed-ratio 1 (FR1) schedule in 2h daily sessions with each session beginning precisely at ZT (Zeitgeber Time) 5. Following acquisition, rats progressed to 4h daily sessions (ZT5-9) that continued for 21d. A control group was disturbed at an equivalent time each day but was not given access to cocaine. Homecage cameras recorded activity in the 2h preceding the self-administration sessions (ZT3-5) in both cocaine and control animals. These videos were manually scored based on six different behaviors: grooming, ambulation, eating, drinking, rearing, and nesting, producing an aggregate activity score or an index of 'cocaine anticipatory activity' (CAA). The day after the final self-administration session, rats were perfused at 4h intervals and brains were processed for orexin and Fos immunoreactivity. ***Results:*** Cocaine intake escalated across the 21d self-administration period. This was associated with a concomitant increase in the expression of CAA. The magnitude of CAA was positively correlated with cocaine-seeking behavior. No change in homecage activity was observed in control rats across the same period. Diurnal fluctuations in orexin cell number and activity were disrupted in cocaine animals but were unaffected in controls. ***Conclusion:*** Rats exhibit an increase in general activity in period immediately preceding cocaine self-administration, indicating that cocaine may act as an entrainable cue. Cocaine self-administration disrupts regular diurnal fluctuations in orexin function, indicating that this system may contribute to circadian regulation of drug-seeking behavior.

Title: Temporal modulation of TANs and PANs in monkey ventral striatum related to reward size and delay to obtain it

Authors: *R. FALCONE[1], D. WEINTRAUB[3], B. RICHMOND[2]
[1]NIMH, Bethesda, MD; [2]NIMH, BETHESDA, MD; [3]Northwell Hlth. Physician Partners Neurosci. Inst. a, Great Neck, NY 11021, NY

Abstract: We recorded neuronal responses from 50 TANs (Tonically Active Neurons) and 101 PANs (Phasically Active Neurons) from ventro-medial part of the striatum of two monkeys while they performed a task in which 9 combinations of reward were offered by mixing 3 sizes (2, 4 or 6 drops of water) and 3 delays (1, 4 or 7s). A visual cue predicting the combination being offered was presented throughout the trial. The monkeys were required to respond in one of two periods represented by the appearance of a yellow or a purple dot. On the appearance of yellow

dot, the monkeys could refuse the offer by releasing a bar immediately or accept by releasing when a purple dot appeared. If a purple dot appeared, the monkeys could accept by releasing immediately or refuse by waiting for the yellow dot. To capture response feature that might represent the information, we used principal component (PC) analysis of the responses elicited by the visual cue. The principal components from all conditions regardless of cue were extracted and the scores of those were examined. We focused on the period immediately following the onset of the visual cue, but before any action were required. We found that for basically all of the TANs (44/50) and almost all of the PANs (72/101) the cue-elicited responses were related to the two factors, reward size and delay as seen through ANOVAs with reward size and delay as factors and spike count or coefficient for the first principal component (PC1) as dependent variable. The information about the offered reward captured by PC1 for both types of neurons expressed as percentage of variance explained by the two factors from the ANOVA, was similar between the two groups (N=116; mean ± SD: 17.9% ± 17.7 and 17.6% ± 11.8 for PANs and TANs respectively; two-sample t-test: 114 df, p=0.92). However, there was striking difference between TANs and PANs in how the neural activity was modulated according to the offered reward. For 24/44 TANs and for all 72 PANs the firing modulation was represented by counting the number of spikes. For the other 20 TANs the modulation was greatly underestimated using the spike count; it was, however, strongly represented as a temporal modulation of the response. That is, for the group having basically no correlation between PC1 and spike count, there is a temporally modulated code carrying information about reward size and delay to reward.

Title: Attentional allocation predicts reward anticipation during appetitive Pavlovian conditioning

Authors: *V. B. MCGINTY[1], W. T. NEWSOME III[2]
[1]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ; [2]Dept Neurobiol, Stanford Univ. Sch. Med., Stanford, CA

Abstract: Neural value representations underlie a wide range of behaviors, from simple consumatory actions to complex economic decisions. In a prior report, we identified frontal lobe value representations that were modulated by overt shifts of attention towards value-associated visual cues (i.e. by shifts of gaze during free viewing). Here, we investigate the behavioral sequelae of this attentional modulation. Specifically, we ask how overt shifts of attention influence a behavioral indicator of reward anticipation, and whether this influence is mediated by attention-driven modulation of the orbitofrontal cortex (OFC).
Two macaque monkeys performed an appetitive Pavlovian conditioning task in which simple color cues were presented on a display for 4 seconds, followed by a juice reward whose volume depended on the cue color. Fixation was not enforced during the 4-second cue presentation, and overt shifts of attention (gaze) towards or away from the cues were measured using an eye tracker. Also measured during cue presentation were reward anticipation, indicated by Pavlovian conditioned licking responses (CRs) before reward delivery; and single neuron activity in OFC, recorded using standard methods.
In general, attention predicted reward anticipation: the longer the monkeys spent looking at a cue at a given time point in a trial, the more likely they were to produce a CR at a later time point in that trial. To address neural mechanisms, mediation analysis measured the extent to which the attention-CR correlation could be statistically explained by the concurrently recorded firing of single OFC neurons. The resulting mediation effects, averaged across 105 OFC neurons, were indistinguishable from chance, meaning there was no evidence that OFC participated in the neural mechanism linking attention and reward anticipation. Finally, to determine whether OFC activity could predict reward anticipation independent of attention, we performed a partial correlation analysis in which linear effects of attention were removed. We found a weak, but significant correlation between OFC firing and CR probability; as with the attention-CR correlation, OFC activity at a given time point in a trial predicted CR probability at a later time point in that trial.
We conclude that overt attentional shifts and OFC activity both predict reward anticipation, and appear to do so independently from one another. However, it is still unclear what neural mechanism links attention and reward anticipation, and whether a similar mechanism may underlie the well-documented influence of attention on economic choice.

Title: Neural correlates of intrinsic motivation and performance during training

Authors: A. D. PASSARO[1], *A. H. OIKNINE[2], P. KHOOSHABEH[1], K. A. POLLARD[1], B. T. FILES[1]
[1]US Army Res. Lab., Los Angeles, CA; [2]US Army Res. Lab. | DCS Corp, Los Angeles, CA

Abstract: Intrinsic motivation can influence task performance and may be observable via electroencephalography (EEG) of brain activity. In our first study, task-based performance during both a feedback-based go/no-go training and subsequent transfer tasks was found to relate to components of intrinsic motivation. A second, follow-up study found a neural relationship with the same component of intrinsic motivation. Subjective data on intrinsic motivation were collected across 90 participants and correlated with performance metrics for both training and transfer tasks. EEG was used to identify the relationship between spectral power across electrodes and measures of intrinsic motivation across 32 participants.
The first study focused on the relationship of accuracy and various subscales of the Intrinsic Motivation Inventory (IMI) including enjoyment, perceived competence, and effort. This study identified a positive correlation between correct rejection and perceived competence in the training task ($r(88) = .316$, $p < .005$) and overall accuracy and both perceived competence ($r(88) = .414$, $p < .005$) and enjoyment ($r(88) = .400$, $p < .005$) in the subsequent target identification transfer task. The second study correlated the same subscales of IMI with a time-frequency decomposition of EEG data acquired using a similar training and transfer task as the previous experiment. Only the perceived competence subscale produced a significant relationship with time-locked spectral power of the last 100 trials of the task. A cluster-based non-parametric correction identified a single cluster ($p< 0.05$) of significant coefficients extending from -0.5 to 1.0s around the stimulus onset within the beta band. The focal points of this cluster resided in channels over the left anterior and posterior brain regions along with channels over the anterior midline. The topography of this cluster suggests a distributed network with beta-band activity that decreases in power as perceived competence increased across participants.
Previous studies have demonstrated that perceived competence after receiving feedback-based training relates to performance metrics on that task for specific situations. The results reported here from the first study corroborate those findings and EEG results from the second experiment extend those findings by identifying neural correlates. Taken together, findings from both studies suggest that neural patterns emerge as the task progresses that reflect both performance and perceived competence during this feedback based task. Future work can assess whether these brain regions can be monitored directly to assess effectiveness of feedback in real-time.

Title: Modulation of motor resonance by the reward value associated with observed actions

Authors: *N. WENDEROTH[1], A. CRETU[2]
[1]Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland; [2]Health, Sci. and Technol., Neural Control of Movement Lab., Zürich, Switzerland

Abstract: The ability to interpret the goals and intentions of others' actions plays a significant role in our every-day interactions. An electrophysiological study by Caggiano et al., (2012) proved that mirror neurons, which discharge when a monkey executes a particular action and when it observes another individual perform the same or a similar action, are modulated by the value associated with the observed movement. In humans, action observation related motor activity, also refered to as 'motor resonance', is modulated by contextual information accompanying others' actions. Interestingly, we recently demonstrated that even in the absence of movement kinematics, reliable contextual information is enough to trigger significant muscle-specific motor resonance in primary motor cortex (M1) of observers. However, it is unknown whether motor resonance in human M1 is modulated by the value associated with an observed action.

For this purpose, we employed single-pulse transcranial magnetic stimulation (TMS) and measured changes in motor-evoked potential amplitude (MEP) in the index (FDI) and little finger (ADM) muscles while participants observed either full view or partly occluded grasping videos that were associated with either high or low reward. The reward was contigent on whether the upcoming grasping action would involve a whole-hand (WHG) or precision-grip (PG), respectively. A number written on the cues indicated whether the current trial was associated with a high or low reward (e.g.,'100'= participant could receive 100 points; '1'= participant could receive 1 point), while the colors of the cues indicated which grip type would lead to winning the reward.

Our prelimimary statistical results show that the reward value influences muscle-specific motor resonance in M1 (reward x muscle specificity $p = .048$). Post hoc analyses revealed a significantly higher motor resonance during the observation of high- versus low-reward trials in the ADM muscle ($p=.003$) but not in the FDI muscle ($p=.68$). These findings support the vital role of the action observation system to the understanding of other's actions.

Title: Dopamine regulation of A-type potassium channels underlies individual differences in motivation for reward

Authors: *B. O'DONOVAN[1], A. ADELUYI[3], S. A. SAMARANAYAKE[2], A. GALLOWAY[1], P. HASHEMI[2], J. R. TURNER[3], P. I. ORTINSKI[1]

Abstract: Motivational drive for reward is an important component of appetitive behavior that varies significantly between individuals. While it is known that dopamine signaling and medium spiny neuron (MSN) firing patterns in the nucleus accumbens (NAc) shell play a prominent role in response to reward; the relationship between endogenous dopamine levels, neuronal output and individual differences in motivation is unclear. In this study we find that, among naïve Sprague-Dawley rats, individual performance on a sucrose-reinforced progressive ratio task is linked to pronounced differences in the NAc dopamine levels in vivo. Rats motivated to complete higher ratios of active lever responding, have increased phasic NAc shell dopamine levels, but similar rates of dopamine clearance, relative to rats completing low ratios of responding. Whole-genome RNA sequencing highlights substantially divergent transcriptome profile among rats that differ in motivational response to sucrose, with notable enrichment at genes related to dopamine signaling and at voltage-gated, including A-type, potassium channel genes. Furthermore, NAc shell MSNs of highly motivated rats have decreased action potential output and increased action potential afterhyperpolarization, which is mediated by A-type potassium current activity. Animals with low motivation for sucrose show increased sensitivity to cocaine effects on behavioral, dopamine signaling, and neuronal excitability measures, whereas cocaine effects are blunted in animals with high motivation for sucrose. This work identifies molecular and functional adaptations that reflect individual motivation for reward in an effort-based task. We show that motivational response to reward is determined by an interaction between dopamine signaling and A-type potassium channels in the NAc.

Title: Nucleus accumbens shell single-unit and local field potential activity encoding of outcome probability estimation

Authors: *J. B. ARROYO[1,3], E. FONSECA[2,3], R. GUTIERREZ[4]
[2]Neurobio. of the Appetite, [1]UNAM, Mexico city, Mexico; [3]Pharmacol., CINVESTAV-IPN, Mexico city, Mexico; [4]CINVESTAV - IPN, Mexico City, Mexico

Abstract: The estimation of reward probability allows an organism to make predictions, adjust its action selection and maximize the cost-benefit of the available response options. This flexible behavior is essential during foraging where, by estimating the probability that a food source is replenished or depleted, the animal needs to minimize energy expenditure and maximize the energy obtained. The capacity to assess reward probability relies on a complex network that includes the Nucleus Accumbens (NAc). Indeed, dopamine levels in the NAc Core are sensitive to reward rate. However, it remains unexplored the role of the NAc Shell in the estimation of reward probability at the single neuronal activity level. To address this issue, we recorded single units and local field potentials (LFP) of the NAcSh, while rats performed an adaptive decision-making task. During a trial, the subject had to approach and place its nose into a central port for 0.7s; subsequently, an auditory stimulus was delivered (Go cue), indicating the subject to press the left or the right lever, each one was associated with an independent reward probability: 10-90, 10-50, 50-90, 50-50%, and counterbalanced. Then the rat had to move to the opposite panel to emit two dry licks in the sipper, followed by three drops of sucrose (one per lick) if rewarded, or dry licks, if unrewarded. The probabilities assigned to each lever were changed periodically every 50 trials without any explicit signal. Thus, animals must continuously estimate reward probability across the session. We found neurons that were selectively modulated by the Go cue, the lever press, or the consummatory behavior; while other neurons encoded more than one feature of the task, displaying a more sensoriomotor integrative profile. Interestingly, some units closely covaried with reward probability. Indeed, a principal component analysis (PCA) confirmed that most of the NAcSh neurons were sensitive to dynamic changes in reward probability across the session, suggesting an abstract representation of reward expectancy. Finally, the LFPs displayed an increase in power at delta, theta, beta, and gamma oscillations in

rewarded trials; furthermore, there were a ramping increase in LFP power as the subject approached to the impending reward. Nevertheless, no modulation in LFP oscillations were observed when reward was omitted neither to the movement direction. We concluded that single unit responses in the NAcSh estimated, trial by trial, reward probability, as well as other variables which could help the subject to increase the chance to obtain a reward; while LFP oscillations were selectively tracking reward expectancy.

Title: Effort disutility measured in behaviour and dopamine neuron activity of non-human primates

Authors: *M. H. BURRELL, A. PASTOR-BERNIER, W. SCHULTZ
Dept. of Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Introduction: Reward follows work, but with finite energy, all life must decide what reward is worth the work. Economic theory provides a framework of how rational decision makers optimise this choice: agents should maximise the possible utility (subjective benefit) discounted by the disutility (subjective cost) of the required effort. The dopamine reward prediction error signal is a potential neuronal substrate of this utility calculation as it is known to capture subjective value of rewards, risk and time. Other work has demonstrated pathologies of midbrain dopamine neurons and drugs that target dopaminergic signalling affect the willingness to expend effort. However, it is not clear how effort disutility is represented in the reward prediction error signal. Here, we provide experimental evidence of the fundamental assumption of a subtractive cost of effort and use this to investigate a biological basis of this valuation process in midbrain dopamine neurons. Methods: Two rhesus macaques (*Macaca mulatta*) made repeated binary choices using a custom-built joystick, in which the reward and effort to obtain the reward were varied. From these choices, we independently estimated the utility of juice reward and disutility of effort using random utility models, validating these models with out-of-sample tests. The activity of dopamine neurons in the Substantia Nigra and Ventral Tegmental Area in one animal was measured using single-cell extracellular recordings during choice. Dopamine neuron activity was compared to the subjective values of reward and effort within a temporal-difference learning model. Results: Empirical choice behaviour was closely matched to

that predicted by the estimated net utility (reward utility minus effort disutility) of choices providing evidence for the subtractive economic model of effort disutility. Dopamine neuron activity captured the utility of reward, as previously demonstrated, but critically also correlated with the estimated disutility of effort at the time of the conditioned stimulus. Moreover, this signal followed subtle shifts in effort disutility over time as predicted by behavioural data. These data suggest dopamine neurons capture the cost of effort by encoding net utility and hence convey value signals that are appropriate for decision-making involving effort.

Title: Satiety changes neuronal correlates of revealed preference in monkeys

Authors: *A. PASTOR-BERNIER[1], A. STASIAK[2], W. SCHULTZ[3]
[2]PDN, [1]Univ. of Cambridge, Cambridge, United Kingdom; [3]Univ. Cambridge, Cambridge, United Kingdom

Abstract: Introduction Rewards or goods contain typically at least two attributes or components, such as taste and calories. We often trade-in some amount of one component to gain one unit of the other component. Experimentally, these components can be modeled as distinct rewards in bundles of two goods. By trying to obtain the most preferable combination of two goods, we are expressing our preferences (revealed preference) and are aiming to maximize their utility. Our previous study demonstrated that monkeys' choices conform with revealed preference theory. Revealed preference was assessed in choices between a reference bundle and a variable bundle. In the variable bundle, a quantity of one juice is given up in order to gain one unit of the other juice without losing overall value. This trade-off is fair when each bundle is chosen by the animal with equal frequency, as assessed by psychophysics (indifference point). Repeated tests with systematic trade-offs resulted in a series of indifference points that conformed to an indifference curve. In the current study, we used revealed preference tests to investigate behavioral and neuronal changes in relation to the satiety of one of the bundle rewards (sensory-specific satiety). Methods The animals were presented with two bundles, each containing two juices on which they became sated to different degree. We assessed sensory-specific satiety as change in preference between the two juice rewards, which was manifested as difference in the slope of the indifference curve. We studied single neuron activity in orbitofrontal cortex (OFC)

during choices among two bundles across unsated and sated states. A support vector machine classifier (SVM) was trained on neuronal responses during unsated and sated states. Results Indifference curves showed slope changes for the juice reward on which the animal was more sated, reflecting a relatively lower preference for that juice. OFC responses to the bundles showed correspondingly stronger changes to the juice on which the animal was more sated, resulting in similar slope changes of neuronal indifference curves. SVM analysis showed that neuronal responses predicted well the satiety-induced, changed behavioral preferences. These results demonstrate that revealed preference theory provides valuable tools to demonstrate neuronal correlates of sensory specific satiety.

Title: Cell type-specific and non-specific mechanisms of cholinergic interneuron-mediated plasticity onto MSNs

Authors: *W. T. FLEMING, J. LEE, I. B. WITTEN
Princeton Neurosci. Inst., Princeton, NJ

Abstract: Cholinergic (ChAT) interneurons in the nucleus accumbens (NAc) bidirectionally regulate the extinction of cocaine associations, likely through their modulation of plasticity on medium spiny neurons (MSNs). In particular, cocaine extinction is associated with a gradual reduction of glutamatergic presynaptic plasticity onto MSNs, and the activation of ChAT cells has been shown to hasten this plasticity (Lee et al., Neuron 2016). However, whether ChAT cells differentially control plasticity onto the two major subtypes of MSNs--those that express D1 receptors (D1Rs) versus D2 receptors (D2Rs)--has not been examined. This is an important question because D1R and D2R MSNs are thought to undergo different forms of dopamine-dependent plasticity, and contribute differentially to reward-related behaviors. Therefore, to compare ChAT-mediated plasticity in D1R and D2R MSNs, we used double transgenic mice (either ChAT::Cre/Drd1a::tdTomato or ChAT::Cre/Drd2::EGFP) to allow for modulation of ChAT cells during behavior as well as identification of subtype-specific MSNs during

electrophysiological recordings. We bilaterally injected an AAV expressing Cre-dependent ChR2-eYFP into the NAc and optogenetically activated ChAT cells during extinction of a cocaine conditioned place preference (CPP). Immediately after, we performed ex vivo whole-cell recordings of D1R or D2R MSNs to measure changes in plasticity mediated by ChAT cells. Consistent with previous findings, ChAT activation during extinction testing significantly reduced cocaine CPP (mean reduction 115.6 ± 27.8 secs in 15 min test; p=0.014 for group, two-way ANOVA; n=18 stim, n=28 control). In addition, ChAT activation during extinction testing reduced the frequency of mini excitatory post-synaptic currents (mEPSCs) at both D1R MSNs (p=0.002, linear, mixed-effects regression (LME); n=8 stim; n=10 control) and D2R MSNs (p=0.001,LME; n=12 stim, n=12 control), suggesting that ChAT activation has a presynaptic effect on glutamatergic transmission that is not specific to MSN subtype. We also observed that ChAT activation reduced mEPSC amplitudes at D2R MSNs (p=0.008, LME; n=12 stim; n=12 control), but not D1R MSNs (p=0.893, LME; stim n=8; control n=10), suggesting that ChAT activation may have cell type-specific postsynaptic effects. Together, these findings begin to clarify both cell type-specific and non-specific mechanisms by which ChAT interneurons regulate synaptic plasticity and behavior.

Title: Spatial segregation of movement and reward encoding across the basal forebrain cholinergic system

Authors: *J. CHOI[1,2], J. AU[3], H. JANG[1], E. A. ENGEL[1], I. B. WITTEN[1,2]
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, [3]Dept. of Mol. Biol., Princeton Univ., Princeton, NJ

Abstract: Ascending cholinergic transmission from the basal forebrain (BF) has been implicated in numerous aspects of behavior and cognition, including learning, memory, attention and reward. However, due to the sparse and distributed nature of these cholinergic neurons, it remains unclear if across different BF subregions these neurons respond in a homogeneous or heterogeneous manner. To address this question, we performed fiber photometry to record from

cholinergic neurons across two BF subregions (medial septum, MS, and nucleus basalis, NB) in ChAT::Cre rats that were trained to perform a delayed non-match to position task in operant chambers (MS: n = 8 recordings, NB: n = 17 recordings, 16 ChAT::Cre males and 1 female, ~3-8 months of age).
In the MS, a substantial fraction of the variability in cholinergic activity was explained by the animal's locomotor behavior, while task events provided little additional explanation of neural activity (average variance explained by speed: R2 = 0.32 + 0.02; explained by task events and speed: R2 = 0.40 + 0.024; mean+se). In contrast, in the NB, cholinergic activity was poorly explained by locomotion, while task events accounted for a substantial fraction of response variability (average variance explained by speed: R2 = 0.087 + 0.03; explained by task events; R2 = 0.33 + 0.028; mean+ se). Further, within the NB, responses were spatially organized, as medial recording sites (within the internal capsule) displayed transiently elevated activity during the reward-seeking action and reward onset, whereas lateral recording sites (within the posterior globus pallidus) exhibited elevated activity throughout reward consumption. These findings provide some of the first evidence in support of spatial organization of heterogeneous functional properties within the BF cholinergic system.

Title: A neural pathway for information seeking: A cingulate-striatum-pallidum network predicts gaze shifts to objects associated with uncertain rewards

Authors: *E. S. BROMBERG-MARTIN[1], J. K. WHITE[1], K. ZHANG[2], J. PAI[3], I. E. MONOSOV[1]
[1]Anat. and Neurobio., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Biomed. Engin., Washington Univ. in St. Louis, St Louis, MO; [3]Neurosci., New York Univ., New York, NY

Abstract: When faced with delayed and uncertain rewards, both humans and animals search for information from their environment to learn what the future holds. However, the neural systems

that motivate information seeking have been primarily investigated in economic choice tasks. Less is known about the most fundamental form of natural information seeking behavior: shifting the eyes to inspect the source of uncertainty. We hypothesized that information seeking is motivated by neurons that we recently discovered in anatomically connected regions of the anterior cingulate cortex (ACC), dorsal striatum (DS), and ventral pallidum (VP). These neurons are selectively activated by visual objects associated with uncertain future rewards, with sustained ramping activity anticipating the moment the uncertainty can be resolved by getting information about the future outcome. This activity would be ideal to motivate gaze shifts to the source of uncertainty to gain information about future outcomes. To test this, we examined neuronal activity and eye movements while monkeys freely gazed at visual stimuli associated with different levels of reward uncertainty and different times of receiving information to resolve the uncertainty. Animals learned that visual conditioned stimuli (CSs) predicted juice reward with different probabilities and amounts, including both certain and uncertain CSs (e.g. 100% vs. 50% chances of reward). In an "information anticipation" version of the conditioning procedure, one set of *informative CSs* were followed by an informative cue that appeared 1s after CS onset and indicated the upcoming reward size in advance of its delivery (thus resolving any uncertainty). A second set of *non-informative CSs* were followed by non-informative cues that did not indicate the upcoming reward size (and hence did not resolve uncertainty). We found that the expectation of gaining information had strong, correlated effects on neurons and eye movements. (1) Many neurons in all three brain areas had activity ramping to the expected time of receiving information. (2) Eye movements to gaze at the CS had a similar information-anticipatory time course. (3) Neural information signals had strong moment-to-moment correlations with gaze (stronger signals during gaze at uncertain CSs). (4) This enhancement of neural information signals started hundreds of milliseconds *before* animals shifted their gaze onto the CS. Thus, the ACC-DS-VP network is ideally positioned to guide information seeking: it anticipates information about future rewards and activates before gaze shifts toward the source of uncertainty.

[1]Anat. and Neurobio., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Neurosci., Washington Univ. In St. Louis, Saint Louis, MO; [3]Biomed. Engin., Washington Univ. in St. Louis, st louis, MO; [4]Ctr. for Neural Sci., New York Univ., Brooklyn, NY

Abstract: What brain systems motivate us to resolve our uncertainty and gain information about the future? While little is known about the underlying neural pathways, we recently discovered a promising candidate. A subpopulation of neurons in an anatomically connected network comprising of the anterior cingulate cortex (ACC), dorsal striatum (DS), and ventral pallidum (VP) are selectively activated by visual objects associated with uncertain rewards, and have sustained ramping activity that anticipates the moment of gaining information about the future outcome (i.e. resolving the uncertainty). This raises a crucial question: is their activity *passively* anticipating the gain of information, or *actively* motivating animals to seek information and resolve their uncertainty? Our linked poster by Bromberg-Martin et al. is consistent with an active role, showing that fluctuations in the activity of these neurons predict the motivation to shift gaze to inspect uncertainty-related objects. Here we put this hypothesis to a direct test by pharmacologically inactivating the basal ganglia regions of the uncertainty-related network. These inactivation experiments were done while monkeys performed a saccadic reaction time task to measure their motivation to obtain information about future rewards. On each trial, a visual conditioned stimulus (CS) was presented peripherally and predicted an uncertain, 50% chance for juice reward to be delivered 3 sec after CS onset. There were two types of CSs. CS1 was *informative*: when the animal shifted gaze onto the CS, the CS was replaced with an informative cue that indicated whether the trial was going to be rewarded (and hence immediately resolved the uncertainty). CS2 was *non-informative*: when the animal gazed at the CS, it was replaced with a non-informative cue that did not predict the upcoming outcome (and hence caused uncertainty to remain until the end of the trial when the outcome was delivered). Importantly, the animal's reaction time to gaze at the CS had no influence on the timing or amount of juice reward; it only influenced their speed of gaining access to the informative or non-informative cues. We found that monkeys displayed a strong motivational bias related to gaining information about future rewards: they fixated the informative CS much earlier than the non-informative CS, and therefore obtained uncertainty-resolving information earlier. Pharmacological manipulation of the targeted striatal and pallidal subregions diminished this reaction time bias. Therefore, basal ganglia play a causal role in animals' motivation to resolve their reward uncertainty and gain information about the future.

Title: Corticotropin releasing factor (CRF) increases excitability of Dorsal Raphe glutamatergic neurons

Authors: *J. A. MIRANDA-BARRIENTOS, B. LIU, M. F. MORALES
NIDA, Baltimore, MD

Abstract: The dorsal raphe (DR) contains serotonin, GABA and glutamate neurons that express the vesicular glutamate transporter 3 (VGluT3) (Gras et al., 2002; Herzog et al., 2004; Jackson et al., 2009; Qi et al., 2014). We had recently demonstrated that axons from DR VGluT3 neurons establish excitatory synapses on ventral tegmental area (VTA) dopamine neurons that innervate the nucleus accumbens, and that VTA activation of inputs from DR VGluT3 neurons is rewarding (Qi et al., 2014). To have a better understanding of cellular properties of DR VGluT3 neurons that may play a role in their regulation, we began analyzing the electrophysiological and pharmacological properties of these neurons. By electrophysiological analysis of the membrane intrinsic properties of DR VGluT3 neurons, we did not find electrophysiological properties that distinguish VGluT3 neurons from neighboring serotonin neurons. Given that the DR has high levels of expression of corticotropin releasing factor (CRF) receptor 2 (CRF-R2), by in situ hybridization we looked for expression of CRF-R2 within DR VGluT3 neurons. We detected expression of CRF-R2 mRNA in some DR neurons expressing VGluT3 alone or in combination with Triptophan Hydroxylase (enzyme for the production of serotonin). Consistent with the presence of CRF-R2 mRNA in some VGluT3 neurons, by patch clamp recordings on genetically identified DR VGluT3 neurons, we found that CRF increased the excitability of a subpopulation of DR VGluT3 neurons. The effect of CRF on DR VGluT3 neurons excitability was blocked by a CRF-R2 antagonist. These findings indicate that DR glutamatergic neurons are modulated by CRF, suggesting a role of stress on controlling the neuronal activity of DR glutamatergic neurons.

Title: Selective activation of GABAergic inputs from the pedunculopontine tegmental nucleus to the ventral tegmental area drives reward

Authors: *H.-L. WANG, Q. SHEN, Y. ZHANG, M. F. MORALES
IRP/NIDA/NIH, Baltimore, MD

Abstract: The pedunculopontine tegmental nucleus (PPTg) is composed of cholinergic, GABAergic, and glutamatergic neurons (Wang & Morales, 2009), which provide inputs to ventral tegmental area (VTA, Wang et al., 2010 SfN 366.4). Recent optogenetic studies have shown that VTA optical activation of PPTg glutamatergic or cholinergic axons produces a reinforcing effect or place preference (Wang et al., 2015 SfN; Yoo et al., 2017; Xiao et al., 2016). However, the functional role of PPTg GABA inputs to VTA is unclear. To determine the role of PPTg GABA inputs to the VTA, PPTg GABA neurons were selectively tagged with either eYFP (VGAT-eYFP) or ChR2 tethered to eYFP (VGAT-ChR2-eYFP) in VGAT::Cre mice. Mice were implanted with optic probes aimed at the VTA. To determine if VTA activation of PPTg GABA inputs is positively reinforcing, mice were trained to earn VTA optical stimulation by rotating one of two response wheels. VGAT-ChR2-eYFP mice, but not VGAT-eYFP mice, rotated the reinforced wheel significantly more than the non-reinforced wheel. To confirm that wheel-turning was goal-directed, we switched the contingencies between the wheels for 5 days after the initial 8 days of training. VGAT-ChR2-eYFP mice quickly increased their responding on the new reinforced wheel, completely reversing their operant performance by the third reversal session. Mice continued to respond on the new reinforced wheel for two subsequent reversal testing sessions. Next, to further characterize the rewarding properties of PPTg GABA inputs to VTA, we conducted real-time place preference studies. VGAT-ChR2-eYFP and VGAT-eYFP mice were tested in a three chambers apparatus and were given continuous trains of optical stimulation when they entered the laser-paired chamber. VGAT-ChR2-eYFP mice spent significantly more time in the laser paired chamber in training and test days. Thus, VGAT-ChR2-eYFP mice not only earned the stimulation by entering the laser-paired chamber when stimulation was available (training day); they also acquired a conditioned place preference for the stimulation-associated chamber when the stimulation was no longer available (test day). Then, we examined c-Fos expression in VTA neurons induced by local activation of PPTg GABA fibers and found that this activation induced c-Fos expression in dopamine and non-dopamine neurons. However, only a small fraction (10%) of the c-Fos-positive neurons expressed tyrosine hydroxylase (a dopaminergic marker). We conclude that VTA selective

excitation of PPTg GABA inputs elicits reward by a mechanism that involves the excitation of mostly non-dopamine neurons.

Title: Monosynaptic inputs to rat GABA neurons of the ventral tegmental area or the rostromedial tegmental nucleus

Authors: *C. MEJIAS-APONTE[1], A. KUPPA[2], Z. H. FUSFELD[2], M. F. MORALES[3]
[1]Neuronal Networks Section, INRB, Natl. Inst. On Drug Abuse, Baltimore, MD; [3]Integrative Neurosci. Res. Br., [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: It is well established that the neuronal activity of dopamine neurons in the ventral tegment area (VTA) is inhibited in part by inputs from local GABA neurons or from the neighboring rostromedial tegmental nucleus (RMTg). Findings from a recent rat study using chemical retrograde track tracers (fluorogold and cholera toxin subunit b) showed differences between the brain structures innervating the VTA and those innervating the RMTg (Yetnikoff et al., 2015). This study showed a stronger innervation from the nucleus accumbens to the VTA than to RMTg, and a stronger innervation from the superior colliculus to the RMTg than to the VTA. While these findings provide crucial circuitry information, it remains to be determined the extent to which neurons from the identified brain structures (innervating the VTA or RMTG) synapse on GABA neurons. To selectively map the rat synaptic inputs to GABA neurons within the VTA or RMTg, we used a monosynaptic viral-vector rabies based tract-tracing and the recently developed GAD1::Cre transgenic rats (provided by NIDA-IRP). Given that the VTA and RMTg are adjacent structures, we used transgenic rats (instead of mice) to maximize the selective viral vector targeting to GABA neurons within the VTA or RMTg. We found that neurons distributed in the basal forebrain, hypothalamus, midbrain and brainstem establish monosynaptic synapses on GABA neurons of the VTA or RMTg. We are currently quantifying the total number of neurons synapsing on GABA neurons of the VTA or RMTg, and determining the phenotypes of these projection neurons.

Title: Ventral tegmental area glutamate neurons drive reinforcement independent of dopamine

Authors: *V. ZELL[1], N. G. HOLLON[2], T. STEINKELLNER[1], E. SOUTER[1], L. FAGET[1], X. JIN[2], T. S. HNASKO[1]
[1]Neurosciences, UCSD, San Diego, CA; [2]Mol. Neurobio. Lab. J, Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The ventral tegmental area (VTA) is a midbrain dopamine center implicated in the control of motivated behaviors. The VTA is a highly heterogeneous structure that also contains GABA and glutamate neurons, subsets of which can co-release more than one of these small molecule transmitters. In a previous study we reported that optogenetic stimulation of VTA VGLUT2 (glutamate) cell bodies or terminals can drive behavioral reinforcement. We further showed that mice displayed marked preference for brief over sustained stimulation, resulting in behavioral responses that were notably distinct when compared to dopamine neuron stimulation. Still, a subset of VTA glutamate neurons co-release dopamine and may directly recruit dopamine neuron activation through intra-VTA connectivity. Thus, a fundamental question remains: is behavioral reinforcement driven by VTA glutamate neuron stimulation dependent on increased dopamine release? To address this we conditionally disrupted the gene encoding tyrosine hydroxylase (*Th*) in VGLUT2-expressing neurons to selectively block dopamine synthesis in and release from VTA glutamate neurons. Co-expression of DA and glutamate markers is abolished in these Th cKO mice. ChR2-mediated stimulation of VTA glutamate neurons leads to robust evoked DA release in the nucleus accumbens (NAc) shell of control mice, and this too is abolished in the cKO. Nevertheless, both groups showed identical patterns of self-stimulation for optogenetic stimulation of VTA glutamate cell bodies or their terminals in the NAc. These data support the hypothesis that activation of VTA glutamate neurons can drive positive reinforcement through a mechanism parallel to mesolimbic dopamine projections and independent of their ability to increase DA signaling in the medial NAc shell.

Title: Distinct expression of calcium binding proteins in glutamatergic neurons in the ventral tegmental area

Authors: *S. MONGIA[1], T. YAMAGUCHI[2], H. WANG[1], J. MIRANDA-BARRIENTOS[1], B. LIU[1], M. MORALES[1]

Abstract: The ventral tegmental area (VTA) has three major subclasses of neurons: dopaminergic, GABAergic and glutamatergic (expressing the vesicular glutamate transporter 2; VGluT2). The VTA dopaminergic and GABAergic neurons have been further characterized based on the expression of calcium-binding proteins (CaBPs). Here we determined whether the VTA VGluT2 neurons express any of the known CaBPs (calbindin, CB; calretinin, CR or parvalbumin, PV). By using a combination of *in situ* hybridization (for the detection of VGluT2 mRNA) and immunohistochemistry (for detection of CB, CR or PV), we found that among the total population of VTA VGluT2 neurons, 30% co-expressed CB, almost 3% co-expressed PV and less than 1% co-expressed CR and were concentrated in the medial aspects of the VTA. We found that within the total population of CaBPs, almost one-third of CB neurons co-expressed VGluT2 mRNA, CR neurons rarely co-expressed VGluT2 mRNA, and over half of the PV neurons co-expressed VGluT2 mRNA. We concluded that one-third of the population of VTA VGluT2 neurons co-express a CaBP, and that about one third of the VTA CB neurons express VGluT2 and approximately half of the population of VTA PV neurons express VGluT2. These findings further provide evidence for heterogeneity among VTA VGluT2 neurons.

Title: Ventral tegmental area glutamate neurons are functionally diverse

Authors: *D. J. ESTRIN[1], D. H. ROOT[1,2], M. MORALES[1]
[1]Neuronal Networks Section, Integrative Neurosci. Res. Br., Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Dept. of Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: The Ventral Tegmental Area (VTA) comprises different neuronal populations; dopaminergic, GABAergic and glutamatergic. The VTA glutamatergic neurons express the Vesicular Glutamate Transporter 2 (VGluT2) for the vesicular accumulation of glutamate. Optogenetic studies have provided evidence for the involvement of VTA-VGluT2 neurons in both reward and aversion learning. Findings from these optogenetic studies have shown that optical stimulation of VTA-VGluT2 cell bodies is rewarding, whereas optical stimulation of VTA-VGluT2 terminals in the Nucleus Accumbens or Lateral Habenula is aversive. To determine the natural electrophysiological role that VTA-VGluT2 neurons play in motivation, we recorded from channelrhodopsin 2 phototagged VTA-VGluT2 neurons (n=27) in response to rewarding or aversive stimuli. We identified two major functionally distinct subpopulations of VTA-VGluT2 neurons: (1) VTA-VGluT2 neurons that increased their firing during an aversive air puff but decreased their firing during sucrose consumption, and (2) VTA-VGluT2 neurons that increased their firing during both sucrose consumption and air puff presentation. Additionally, we found minor subpopulations of VTA-VGluT2 neurons that increased their firing rates in response to learned cues and reward-approach behavior. We identified separate VTA VGluT2 subpopulations which differ in firing by signaling either outcome evaluation or reward expectation. From these findings, we deduce that there is functional diversity among the VTA-VGluT2 neurons. This functional diversity may reflect the molecular heterogeneity within the VTA-VGluT2 population.

Title: Opponent signals from the lateral preoptic utilize the heterogeneity of the ventral tegmental area to drive motivated behavior

Authors: *D. J. BARKER, R. JUZA, S. ZHANG, J. MIRANDA-BARRIENTOS, B. LIU, C. MEJIAS-APONTE, S. MONGIA, M. MORALES
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The lateral preoptic area (LPO) is comprised of a mixture of glutamatergic and GABAergic neurons and participates reward, aversion, stress, and drug addiction. It has long been established that the LPO provides substantial input to the ventral tegmental area (VTA), however the exact nature of this connection has remained elusive. Here we show that LPO inputs to the VTA establish a complex functional network with the VTA that is necessary for generating simple, but functionally opposing behavioral responses. By the combination of retrograde tracing and *in situ* hybridization, we determined that 65.6 ± 3.9% of lateral preoptic area inputs to the VTA neurons expressed the vesicular GABA transporter mRNA, while 42.4 ± 2.4% expressed the vesicular glutamate transporter mRNA. Further, by psuedorabies monosynaptic tracing, we determined that LPO neurons synapse on each major cell type in the ventral tegmental area: glutamate, GABA, and dopamine. To determine the exact nature of these connections, we then used triple immuno-electron microscopy to label both pre- and post-synaptic cell types simultaneously, revealing that the lateral preoptic area glutamate and GABA neurons each target dopamine, glutamate, and GABA neurons in the ventral tegmental area, but with relatively different proportions. In spite of this synaptic complexity, activation of LPO glutamatergic or GABAergic inputs to the VTA drives simple, yet opposing behaviors: activation of LPO glutamatergic inputs to the VTA is aversive while activation of GABAergic inputs is rewarding. Thus, our ongoing work is focused on the types of information being encoded by LPO glutamatergic and GABAergic inputs to the VTA and to determine how their integration by VTA neurons might yield opposing behavioral states.

Title: VTA glutamatergic neurons play a role in defensive behaviors via glutamatergic inputs from the lateral hypothalamus

Authors: *M. F. BARBANO, H.-L. WANG, S. ZHANG, J. A. MIRANDA-BARRIENTOS, M. F. MORALES
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The selection of the adequate strategy to cope with a life-threatening situation is vital for the survival of both the individual and the species. Defensive behavior is characterized by different responses, such as freezing, fighting or escape. The brain circuits underlying freezing and fighting behaviors have been extensively studied but those underlying escape are not well understood. Findings from electrical stimulation and lesion studies performed over 30 years ago suggest that interactions between the lateral hypothalamus (LH) and the ventral tegmental area (VTA) play a role in escape responses. Since then, optogenetic studies have implied that glutamatergic LH inputs activate VTA GABA neurons to induce escape responses (Nieh et al. 2016). However, it is unclear if other types of VTA neurons (dopaminergic or glutamatergic) play a role in escape responses. To investigate the role of LH glutamate neurotransmission to VTA, we injected Cre-dependent viral vectors encoding ChR2 tethered to mCherry in the LH of VGluT2::Cre mice to tag LH axons expressing the vesicular glutamate transporter 2 (VGluT2). By immunoelectron microscopy, we found that VGluT2-axons from LH neurons more frequently established synapses on VTA glutamatergic than dopaminergic neurons (Zhang et al., SfN 2018). By electrophysiological recordings, we found that VTA photoactivation of VGluT2 terminals from LH neurons induced excitatory postsynaptic currents and evoked action potential firing on VTA VGluT2 neurons. These findings indicate that LH glutamatergic neurons provide a glutamatergic input to VTA glutamatergic neurons. Next, to evaluate the behavioral consequences of VTA optical stimulation of VGluT2 LH inputs, we conducted optogenetic studies while mice were trained in real time place aversion (RTPA) or open field (OF) tests. We found that VTA photoactivation of VGluT2 LH terminals elicited active avoidance and long-lasting aversion in the RTPA test, as well as escape responses in the OF test. To determine the participation of VGluT2 LH inputs to VTA in innate escape responses, we inhibited glutamate release from LH onto VTA neurons, and found that VTA photoinhibition of VGluT2 terminals

derived from LH decreased escape responses in mice confronted to predator odor or forced swimming. From these behavioral findings, together with the observation that LH VGluT2 neurons preferentially synapse on VTA glutamatergic neurons, we conclude that glutamatergic neurotransmission from LH to VTA glutamatergic neurons plays a role in defensive behaviors.

Title: VTA glutamatergic neurons receive major glutamatergic inputs from the lateral hypothalamus

Authors: *S. ZHANG[1], M. F. BARBANO[2], H.-L. WANG[3], J. A. MIRANDA-BARRIENTOS[4], M. F. MORALES[5]
[1]Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD; [2]Natl. Inst. on Drug Abuse, Baltimore, MD; [3]IRP/NIDA/NIH, Baltimore, MD; [4]NIDA, Baltimore, MD; [5]Cell Neurobiol Res. Br., IRP, NIDA, NIH, Baltimore, MD

Abstract: Emerging evidence indicates that different neurons of the ventral tegmental area (VTA) participate in specific aspects of behavior. The VTA has three major classes of neurons: dopaminergic, GABAegic and glutamatergic. The VTA glutamatergic neurons express vesicular glutamate transporter 2 (VGluT2) for accumulation of glutamate into synaptic vesicles. We recently found that glutamate released in VTA from lateral hypothalamic (LH) glutamatergic neurons (expressing VGluT2) plays a role in defensive behaviors (Barbano et al., 2018 SfN). To determine the synaptic connectivity established by LH VGluT2 neurons in VTA, we used a combination of cell specific viral vector tracing and immunoelectron microscopy. To tag LH VGluT2 neurons and their axons, we injected into the LH of VGluT2::Cre mice a Cre-inducible adeno-associated virus (AAV) with a double-floxed inverted open reading frame (DIO) expressing ChR2 (AAV-DIO-ChR2) tethered to mCherry. In the same mice, we tagged VTA VGluT2 neurons by local injection of AAV-DIO tethered to eYFP. By immunolabeling and electron microscopy, we detected in the VTA many fibers and axon terminals containing mCherry, all mCherry axon terminals expressed VGluT2, indicating that mCherry terminals were originated from LH VGluT2 neurons. Through the analysis of VTA sections labeled for the detection of mCherry (VGluT2 LH inputs) and eYFP (VTA VGluT2 neurons), we detected

mCherry in both axons and axon terminals, and eYFP in both cell bodies and dendrites. We found that 43.98 ± 4.27% of the LH mCherry terminals made asymmetric (excitatory type) synapses on both eYFP-dendrites and eYFP-cell bodies. Further, we observed that multiple mCherry-terminals synapsed on a single eYFP-dendrite. These findings indicate that VTA glutamatergic neurons are highly innervated by LH glutamatergic neurons. Through the analysis of VTA sections labeled for the detection of mCherry (VGluT2 LH inputs) and tyrosine hydroxylase (TH; a marker of dopaminergic neurons), we found that 34.72 ± 0.79% of the LH mCherry terminals made asymmetric synapses on TH dendrites. We conclude that within the VTA, LH glutamatergic terminals establish synapses on VTA glutamatergic cell bodies and multiple synapses on single glutamatergic dendrites. In contrast, LH glutamatergic terminals establish fewer synapses on single dopaminergic dendrites, and do not establish synapses on dopaminergic cell bodies. From these ultrastructural findings, we suggest that release of glutamate in the VTA evoked by photostimulation of LH glutamatergic inputs is likely to have a stronger excitatory influence on VTA glutamatergic neurons than on dopaminergic neurons.

Title: Fingolimod (FTY720) suppresses cocaine-induced hyper locomotion, which attenuate striatal D_1-type medium spiny neurons of PKA/DARPP-32 signaling

Authors: *K. UEMATSU[1], T. SHUTO[2], Y. SYOJI[1], N. UCHIMURA[1], A. NISHI[2]
[1]Cognitive and Mol. Res. Inst. of Brain Dis., Kurume Univ. Sch. of Med., Kurume, Fukuoka, Japan; [2]Dept. of Pharmacol., Kurume Univ. Sch. of Med., Kurume-Shi, Japan

Abstract: Sphingosine-1-phosphate (S1P) is a bioactive sphingolipid metabolite that regulates critical cellular processes such as proliferation, survival and migration as well as immune responses. S1P exerts its function by activating S1P receptors (S1PRs). There are five S1PR subtypes: $S1P_1R$, $S1P_2R$, $S1P_3R$, $S1P_4R$ and $S1P_5R$. It has been reported that S1PRs are expressed in many cell types including neurons in the brain. Fingolimod (FTY720) is an agonist of S1PRs and a new oral drug for multiple sclerosis. Fingolimod binds to all S1PR subtypes except $S1P_2R$. There are few reports about a possible role of S1P and fingolimod in neurons. In this study, we investigated the effect of S1P and fingolimod on cAMP/PKA signaling in mouse

striatal slices by monitoring the phosphorylation states of an intracellular phosphoprotein, dopamine- and cAMP-regulated phosphoprotein of M_r 32 kDa (DARPP-32) at Thr34 (PKA-site). In striatal slices prepared from D_1-DARPP-32-Flag/D_2-DARPP-32-Myc transgenic mice, fingolimod (100 nM) increased DARPP-32 Thr34 phosphorylation in D_2-type/striatopallidal neurons at 30 sec by 2-fold, but decreased P-Thr34 DARPP-32 in D_1-type/striatonigral neurons at 30 min to 60% of control. The increase in DARPP-32 Thr34 phosphorylation in striatopallidal neurons was mimicked by treatment with S1P (10 μM) (3-fold increase at 1 min of incubation) and with a selective $S1P_1R$ agonist SEW2871 (10 μM) (2.2-fold increase at 1min of incubation). The cocaine (100 μM)- and a dopamine D_1 agonist (±)-SKF-81297 (1.0 μM)-induced increases in P-Thr34 DARPP-32 were abolished after 30 min of pre-treatment with fingolimod (100 nM). In behavioral studies, pretreatment with fingolimod (1.0 mg/kg, i.p.) attenuated cocaine (20 mg/kg, i.p.)- and R(+)-SKF-81297 (0.7 mg/kg, i.p.)-induced locomoter activities. AAV injection to striatal result to over-expression of $S1P_1R$ on D_1-cre mice, is further decrease cocaine-induced locomotion by pretreatment with fingolimod (1.0 mg/kg, i.p.) than wild-type. Thus, fingolimod inhibits cAMP/PKA signaling in striatonigral neurons, resulting in the suppression of psychostimulant-induced activation of dopamine signaling and behavior.

Title: Impaired social interactions in the offspring of cocaine-exposed fathers

Authors: *A. YAW[1], J. D. GLASS[2,1], H. K. CALDWELL[2,1]
[1]Biomed. Sci., [2]Dept. of Biol. Sci., Kent State Univ., Kent, OH

Abstract: It is well established that the damaging effects of drugs of abuse, such as cocaine, can extend beyond the user to their offspring. While most preclinical models of the generational effects of cocaine abuse have focused on maternal effects, we, and others, see distinct effects on offspring sired by fathers that have used cocaine. However, little is known about the effects of paternal cocaine use on first generation (F1) offspring social behaviors. Thus, we examined anxiety-like behaviors (open field and elevated plus) in both sexes, as well as aggressive behavior (resident-intruder task) and social recognition memory (social habituation/dishabituation task) in male F1 offspring. We found that there were sire-dependent effects on anxiety-like behaviors and social memory. Specifically, cocaine-sired male offspring had reduced anxiety, as measured by increased time spent in the open arms of an elevated plus

maze (%), while there were no differences in female offspring. Further, in the social recognition test, while F1 males were able to recognize a novel mouse, they did show marked increases in sniffing times during later trials − which could be indicative of altered social motivation or cognitive deficits. Taken together, these data suggest that both anxiety-like and social behaviors in F1 males are altered by paternal cocaine use.

Title: Linking cocaine-induced structural brain changes to altered cognition in rhesus monkeys

Authors: *H. P. JEDEMA[1], X. SONG[1], H. J. AIZENSTEIN[2], Y. YANG[1], C. W. BRADBERRY[1]
[1]NIDA Intramural Res. Program, NIH, Baltimore, MD; [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Altered cognitive performance and structural changes in brains of patients suffering from cocaine dependence have been reported in multiple clinical studies. Due to the cross-sectional nature of these studies, it remains unclear whether these differences are caused by chronic stimulant use or whether they preceded use and may instead reflect a predisposition to development of drug dependence. Longitudinal preclinical studies can provide insight into the nature of these changes. In this study, we obtained structural MRI scans from 14 adult male rhesus macaques and established baseline performance on a visual working memory task (delayed match to sample; DMS) and a stimulus reversal learning task (RevL). Subsequently, 8 subjects self-administered cocaine intravenously, 4 days a week (up to 4.8mg/kg/day) while control subjects performed similar tasks for water reward. Impairment of cognitive performance on drug free days for these subjects was published previously. After 12 months of cocaine self-administration a second set of MRI scans were obtained. We used voxel-based morphometry (VBM) to examine the treatment group by time structural interaction on gray matter density (GMD). We observed clusters of decreased GMD in the medial and lateral temporal lobe (parahippocampal fusiform gyri and along the superior temporal sulcus) in the cocaine group. In addition, clusters of decreased GMD were observed in the thalamus, superior parietal cortex,

insula, and orbitofrontal and superior frontal cortex. Clusters of increased GMD in the cocaine group were observed in cerebellum, bilateral temporal poles and ventral frontal cortex, superior parietal, precentral and postcentral cortex, and rostral caudate nucleus. The impaired performance on the DMS task showed a significant correlation with the reduced GMD in the temporal lobe and superior frontal cortex in the cocaine group. Impairments in performance on the RevL task correlated significantly with the reduced GMD in orbitofrontal and superior frontal cortex, and the superior temporal and parietal cortex. These findings are consistent with altered metabolic activity in non-human primates after chronic cocaine. Furthermore, most of the observed GMD interactions are consistent with the clinical gray matter alterations in stimulant-dependent patients, suggesting these alterations are the result of prolonged stimulant exposure rather than a pre-existing condition.

Title: The effects of genetic brain serotonin deficiency on responses to repeated cocaine

Authors: *B. D. SACHS[1], M. M. KARTH[2], M. D. KARTH[2], D. VANDYK[2], G. PEREZ[2], M. G. CARON[3]
[2]Dept. of Psychological and Brain Sci., [1]Villanova Univ., Villanova, PA; [3]Duke Univ. Hosp., Durham, NC

Abstract: Substance abuse disorders are poorly understood conditions that exert a devastating toll on society. While the exact causes of these disorders are not known, the fact that substance abuse is highly heritable highlights the important role of genetics in the development of these conditions. Although many factors are likely involved in the progression from drug use to addiction, long-term drug-induced changes in gene expression have been hypothesized to play a major role. Thus, it is possible that genetic factors contribute substance abuse risk at least in part by influencing transcriptional responses to repeated drug use. The current study sought to determine the effects of genetically induced brain serotonin (5-HT) deficiency on a subset of behavioral and transcriptional responses to repeated cocaine. Cocaine is known to significantly impact multiple neurotransmitter systems, including the dopamine, 5-HT, and norepinephrine

systems, but whether genetic reductions in brain 5-HT synthesis lead to significant alterations in cocaine responses has not been established. To model 5-HT deficiency, this study took advantage of a genetically modified mouse line that harbors a partial loss of function mutation in the brain 5-HT synthesis enzyme, tryptophan hydroxylase 2 (Tph2). Tph2(R439H) knock-in (Tph2KI) mice have been shown to exhibit 60-80% reductions in the levels of brain 5-HT compared to their wild-type littermates. Prior work has shown that elevation of 5-HT levels via the administration of 5-hydroxytryptophan, the precursor to 5-HT, reduces locomotor responses to acute cocaine, whereas pharmacological reductions in 5-HT levels potentiate the locomotor-stimulating effects of acute cocaine. Thus, we had hypothesized that brain 5-HT deficiency would lead to exaggerated locomotor responses to cocaine. In contrast to our initial hypothesis, our results revealed no significant genotype differences in locomotor activity following acute or repeated cocaine administration in male mice. However, brain 5-HT significantly impacted the effects of cocaine on the striatal expression of several genes that have been previously implicated in cocaine responses, including BDNF, the D2 dopamine receptor, FosB, and CREB. Although our data reveal that genetically impaired brain 5-HT synthesis is not sufficient to alter cocaine-induced locomotor sensitization, future research will be required to determine whether other behavioral responses to cocaine are impacted by brain 5-HT deficiency.

Title: Role of D1 and D2 medium spiny neurons responses to psychostimulants and antipsychotics, understading drug addiction vulnerability in schizophrenia

Authors: *D. AMATO[1,2], J. A. HEINSBROEK[3], P. W. KALIVAS[4]
[1]Neurosci., Med. Univ. of South Carolina., Charleston, SC; [2]Dept. of Psychiatry and Psychotherapy, Friedrich-Alexander Univ. Erlangen-Nürnberg, Germany, Erlangen, Germany; [3]Med. Univ. of South Carolina, Charleston, SC; [4]Neurosci. Res., Med. Univ. S Carolina, Charleston, SC

Abstract: Nearly half of patients with schizophrenia abuses addictive substances such as cocaine. The neurobiology underlying this high prevalence is unknown. A possible interpretation for this comorbidity is linked with cocaine efficacy to enhance rewarding responses in

schizophrenia, which are impaired by chronic antipsychotics. D1 and D2 medium spiny neurons (MSNs) in the nucleus NAc (NAc) differently mediate the rewarding properties of cocaine. Using in vivo Ca2+ miniature microscopic imaging, we measured NAc Ca2+ transients using head mounted miniature microscope to monitor D1 and D2 MSNs responses in mono- and a cross- sensitization protocols. To target specific cell-type responses, we injected Cre dependent Ca2+indicator (gCaMP6f) in D1- and D2-Cre mice. Cocaine sensitization was induced by 2 injections of cocaine separated by 7 days-interval, performed after an independent session with saline treatment to set out baseline MSNs responses. The cross-sensitization between haloperidol (HAL) and cocaine was induced by a single cocaine injection given after chronic pretreatment with clinical-like doses of HAL. These measurements were performed after recording locomotion and MSNs responses to an acute injection of HAL. Cocaine sensitization: Two cocaine injections induced locomotor sensitization and differently modulated D1 and D2 MSNs. Sub-populations of D1-MSNs responses decreased after acute cocaine. This suppression reversed during locomotor sensitization. D2-MSNs responses were also suppressed after acute cocaine, but this inhibition persisted during locomotor sensitization. At baseline, D2-MSNs were largely active while the majority of D1-MSNs activity was depressed. Acute HAL effects: A single HAL injection stimulated most of D1-MSNs responses, but depressed locomotion and D2-MSNs responses. Cross-sensitization: the pretreatment with HAL evoked a locomotor response to cocaine higher than the response observed in the mono-sensitization protocol. D1- and D2-MSNs responses were now equalized by HAL pretreatment, in that a similar percentage of both cell-types were now activated. This outcome is opposite to that one observed in the mono-sensitization protocol in which D2-MSNs responses were abolished. Locomotor sensitization is accompanied by increased D1-MSNs and decreased D2-MSNs activity in the mono-sensitization protocol. Instead, both the D1- and D2-MSNs are activated during cross-sensitization. These results reveal important new insights into the role of NAc MSNs as putative moderators of drug addiction in schizophrenia.

Title: Deletion of the trpc4 gene reduces cocaine induced impulsivity

Authors: M. GEREAU, D. SHIVAPUJA, B. GOULD, *W. D. KLIPEC
Dept. of Psychology and Neurosci., Drake Univ., Des Moines, IA

Abstract: The canonical transient receptor potential (TRPC) family of calcium permeable, non-selective cation channels is abundantly expressed throughout the mammalian brain, playing a pivotal role in modulating cellular excitability. We have developed a *trpc4* knockout rat that shows a brain-wide elimination of TRPC4 channels, including within a subpopulation of TRPC4 bearing dopamine neurons in the ventral tegmental area (VTA). Our previous research has shown that knockout rats (*trpc4* KO), compared to normal (WT) rats, exhibit reduced cocaine self-administration and reduced dopamine cell firing rates in the VTA, with no differences in simple or complex learning using food or water rewards. Here, we measured the effects of acute cocaine administration (15, 10, 5 and 0 mg/kg i.p.) on early response errors (impulsivity) made by *trpc4* KO and WT rats during a differential reinforcement of low rate (DRL) reinforcement schedule. The DRL schedule required rats to withhold a response for 14-sec to obtain water reinforcement while responses before 14 second reset the clock without providing water reinforcement. Cocaine administration produced a significant dose dependent increase in early responding (impulsiveness) in WT compared to *trpc4* KO rats. These data, in conjunction with our previous research demonstrating that the deletion of the *trpc4* gene does not impair learning involving natural rewards but does affect cocaine self-administration, further demonstrate a novel role for the TRPC4 channel in cocaine reinforcement as well as other dopamine disorders. The findings further suggest that functional TRPC4 expression may be an important model for investigating cocaine addiction, and also suggest that novel drug therapies targeting the subpopulation of TRPC4 VTA DA neurons may be useful in treating cocaine addiction, without side effects on learning and performance of behaviors controlled by natural rewards.

Title: A persistence of habitual responding for cocaine underlies punishment resistance

Authors: H. F. SPENCER[1], T. H. KIM[2], *R. J. SMITH[1]
[1]Dept Psychological and Brain Sci., Texas A&M Univ., College Station, TX; [2]Dept Psychological & Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Addiction is characterized by compulsive drug use that persists even when faced with negative consequences. In other words, addiction is defined by drug-seeking behavior that is resistant to punishment. This type of punishment resistance is also observed in animal models of

addiction, with a subset of rats continuing to self-administer cocaine despite receiving footshock. We sought to test the hypothesis that punishment resistance arises from failure to exert goal-directed control over habitual drug seeking. Male and female Sprague Dawley rats were trained on a seeking-taking chained schedule of cocaine self-administration (2 h/day), in which presses on a seeking lever gave access to a separate taking lever reinforced with intravenous cocaine (0.5 mg/kg/infusion). The seeking link of the chain required completion of a random ratio (RR20) or random interval (RI60) schedule, and the taking link was reinforced under a fixed ratio (FR1) schedule. Following at least 12 days on the final seeking-taking reinforcement schedule, animals were exposed to 4 days of punishment testing, in which footshock (0.4 mA, 0.3 s) was delivered randomly on one-third of trials, immediately following completion of seeking and prior to extension of the taking lever. Both before and after punishment testing (4 days prior to punishment, and then 4 days after rats had resumed self-administration), instrumental response strategy was assessed using an outcome devaluation procedure we developed for intravenous cocaine. Sensitivity to outcome devaluation indicated goal-directed responding, while insensitivity to outcome devaluation indicated habitual responding. We observed punishment resistance in a subset of animals under both reinforcement schedules (RR20 or RI60). Further, we found that punishment resistance was associated with a persistence of habitual responding, whereas punishment sensitivity was associated with a switch to goal-directed responding after punishment (even if animals showed habitual responding prior to punishment). These findings indicate that punishment resistance is related to a dominant habit system that persists under conditions that should encourage a transition to goal-directed behavior.

Title: Modulatory effects of cocaine intake and escalation on anterior cingulate encoding during reward-guided decision-making

Authors: *D. VAZQUEZ[1], A. C. BURTON[1], H. J. PRIBUT[2], S. S. TENNYSON[1], M. R. ROESCH[3]
[2]Neurosci. and Cognitive Sci., [1]Univ. of Maryland, College Park, MD; [3]Univ. of Maryland at Col. Park, College Park, MD

Abstract: Maladaptive decision-making, impulsivity, and impaired cognitive flexibility are defining features of cocaine addiction. The anterior cingulate cortex (ACC) has generally been implicated in functional decision-making and attention, and plays a role in encoding reward prediction errors. Previously, we have shown that ACC correlates are critical for online learning, signaling the need for attention to cues after error commission arising from reward expectancy violations. We have also found an exaggerated behavioral response bias in cocaine rats towards high-value rewards, demonstrating their enhanced sensitivity to reward value manipulations. As a result of these findings, we decided to examine the impact of cocaine self-administration on ACC error encoding. We hypothesized that chronic cocaine self-administration alters flexible reward-guided decision-making through disruption of attention for learning correlates in the ACC. To address this issue, we recorded ACC single-unit activity during rat performance of a reward-guided decision-making odor task involving reversal learning. In the functional ACC, outcome expectancy violations result in increased attention to predictive stimuli, subsequently facilitating online adaptations in behavior. In our task, cocaine rats displayed reversal learning deficits, a bias towards short delays to reward, and faster reaction times across all trial blocks; these behavioral effects were moderated by cocaine intake. Additionally, we found dosage-dependent modulation of ACC attention for learning correlates following unsigned prediction errors. There was an inverse correlation between cocaine intake and ACC firing rate to up-shifts in reward value, which also translated into an inverse correlation between escalations in cocaine intake and average ACC firing rates. These dosage-dependent effects on response bias and neural responsiveness to cues suggests that cocaine intake induces graded modulatory effects in the ACC, which translates into disrupted cognitive flexibility.

Title: Effect of N-acetylcysteine on the expression of cocaine-induced locomotor sensitization and cocaine-enhanced brain stimulation rewards in rats

Authors: *R. HODEBOURG[1], P.-P. ROMPRÉ[2]
[1]Dept. of Pharmacol. and Physiol., [2]Dept. of Neurosciences, Univ. of Montreal, Montreal, QC, Canada

Abstract: Repeated exposure to cocaine decreases basal extracellular levels of glutamate in the nucleus accumbens, a brain region that plays a key role in reward and motivation. This reduction in glutamate, which is due to downregulation of the cysteine/glutamate antiporter located on glial cells, is correlated with a vulnerability to cocaine relapse in rats. It has been shown that N-acetylcysteine (NAC), a cysteine prodrug, restores the function of the cysteine/glutamate exchanger and reduces the vulnerability to relapse. Furthermore, our previous studies have shown that acute NAC treatment reduces the motivation to self-administer cocaine in rats. Since the motivation to take cocaine and sensitization to the psychomotor effect of cocaine share common neural substrates, we carried out a first study to determine whether acute NAC administration decreases the expression of cocaine-induced sensitization. Adult male rats received daily cocaine (20 mg/kg) or vehicle injections for 5 consecutive days. After 7 days of withdrawal, rats received a NAC (60 mg/kg) or vehicle injection 3 h before a single cocaine challenge (15 mg/kg). Locomotor activity was recorded for 1 h immediately after each cocaine injection. Acute NAC administration decreased the expression of cocaine sensitization, but not acute locomotor stimulant effect of cocaine. A second study evaluated the effect of an acute NAC administration on the enhancement effect of cocaine on brain stimulation reward. A new cohort of rats was trained to self-administer an electrical stimulation in the lateral hypothalamus. Reward thresholds were measured before and after systemic injection of NAC (60 mg/kg) of its vehicle with or without cocaine (0, 4 mg/kg). NAC had no effect on reward and on the enhancement effect of cocaine on reward. These findings contribute to a growing literature suggesting that NAC deserves clinical attention as a treatment for cocaine addiction.

Title: Environmental modulation on oxytocin's anxiolytic effectiveness in cocaine treated animals

Authors: *D. M. OJEDA, S. FONSECA, G. MOLINA, E. TORRES, C. MALDONADO-VLAAR
Col. of Natural Sci., Univ. de Puerto Rico, Rio Piedras Campus, San Juan, Puerto Rico

Abstract: Drug addiction is a common and debilitating condition that effects an individual’s biological constitution and social stability. This condition has a high prevalence worldwide and

its coupled with anxiety-like symptoms. The neuropeptide oxytocin has been considered to be a potential therapy for this condition due to its use as an anxiolytic in cocaine treated subjects. However, the role of the environment on the anxiolytic effectiveness of oxytocin has yet to be further evaluated. The present set of experiments are aimed to address this question. The protocol consisted of 6-day systemic cocaine injections treatment schedule. Sprague-Dawley male rats were assigned to two separate groups: one exposed to "noise- environment" and the other to "no noise-environment" conditions. The "noise-environment" consisted of exposing animals, post-cocaine injection, to a three-minute period of 86 +/- dB white noise sound stressor within an operant chamber. The "no-noise-environment" consisted of cocaine pre-treated animals exposed to the operant chamber without any sound. On the 6th testing day, cocaine treatment was withheld and subjects were treated with either intranasal oxytocin or vehicle and divided in four groups: "oxytocin-noise", "vehicle-noise", "oxytocin-no noise" and "vehicle-no noise" and subsequently tested in an elevated plus maze (EPM) apparatus. On Day 6, we measured locomotion during the time in the operant chamber and EPM behavioral parameters. Results showed that both groups of the "no noise-environment" had higher levels of locomotion when compared to the "noise-environment" groups. In addition, we found that oxytocin decreased locomotion in the "no noise-environment" exposed animals but had no effect in the "noise-environment" animals when compared to subjects exposed to vehicle injections. Animals that received intranasal oxytocin treatment spent a significant more time in the open arms when compared to their respective controls. However, the "oxytocin-no noise" group spent significantly more time in the open arms than the "oxytocin-noise" group. These preliminary findings reveal differences in oxytocin's behavioral effects between subjects exposed to the two different environments. These results indicate a potential modulatory role of the stress environment on the anxiolytic potential of oxytocin in cocaine treated animals.

Title: Effects of adenosine A_{2A} receptor antagonists on cocaine-induced behaviors

Authors: *N. HAYNES, R. BACHTELL
Psychology and Neurosci., Univ. of Colorado, Boulder, CO

Abstract: Cocaine addiction is a chronic and relapsing disorder with no current pharmacologic intervention. Repeated cocaine use affects the nucleus accumbens (NAc) by altering various neurotransmitter systems. Adenosine A_{2A} receptors ($A_{2A}R$) in the NAc modulate both dopamine and glutamate neurotransmission depending on their synaptic localization and may ultimately influence cocaine-induced behavior. The aim of these studies was to examine the role of $A_{2A}R$ subpopulations on cocaine-induced locomotor activity by using pharmacological antagonists targeting pre- and postsynaptic $A_{2A}R$. Pharmacologic inhibition of postsynaptically-expressed $A_{2A}R$ with KW 6002 (1.0 mg/kg, ip) increased locomotor activity and enhanced locomotion induced by an acute injection of cocaine. Interestingly, the effects of the presynaptic $A_{2A}R$ antagonist, SCH 442416 (1.0 mg/kg, ip), were distinct from KW 6002. In particular, SCH 442416 had no effect on acute cocaine-induced locomotion but blunted the expression of cocaine-sensitizated locomotor activity. Alternatively, KW 6002 had no effect on the expression of cocaine-sensitized locomotion. Together, these results suggest a differential role of $A_{2A}R$ in the NAc depending on synaptic localization. These studies ultimately suggest that blockade of presynaptic $A_{2A}R$ attenuates cocaine-induced behavior following a sensitizing cocaine regimen and may serve as targets for future pharmacologic therapy to treat cocaine addiction.

Title: Estradiol's potentiation of the acquisition of cocaine place preference may involve mTOR signaling

Authors: *S. S. KOKANE[1], L. I. PERROTTI[2]
[1]Psychology, The Univ. of Texas At Arlington, Arlington, TX; [2]Psychology, UT Arlington, Arlington, TX

Abstract: Women show an increased vulnerability to drug abuse. They experience more intense subjective effects of psychostimulant drugs and stronger cravings during abstinence, consequently leading to higher rates of relapse. There is an abundance of empirical data supporting the idea that the ovarian hormone estradiol is responsible for mediating and potentiating these sex-specific responses to psychostimulants. Interestingly, previous data from our lab demonstrated that acutely elevating estradiol (EB) levels in cocaine-conditioned, ovariectomized (OVX) female rats prior to a test for conditioned place preference (cocaine-CPP)

increased the magnitude of the dose required for the expression of cocaine-CPP. However, the direct effects of acute elevations of estradiol at different stages of cocaine-CPP and their molecular underpinnings remain virtually unknown. Recently, mTOR signaling has been shown to be a key molecular mechanism by which psychostimulant drugs of abuse, including cocaine, exhibit their effects within the mesolimbic reward circuit of male rodents. Moreover, inhibition of mTOR has been demonstrated to attenuate cocaine-CPP. Thus, the goal of the present study was - a) to determine if estradiol potentiates cocaine-CPP via enhancing the drug-cue associations and b) to measure alterations in the expression of mTOR in mesolimbic reward circuit. We subjected adult OVX female rats to a cocaine-CPP paradigm over five days; we used a 3/3 (AM/PM) conditioning procedure with intraperitoneal injections of 10mg/kg of cocaine hydrochloride. To systematically compare the effects of EB on drug-cue associations that develop during the conditioning stage of the CPP paradigm (i.e. CPP acquisition), rats were treated with either EB (5 µg; s.c.) or peanut oil (PO; equal volume; s.c.) 30 minutes prior to the start of each daily conditioning session. Expression of cocaine-CPP was assessed under a drug- and hormone-free state 24h following the last conditioning session. Immediately after the CPP test, animals were euthanized and brain tissue comprising VTA, NAc and dorsal striatum was isolated. Results demonstrated that EB-treatment during the conditioning phase of CPP augmented the preference for the drug-paired compartment. Moreover, EB-treatment increased levels of mTOR protein expression in VTA, NAc, and dorsal striatum after cocaine-CPP. In conclusion, our results demonstrated for the first time that drug-cue associations are potentiated by estradiol and may be mediated by increased expression of mTOR.

Title: Combined effects of phenmetrazine and nor-binaltorphimine on dopamine function and motivation to self-adminster cocaine

Authors: *P. ESTAVE, S. R. JONES
Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Despite numerous clinical trials, the FDA has not approved any medication assisted treatment for cocaine addiction. Our laboratory has shown that chronic cocaine self-administration reduced overall dopamine (DA) neurotransmission, resulting in a

hypodopaminergic state. Other studies have shown that repeated, non-contingent cocaine exposure resulted in a hyper-functioning kappa opioid receptor (KOR) system. Thus, this study aims to examine the effectiveness of a combination therapy, targeting the dopamine transporter and the KOR, in reducing cocaine-seeking behaviors in rats chronically exposed to cocaine.
In order to understand the impacts of cocaine self-administration on the DA and KOR systems, we used *ex vivo* fast scan cyclic voltammetry in the nucleus accumbens core to examine DA dynamics after chronic cocaine exposure (40 infusions of cocaine for 5 consecutive days). We found that cocaine exposure reduced stimulated DA release and attenuated cocaine potency at the dopamine transporter. Additionally, we examined KOR function through activation of KORs using the agonist U50,488, which inhibited DA release. We observed that responses to U50,488 were augmented post-cocaine exposure.
Male Sprague Dawley rats were used to determine the individual and combined behavioral effects of the DA releaser phenmetrazine and the KOR antagonist nor-binaltorphimine (nor-BNI). After rats self-administered forty infusions of cocaine (1.5 mg/kg/infusion) on a fixed-ratio 1 schedule for five consecutive days, a progressive ratio schedule was used to determine cocaine breakpoints (0.1875 mg/kg/infusion) at baseline, and following phenmetrazine (25 mg/kg/day; osmotic mini-pump), nor-BNI (10 mg/kg; i.p.), or a combination of the two drugs.
Administration of phenmetrazine alone significantly reduced breakpoints (60% of baseline), while nor-BNI had no effect as a monotherapy. Interestingly, cocaine breakpoints were further attenuated by the combination (20% of baseline), indicating augmented effects of targeting both the DA and KOR systems.
In this study, voltammetry results showed that chronic cocaine exposure reduced DA transmission and augmented KOR function. Dual targeting of the DA and KOR systems through a combination therapy approach revealed a greater decrease in motivation to take cocaine compared to either monotherapy. Taken together, these data support the potential beneficial effects of the dopamine transporter and KOR as dual-cellular targets to treat multiple aspects of the withdrawal syndrome, ultimately decreasing the risk of relapse in individuals with cocaine dependence.

Title: The ketogenic diet decreases behavioral responses to cocaine in male and female rats

Authors: *L. A. MARTINEZ[1], M. E. LEES[1], D. N. RUSKIN[2], S. A. MASINO[2]
[1]Neurosci., [2]Neuroscience/Psychology, Trinity Col., Hartford, CT

Abstract: The ketogenic diet (KD) is a high fat, low carbohydrate and adequate protein formulation that has traditionally been used as a treatment for epilepsy; however, there is growing evidence that this diet has broader therapeutic potential due to its diverse, positive effects on nervous system function. Recent drug addiction studies suggest that activation of the brain adenosine system decreases behavioral responses to many drugs of abuse, including cocaine. Given that one consequence of the KD is an increase in brain adenosine, we sought to address whether the KD has potential as a novel therapy for drug addiction. In this study, male and female Sprague-Dawley rats were placed on a strict 6.6:1 (fat:[carbohydrates+protein], by weight) KD or control diet at 5 weeks of age and then maintained on those diets for 3 weeks prior to behavioral testing. During testing, rats received daily i.p. injections of cocaine (15 mg/kg/ml) or saline vehicle for one week, were abstinent for a subsequent week, and then all animals received a final challenge injection of 15 mg/kg/ml cocaine. We found that both males and females on the KD exhibited decreased cocaine-induced stereotyped responses, during the week of repeated cocaine injections as well as on the final challenge day. These results suggest that the KD may indeed hold potential as a therapy for drug addiction. Future studies will focus on exploring the neural mechanisms underlying the behavioral effects of this diet.

Title: The effects of environmental enrichment or impoverishment on the development and extinction of cocaine and amphetamine conditioned place preference and nucleus accumbens c-Fos expression

Authors: C. IRVING[1], A. SAPERSTEIN[1], C. CHADWICK[1], A. F. SCHROEDER[2], E. ANDERSON[1], I. LAMPTEY[1], V. DUSZAK[1], A. SHAIKH[1], *J. A. SCHROEDER[1]
[1]Dept Psychol, Connecticut Col., New London, CT; [2]Bates Col., Lewiston, ME

Abstract: Environmental factors can increase or decrease a person's susceptibility to addiction to drugs of abuse. Childhood trauma and community poverty may increase the likelihood of drug abuse, and environmental enrichment can reduce drug-seeking behaviors. The same environmental factors may influence cravings and relapse potential during drug abstinence. In this study, conditioned place preference (CPP) was used to measure cocaine and amphetamine

reward behavior. Animals were exposed to environmental enrichment (group housing, novel objects, food treats) or impoverishment (single housing, food, bedding and water only) for 3 weeks prior to CPP. Environmental impoverishment prior to conditioning enhanced cocaine, but not amphetamine CPP. In a follow-up study, animals were exposed to enrichment or impoverishment following CPP and were re-assessed for their preference one week later to measure the extinction of CPP. Animals exposed to one week of enrichment following cocaine or amphetamine CPP displayed a weaker preference for the drug-paired environment after extinction. Immunohistochemical evaluation of the nucleus accumbens revealed significant differences in c-Fos expression in enriched versus impoverished animals. These results add to the body of evidence suggesting that environmental enrichment or impoverishment can have a significant impact on conditioning to psychostimulants and the activation of brain reward centers.

Title: Psychomotor sensitization following an intermittent access schedule of cocaine self-administration

Authors: *C. CARR, J. XIA, J. HILDENBRAND, C. FERRARIO, T. ROBINSON
Dept. of Psychology, Univ. of Michgan, Ann Arbor, MI

Abstract: The ability of self-administration procedures to produce symptoms of addiction is critical to understanding the neural and behavioral plasticity associated with the transition from controlled to compulsive intake. Traditionally, the amount of drug consumed was considered critical to the development of addiction-like behavior. More recently, the temporal pattern of use has been shown to be an important factor. The Intermittent Access (IntA) model of cocaine self-administration produces a pharmacokinetic profile characterized by spikes in blood cocaine levels by alternating brief periods of drug availability with longer periods of unavailability. Similar to the oft-used Long Access (LgA) procedure, IntA is capable of producing an escalation of intake, a progressive increase in cocaine demand, robust drug- and cue-induced reinstatement of drug-seeking, and other hallmarks of addiction, despite far less total cocaine consumption. A

recent report has shown tolerance to the psychomotor activating effects of cocaine when tested soon after discontinuation of LgA, the opposite of which is hypothesized for IntA. Here we asked whether IntA to cocaine produces drug-induced psychomotor sensitization. Research has shown that repeated treatment with psychostimulant drugs produces sensitization to both their psychomotor activating and incentive motivational effects. This behavioral sensitization has been associated with neuroadapations in brain regions involved in reward processing and decision making, which are especially important for the transition to addiction. We report, relative to rats given LgA to cocaine (6 hours/day), rats given IntA were hypersensitive (sensitized) to the psychomotor activating effects of cocaine following one day of withdrawal, evidenced by increased locomotor activity. These findings add to the growing literature that the IntA procedure is capable of producing more robust addiction-like behavior and is especially valuable for studying associated neuroadaptations.

Title: The impact of addiction-associated risk factors on neuronal ensemble activation

Authors: *N. N. NAWARAWONG[1], M. SLAKER[1], C. M. OLSEN[2]
[1]Pharmacol. and Toxicology, [2]Neurosci. Res. Ctr., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Addiction is a chronic relapsing disorder, with many known risk factors such as novelty seeking and stress. High novelty seeking is a trait associated with increased vulnerability for addiction, while stress is a major cause of craving and relapse. Previous studies have shown that novelty, drugs of abuse, and stress engage mesocorticolimbic circuitry, however, it is unknown whether the same *cells* mediate both risk factors and addiction. Using TetTag H2B-EGFP mice, our lab has previously identified a drug-seeking neuronal ensemble within the prelimbic prefrontal cortex (PrL PFC) that could be reactivated by a subsequent drug-seeking session. The proportion of the ensemble that was reactivated was correlated to the persistence of

the drug-seeking behavior. However, it is still unclear how novelty or stress engages this ensemble. In the first experiment, mice were trained to self-administer cocaine and the ensemble was tagged during a drug seeking session. Mice then underwent an additional 2 wks of abstinence, during which time they were exposed to episodic social defeat stress. Mice underwent an additional drug-seeking test and tissue was analyzed for ensemble reactivation using c-Fos immunohistochemistry. In the second experiment, we examined the ensembles associated with novelty and cocaine in the nucleus accumbens (NAc) and PFC. A novel experience or continued home cage exposure was used to induce tagging to identify neurons involved with a novel experience. Three days later, animals were administered a single cocaine or saline injection in a habituated chamber, and ensemble reactivation was assessed. While we found significantly more c-Fos positive neurons in the PrL PFC, NAc core, and NAc shell in cocaine treated animals, it was only in the NAc shell that the novelty-tagged ensemble showed greater reactivation. This suggests that different types of rewards may engage a common ensemble in the NAc shell, while ensembles in the other areas may be more specific to reward type. Ongoing experiments are assessing whether this trend is observed following other classes of psychoactive drugs. Together, these studies provide further insight into how drug experiences and risk factors for addiction are processed in the brain.

Title: Phasic dopamine release within the nucleus accumbens core differentially mediates drug-taking and drug-seeking

Authors: *R. D. FARERO[1], L. M. BURGENO[3], N. L. MURRAY[1], J. S. STEGER[2], M. E. SODEN[2], L. S. ZWEIFEL[2], P. E. PHILLIPS[1]

Abstract: Altered dopamine (DA) transmission is implicated in most contemporary theories of drug abuse. However, the direction, timing, and context in which alterations of DA transmission occur remain a matter of debate. Both drug themselves, and the cues that are repeatedly paired with drugs are capable of driving DA release in the nucleus accumbens core (NAcc). Recent work from our lab identifies opposite trajectories of cue-evoked DA release in the NAcc over chronic drug use, depending on whether the cue is a result of an action by the subject to obtain the drug, or whether the cue was delivered by the investigator. Attenuation of phasic DA transmission to response-contingent drug cues was observed in animals that escalated their daily drug intake. Systemic administration of L-DOPA restored the neurochemical change and returned drug consumption to pre-escalated levels. Conversely, phasic DA transmission increased within the NAcc in response to non-contingent drug-cues, which coincided with increases of drug-seeking behaviors. Therefore, we postulated that phasic DA transmission in the NAcc mediates increased drug-taking and drug-seeking in a divergent manner. To investigate this hypothesis, we evoke phasic DA release with optogenetics during drug-taking and drug-seeking contexts. We injected a viral vector that expresses channelrhodopsin2 under the control of the CaMKIIδ promoter (AAV1-CaMKIIδ-ChR2-mCherry) bilaterally into the ventral tegmental area, and implanted optic fibers in the NAcc of male Wistar rats. Photostimulation (6 pulses, 30 Hz) paired with response-contingent drug cues decreased drug consumption in animals that escalate daily drug intake ($p<0.01$), but had no effect in their non-escalating counterparts ($p>0.05$), indicating that escalation of consumption is driven by low phasic DA. However, photostimulation paired with cues presented in a non-contingent manner prevented habituation of their ability to drive drug seeking ($p<0.05$), indicating that increased drug seeking is driven by high phasic DA. Therefore, these direct, temporally resolved manipulations indicate that diametric changes in NAcc phasic DA transmission mediate increased drug-taking and drug-seeking behaviors following chronic use.

Title: The $5HT_{1B}$receptor agonist, CP 94,253, attenuates the reinforcing effects of cocaine self-administration during the estrus phase post-abstinence

Authors: *S. N. SCOTT[1], T. T. NGUYEN[2], S. M. DOYLE[3], J. L. NIESEWANDER[3]
[2]Sch. of Biol. Hlth. Systems Engin., [3]Sch. of Life Sci., [1]Arizona State Univ., Tempe, AZ

Abstract: We have found that serotonin 5-HT_{1B} receptors ($5HT_{1B}$Rs) modulate cocaine self-administration in opposite directions depending on the phase of the addiction cycle in male rats. Specifically, administration of a $5HT_{1B}$R agonist, CP 94,253 (CP), facilitates cocaine intake during the active drug-taking phase, while attenuating cocaine intake and drug seeking behavior following 21 days of protracted abstinence. We recently found that CP facilitates cocaine intake in female rats tested during the active drug-taking phase, similar to effects observed in male rats. In this study, we examined if female rats show the same abstinence-dependent change in CP effects as observed in males. Clinical and preclinical research suggests that females are more susceptible to cocaine craving and relapse, and this phenomenon is influenced by gonadal hormones. For instance, heightened sensitivity to the effects of cocaine is observed during the estrus phase compared to other phases of the estrous cycle, suggesting that estrogen enhances the reinforcing properties of cocaine. For this reason, the present study tested female rats during the estrus phase. Female Sprague-Dawley rats were trained to self-administer 0.75 mg/kg, IV cocaine on a fixed ratio (FR) 5 schedule of reinforcement for 2 hours/day. Once reinforcement rates stabilized, rats were given at least 21 days of abstinence during which daily vaginal smears were taken starting on abstinence day 14. Once rats were predicted to be in the estrus phase, they underwent pretreatment with CP (5.6 mg/kg, SC) or vehicle. Testing commenced 15 min later with access to 0.75 mg/kg, IV, cocaine on an FR5 schedule for one hour and then with access to 0.075 mg/kg for the second hour of testing. This study is ongoing and thus far, preliminary results indicate that CP decreases cocaine intake and response rates similar to the effects observed in male rats. This suggests that CP attenuates the reinforcing properties of cocaine. These findings have important implications for developing treatments for cocaine dependence in women.

Title: Sex differences in nucleus accumbens CREB activity after cocaine-induced conditioned place preference

Authors: *B. D. BUTLER, J. H. ANTONIO, A. C. HOCH, J. C. HOLT, S. S. KOKANE, L. I. PERROTTI
Psychology, Univ. of Texas at Arlington, Arlington, TX

Abstract: Sex-differences in behaviors related to drug-craving and relapse have been observed to be more intense in addicted women than in addicted men. Cue-reactivity has been proposed to be an underlying cause of craving and relapse in addicted individuals. Preclinical evidence indicates involvement of the CREB signaling pathway in the nucleus accumbens (NAc) as a molecular basis of drug-cue associations. The main aim of this study was to determine dose-dependent sex differences in cocaine place preference and also to observe sex differences in the CREB activity across different cocaine conditioning doses and sex. Both male and female Long-Evans rats underwent a cocaine-conditioned place preference (cocaine-CPP) paradigm over eight days. Briefly, the first day consisted of a pre-test in which rats were allowed to roam freely in a CPP apparatus for 15 minutes. Twenty-four hours following the pre-test, rats were conditioned with one of three doses of cocaine (0, 5, 10, and 15 mg/kg) or 0.9% saline on alternate days and in alternate compartments of the CPP apparatus. Twenty-four hours after the last conditioning session animals were tested for cocaine-CPP by allowing them to freely roam throughout the CPP apparatus and the time spent in each compartment was measured. Thereafter, rats were euthanized, their brains extracted, and processed for immunohistochemistry (IHC) for phosphorylated CREB (pCREB). Overall, females exhibited significant cocaine-CPP across all three conditioning doses of cocaine. Interestingly, males exhibited a cocaine-CPP for only the 10 and 15 mg/kg doses. Respectively, our IHC results show increased pCREB expression in the NAc of both males and females when they exhibited significant cocaine-CPP (Females 5, 10, 15 mg/kg; Males 10, 15mg/kg). Interestingly, our data indicate a trend for higher NAc pCREB levels in cocaine-preferring females than in cocaine-preferring males (10, 15mg/kg). Males conditioned with 5 mg/kg of cocaine did not develop CPP and had comparatively lower levels of pCREB expression. In conclusion, our study shows that females develop CPP for cocaine at lower conditioning doses than males and that altered CREB activity in the NAc may be an underlying mechanism mediating this effect.

Title: Environmental enrichment facilitates cocaine abstinence in an animal conflict model

Authors: *S. EWING, R. RANALDI
Psychology Dept., The Grad. Center, CUNY, New York, NY

Abstract: An ongoing challenge of using animal subjects to explore novel interventions for drug addiction is the construct validity of animal addiction models. In this study, we tested the utility of a newer "conflict" model of abstinence using environmental enrichment (EE), a well-researched experimental intervention for reducing addiction-related behaviors. Long-Evans rats (n=16) were trained in 3-h daily sessions to self-administer a cocaine/saline solution (1 mg/kg/infusion) until each demonstrated a stable pattern of drug-seeking. Afterward, half were placed in EE cages equipped with toys, obstacles, and a running wheel, while the other half were given clean, standard laboratory housing (non-EE). All rats then completed daily 30-min sessions during which the 2/3 of flooring closest to the self-administration levers was electrified, causing discomfort should they approach the levers; current strength (mA) was increased after every day of drug seeking until the rat ceased activity on the active lever for 3 consecutive sessions. Rats housed in EE reached this "abstinence" criterion after fewer days and at lower current strengths than non-EE rats. These results suggest that EE administered after the development of a cocaine-taking habit may be an effective strategy to facilitate abstinence.

Title: Investigating addiction and reward prediction in mice using a modular open-source operant behavior system

Authors: D. CASSATARO, A. CUMPELIK, *L. L. SJULSON
Albert Einstein Col. of Med., Bronx, NY

Abstract: Due to the popularity of genetic tools in neuroscience, investigators increasingly are using mice in complex behavioral tasks that were previously used only with rats or primates. Here we describe the development of a modular open source operant behavior system for mice

and outline its application to drug self-administration and reward-guided behavior. This Arduino-based system is built entirely from low-cost or 3D-printed parts, enabling rapid reconfiguration, scalability, and straightforward integration with electrophysiological recording, fiber photometry, and closed loop optogenetic manipulation.

Title: In-vivo visualization of Zn dynamics using PET and fiber photometry

Authors: *J. BONAVENTURA, S. LAM, J. GOMEZ, M. MICHAELIDES
NIDA/NIH, Baltimore, MD

Abstract: Zinc (Zn^{2+}) is a trace element involved in multiple biological functions. Besides numerous proteins (i.e. enzymes and transcription factors) containing Zn2+ binding sites where Zn^{2+} is required for either structural or catalytic purposes, there is also unbound Zinc putatively able to act as a signaling ion. Zinc transport is highly regulated by several transporters from the ZIP (Zrt- and Irt-like protein) family which control influx of Zn^{2+} into the cytoplasm, and the ZnT (or SLC30) family which mediate Zn^{2+} efflux from the cytoplasm. In particular, the ZnT-3 transporter is expressed in glutamatergic neurons in the prefrontal cortex, amygdala and hippocampus and the mediates the accumulation of Zn^{2+} in synaptic vesicles, where the ion is co-packaged (and co-released) with Glutamate and is able to modulate synaptic transmission. However, little is known about the dynamics of 'zincergic' transmission so we developed tools that allowed us to explore this topic. In this study we developed the use of a long-lived and positron-emitting isotope of Zinc (^{65}Zn) to non-invasively visualize Zinc dynamics in longitudinal studies via positron-emission tomography (PET) imaging. In parallel, we used a virally transduced FRET based biosensor to visualize acute free Zn^{2+} fluctuations upon neuronal activation through fiber photometry. These new approaches, combined with the use of ZnT-3 knock-out mice, allowed us to elucidate the role of synaptic Zinc release in the neurocircuitry involved in the rewarding and addictive properties of cocaine and other psychostimulants.

Title: Longitudinal changes in brain activity during acquisition of cocaine locomotor sensitization and its modulation by synaptic zinc

Authors: *J. L. GOMEZ, J. BONAVENTURA, M. MICHAELIDES
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Zinc (Zn^{2+}) is an essential element and its dysregulation or deficiency is associated with various disorders. Zn^{2+} is highly concentrated in the brain where it is thought to exert effects on synaptic plasticity, neurotransmission, protein/enzyme function, and transcriptional regulation. Chronic cocaine exposure leads to a phenomenon called behavioral sensitization where repeated injections of the same cocaine dose lead to elevation of locomotor activity with repeated exposure. This change in locomotor activity is believed to reflect cocaine-induced changes in brain plasticity. We investigated the role of synaptic Zn^{2+} in modulating cocaine locomotor sensitization via use of a transgenic mouse line lacking the gene (Slc30a3) encoding the neuronal zinc transporter (ZnT3). The ZnT3 packages Zn^{2+}into glutamatergic vesicles for synaptic co-release and is enriched in brain regions implicated in drug-induced sensitization. In parallel, we used PET and the [^{18}F]FDG radiotracer to identify changes in regional brain activity at different time points of the sensitization paradigm. Mice were scanned prior to any experimental manipulation (scan-1); after first exposure to cocaine (scan-2); after fifth exposure to cocaine (scan-3); and after one-week withdrawal plus re-exposure to cocaine (scan-4). *In vitro* assays were also undertaken in different cohorts to examine synaptic plasticity markers in brain areas indicated by PET experiments. These experiments aim to highlight the mechanistic involvement of neuronal Zn^{2+} in behavioral sensitization to cocaine.

Title: Stressor controllability alters the severity of cocaine-induced encoding deficits in accumbal neurons for reward-predictive cues

Authors: *K. A. SILETTI, K. S. MCCONOMY, A. K. MONTGOMERY, M. P. SADDORIS
Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Repeated experience with drugs of abuse can induce lasting changes in neural function. Even after enforced periods of drug abstinence, animals show heightened responsivity to cocaine-associated cues and impaired discrimination of natural reward-associated cues. Work from our lab and others has demonstrated dysregulation of mesolimbic circuitry as an underlying mechanism for deficits in reward-associated learning in cocaine-experienced rats. For example, electrophysiological activity in the nucleus accumbens (NAc) core and shell both exhibit abnormal and often attenuated encoding during Pavlovian conditioning for non-drug rewards weeks after the cessation of cocaine self-administration. Furthermore, these cocaine-induced cognitive deficits appear to significantly worsen after periods of drug abstinence, such that changes during this period induce robustly greater drug seeking and relapse. One potential mechanism by which this may occur is due to the chronic stress of withdrawal during abstinence. If so, providing animals with an active coping mechanism during this period could endow animals with resilience to prevent worsening cognitive deficits. To test this, rats with a history of cocaine self-administration (1 mg/kg iv; 2hr access, 14d) were given a single session of stressor controllability, wherein unsignaled tailshocks could be terminated with a wheel turn. Behavioral control learned in this situation is known to trans-situationally promote resiliency and was thus hypothesized to behaviorally immunize these subjects against other stressors (such as withdrawal or drug craving). These rats were compared to animals that received similar tailshocks but had no control over their termination, where the lack of control precipitates a more pathological stress phenotype. Here we demonstrate that neural encoding in the NAc in subsequent behavioral tasks is comparable to drug-naïve controls in rats with behavioral control, while the inescapable shock subjects show significantly worsened encoding. These findings suggest that stress exposure during drug abstinence significantly affects subsequent learning and, in particular, that controllability may impart resilience against drug-related cognitive deficits.

Title: Differential encoding in prefrontal and accumbal neurons during a continuously updating risk-based decision making task

Authors: *M. SADDORIS, K. S. MCCONOMY
Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Value-based decisions involve assessing how potential gains are offset by a variety of costs. For example, animals may desire a valuable food, but the risks of obtaining that item (e.g., potential injury, predation, energy expended) may be sufficiently great to bias animals towards less desired (but less risky) options. Many studies have now shown an important role for limbic system structures in risk-based decision making, including contributions from prefrontal cortex, nucleus accumbens and mesolimbic dopamine afferents. However, in nearly all of these tasks, rats learn a stable dichotomy of options where one response is associated with a "safe" option, while a different response with a "risky" option. These binary choice models provide information about which option is preferred, but such all-or-none choices cannot determine how much an option is preferred or the extent to which risk tolerance is stable across trials or sessions. To overcome this limitation, we adapted a task used in human clinical settings for rodent use known as the Balloon Analogue Risk Task (BART). Here, rats can press a lever and each press "inflates" the size of the potential reward, and rats can "cash out" at the foodcup to obtain accumulated food rewards. However, there is a probability of the trial "busting" if the rat presses too much (entailing lost rewards and a timeout period), so rats must continuously update their risk tolerance in the press sequence to maximize rewards while avoiding busts. In this task we recorded from neurons in both the prelimbic cortex (PL) and nucleus accumbens core (NAc) of the same animals during the BART task. In general, both PL and NAc are highly engaged in the BART task, with most cells displaying phasic responses to at least one of the task events (e.g., press, cashout delay, reward/bust). Preliminary data suggests that PL neurons play a prioritized role in encoding activity related to the cashout decision, and thus may be important for disengaging in reward seeking behavior. In contrast, NAc showed more activity in the reward/bust period, suggesting a role in assessment of task outcome for behavioral updating.

These findings suggest that NAc and PL may coordinate activity and differentially contribute to discrete aspects of risk tolerance.

Title: Optical stimulation midbrain dopamine neurons drives self-administration in cocaine-experienced rats, but fails to elicit phasic neural encoding in nucleus accumbens shell

Authors: *K. MCCONOMY[1], M. SHAH[1], M. P. SADDORIS[2]
[1]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]Psychology and Neurosci., Univ. of Colorado, Boulder, Boulder, CO

Abstract: Repeated exposure to cocaine results in abnormal encoding for motivationally-salient stimuli in the nucleus accumbens (NAc). For example, we and others have shown that phasic responses of NAc neurons as well as phasic dopamine release within the NAc are strikingly altered in drug-abstinent rats with a history of cocaine self-administration. Furthermore, this effect is most pronounced in the NAc shell, a region important for mediating the reinforcing properties of cocaine, and is also thought to be important for supporting motivationally-related behavior. To date, investigations have largely focused on how prior experience with cocaine can produce altered encoding and behavior in subsequent Pavlovian or operant settings, but less is known about whether the function of of the dopamine system itself if appropriately engaged in motivated goal-directed action. To test this, TH::cre rats or littermate controls were first allowed to self-administer either cocaine iv or water to a port (2hr/d, 14d), followed by a period of abstinence. Later, all rats receive infusions of channelrhodopsin (AAV-DIO-ChR2-mCherry) into the ventral tegmental area (VTA), along with chronically implanted optical fibers into the VTA and electrophysiological arrays into the NAc shell. Rats were allowed to press a lever to receive optical stimulation of the VTA (5sec, 20Hz, 4ms pulsewidth, 20mW) and neural activity was recorded in the NAc shell during the task. TH::cre rats showed high levels of self-administration regardless of drug background compared to non-transgenic controls, though cocaine TH::cre rats showed excessive levels of pressing during the stimulation itself (lockout period). However, while drug-naïve TH::cre rats showed robust activity related to the press, this phasic activity was largely absent in cocaine TH::cre rats. Surprisingly, both cocaine and drug-naïve TH::cre groups showed rapid extinction of pressing when the laser was off, though only

the cocaine group also displayed rapid reinstatement post-extinction. Thus, stimulation of dopamine is sufficient to support self-administration after cocaine, but does not rescue phasic responses in mesolimbic target regions important for motivation.

Title: Sex differences in expression of deltafosb in taurine and cocaine treated rat brains

Authors: *T. D. IRVING[1], A. COLE[1], C. VASQUEZ[1], T. ADEBOWALE[1], U. AKPARA[1], K. Y. SALAS-RAMIREZ[2]
[2]Physiology, Pharmacol. and Neurosci., [1]CUNY Sch. of Med., New York, NY

Abstract: Cocaine use is responsible for 15,000 yearly deaths in the United States, yet there are limited effective interventions for cocaine addiction. Chronic cocaine use stimulates the production of transcription factor deltaFosB in regions of the brain that mediate reward, particularly the nucleus accumbens (NAC). Accumulation of deltaFosB represents a molecular marker for addiction that increases sensitivity to compulsive drug-seeking behaviors. Taurine, a dietary and endogenous amino acid produced by the liver and glial cells, has neuroprotective capabilities. Studies have shown that taurine can effectively inhibit cocaine reward in both male and female rodents; therefore, this study aims to determine whether taurine has the capacity to downregulate deltaFosB expression in the NAC of cocaine treated rats and if these effects are sex-specific. Forty adult male and female rats were divided into treatment groups that were either exposed to a saline or taurine pretreatment for two weeks. Afterwards, they were divided into five groups: (1) pre-sal/saline, (2) pre-sal/cocaine (3) pre-tau/taurine, (4) pre-tau/cocaine and (5) pre-tau /taurine + cocaine while being tested for the psychomotor effects of cocaine using a behavioral sensitization protocol. Immediately after the behavioral assessments, animals were perfused and tissue was stored in cryoprotectant. We examined the expression of deltaFosB using immunocytochemical techniques, followed by microscopic analysis with Neurolucida software to trace regions of the NAC and determine the mean quantity of deltaFosB stained cells per area. As determined by a one-way ANOVA, cocaine significantly increased expression of

deltaFosB in the NAC core of female rats compared to control (p=.0339), and both pretreatment and co-administration with taurine reduced deltaFosB levels. Preliminary analysis of male rats similarly showed DeltaFosB attenuation in taurine pre-treatment and co-administration in the NAC core (p=.0212), however, these effects are seen in the NAC shell as well (p=.0403). There were no significant differences in deltaFosB in the NAC of animals treated with taurine independent of cocaine treatment. These findings support previous studies where cocaine increases deltaFosB expression in the transition of an non-addicted to an addicted brain; however, taurine effectively reduces the expression of deltaFosB in the NAC in both male and female rats with sex-specific effects on the core and shell deltaFosB expression. Further studies are needed to determine the sex specific efficacy of taurine as a treatment for cocaine addiction and relapse.

Title: The effects of the COMT inhibitor tolcapone and sex on alcohol consumption in individuals with alcohol use disorder (AUD)

Authors: *J. MITCHELL, A. R. COKER, D. WEINSTEIN, T. A. VEGA, C. S. MILLER, A. S. KAYSER
UCSF: Dept. of Neurol., San Francisco, CA

Abstract: Previous data suggest that hypo-dopaminergic tone in frontal brain regions contributes to impulsivity (1) and by extension to problems with alcohol and drug abuse (2). Consistent with these findings, variations in the dopamine-metabolizing enzyme catechol-O-methyltransferase (COMT) have been linked to behavioral differences in drug and alcohol consumption and decision making (3). The catechol-O-methyltransferase (COMT) inhibitor tolcapone, which increases cortical dopamine tone in frontal brain regions (4), could therefore prove useful in assessing the effects of frontal dopamine levels on behavior. Aims: We administered tolcapone to individuals meeting DSM-V criteria for alcohol use disorder (AUD) to assess whether tolcapone administration attenuates alcohol consumption and subjective high. Methods: Here we assessed the effects of a randomized double-blind administration of the catechol-O-

methyltransferase (COMT) inhibitor tolcapone (100mg TID for 5 days) on alcohol consumption, impulsive choice, and laboratory tasks assessing impulsivity and subjective high in 55 non-treatment seeking male and female AUD subjects. Results: We found that 5 days of 100mg TID tolcapone significantly attenuated self-reported alcohol consumption ($n = 55$, $F = 4.36$, $p = .041$), and this effect was driven by female subjects (drug x gender, $n = 55$, $F = 3.33$, $p = .07$). In addition, while tolcapone significantly attenuated subjective high across all subjects ($n = 51$, $F = 10.2392$, $p = .002$), it decreased intoxication (BAC) only in females ($n = 22$, $T = 2.045$, $p = .053$). The tolcapone effect on alcohol consumption was significantly correlated to different sub-types of impulsivity in males and females. Females with lower attentional impulsivity were more likely to decrease their consumption on tolcapone ($n = 23$, $F = 6.99$, $p = .015$), while males with greater motor impulsivity were more likely to decrease their consumption on tolcapone ($n = 32$, $F = 7.17$, $p = .012$). This suggests that males and females may be using different factors to impact their alcohol related decision making. Conclusions: These data provide preliminary evidence to suggest that tolcapone may be an advantageous therapeutic for females with AUD.

Title: A closer look at transcranial magnetic stimulation through *in vivo* neuroimaging

Authors: *M. A. BOEHM[1,2], J. GOMEZ[1], J. BONAVENTURA[1], Z. JUSTINOVA[1], H. JEDEMA[1], E. STEIN[1], C. BRADBERRY[1], M. MICHAELIDES[1]
[1]Neuroimaging Res. Br., Natl. Inst. on Drug Abuse, Baltimore, MD; [2]Neurosci., Brown Univ., Providence, RI

Abstract: Transcranial magnetic stimulation (TMS) is a noninvasive technique used to induce electric fields in the brain. Over the past 30 years, TMS has emerged as a potential therapeutic tool for several disorders including depression, addiction, and Parkinson's disease. Despite increasing use in research and medicine, basic questions remain about the underlying mechanisms of TMS and how to optimize stimulation protocols for treating different disorders. Animal TMS studies have proven useful in revealing some mechanisms, but the wide range of parameters (e.g. intensity and frequency) and limited focality of rodent TMS make it difficult to

compare and translate findings. TMS in nonhuman primates (NHPs) allows for more focal stimulation and improved translatability to human applications of TMS. Previous TMS studies using NHPs have shown to be useful in investigating the effects of TMS parameters, but most studies have been limited to applications in the motor cortex. The objective of this pilot TMS study is to utilize [^{18}F]-fluorodeoxyglucose positron emission tomography (FDG-PET) to systematically assess the impact of varying intensity and frequency on motor and prefrontal TMS-induced brain activity in two *Saimiri sciureus* monkeys. Two male *Saimiri sciureus* monkeys will undergo acute (600 pulses) and short-term (1800 pulses) stimulation protocols targeting either motor or prefrontal cortex. FDG-PET will be used to compare TMS-induced brain activity at different intensities (25-150% resting motor threshold) and frequencies (1-20Hz, iTBS, cTBS). Brain activity will be normalized to within-subject sham control experiments. Acute experiments will assess brain activity during a 10 minute stimulation procedure, while short-term experiments will assess brain activity immediately following a 30 minute stimulation procedure. Overall, this project aims to improve our understanding of the role of intensity and frequency in rTMS targeting the motor and prefrontal cortex. This systematic characterization of TMS parameters could inform therapeutic applications for addiction and other disorders.

Title: 5-methoxy-N,N-dimethytryptamine's influence on the right angular gyrus: Evidence for altered default mode functioning

Authors: *M. VILLANUEVA, P. GAST
Alpha Theta Ctr., San Diego, CA

Abstract: Psychedelic tryptamines, pervasive in both plant and animal life, are widely used in non-US clinics for the treatment of opioid addiction as well as spiritual retreats. We conducted an EEG study on pre- and post-inhalation of 5-Methoxy-N,N-dimethyltryptamine (Bufo Alvarius toad) administered by Shamans in Mexico and Australia to reveal its influence on resting-state EEG. We performed independent component (IC) analysis (ICA) on individual data and used Measure Projection Toolbox, a group-level analysis scheme for EEGLAB, to cluster the results based on the estimated source locations weighted by power spectrum density. The results revealed that alpha and gamma band power levels within the right angular gyrus showed increased alpha and decreased gamma frequency power after administration. This pattern was

observed only in the eyes closed condition. Because the angular gyrus is one of nodes of the default mode network (DMN), the increased alpha band power during eyes closed indicates decreased activation of DMN. The result may be related to the decrease in, often negative, self-referential mentations and may explain the usefulness of DMT for treatment of psychiatric disorders, especially addictions.

Title: High frequency but not low frequency deep brain stimulation of the subthalamic nucleus reduces motivation for cocaine, while increasing that for apple sauce in the monkey

Authors: *S. RAVEL[1], J. NACEF[2], J.-L. ANTON[1], I. BALANSARD[3], P.-Y. BORIUS[4], R. DESBRIÈRE[5], A. EUSEBIO[1,6], B. NAZARIAN[1], L. RENAUD[3], J.-M. RÉGIS[7], C. W. BRADBERRY[8], C. BAUNEZ[1]

Abstract: There is currently no pharmacological treatment for cocaine addiction, therefore it is important to look for alternative treatment strategies. One possibility could be a surgical approach. Indeed, it has been shown in the rat that the inactivation of the subthalamic nucleus (STN), by either lesions or high frequency Deep Brain Stimulation (DBS), reduces motivation for cocaine while increasing motivation for food. It has thus been suggested that STN high frequency DBS could be a good strategy to treat cocaine addiction. Before testing in human addicts, the aim of the present study was to validate this hypothesis in non-human primates. We have trained two monkeys to work under various schedules of reinforcement (Fixed Ratio 15 (FR15) and Progressive Ratio (PR)) for either apple sauce or cocaine (intraveinous 0.1 mg/kg/injection). After stabilisation of performances, electrodes have been implanted bilaterally in the STN, and high or low frequency chronic stimulation has been applied (HF : 130 Hz, 2V or

LF : 50 Hz, 3V respectively). All conditions (apple sauce-HF/LF stimulation ON, apple sauce-stimulation OFF, cocaine-HF/LF stimulation ON, cocaine-stimulation OFF) have been tested in alternance. Results have first shown that, after STN HF DBS, the motivation for apple sauce was significantly increased, while that for cocaine was significantly decreased. Conversely, STN LF DBS failed to show any modulation. These results confirm the opposite effect of STN HF DBS on motivation previously observed in rats, and further allowed us to demonstrate the selectivity of the HF over LF to elicit this effect. Since decreasing the motivation for the drug, without diminishing other forms of motivation is the goal for a possible treatment of cocaine addiction, STN HF DBS may thus be the appropriate strategy.

Title: A deeper insight into how GABA-B receptor agonism via baclofen may affect alcohol seeking and consummatory behaviors: Lessons learned from a human laboratory investigation

Authors: *M. FAROKHNIA[1], S. DESCHAINE[1], A. SADIGHI[2], F. AKHLAGHI[2], L. LEGGIO[1]
[1]NIH, Bethesda, MD; [2]Univ. of Rhode Island, Kingston, RI

Abstract: The GABA-B receptor agonist baclofen has been sugested as a potential pharmacotherapy for alcohol use disorder. Despite promising data from preclinical experiments, human studies with baclofen have shown mixed results. Additional research is needed to understand how this medication works from a biobehavioral standpoint; well-controlled human laboratory studies provide an informative platform to address this question. Here, we analyzed data from a laboratory experiment before which alcohol-dependent individuals (N = 34) received baclofen (30 mg/day) or placebo for a week. The experimental session included three consecutive phases: alcohol cue-reactivity (water trial followed by two alcohol trials), fixed-dose alcohol priming (40 minutes, target blood alcohol concentration: 0.03 g/dL), and alcohol self-administration (2 hours, up to 8 mini-drinks). Alcohol craving and subjective responses were also assessed throughout the session, and blood samples were collected for pharmacokinetic

measurements. Baclofen, compared to placebo, did not significantly attenuate cue-elicited craving or the amount of alcohol self-administration. However, baclofen moderated the relationship between alcohol priming and self-administration as shown by significant interaction effects between drug condition (baclofen vs. placebo) and priming variables (alcohol craving: $F_{3,9} = 6.03$, $p = 0.01$; alcohol sedation: $F_{3,6} = 7.16$, $p = 0.01$; breath alcohol concentration: $F_{1,25} = 5.22$, $p = 0.03$) on the total amount of alcohol self-administered. Baclofen pharmacokinetic parameters were calculated as follows (mean ± standard error): maximum plasma concentration (C_{max}) = 84.90 (13.58) ng/mL; time to C_{max} (t_{max}) = 2.47 (0.21) h; apparent plasma clearance at steady state (CL_{ss}/F) = 60866.52 (12641.72) mL/h; half-life ($t_{1/2}$) = 4.42 (0.29) h; area under plasma concentration - time curve (AUC) = 1033.49 (97.77) h*ng/mL. Bivariate correlation analyses between pharmacokinetic parameters and behavioral outcomes showed that baclofen C_{max} was negatively correlated with alcohol craving during cue-reactivity ($r = -0.57$, $p = 0.03$) and ratings of 'like more' during priming phase ($r = -0.59$, $p = 0.02$). These data suggest that baclofen may act through dissociating the link between an initial drink (priming) and subsequent alcohol consumption (self-administration). This study also sheds light on how baclofen pharmacokinetic parameters are correlated with behavioral outcomes assessed in a laboratory setting.

Title: Sex differences in ketamine addiction-like behavior and nucleus accumbens spine morphology in chronic mild-stressed rats pre-treated with ketamine

Authors: K. N. WRIGHT, *D. P. HAGARTY, C. STRONG, K. J. SCHOEPFER, M. KABBAJ
Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Sub-anesthetic doses of ketamine provide rapid alleviation of depressive symptoms in individuals with Major Depressive Disorder (MDD). Important caveats that may hinder its widespread use are MDD is highly comorbid with drug addiction, and ketamine at higher doses is well-known for its abuse liability. Furthermore, women have a twofold higher rate of MDD and display a more rapid progression towards addiction than men. While ketamine at low doses has a clear therapeutic benefit, it is important to investigate the abuse potential along with the

therapeutic effects of ketamine in preclinical studies of both sexes displaying phenotypic MDD. Our lab was the first to show that female rats are more sensitive than males to ketamine's antidepressant-like and addictive-like effects, and at lower doses. Also, after intermittent intravenous ketamine self-administration (SA), both sexes exhibit ketamine-seeking behavior during extinction-reinstatement testing. These studies used stress-naïve rats, so it is uncertain if rats displaying the depressed-like phenotype will have a greater propensity to the SA of ketamine. To address these questions, male and female rats underwent chronic mild stress (CMS) and were treated with four intermittent, iv infusions of sub-anesthetic ketamine. Ketamine infusions ameliorated some of the depression-like traits as measured by the novelty-suppressed feeding test and sucrose preference test. Then, rats underwent SA of 0.5 mg/kg/inf ketamine under fixed-ratio 1 and progressive ratio schedules of reinforcement, and incubation of ketamine craving at multiple time points after the last exposure. Finally, alterations in dendritic spine morphology were measured in the nucleus accumbens, an area affected by both depression and addiction, using 3-dimensional reconstruction. CMS females displayed greater ketamine addiction-like behaviors than non-stressed females or males of either condition. Interestingly, CMS females pre-treated with ketamine display augmented addiction-like behavior compared to CMS females without ketamine pre-treatment, an effect not observed in male counterparts. The integration of these two models helps elucidate the complex relationship between ketamine's therapeutic and abusive properties in susceptible populations.

Title: Evaluation of a combination opioid/antipsychotic drug to reduce the abuse liability of opioid analgesics: A preclinical and clinical feasibility study

Authors: *A. M. BOLEY, M. E. CURTIS[1], G. T. COLLINS[2,5], M. S. ECKMANN[3], A. S. NAGPAL[3], J. S. POTTER[4], A. FRAZER[2], D. J. LODGE[2]
[1]Psychology, Univ. of Texas at San Antonio, San Antonio, TX; [2]Pharmacol., [3]Anesthesiol., [4]Psychiatry, UT Hlth. San Antonio, San Antonio, TX; [5]South Texas Veterans Hlth. Care Syst., San Antonio, TX

Abstract: Opioid abuse is a public health epidemic, with more than 115 overdose deaths each day in the United States. Opioid analgesics are routinely prescribed for pain, which is a debilitating condition that must be adequately treated to improve the quality of life of patients; however, this treatment puts the patient at risk by exposure to opioid medications that can lead to misuse. Thus, better treatment options are needed to help these patients without the risk of addiction and abuse. Given that the reinforcing properties of opioids are mediated, at least in part, by dopamine transmission, we posit that blocking dopaminergic D2 receptors will reduce the abuse liability of opioids without altering analgesic efficacy. Here we present initial feasibility data examining fixed dose combinations of oxycodone (OXY) with an atypical antipsychotic drug. Our initial preclinical studies suggest that the analgesic efficacy of OXY (2mg/kg i.p.), determined by the tail flick latency task, is not altered by its co-administration with an atypical antipsychotic drug. Similarly, respiratory depression, the primary reason for opioid-induced death, was not exacerbated by this combination. Interestingly, the antipsychotic drug reduced opioid self-administration, the gold standard for examining abuse liability in preclinical models. Taken together, these initial preclinical studies suggest that this drug combination may reduce the abuse liability of prescription opioids without altering analgesic efficacy or respiratory depression. To further confirm safety and demonstrate feasibility, we have now carried out initial clinical experiments. Specifically, healthy human subjects were enrolled in a double-blind crossover study involving three visits to the UT Health Pain Clinic. On visit 1, subjects became familiar with the experimental procedures and baseline pain thresholds were established using experimenter-administered pain. On visits 2 and 3, patients were given a single capsule containing either OXY plus placebo or OXY plus one of two atypical antipsychotics [risperidone (2mg) or ziprasidone (80mg)], with the order of the drug combinations randomized. Three different doses of OXY were examined in separate groups of subjects (5mg, 10mg, or 15mg). Preliminary data from these studies suggest that the drug combination did not alter the analgesic response of OXY or increase the incidence of adverse effects when compared to OXY alone. Future studies are underway to examine the effect of the combination on abuse liability in recreational drug users. If effective, this approach could be beneficial in the management of opioid treatments for disorders such as chronic pain.

Title: Peripheral mechanoreceptor activation modulates mesolimibic gaba and dopamine neurons and dopamine release in the nucleus accumbens via delta opioid receptors

Authors: *K. BILLS, T. CLARKE, M. NELSON, Z. NEY, S. STEFFENSEN
Interdepartmental Program in Neurosci., Brigham Young Univ., Provo, UT

Abstract: Acupuncture has been shown to reduce drug-seeking behavior; however, the neurobiological mechanisms underlying its mechanism remain elusive. We have previously demonstrated that activation of the ulnar nerve at the Shenmen acupoint HT7 reduces cocaine, alcohol and methamphetamine self-administration and modulates GABA neurons in the midbrain ventral tegmental area (VTA) via an opioid receptor (OR)-dependent mechanism. A component of the neurological pathway mediating HT7's effects begin with activation of peripheral mechanoreceptors in the ulnar nerve. These receptors activate the dorsal column medial lemniscal (DCML) pathway and progressively synapse in the nucleus cuneatus, thalamus and lateral habenula before influencing the VTA. There, activation of opioid receptors produces a transient decrease in GABA neuron firing. The specific receptors mediating these effects, the optimal frequency of activation, regional specificity of activation and ultimate impact on dopamine (DA) release in the nucleus accumbens (NAc) have not been described. Here, we test a novel mechanism of activating the DCML via subcutaneous vibratory implants at the C7-T1 vertebral levels. We show that activation of peripheral mechanoreceptors at vibrational frequency of < 100 Hz, independent of the HT7 acupoint, is sufficient to depress VTA GABA neuron firing rate, increase DA neuron firing rate and produce a subsequent increase in DA release in the NAc. The effects are blocked with general and local administration of naltrindole, a selective delta opioid receptor antagonist. This suggests that summation of sensory input rather than acupoint based stimuli is responsible for the observed modulation of the mesolimbic system.

Abstract: AIM: Lorcaserin is a selective agonist for 2C serotonin receptors that can attenuate cocaine-reinforced behavior in rats and rhesus monkeys. Its interaction with cocaine-induced cardiovascular effects has not been described. The goal of this study was to determine whether lorcaserin modified craving, cognitive function, or cardiovascular effects of cocaine.
METHODS: Cocaine experienced users received either oral placebo (12 participants) or lorcaserin (n=9), followed by low- or high- doses of intravenous cocaine (0.23 or 0.46 mg/kg-injection). They were then allowed to self-administer the lower dose of cocaine, and afterwards reported script-induced craving and completed the Repeatable Battery for the Assessment of Neuropsychological Status.
RESULTS: As previously reported, oral lorcaserin did not modify cocaine self-administration. When collapsed across intravenous dose, lorcaserin treatment increased both systolic blood pressure and heart rate following noncontingent injections. During cocaine self-administration, lorcaserin decreased heart rate after a choice of monetary reinforcement, but increased heart rate following an intravenous choice. The availability of active cocaine increased systolic blood pressure, after a choice of either monetary or intravenous reinforcement, but was uneffected by lorcaserin. Lorcaserin did not significantly modify peak heart rate or blood pressure values, and no participant met stopping criteria for dosing because of elevated heart rate or blood pressure. No arrhythmias or electrocardiogram changes were identified, and lorcaserin did not modify script-induced craving or cognitive function.
CONCLUSION: Combined treatment with cocaine and lorcaserin had complex effects on cardiovascular measures. During cocaine self-administration, lorcaserin increased heart rate after an intravenous choice, but had an opposite effect after monetary reinforcement. Cardiovascular effects did not appear to be clinically significant. Lorcaserin treatment did not alter either craving or cognitive function.

Title: Novel small molecule inhibitors of protein kinase C epsilon for reducing consumptions of alcohol and nicotine

Authors: *J. WANG[1], A. BLASIO[2], M. B. POMRENZE[3], H.-Y. WANG[5], S. MCHARDY[5], R. O. MESSING[4]
[1]The Univ. of Texas At Austin, Austin, TX; [2]Univ. of Texas At Austin Col. of Pharm., Austin, TX; [3]Neurosci., [4]Neurology/Neuroscience, Univ. of Texas at Austin, Austin, TX; [5]Ctr. for Innovative Drug Discovery, Dept. of Chem., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Alcohol use disorder and smoking are highly comorbid and are among the top five preventative causes of death. Despite the large social and economic burden that they cause, current treatments for alcohol and nicotine addiction have limited efficacy. Based on prior biochemical and animal studies, we have proposed that protein kinase C epsilon is a drug target for reducing alcohol consumption. Thus, we derived several potent and novel small molecule inhibitors of protein kinase C epsilon (PKC epsilon) from the Rho-associated protein kinase (ROCK) inhibitor Y-27632, which has weak activity against PKC epsilon. *In vitro* kinase and binding assays showed that two compounds (1.0 and 1.3) are potent and selective against PKC epsilon, with *K*i values less than 20 nM. Both compounds crossed the blood brain barrier, achieved effective concentrations in mouse brain, and acutely reduced ethanol consumption when administered intraperitoneally at 40 mg/kg in wild type but not in *Prkce*$^{-/-}$ mice. Since medications for addiction are dosed repeatedly, here we investigated whether compound 1.0 was effective with repeated administration. Mice were provided with one bottle of water and one bottle of 10% ethanol continuously every day. After baseline drinking was stable, mice received once daily intraperitoneal injections of vehicle or 40 mg/kg compound 1.0 for five consecutive days. In the first cohort of mice (n=5 for vehicle group and n=3 for drug group), compound 1.0 reduced ethanol consumption on all injection days by 30-59 %. One day after the last injection, ethanol drinking returned to baseline. This result is consistent with the 15-hour half-life of compound 1.0 in the mouse brain. Since we also previously found that *Prkce*$^{-/-}$ mice consume less nicotine containing solutions and show decreased conditioned place preference for nicotine, we hypothesized that our PKC epsilon inhibitors would reduce oral nicotine consumption. Using a two-bottle choice voluntary nicotine drinking procedure, we found that intraperitoneal administration of compound 1.0 or 1.3 reduced consumption of 20 µg/ml nicotine by 31% and 24%. These results suggest that inhibitors of PKC epsilon are effective in reducing ethanol consumption when administered repeatedly and are also effective in reducing nicotine intake in mice.

Title: Mechanism of action of ITI-333, a novel modulators of serotonin, dopamine and mu opioid receptors for the treatment of opioid use disorder

Authors: *G. L. SNYDER[1], R. E. DAVIS[2], P. LI[2], W. YAO[2], S. CRUZ[2], L. ZHANG[2], J. P. HENDRICK[2], A. FIENBERG[2], K. E. VANOVER[2], S. MATES[2]
[1]Executive Director, Mol. Neuropharm., [2]Intra-Cellular Therapies Inc, New York, NY

Abstract: New medications are needed to treat opioid use disorder (OUD) by easing the somatic symptoms of drug withdrawal and effectively mitigating the dysphoria and psychiatric comorbidities (e.g., mood and anxiety disorders) that drive opioid use/abuse. Here, we describe the properties of ITI-333, a novel molecule combining high affinity binding (Ki < 50 nM) to three receptors that individually have been associated with treatment of substance use disorders and psychiatric comorbidities: the mu opioid (MOP), serotonin 5-$HT_{2A,}$ and dopamine D_1 receptors. Data from cell-based and *in vivo* assays, demonstrate that ITI-333 functions as a biased MOP receptor ligand with partial agonist activity, acting as an antagonist to block effects of high doses of morphine in both pain and motor activity models while acting alone to provide potent analgesia in models of acute and inflammatory pain. In cell-based assays using human recombinant MOP receptors expressed in CHO cells, ITI-333 alone induces cAMP accumulation (agonism) while blocking the effects of a full MOP agonist, DAMGO (antagonism). Further, ITI-333 displays biased agonism at MOP receptors, acting as an antagonist on beta-arrestin pathways that mediate opioid side effects. In mice, ITI-333, alone (0.01-1mg/kg, SC, 10 mice/group), produces naloxone-sensitive analgesia in the tail flick (TF) assay, while attenuating morphine-induced analgesia in TF (0.1-1mg/kg, SC, 10 mice/group). ITI-333 blocks hyperactivity induced by morphine (32mg/kg, SC, 6 mice/group) without significant effects on spontaneous locomotor activity. In drug abuse assays, ITI-333 (0.3, 1, and 3mg/kg, SC) dose-dependently suppresses the somatic and behavioral signs of opioid withdrawal precipitated by naloxone injection in oxycodone-dependent mice (i.e., oxycodone given for 8 days at increasing daily doses of 9-33 mg/kg b.i.d., 10 mice/group). Chronic (28 day q.d. treatment) of ITI-333 (0.3 or 3mg/kg, SC) does not result in tolerance or physical dependence in rats; acute doses of ITI-333 (0.3 or 3mg/kg, SC, 8 rats/group) do not induce GI or pulmonary side effects. Finally, ITI-333 (0.003-0.01mg/kg, IV, 8/group) is not self-administered by heroin-maintained rats. In summary, evidence supports a role for ITI-333 in mitigating symptoms of opioid withdrawal and supports its potential as a treatment for OUD, associated comorbid mood and dysphoric symptoms, and pain.

Title: Functional connectivity changes related to self-regulation among moderate to heavy smokers

Authors: *L. MARTIN[1], M. G. BRUCKS[1], D. CATLEY[3], K. P. RICHTER[2], E. F. ELLERBECK[2], V. B. PAPA[1], A. T. FOX[1]
[1]Hoglund Brain Imaging Ctr., [2]Preventive Med. and Publ. Hlth., Univ. of Kansas Med. Ctr., Kansas City, KS; [3]Children's Mercy, Kansas City, MO

Abstract: Resting-state functional connectivity (rsFC) has been shown to predict behavioral and pharmacological treatment outcomes. For example, functional connectivity has been shown to predict treatment outcomes following cognitive behavioral therapy (CBT) for depression. Moreover, functional connectivity between self-regulation and reward regions have been shown to predict smoking cessation following a pharmacological intervention. However, little is known about how functional connectivity changes over the course of health behavior interventions. The current pilot study examined the impact of a health behavior intervention approach on rsFC in moderate to heavy smokers. Smokers (n=23) were recruited and adhered to study procedures. Participants completed a baseline rsFC scan and follow-up scans (2 weeks and 4 weeks), as well as 4 weeks of a CBT intervention to help change health behaviors through scheduled smoking reduction (n=6), scheduled smoking (n=8) or increased fruit and vegetable consumption (n=9). A

whole-brain seed-based functional connectivity analysis was performed to identify changes over time in functional connectivity related to self-regulation using a left dorsolateral prefrontal (dlPFC) seed region. The results showed increased connectivity over time between the left dlPFC and the medial prefrontal cortex, right insula, left middle frontal gyrus, right middle temporal gyrus, and right superior temporal gyrus. Exploratory analyses demonstrated a time by group interaction for connectivity between the dlPFC, middle temporal gyrus, superior temporal gyrus and left middle gyrus ($p < .05$). These results indicate that the group receiving CBT directed at scheduled smoking reduction and CBT directed at increasing fruits and vegetables showed changes in connectivity from baseline to end of treatment. Together these pilot data indicate that self-regulation related functional connectivity changes over the course of 4 weeks of CBT and type of treatment may influence the strength of these connectivity changes. Overall this project will inform future studies aimed at examining neural mechanisms related to treatment changes and identifying the duration of behavioral treatment interventions to see optimal brain changes.

Title: Physiological and psychological cocaine dependence affect neural processing of drug and food stimuli: Correlations with substance use severity and psychopathic traits

Authors: *W. DENOMME[1], M. S. SHANE[2,3]
[2]Social Sci. and Humanities, [1]Univ. of Ontario Inst. of Technol., Oshawa, ON, Canada; [3]The Mind Res. Network, Albuquerque, NM

Abstract: Recently, we demonstrated at the Society of Biological Psychiatry's annual meeting that 1) individuals with a cocaine-dependence disorder exhibit a neural processing bias towards drug-related rewards relative to non-drug rewards; 2) psychopathic traits are associated with a sensitized neural processing bias among cocaine-dependent individuals (Denomme, Simard, & Shane, 2018). Animal and theoretical models of addiction suggested that biases were due to neuroplastic changes within a corticolimbic circuit that are mediated by chronic substance use and drug withdrawal (Goldstein & Volkow, 2002). Thus, we investigated differences in neural processing biases between participants with a physiological and psychological cocaine dependence within a sample of 101 parolees who viewed drug- and food-related videos while

undergoing an fMRI scan. Physiologically-dependent participants (Phys-D; *n* = 20) exhibited a significantly greater neural processing bias towards drug-related videos compared to both psychologically-dependent (Psyc-D; *n* = 24) and non-dependent (ND; *n* = 57) participants. The Phys-D group exhibited significantly greater drug > food reactivity within the anterior cingulate cortex, dorsomedial prefrontal cortex, and caudate nucleus compared to the Psyc-D group; and greater drug > food reactivity within the anterior cingulate cortex, dorsomedial prefrontal cortex, amygdala, ventral striatum, and caudate nucleus compared to the ND group. There were no significant differences between Psyc-D and ND groups in terms of drug- and food-related neural activity. When assessing correlations between drug > food reactivity with substance use and psychopathic traits, correlations were only observed in Psyc-D participants. Psychopathic traits correlated with increased drug > food reactivity within the dorsomedial prefrontal cortex, whereas substance use correlated with increased activity within the anterior cingulate cortex, ventral striatum and amygdala. Significant psychopathy*substance use interaction effects were observed within the cerebellum and the insula. Our results suggest that previously documented neural processing biases are modulated by whether or not the participant has met diagnostic threshold for cocaine withdrawal and tolerance, and that psychopathic traits and substance use only have statistically significant effects among dependent participants who have not experienced physiological components of dependence. These results have implications for the prevention, diagnosis and treatment of substance use disorders, as well as externalizing behaviors in psychopathic personality disorder.

Title: Neural activity of anterior insula during a size-delay task is enhanced after cocaine exposure

Authors: *H. J. PRIBUT[1,2], A. T. BROCKETT[1,2], D. VAZQUEZ[2], E. ALVAREZ[2], M. R. ROESCH[1,2]
[1]Neurosci. and Cognitive Sci., [2]Psychology, Univ. of Maryland, College Park, MD

Abstract: Decision making is a critical aspect of cognitive function that is impaired after exposure to drugs of abuse, causing individuals to pursue drug use even in the face of significant negative consequence. Such behavior most likely arises from impairments of circuitry involved

not just in reward learning, but also in stress and executive control (Keiflin and Janak, 2015; Koob and Volkow, 2016). The insula has recently been examined for its potential role in addiction, with current literature in both human and animal subjects finding activity related to impulsivity (Mechelmans et al., 2017), reward anticipation (Kusumoto-Yoshida et al., 2015), and regret (Jo and Jung, 2016). Given these findings we were interested in whether the insula is responsible for encoding the value of different rewards, and how such encoding may be altered after exposure to drugs of abuse. To explore these questions, we recorded from single neurons in the anterior insula of rats as they performed an odor-guided decision-making task for rewards varying in size and delay of arrival. Preliminary data suggest that subjects who had previously self-administered for cocaine exhibit greater sensitivity to delayed rewards compared to control animals who had previously self-administered sucrose. Single neuron firing in rats from both the cocaine and control group additionally demonstrate a trend for greater activity during blocks of trials where the size of reward is manipulated. These effects are evident especially in cells responsive to reward as opposed to cue onset. Our data suggest the insula encodes both the value of incoming rewards and contextual states, and that such activity is enhanced after exposure to drugs of abuse during anticipation and delivery of delayed reward. This work additionally fits into the greater body of literature suggesting a role for the insula in network of circuitry impaired by addiction.

Title: Inhibition of GABA neurons in the prelimbic cortex mimics locomotor activation evoked by cocaine

Authors: *E. MARRON, T. ROSE, H. OBERLE, K. WICKMAN
Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: GABA neurons are the major source of inhibition in the mammalian nervous system. They normally exert their actions in focalized networks; however, recent findings have shown the presence of non-classical long range GABA projections connecting cortical structures (cortico-cortical) or cortical and subcortical structures (cortico-fugal). New technological

advances such as powerful retrograde tracers, opto- and chemogonetics have allowed precise circuit interrogation, including studying the role of these long inhibitory projections. For example, connections between different cortical regions, such as the medial prefrontal cortex and the striatum have been explored demonstrating that these connections can control specific behaviors. Here, we explore the contribution of a corticostriatal GABA projection in the context of drug addiction. Cocaine, and other psychostimulants, produces a pronounced increase in locomotor activity, and previous work from our lab has shown that the excitability of pyramidal cells in the prelimbic cortex (PrLC) controls, at least in part, the magnitude of this response. We started by manipulating the excitability of PrLC GABA neurons by expressing a Designer Receptor Exclusively Activated by Designer Drug (DREADD) virally under the control of the mDlx promoter, a forebrain GABA neuron promoter (Male mice, ~ 50 d at the time of surgery and ~ 70-80 d at the end of behavior). When using the inhibitory DREADD, hM4Di, CNO administration evoked an increase in locomotor activity comparable to that produced by cocaine administration. CNO administration also potentiated locomotion induced by a 15mg/kg dose of cocaine. Electrophysiological recordings confirmed that GABA neuron excitability was reduced in the presence of CNO and that translated in a reduction of $GABA_AR$ responses recorded from pyramidal neurons. Interestingly, direct excitation of PrLC pyramidal neurons using the excitatory DREADD hM3Dq did not have an effect in locomotion, suggesting that the disinhibition of pyramidal neurons might not be the mechanism for the increase in locomotion. We then used a combination of retrograde and anterograde tracing to determine the presence, extension and neurochemical signature of long range GABAergic projections from the PrLC to the nucleus accumbens. Finally, by injecting halorhodopsin in the PrLC cortex under the mDlx promoter and implanting fiber optics in the nucleus accumbens core we manipulated the activity of long range GABA neurons in an open field test confirming our chemogenetic observations. Future efforts will focus on the possible role this projection plays in drug addiction.

Title: Prior cocaine self-administration increases strength of encoding states with different response rules by DMS cholinergic interneurons

Authors: *L. MUELLER[1,2], A. M. WIKENHEISER[1], M. J. SHARPE[1], D. M. DIETZ[2], T. A. STALNAKER[1], G. SCHOENBAUM[1]
[1]NIH, NIDA IRP, Baltimore, MD; [2]Neurosci., State Univ. of New York at Buffalo, Buffalo, NY

Abstract: When associative rules in effect change abruptly, it is useful to learn about the new situation or context in a manner which does not interfere with the old. To do this, learning in each context is compartmentalized into different "states" which contain the rules appropriate for guiding behavior under those distinct circumstances. Thus, adaptive responding when situations change is dependent upon the ability of an individual to develop and alternate between states. We have previously shown that dorsomedial striatal (DMS) cholinergic interneurons (CINs) encode states with distinct response rules in an odor-guided choice task, consistent with data from Bradfield et al. that the disruption of DMS CIN activity leads to situationally-inappropriate behavior when response-reward contingencies change (2013). Since CINs are activated by cocaine and are implicated in the regulation of extinction learning to cocaine-context associations, cocaine use may disrupt DMS CIN encoding of current state representations and lead to situationally-inappropriate behavior. Here we tested this hypothesis by recording DMS CIN activity in a similar odor task in rats with experience self-administering cocaine. We found that rats that had previously self-administered cocaine were slower to adjust their responding following a state change when compared to controls that had previously self-administered sucrose. Moreover, CINs recorded from these rats display enhanced state encoding across the trial. Interestingly, this effect is particularly robust on suboptimal choices when rats chose the less preferred outcome. These results are consistent with a role for CINs in the reduction of behavioral flexibility and poor decision-making that is observed in individuals following exposure to drugs of abuse.

Title: Melanin-concentrating hormone system in REM sleep-mediated regulation of cocaine craving

Authors: *R. GUO[1], Y. WANG[2], B. CHEN[3], L. CAI[1], Y. LI[2], O. M. SCHLÜTER[2], J. FANG[4], Y. DONG[2], Y. H. HUANG[1]
[1]Psychiatry, [2]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept. of Neurosci., Wenzhou Med. Univ., Wenzhou, China; [4]Psychiatry, Pennsylvania State Univ., Hershey, PA

Abstract: Sleep abnormalities commonly occur among chronic cocaine users long after withdrawal. The withdrawal-associated sleep problems, including loss of sleep and sleep fragmentation, may increase the risk for cocaine use and relapse. Previously we reported that lengthening rapid eye movement (REM) sleep episode duration by behavioral interventions reduces cue-induced cocaine craving after withdrawal in rats. Furthermore, calcium-permeable AMPA receptors (CP-AMPARs) in the nucleus accumbens (NAc) medium spiny principal neuron synapses are likely a key neuronal substrate that expresses REM sleep-induced regulation of cocaine craving and relapse. In this study, we identify the melanin-concentrating hormone (MCH) neurons in the lateral hypothalamus and zona incerta (LH for short) as a potential REM sleep mechanism in regulating NAc CP-AMPAR accumulation and cocaine craving after withdrawal. Male rats (~ 6-8 weeks old) were trained with cocaine self-administration (overnight followed by 2 hr/day x 5 days). After 21 d withdrawal, REM sleep time and episode duration were inversely correlated with the amount of cocaine intake during training. At this time, in vitro slice recordings from LH MCH neurons from cocaine-trained rats revealed decreased frequency of spontaneous firing and reduced intrinsic membrane excitability, suggesting reduced MCH neural activity after withdrawal. Furthermore, increasing MCH neural activity by either chemogenetic activation (AAV5-MCHp-DREADDs (Gq); clozapine-N-oxide) or optogenetic stimulation (AAV5-MCHp-ChR2-EYFP; 473 nm; 10 Hz) increased REM sleep in rats after cocaine withdrawal. To determine whether MCH receptor signaling in the NAc may regulate CP-AMPARs, we did intra-NAc MCH infusions (1 µg/µl) on withdrawal days 42 and 43 at onset of light phase. Intra-NAc MCH infusions reduced the cocaine-induced CP-AMPAR accumulation in the NAc synapses, and reduced incubation of cocaine craving. In conclusion, our study suggests that LH MCH neural activity is reduced after withdrawal from cocaine; enhancing MCH activity may facilitate REM sleep normalization after cocaine withdrawal; increasing MCH receptor signaling in the NAc may facilitate the attenuation of cocaine craving after withdrawal by down-regulating CP-AMPARs in the NAc.

Title: Ventral pallidum Drd3-expressing neurons mediate cocaine-seeking behavior

Authors: *H. PRIBIAG, S. SHIN, E. H. WANG, P. HONMA, V. LILASCHAROEN, B. LIM
UCSD, LA Jolla, CA

Abstract: Addictive substances hijack the brain's reward system, generating a persistent drive for drug seeking at the expense of natural rewards. Although drug-induced plasticity in the striatum is known to play a critical role in addictive behaviors, persistent drug-induced alterations in other mesolimbic brain structures that integrate and convey reward-related information remain less understood. We identified a population of neurons in the ventral pallidum (VP) that expresses dopamine receptor D3 (Drd3) and that sends projections to several mesolimbic structures implicated in reward and addiction. We explored the role of VP Drd3 signaling in plasticity and drug seeking following withdrawal from cocaine self-administration, and uncovered significantly altered activity of VP Drd3+ neurons during drug seeking. Using viral-mediated tracing, electrophysiology and optogenetics we characterized VP Drd3+ projections to different brains areas, identifying roles for distinct projections in mediating reward-related behavior. Our results provide insight into the role of dopaminergic signaling in the VP and a mechanistic understanding of how VP Drd3+ neurons contribute to persistent drug seeking behavior.

Title: Ventral pallidal glutamatergic and enkephalinergic neurons oppositely regulate cocaine seeking

Authors: *J. A. HEINSBROEK, A.-C. BOBADILLA, D. NEUHOFER, T. B. NENTWIG, E. DERESCHEWITZ, P. W. KALIVAS
Med. Univ. of South Carolina, Charleston, SC

Abstract: The ventral pallidum (VP) is a critical structure for driving drug related motivation in addiction, yet precisely how distinct VP circuits mediate drug use and drug seeking during relapse remains unknown. While the VP is thought to be an inhibitory basal ganglia relay nucleus comprised of GABAergic projection neurons (VP^{GABA}) the VP also contains a large number of glutamatergic projection neurons (VP^{Glu}), and a subpopulation of GABAergic projection neurons that co-express the neuropeptide enkephalin (VP^{Penk}). We investigated how these populations of neurons regulate the motivation to seek and take cocaine, mapped their anatomical connectivity and recorded their activity during self-administration.
Virus-based anterograde and retrograde tracing methods, as well as chemogenetics and single cell calcium imaging were used in Vglut2-IRES-Cre, Vgat-IRES-Cre, and PENK-IRES-Cre mice. Animals received indwelling jugular vein catheters, were implanted GRIN lenses, and were trained to self-administer cocaine. After mice reached a stable baseline of responding, the roles of distinct VP neurons during drug taking were tested using a progressive ratio test. Afterwards, mice underwent extinction training and VP neuron contributions to drug seeking were assessed during cue-induced reinstatement.
VP^{Glu}, VP^{GABA} and VP^{Penk} neurons receive differential but overlapping inputs from the nucleus accumbens and other limbic structures, and single cell calcium imaging demonstrated that these populations of VP neurons are differentially engaged during cocaine sensitization and self-administration. Global chemogenetic stimulation of the VP greatly enhanced drug seeking during cue-induced reinstatement, while inhibiting the VP reduced reinstatement. Specific stimulation of VP^{Glu} neurons produced the opposite effect; it abolished the motivation to take cocaine, and reduced cue-induced reinstatement, while inhibiting VP^{Glu} neurons augmented these behaviors. Manipulating VP^{Penk} neuron activity mimicked the effects of global VP manipulations, whereas stimulation of VP^{GABA} neurons produced mixed effects by increasing the motivation to take drugs, while decreasing the motivation to seek drugs during reinstatement.
These results expand our knowledge of the addiction circuitry by showing that VP glutamatergic, GABAergic and enkephalinergic neurons give rise to distinct VP subcircuits and regulate different motivated states underlying drug use and drug seeking.

Title: Estrogenic modulation of cocaine response in the medial preoptic area is dependent on biological sex

Authors: *J. R. MARTZ[1,2], C. L. ROBISON[1,2], J. M. DOMINGUEZ[1,2,3,4]
[1]Psychology, The Univ. of Texas At Austin, Austin, TX; [2]Waggoner Ctr. for Alcohol & Addiction, Austin, TX; [3]Pharmacol. & Toxicology, [4]Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: Behavioral response to cocaine is sex dependent. Which neuroendocrine factors regulate these differences is still unclear. Evidence indicates that the medial preoptic area (mPOA) in the hypothalamus regulates cocaine response, both neural and behavioral activity, as evidenced by conditioned-place preference (CPP) and microdialysis experiments. The hormone estrogen, in particular, acts in the mPOA to modulate response to cocaine. Because the mPOA is a major regulator of sex-specific behavioral differences across various species and for a variety of behaviors, here we investigated whether modulation of cocaine by estrogen in the mPOA is dependent on sex. To this end, male and female rats were divided into groups receiving systemic cocaine or vehicle injections. These were then further subdivided into those receiving estradiol or vehicle microinjections directly into their mPOA, for a total of 8 groups. After receiving cocaine, animals were given a CPP and locomotor test to measure their behavioral response to the drug. Results indicate an important role for estrogen in the mPOA modulating sex differences in the animal's response to the drug. Namely, estradiol microinjections enhanced cocaine-induced CPP in females but not in males. This confirms that cocaine response is sensitive to estrogenic signaling in the mPOA, as previously shown, and moreover, that this influence is dependent on biological sex.

Title: Individual differences in cocaine aversion response correlate with distinct intrinsic and synaptic neuroadaptation in the RMTg to VTA pathway

Authors: *J. PARRILLA-CARRERO[1], Y. S. CHAO[1], M. EID[2], D. PULLMANN[1], H. LI[2], T. C. JHOU[1]
[2]Neurosci., [1]Med. Univ. of South Carolina, Charleston, SC

Abstract: Aside from the strong rewarding effects elicited by drugs of abuse, drugs like cocaine also produce conditioned aversive effects that are most prominent after the rewarding effects dissipate. However, conditioned aversive responses to cocaine vary between individuals, and may influence the predisposition to develop addictive behaviors, but the neural mechanisms involved are not well known. Is well established that Rostromedial Tegmental nucleus (RMTg) efferents to the Ventral Tegmental Area (VTA) modulate the neural response to cocaine, specifically by inducing conditioned place aversions. Thus, we hypothesized that RMTg neurons that project to the VTA (RMTg-VTA) undergo distinct synaptic and intrinsic adaptations that might critically modulate individual differences in cocaine-induced avoidance behaviors. To test this hypothesis, we use a runway operant model that has been extensively used to test the aversive effects of cocaine, and which we found to separate animals into “high cocaine avoiders” and “low cocaine avoiders”, based on latencies to obtain cocaine. After behavioral testing, we used whole cell patch clamp recording techniques to record from RMTg-VTA neurons. We found that RMTg-VTA neurons from high-avoider rats had significantly more current-evoked action-potentials compared to low-avoiders and controls unexposed to cocaine. We also found that high-avoider rats exhibited increased frequency (but not amplitude) of spontaneous excitatory postsynaptic current (sEPSC) activity in RMTg-VTA neurons, consistent with enhanced presynaptic release. Conversely, low-avoider rats showed decreased sEPSC frequency and amplitude compared to drug-naïve controls, which could reflect either pre- or post-synaptic changes. To test for the locus of this synaptic adaptation we measured the eEPSC paired-pulse ratio (PPR) and the AMPA/NMDA ratio recorded at +40mV. High-avoider rats showed a decrease in the eEPSC PPR compared to low-avoider and drug-naive controls, indicating an increase in presynaptic release. The AMPA/NMDA ratio did not differ between high-avoider rats and controls, but was decreased in low-avoiders rats in compared to controls, indicating reduced postsynaptic excitatory transmission specifically in low avoiders. Altogether, these results indicate that distinct neuronal adaptations in the RMTg-VTA pathway are correlated with the aversive phenotype toward cocaine, and suggest that specific phenotypical neural adaptations in the RMTg-VTA pathway may contribute, at least partially, to the development of aversion to cocaine and addiction vulnerability.

Title: Chemogenetic activation of hindbrain projections to the lateral dorsal tegmental nucleus attenuates cocaine-seeking behavior

Authors: *N. S. HERNANDEZ, V. R. WEIR, H. D. SCHMIDT
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Glucagon-like peptide-1 (GLP-1) is an incretin hormone and neuropeptide that is produced centrally in the nucleus tractus solitarius (NTS). Emerging literature shows that GLP-1 receptor (GLP-1R) agonists reduce cocaine-mediated behaviors in rodents. The lateral dorsal tegmental nucleus (LDTg) is a brain region that plays a critical role in cocaine seeking, expresses GLP-1Rs, and receives direct projections from the NTS. Therefore, the goal of this study was to test if GLP-1R activation in LDTg plays a critical role in the reinstatement of cocaine-seeking behavior, an animal model of relapse. Rats were pretreated with intra-LDTg infusions of the GLP-1R agonist exendin-4 (Ex-4; 0, 0.005 and 0.025 μg) prior to cocaine priming-induced reinstatement test sessions. We show that intra-LDTg Ex-4 attenuated cocaine reinstatement at a dose that does not affect sucrose seeking or *ad libidum* food intake in cocaine-experienced rats. Next, we used a viral-mediated chemogenetic approach to characterize the role of monosynaptic projections from the NTS to the LDTg in cocaine seeking. To selectively activate NTS to LDTg projections, a cre-expressing retrograde canine adenovirus and cre-dependent neural activating DREADD (hM3Dq) and was infused in the LDTg and NTS, respectively. Prior to reinstatement test sessions, rats were pretreated with clozapine-N-oxide (CNO; 0, 0.1, 1 mg/kg) to activate endogenous NTS to LDTg circuits prior to a priming injection of cocaine. CNO pretreatment significant attenuated cocaine seeking, indicating that activation of this hindbrain circuit is sufficient to reduce drug-seeking behavior in rats. To determine if GLP-1-expressing neurons in the NTS were mediating the suppressive effects of CNO on cocaine seeking, we pretreated rats with the GLP-1 receptor antagonist exendin-(9-39) (Ex-9, 10 μg) directly into the LDTg prior to CNO and an acute priming injection of cocaine. We found that pharmacological inhibition of GLP-1 receptors in the LDTg prevented the ability of DREADD activation of the NTS to reduce cocaine seeking. These results highlight a novel role for hindbrain circuits and GLP-1R signaling in cocaine-seeking behavior.

Title: Suppression of operant responding for a natural reinforcer by a cocaine-associated auditory stimulus in rats: Role of locus coeruleus activity and auditory brainstem plasticity

Authors: *M. A. PRESKER, JR[1], D. SOSIDKO[2], S. S. BASKAR[2], K. M. BIESZCZAD[3], G. S. ASTON-JONES[4]
[1]Brain Hlth. Inst., [2]Rutgers - The State Univ. of New Jersey, Piscataway, NJ; [3]Psychology, Behavioral and Systems Neurosci., Rutgers The State Univ. of New Jersey, Piscataway, NJ; [4]Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: A major obstacle in treating addiction to cocaine is the high propensity for relapse. Stimulus-driven cocaine seeking occurs despite efforts to remain abstinent, and competes with ongoing alternative positive behaviors such as occupational or social activities. Noradrenergic locus coeruleus (LC) neurons project throughout the neuraxis, and modulate sensory processing and attention to orient organisms to sensory stimuli. Previous work has shown that LC activity is altered both acutely and chronically by cocaine and supports a role for LC in mediating the stimulus control of attention by cocaine-cues observed in cocaine addiction. However, few studies have examined whether cocaine-associated stimuli activate LC or exert control over non-drug seeking behaviors. Here we implement a behavioral paradigm specifically designed to examine the effects of cocaine-paired, saline-paired, and unpaired auditory stimuli (tones) on operant responding for a natural reinforcer (water) in rats using a within-subjects paradigm. We found that a cocaine-paired tone suppresses water self-administration compared to saline-paired or unpaired tones (n=12 rats). In a separate group of animals, we performed timed-perfusions to assess Fos expression in LC of rats exposed to cocaine-paired, saline-paired, or unpaired tones, no tones, or homecage controls (n=4 per condition). Imaging and counting of Fos in LC was conducted by an experimenter blind to the treatment conditions. We observed a correlation between expression of Fos in noradrenergic LC neurons and suppression of water self-administration by cocaine- vs. saline-paired tones. These data indicate that LC activity may be involved in modulating the control of behavior by cocaine-associated stimuli. Furthermore, we plan to record auditory brainstem responses to cocaine-paired, saline-paired, or unpaired tones in a separate group of animals (n=8) before, during, and after the conditioning procedure. We will analyze changes in ABR peak latencies to each tone over the course of conditioning to assess potential changes in auditory processing of a cocaine-associated tone compared to control tones. Given the significance of cocaine stimuli for driving relapse, this behavioral regulation by LC may be a target for therapeutic intervention.

Title: Retinoic acid signaling and homeostatic plasticity in nucleus accumbens medium spiny neurons

Authors: *A. M. WUNSCH[1], D. C. CHRISTIAN[1], M. T. STEFANIK[1], M. HINTZE[2], L. CHEN[2], M. E. WOLF[1]
[1]Neurosci., Rosalind Franklin Univ., North Chicago, IL; [2]Neurosurgery, Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: Synaptic plasticity in response to cocaine use leads to a time-dependent heightening in responsiveness to cues during abstinence, a phenomenon termed incubation of cocaine craving. In rodents, profound alterations in glutamate transmission in the nucleus accumbens (NAc) accompany incubation of cocaine craving. In drug naïve rats, calcium (Ca^{2+})-impermeable AMPARs (CI-AMPAR) are responsible for a majority of excitatory postsynaptic AMPAR currents. However, following ~1 month of abstinence from cocaine self-administration, Ca^{2+}-permeable AMPARs (CP-AMPAR) are inserted into excitatory synapses on NAc medium spiny neurons (MSN) and are required for expression of incubation. Some data support the idea that cocaine use leads to reduced activity of MSNs at baseline, which may trigger plasticity leading to incubation. Little is known about signaling cascades that might link reduced activity in the NAc to CP-AMPAR insertion in NAc MSNs. Synaptic scaling is a form of homeostatic plasticity that adjusts synaptic strength to compensate for changes in neuronal activity. One form of inactivity-induced synaptic scaling involves activity-dependent regulation of dendritic protein translation by retinoic acid (RA). In hippocampal neurons, blockade of neuronal activity reduces intracellular Ca^{2+} to disinhibit RA synthesis. This in turn leads to GluA1 translation and synaptic insertion of homomeric GluA1 CP-AMPARs. Thus, RA signaling cascades in MSN may be a critical link between cocaine-induced decreases in NAc activity and CP-AMPAR insertion. Two lines of work are underway to determine if RA contributes to inactivity-induced synaptic scaling and regulates CP-AMPAR insertion in NAc MSNs. First, NAc neurons from postnatal rats are cultured with cortical neurons (to restore excitatory synapses) and transfected with a RA reporter system. We have confirmed that the RA reporter is responsive to changes in intracellular Ca^{2+} levels. Studies are underway to determine how altering excitatory synaptic transmission in the

cultures affects RA signaling and AMPAR subunit composition. Second, whole cell patch clamp recordings are performed on NAc core MSN in brain slices from rats that have undergone incubation of craving leading to CP-AMPAR accumulation. Preliminary data suggest that inhibiting RA synthesis with 4-diethylaminobenzaldehyde (DEAB) may normalize CP-AMPAR levels to those seen in drug naïve rats, suggesting that RA may be an important regulator of CP-AMPARs during abstinence. Ultimately, this work has the potential to define novel targets to reduce drug craving and prolong abstinence in people with substance use disorders.

Title: Formation and refinement of distributed corticostriatal ensembles engaged by cocaine

Authors: *N. R. WALL[1], P. A. NEUMANN[1], K. T. BEIER[1,2], A. K. MOKHTARI[1], L. LUO[2], R. C. MALENKA[1]

Abstract: Identification of neuronal ensembles mediating various forms of experience-dependent plasticity has been greatly facilitated by genetic strategies that allow labeling of neurons activated by an experience. Identification of more complex, synaptically connected neuronal ensembles mediating behavioral changes has been more challenging, particularly when these ensembles span multiple distinct brain areas. Here we use the Arc-TRAP line of mice, which expresses CreERT2 under the control of the immediate early gene Arc promoter, to identify ensembles of cortical and dorsal striatal neurons activated by a cocaine experience; we then combine this approach with monosynaptic rabies virus tracing to identify their synaptic connectivity. We also used a complementary targeting strategy to gain genetic access to neuronal ensembles that were not activated by cocaine. We find that cocaine-activated corticostriatal neurons, arising from diverse upstream sources including the somatosensory cortices, primary motor cortex, secondary motor areas, and various subdivisions of the prefrontal cortex,

preferentially wired onto co-activated striatal neurons, while more sparsely innervating neighboring non-active neurons. These results suggest that cocaine engages a privileged experience-specific subnetwork linking broadly distributed populations of synaptically connected cocaine-activated neurons in the cortex and dorsal striatum.
Repeated prior cocaine exposure, which elicited locomotor sensitization, further enhanced the connectivity between a select population of cocaine-activated prefrontal cortical neurons and their co-active striatal medium spiny neuron targets. Selective chemogenetic inhibition of the terminals in the dorsal striatum arising from cocaine-activated prefrontal neurons disrupted the expression of cocaine-induced locomotor sensitization, whereas inhibition of terminals arising from non-active prefrontal neurons had no effect. Taken together, these results identify a broadly distributed cocaine-activated corticostriatal neuronal ensemble and reveal portions of the drug-specific subcircuit that may be particularly amenable to targeted therapeutic intervention for drug abuse. In an accompanying abstract (Neumann et al.,) we present results characterizing the properties of corticostriatal synapses made between cocaine-activated versus non-activated cortical and dorsal striatal neuronal populations. The methodology used in these experiments should be applicable to the elucidation of the circuit adaptations mediating a broad range of adaptive and pathological forms of experience-dependent plasticity.

Title: Characterization of corticostriatal cocaine ensemble physiology and behavior

Authors: *P. A. NEUMANN, N. R. WALL, K. T. BEIER, R. C. MALENKA
Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: Genetic strategies to label active neurons during a limited time window have greatly improved our ability to not only visualize neural ensembles, but also to examine how these ensembles may function to mediate various behaviors. This ability to identify experience-specific ensembles is especially relevant to investigating complex experiences mediated by brain regions

with diverse neural connectivity, such as the striatum. In a complementary abstract (Wall et al.), we demonstrate how activity-dependent labeling (using Targeted Recombination of Active Populations, TRAP) can be combined with monosynaptic rabies viral tracing in mice to characterize cocaine-induced changes to corticostriatal synaptic connectivity. These results identify cocaine-induced connectivity changes in motor cortex and orbital frontal cortex inputs to dorsal striatal neurons.
Here, we build upon these connectivity results and examine cocaine-induced physiology changes at cocaine-activated corticostriatal synapses using acute slice physiology. We employ Cre-activation and -inactivation techniques to target channelrhodopsin expression specifically to cocaine-activated or -non-activated neurons, respectively. Our results reveal differences in AMPAR/NMDAR ratios, quantal amplitudes, and paired-pulse ratios at activated vs. non-activated synapses. We then show that chemogenetic inhibition specifically of cocaine-activated ensembles in the orbital frontal cortex inhibits the expression of cocaine locomotor sensitization, whereas inhibition of neighboring non-activated neurons has no apparent effect.
Taken together, these results along with the results shown by Wall et al. demonstrate how a range of techniques, including TRAP labeling, rabies tracing, opto and chemogenetics, and slice electrophysiology, can be combined to analyze circuit connectivity and adaptations that mediate behaviorally-induced plasticity in an unbiased manner.

Title: Destabilization of a synaptic engram underlying drug-associated memories

Authors: *W. WRIGHT[1], N. M. GRAZIANE[1], P. A. NEUMANN[1], P. J. HAMILTON[2], H. M. CATES[2], L. E. FUERST[1], Y. SHAHAM[3], O. M. SCHLÜTER[1], E. J. NESTLER[2], Y. DONG[1]

[1]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [3]IRP/NIDA/NIH, Baltimore, MD

Abstract: Experiencing drugs of abuse produces drug-associated memories, among which drug-cue associations persistently promote drug seeking and relapse. Like other cue-associative memories, upon cue-induced retrieval, cocaine-associated memories are destabilized for ~6h, followed by reconsolidation. This 6h destabilization window is a therapeutic opportunity to compromise drug-associated memories and reduce drug relapse. Since clear cellular and synaptic mechanisms underlying memory destabilization remain elusive, non-specific amnestic manipulations fail to achieve consistent anti-relapse effects clinically. To explore specific neural substrates underlying drug-associated memories, our previous work shows cocaine experience generates new, immature silent synapses in nucleus accumbens (NAc) medium spiny neurons (MSNs). During withdrawal, these silent synapses functionally mature by recruiting calcium permeable AMPARs (CP-AMPARs), strengthening and consolidating the newly established neurocircuits. Our subsequent results suggest that generation and maturation of silent synapses critically contribute to the acquisition and consolidation of cocaine-cue associative memories. Thus, these cocaine-generated synapses may represent a putative synaptic engram for drug-associated memories. Here, we show that upon cue-induced memory reactivation in male rats, the matured cocaine-generated synapses were re-silenced through CP-AMPAR internalization and destabilized for ~6h, followed by re-insertion of CP-AMPARs and re-maturation. Preventing silent synapse re-maturation during the destabilization phase by disrupting CP-AMPAR re-insertion significantly decreased cue-induced cocaine seeking. Furthermore, the activity of small GTPase, Rac1, acted as a molecular switch to trigger and/or prevent the destabilization window. Taken together, these findings suggest that cocaine-generated silent synapses are key synaptic components of the drug memory engram, through which drug-associated memories can be precisely manipulated for therapeutic benefits.

Title: Dynamic neuronal signaling in the nucleus accumbens tracks cocaine experience and contributes to motivated behavior

Authors: *M. E. ZIPPERLY[1,2], J. O'MALLEY[3], A. C. BRANE[1], N. A. SIMPKINS[1], D. S. MURRAY[1], K. D. BUNNER[4], J. J. DAY[1]
[1]Neurobio., [2]Med. Scientist Training Program, Univ. of Alabama at Birmingham, Birmingham, AL; [3]Neurobio. and Anat., McGovern Med. Sch. at Uthealth, Houston, TX; [4]Indiana Univ., Bloomington, IN

Abstract: Exposure to drugs of abuse leads to reorganization of neural circuits and alteration of synapses, which outlive the direct effects of the drug and may contribute to addiction. The nucleus accumbens (NAc) has a significant role in motivation, reward, and reward-related learning, and has been identified as a key area in the development and maintenance of addiction. Furthermore, the prefrontal cortex (PFC) is known to be involved in decision making and impulsive behaviors, and this brain region sends glutamatergic projections to the NAc. However, the contribution of specific NAc neuronal populations and PFC efferents to the NAc in drug reward is still poorly understood. The present study aims to determine how neuronal activity in the NAc is altered in response to acute cocaine experience, and how these changes in activity influence reward and goal-motivated behavior. Neuronal activity was recorded *in vivo* from electrode microarrays bilaterally implanted in the NAc of freely-moving naive male Sprague Dawley rats that were exposed to either cocaine (10mg/kg) or saline. Acute cocaine exposure produced rapid but prolonged increases in activity of a subpopulation of neurons in the NAc, independent of environment or context. We were able to recapitulate similar response profiles in rat primary striatal neurons cultured on multielectrode arrays using the dopamine receptor type 1 (Drd1) agonist SKF38393 (1 μM), suggesting that acute increases in neuronal activity are occurring in Drd1-positive medium spiny neurons. In an additional group of animals, channelrhodopsin (ChR2) was virally expressed in the NAc to determine if photostimulation of neurons in this area is sufficient for reward-related behavior, as measured by real-time place conditioning. Preliminary data show that real-time place preference was generated by ChR2 photostimulation in the NAc core, but not the NAc medial shell. Together with circuit-tracing techniques, ongoing studies aim to combine *in vivo* optogenetic and electrophysiological approaches to investigate how projections from the PFC influence neuronal activity in the NAc, giving rise to motivated behaviors. Overall, these findings suggest that acute cocaine experience significantly increases medium spiny neuron firing in the NAc, and that this activity is sufficient to drive reward-seeking behaviors important in the development of addiction.

Title: Contingent versus non-contingent cocaine administration differentially affects the persistence of neuronal intrinsic plasticity of medium spiny neurons in the nucleus accumbens shell

Authors: *A. SEGEV, I. DELINT-RAMIREZ, S. KOURRICH
Psychiatry, UT Southwestern Med. Ctr., Dallas, TX

Abstract: The ability of cocaine to decrease neuronal intrinsic excitability of medium spiny neurons (MSNs) in the nucleus accumbens shell (NAcSh) has gained prominence in recent years as a novel adaptation contributing to addiction processes. However, it is unclear how the route of administration, contingency of drug administration, and drug regimen affect the persistence of cocaine-induced depression of neuronal intrinsic excitability (i.e., firing rate). To address this question, we used both non-contingent intraperitoneal (i.p.) cocaine (5 d, 15 mg/kg) and contingent cocaine self-administration (SA) (short protocol; 5 d intravenous, i.v.; 0.5 mg/kg) and assessed NAcSh MSNs firing rate at various delays after cessation of drug treatments. We found that non-contingent i.p. cocaine depresses NAcSh MSNs firing rate up to 15 d after the last exposure, consistent with previous studies, and dissipates by 30 d post-treatment. In contrast, contingent cocaine SA depresses NAcSh MSNs firing rate up to 30 d after cessation of drug taking. We also found that cocaine-induced firing rate depression occurs specifically in D1 receptor-expressing (D1R-) MSNs but not in D2R-MSNs. Moreover and similar to i.p. cocaine, blockade of the sigma-1 receptor (σ1) with BD1063, an endoplasmic reticulum chaperone protein, prevents cocaine from depressing NAcSh MSNs firing rate. Importantly, we found that σ1 blockade attenuates cocaine but not food SA, suggesting that BD1063 at the dose used here (40 mg/kg), does not alter basic locomotor behavior or pressing lever for a natural reward. Finally and similar to non-contingent i.p. cocaine, cocaine SA enhances physical interactions between σ1 and Kv1.2 potassium channels and surface Kv1.2. However, in contrast to i.p. cocaine, cocaine SA enhances total protein levels of Kv1.2. In conclusion, the mode of cocaine administration, i.e., non-contingent i.p. versus contingent i.v. cocaine, differentially affects both the persistence and the cellular adaptations underlying cocaine-induced firing rate depression in NAcSh MSNs. To investigate further the persistence of cocaine-induced firing rate depression following cocaine SA, we will also use a drug paradigm that induces incubation of cocaine craving (long protocol: 10 day cocaine SA; Pascoli et al., *Nature*, 2014), and assess its effects on the persistence of MSNs firing rate depression in the NAcSh.

Abstract: Drug addiction is a disease which represents a pathological change of the neural mechanisms of learning and memory in brain. Among brain regions affected, Nucleus Accumbens (NAc) is well-known for its role in drug addiction and studies have revealed NAc underwent profound changes in neuronal circuits and neurons functions after drug withdrawal. While the role of excitatory transmission in NAc is well-documented in drug-induced behavior change, less is known for inhibitory GABAergic inputs to MSNs neurons in the same process, nor the functional consequence of it. In NAc, the principle neuron type is medium spiny neurons (MSN) who comprise more than 95 % of all NAc neurons, and are the major output neurons of NAc. Besides these neurons another major neuron type is aspiny interneurons. MSNs are GABAergic projection neurons, they also form connections between each other in NAc. Among interneurons, GABAergic parvalbumin interneurons are important in regulating striatal output, while they only represent a few percent of NAc neurons. Here, we investigated whether drug withdrawal also induced changes in inhibitory transmission of NAc shell in cocaine-conditioned place preference (CPP). We found that following withdrawal from cocaine, both the excitatory and inhibitory inputs to MSNs of C57BL/6J mice endured persistent changes 2 weeks after withdrawal. We observed that cocaine withdrawal led to a reduction of inhibitory transmission. The frequency of mIPSCs significantly reduced in cocaine-treated mice; half-width of mIPSCs also were significantly different between mutant and wild type neurons. On the other hand, the mean peak amplitude of mIPSCs was not altered in MSNs. Using PV-Cre mice, we found activity change in PV+ interneuron activity following withdrawal contributed to disinhibition of MSNs. Our results indicate that both inhibitory and excitatory transmission in NAc endured

persistent change after withdrawal from cocaine, and intervention of the activity of PV+ interneurons might help to alleviate cocaine induced functional change in NAc.

Title: NMDA receptors in rat nucleus accumbens are dynamically regulated during withdrawal from cocaine self-administration

Authors: *D. T. CHRISTIAN[1], M. T. STEFANIK[1], A. M. WUNSCH[1], J. R. FUNKE[1], L. A. BEAN[2], C. A. BRIGGS[1], J. LYONS[1], D. NEAL[2], M. MILOVANOVIC[1], G. E. STUTZMANN[1], D. A. NICHOLSON[2], K.-Y. TSENG[3], M. E. WOLF[1]

Abstract: Cue-induced cocaine craving intensifies or incubates during withdrawal from extended-access cocaine self-administration. After prolonged withdrawal, the expression of incubated cocaine craving is mediated by GluA2-lacking, Ca^{2+}-permeable AMPARs (CP-AMPARs) that accumulate in the nucleus accumbens (NAc). We have focused on this phenomenon in the NAc core. Less is known about NMDAR plasticity during incubation, especially in the NAc core. However, it has been shown that elevated levels of GluN2B-containing NMDARs in the NAc shell during very early withdrawal are important for subsequent incubation (Lee et al., 2013; Ma et al., 2014). Furthermore, incorporation of GluN3- and GluN2B-containing NMDARs accompanies the increase in CP-AMPAR levels in the ventral tegmental area elicited by a single cocaine injection (Yuan et al., 2013). To evaluate NMDAR transmission in NAc core throughout the incubation process, we conducted whole-cell patch clamp recordings in NAc medium spiny neurons (MSN) at different withdrawal times following extended-access cocaine self-administration. By measuring evoked NMDAR-mediated synaptic responses across various membrane holding potentials (-80 to +40) in the presence of subtype selective blockers, we identified an increase in GluN2B-containing receptors beginning on withdrawal day 4-5. During a later period (withdrawal day 13-20), we detected atypical NMDARs not found in saline control animals that are comprised of GluN3 and GluN2B

subunits. These atypical NMDARs persisted in MSN synapses in late withdrawal (withdrawal day 39 and greater). We are presently conducting super-resolution light microscopy immunofluorescence array tomography to characterize the expression pattern of NMDAR subunits in control rats and following incubation of craving. Early results suggest differential expression of NMDAR subunits between treatment groups. Behavioral studies are also in progress to determine if GluN2B- or GluN3-containing NMDARs contribute to the incubation of cocaine craving. To date, our results indicate that alterations in NAc NMDAR function are dynamic and precede the incorporation of CP-AMPARs during withdrawal from extended-access cocaine self-administration, and are then maintained throughout the period when incubated drug seeking is maximal.

Title: Differential role of NMDA receptors GluN2C and GluN2D subunits in cocaine addiction

Authors: *G. P. SHELKAR, R. PAVULURI, J. LIU, P. GANDHI, S. M. DRAVID
Pharmacol., Creighton Univ., Omaha, NE

Abstract: Although the N-methyl-D-aspartate receptors (NMDARs) are shown to play an important role in cocaine induced behaviors including place preference, extinction, reinstatement and self-administration, the precise role of NMDARs subtype in these behaviors is not fully explored. This is critical since NMDARs subunits exhibits differential biophysical and pharmacological properties and in particular GluN2C and GluN2D subunits exhibit, lower sensitivity to Mg^{2+}-block and lack desensitization. This allows their activation under basal conditions facilitating firing or oscillatory activity. Therefore, we attempted to address the subunit specific role of NMDARs in cocaine induced behaviors. We studied cocaine (15 mg/kg, intraperitoneal) induced place preference, extinction and reinstatement in the two-chamber bias design conditioned place preference (CPP) apparatus. To study the role of GluN2C subunit, we employed a novel reporter mouse model in which an EGFP cassette is inserted in the intronic region between exons 6 and 7 (C57/B6-Grin2C$^{tm1(EGFP/CreERT2)}$) which also serves as a knockout

model. We also studied the role of GluN2D subunits by using GluN2D WT and KO animals. In the immunohistochemistry, we found enriched expression of GluN2C subunits in reward controlling brain regions including substantia nigra, prefrontal cortex and ventral striatum. The expression of GluN2C in these regions was in distinct cell-types. Additionally, GluN2D subunits expression is also reported in substantia nigra, ventral tegmental area and ventral striatum but in different cell-types compared to GluN2C. GluN2C WT and KO mice were found to have similar level of locomotor sensitization following repeated exposure to cocaine. However, the GluN2D KO animals showed reduced locomotor sensitization to cocaine as compared to WT animals. In CPP, the GluN2C WT and KO animals showed similar responses in conditioning and reinstatement sessions. However, GluN2C KO mice exhibited facilitated extinction compare to WT animals. Moreover, GluN2D KO animals exhibited deficits in extinction and reinstatement of cocaine CPP as compared to WT animals. Thus, the present study for the first time showed subunit specific role of GluN2C and GluN2D in cocaine CPP.

Title: AMPA receptor and mGlu1 expression and interactions in the nucleus accumbens core during the incubation of methamphetamine craving

Authors: *C. MURRAY[1], M. E. WOLF[2], M. MILOVANOVIC[2], J. FUNKE[2], A. CACCAMISE[2]
[1]Neurosci., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [2]Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: The incubation of cue-induced drug craving in rodents provides a model for persistent vulnerability to relapse in abstinent drug users. After prolonged withdrawal (>30 days) from extended-access cocaine self-administration, we have shown that incubated cocaine craving depends on the strengthening of nucleus accumbens (NAc) core synapses through the accumulation of homomeric GluA1 Ca2+-permeable AMPA receptors (CP-AMPARs) (Conrad et al., 2008). Their accumulation is associated with increased GluA1 translation (Stefanik et al., 2018). Furthermore, we have shown that CP-AMPAR accumulation is preceded and enabled by a downregulation of mGlu1 in the NAc, and that acutely activating mGlu1 removes CP-

AMPARs once they have accumulated (Loweth et al., 2014). In the NAc core of rats that had undergone incubation of methamphetamine (Meth) craving, CP-AMPARs similarly accumulate and are removed by acute mGlu1 activation (Scheyer et al., 2016). The goal of this project was to more thoroughly characterize CP-AMPARs and their relationship to mGlu1 expression during withdrawal from extended-access Meth self-administration. Contrasting with cocaine findings, biotinylation studies and quantitative co-IP studies starting from NAc homogenates failed to reveal increased GluA1 surface expression or an increase in homomeric GluA1 receptors at a Meth withdrawal time when CP-AMPARs can be detected electrophysiologically. Both results suggest local regulation confined to synapses. Studies are underway to assess the rate of GluA1 translation. Also contrasting with cocaine, a time-course study revealed no change in mGlu1 surface expression during Meth withdrawal. Next, we will determine if increasing mGlu1 tone in early withdrawal, via repeated injections of a positive allosteric modulator, prevents CP-AMPAR accumulation during Meth withdrawal. Overall, these results reveal that a similar strengthening of NAc core synapses via CP-AMPAR accumulation occurs during incubation of cocaine and Meth craving, but the mechanisms underlying this plasticity may differ between the two psychostimulants.

Title: Modulation of dopamine D2R sensitivity following cocaine exposure

Authors: *S. GONG[1], P. MARCOTT[2], C. FORD[1,2]
[1]Univ. of Colorado, Anschutz Med. Campus, Aurora, CO; [2]Dept. of Physiol. & Biophysics, Case Western Reserve Univ., Cleveland, OH

Abstract: The dorsal (Dstr) and nucleus accumbens (NAc) receives dopamine input from separate midbrain neurons, are associated with different behaviors, and are modulated differently by drugs of abuse. How dopamine release is encoded by postsynaptic D2 receptors in each region is poorly understood. To measure D2 receptor activation, we virally overexpressed G protein-coupled inward rectifying potassium (GIRK2) channels in medium spiny neurons (MSNs). Using the resulting outward GIRK current, we found that the sensitivity of D2 receptors

on MSNs was higher in the NAc than the Dstr (EC50: 1.3 vs 5.9 µM). The regional difference in D2 receptor sensitivity resulted from higher levels of $G\alpha_o$ expression in the NAc than Dstr. When coupled to D2-receptors we found that $G\alpha_o$ was more potent at activating downstream signaling cascades than $G\alpha_i$. The regional difference was not seen for other GPCRs as opioid receptors exhibited similar sensitivity across regions and equal sensitivity to leu-enkephalin when coupled to either $G\alpha_o$ or $G\alpha_i$. Similar to the results using GIRK channels, we found that axonal D2 receptors that regulate collateral transmission between MSNs also had higher sensitivity in the NAc than in Dstr (EC50: 2.1 vs 4.8 µM). To examine how exposure to drugs of abuse might alter D2-receptor signaling across regions, we chronically treated animals with cocaine for 7 days (20mg/kg; ip). We found that cocaine reduced the sensitivity of D2-receptors and decreased the expression of $G\alpha_o$ selectively in the NAc. No change was observed in levels of $G\alpha_i$ and only a single day of cocaine treatment had no effect on D2-receptor expression or $G\alpha_o$ expression. These results suggest that chronic cocaine exposure modulates D2 receptors sensitivity in the NAc by altering G-protein coupling.

Title: Effects of nucleus accumbens core-directed D_2 receptor antagonism on motivation for cocaine following the development of an addicted phenotype

Authors: *T. NESIL, A. BAKHTI-SUROOSH, W. J. LYNCH
Dept. of Psychiatry & Neurobio. Sci., Univ. of Virginia, Charlottesville, VA

Abstract: The transition from a non-addicted to an addicted stage is accompanied by a diminished role of nucleus accumbens (NAc) dopamine (DA) D_1 receptor (D_1R) signaling in motivating cocaine self-administration. However, it is not yet known whether such a shift also occurs for DA D_2R signaling. In this study, we examined the effects of DA D_2R antagonism in the NAc core on motivation for cocaine following extended access (ExA) cocaine self-administration and 14-days of abstinence, conditions previously shown to induce an addicted phenotype (defined as enhanced motivation for cocaine as compared to short access (ShA) controls). Adult male Sprague-Dawley rats (N=52) were trained to self-administer cocaine (1.5 mg/kg/infusion) under a fixed-ratio 1 (FR1) schedule with a maximum of 20 infusions. Following acquisition, rats were given either ShA (i.e., 3 additional FR1 sessions) or ExA to

cocaine (i.e., 24-hr access under a discrete trial procedure; 4 trials/hr, 1.5 mg/kg/infusion). Motivation for cocaine was then assessed after abstinence using a progressive-ratio (PR) schedule. The effects of NAc infusions of eticlopride (0, 0.3, 1.0, 3.0, and 10.0 µg/side) were tested once a stable PR baseline was established using a within-subject design (baseline was re-established after each dose). Intra-NAc D_2R antagonism produced differential effects on PR responding for cocaine in the ShA versus ExA group, with evidence to suggest an enhanced sensitivity in the ShA group. Specifically, while the low dose of eticlopride robustly decreased PR responding for cocaine in the ShA group (28% decrease), its effect was much less pronounced in the ExA group (16% decrease). Moreover, in the ShA group, higher doses of eticlopride did not further enhance the decrease in PR responding for cocaine indicating that a maximal effect, or ceiling, had been reached at the lowest dose. In contrast, in the ExA group, eticlopride dose-dependently decreased PR responding for cocaine with the greatest decreases observed at the two highest doses. Although a ceiling effect also occurred in the ExA group, it was not evident until higher doses (the 3.0 µg dose). These data consistent with our previous findings for D_1 receptor antagonism (Ramôa et al., 2014), and suggest that the role of NAcc D_2R signaling also becomes diminished with the development of cocaine addiction. However, in contrast to our previous findings with the D_1 receptor antagonism, motivation for cocaine was decreased in the ExA group following both medium and high doses of eticlopride (3.0 and 10.0 µg). These findings indicate that while the role of D_2 receptor in motivating cocaine use decreased with the development of addiction, it is still involved.

Title: SNC80, a delta opioid receptor agonist, reduces cocaine-induced increases in CRF mRNA in female rats

Authors: *K. L. CONNELLY, E. M. UNTERWALD
Ctr. for Substance Abuse Res., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: One of the largest obstacles to effective treatment of drug addiction is the high rates of relapse to further drug use. A major contributor to relapse is the negative affective state produced

by withdrawal. Withdrawal from chronic cocaine activates the hypothalamic-pituitary-adrenal (HPA) axis as well as other extrahypothalmic stress systems, including the extended amygdala. The delta opioid receptor agonist SNC80 attenuates cocaine withdrawal-induced anxiety in rats; however, the mechanism underlying this effect is unknown. This study first determined the time course of gene regulation following withdrawal from cocaine. Male and female adult Sprague Dawley rats (n=5-6/time) were injected with saline or cocaine in a binge-pattern for 14 days. Brains were collected 30 minutes, 24 hours, 48 hours, or 7 days after the last injection. The central amygdala (CeA), bed nucleus of the stria terminalis (BNST), and paraventricular nucleus of the hypothalamus (PVN) were microdissected and expression levels of CRF, CRFR1, and FKBP5 measured by quantitative RT-PCR. Results were analyzed for statistical significance with 2-way ANOVA and Bonferroni post-hoc tests. Following chronic cocaine, CRF mRNA was significantly elevated in the BNST at 30 minutes withdrawal, CeA at 24 hours and PVN at 48 hours. CRF mRNA was elevated at 24 hours in the BNST of females, but not males. FKBP5 mRNA was elevated in the PVN and BNST 30 minutes following cocaine and remained elevated in both regions at 24 hours. FKBP5 mRNA was also elevated in the CeA of females at 30 minutes. To test if SNC80 normalizes expression of stress-related genes, a separate cohort (n=7-8) received SNC80 (10mg/kg) twice after the last injection and brains were collected at 24 hours withdrawal. A significant interaction was found between chronic cocaine and SNC80 administration in the CeA of female rats. Specifically, SNC80 significantly reversed the increase in CRF mRNA produced by cocaine withdrawal. No significant differences were found in males. These studies demonstrate time-dependent alterations in stress-related gene expression during withdrawal from chronic cocaine. These results also provide insight into the anxiolytic effect of SNC80 following chronic cocaine, and suggest that delta opioid receptor agonists may be useful therapeutics for cocaine withdrawal-induced negative affect, particularly in females.

Title: The psychedelic 5-meo-dmt reverses key molecular changes caused by chronic cocaine across multiple brain structures

Authors: *J. O'SULLIVAN[1,2], K. J. MURPHY[2]
[1]Dublin, Ireland; [2]Neurotherapeutics Res. Group, UCD Conway Inst., Dublin, Ireland

Abstract: Addictive substances activate the reward circuitry in the brain, specifically the mesolimbic dopaminergic neurons originating in the ventral tegmental area projecting to the nucleus accumbens and other limbic structures including the dorsal striatum (DS), hippocampus, amygdala (Amyg) and regions of the prefrontal cortex. Chronic exposure to drugs like cocaine alters gene expression and produces long-term changes in such neural networks to underlie compulsive drug seeking and taking. One of the relatively persistent changes is the accumulation of ΔFosB, a highly stable variant of the FosB protein, in the NAc and connected brain circuitry following chronic drug exposure. ΔFosB, regulates drug-induced synaptic plasticity and is both necessary and sufficient for mediating various addiction-behaviours including the locomotor response to cocaine, conditioned place preference and increased drug self-administration. Targeting the molecular and transcriptional changes underlying alterations in behaviour, mood and cognition associated with persistent drug use may decrease the long-term risk of relapse. Psychedelic drugs produce strong subjective effects including changes in thought, mood, and perception. There is a growing body of evidence supporting the use of psychedelic drugs in treating various affective disorders. Beneficial effects have been reported in clinical trials of various serotonergic (5-HT) psychedelics in the treatment of major depressive disorder, end-of life anxiety and addiction. However, little is understood regarding the mechanism through which these drugs are mediating their benefits. For this study we used the 5-HT targeting psychedelic 5-methoxy-N,N-dimethyltryptamine (5-Meo). 5-Meo is a 5-HT receptor agonist at 5-HT-1A, 5-HT-2A and 5-HT-2C receptors.
The aim of the study was to investigate molecular changes induced by 5-Meo in mesolimbic circuitry following chronic cocaine exposure. Wistar rats were administered cocaine (15 and 20mg/kg i.p.) for 14 days and subsequently received a single administration of 5-Meo. Repeated cocaine induced stable changes previously established within the mesolimbic circuitry, including accumulation ΔFosB. 5-Meo was able to reverse the majority of measured changes induced by the repeated cocaine administration, including restoring expression levels of ΔFosB in the DS and Amyg to levels seen in saline-treated animals. The findings are discussed in the context of the use of psychedelics as treatments for addiction.

Title: A novel high affinity cocaine receptor inhibits dopamine reuptake via rapid degradation of the dopamine transporter

Authors: *M. M. HARRAZ, P. GUHA, A. MALLA, I. KANG, E. R. SEMENZA, P. CORTES, S. H. SNYDER
Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Increased dopamine (DA) concentration in the nucleus accumbens (NAc) mediates cocaine's stimulant effect. Cocaine directly inhibits the DA, serotonin and norepinephrine transporters at high nanomolar to low micromolar levels. Hence, presumably direct inhibition by cocaine of the DA transporter (DAT)-function mediates DA reuptake inhibition and increased dopamine signaling. Potentiation of DA neurotransmission, in turn, mediates cocaine's stimulant actions. However, multiple DA reuptake inhibitors do not produce psychotropic effects like cocaine. This might suggest that inhibition of DAT function is not sufficient to cause the stimulant actions of cocaine. Here, we identify the brain abundant signal protein -1 (BASP1) as a high-affinity cocaine receptor. Cocaine induces autophagy with extremely high potency through BASP1. Autophagy, in turn, selectively targets DAT for degradation resulting in DA reuptake inhibition. In primary cortical cultures, cocaine potently induces autophagy (at sub-nanomoalr levels). Stereotaxic injection of 10 femtomoles cocaine into the mouse NAc rapidly induces autophagy in presynaptic axonal terminals. Autophagy is involved in regulating behavior since blocking autophagy, using three different pharmacologic inhibitors, abolishes cocaine's stimulant effect. Autophagy selectively degrades DAT but not the serotonin or norepinephrine transporters in NAc. We performed anti-cocaine IP from primary cortical cultures. Using Mass spectrometry, we identified BASP1 as a cocaine binding protein. BASP1 is a membrane-associated protein that is enriched in axonal terminals of the forebrain. Using radioligand-binding assays, we demonstrate that BASP1 binds potently to cocaine (Kd 8.1 nM). Stereotaxic injection of a viral vector, capable of retrograde transduction, in NAc to knock down BASP1, inhibits cocaine's stimulant effect in mice. In addition, depletion of BASP1 prevents the potent autophagic actions of cocaine. Taken together, these data suggest a novel mechanism for the behavioral actions of cocaine through BASP1-mediated autophagy. Our findings support a model wherein cocaine acts through BASP1 to induce autophagy, which inhibits DA reuptake by degrading DAT. These findings identify BASP1 and autophagy as novel therapeutic targets for cocaine addiction.

Title: Modeling opioid maintenance therapy in rats: Effects of chronic buprenorphine and the biased mu-opioid receptor agonist TRV130 on relapse to oxycodone seeking

Authors: *J. M. BOSSERT[1], J. K. HOOTS[1], S. S. NEGUS[2], B. E. BLOUGH[3], Y. SHAHAM[1]
[1]Behavioral Neurosci., NIH, NIDA, IRP, Baltimore, MD; [2]Pharmacol, Toxicol, Virginia Commonwealth Univ., Richmond, VA; [3]Ctr. for Drug Discovery, Res. Triangle Inst., Research Triangle Park, NC

Abstract: Background: High relapse rates perpetuate opioid addiction and are a major obstacle in addressing the current U.S. opioid epidemic. Maintenance therapy with opioid agonists (buprenorphine, methadone) is an effective treatment for opioid addiction. Here, we establish an experimental procedure in rats trained to self-administer the prescription opioid oxycodone to compare the efficacy of an established treatment (buprenorphine) with that of a newer biased mu-opioid agonist, TRV130. **Methods:** We trained rats to self-administer oxycodone (0.1 & 0.05 mg/kg/infusion; 7 d/dose, 6-h/d) in Context A where infusions were paired with a discrete tone-light cue. We implanted Alzet osmotic pumps containing vehicle, buprenorphine (3, 6, or 9 mg/kg/d), or TRV130 (3, 6, or 9 mg/kg/d) and performed three tests: (1) responding for drug-paired discrete cues under extinction conditions in a non-drug context (Context B), (2) context-induced reinstatement of oxycodone seeking in Context A after extinction in Context B, and (3) reacquisition of oxycodone self-administration in Context A. **Results:** Chronic buprenorphine decreased responding reinforced by drug-paired discrete cues in Context B and reacquisition of oxycodone self-administration in Context A but did not significantly decrease context-induced reinstatement of oxycodone seeking. The experiment with TRV130 is currently ongoing and results will be reported at the meeting. **Conclusions:** We introduce a rat model to study the effect of agonist-based maintenance therapy on relapse to prescription opioid seeking. We showed that chronic buprenorphine reduced oxycodone seeking provoked by exposure to oxycodone-associated discrete cues and by exposure to oxycodone itself, demonstrating the predictive validity of the model.

Title: Long-term impact of acute stress on cognition, anxiety, and reinstated heroin seeking in male and female rats

Authors: *J. S. CARTER, A. M. KEARNS, R. A. WEBER, C. M. REICHEL
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Withdrawal symptoms following substance use disorders (SUD) and post-traumatic stress disorder (PTSD) reciprocally exacerbate one another. Symptoms induced by cessation of substance use culminate as stressors and lead to persistent and compulsive relapse behavior. In addition, PTSD can be triggered by, and contribute to, withdrawal-induced stress responses further increasing relapse potential. In a model used to mimic PTSD in rodents, restraint stress potentiated cocaine-seeking behavior and resulted in similar neuroplasticity consequences as cocaine. Here, we examined the effects of restraint stress paired with a neutral odor on heroin seeking, anxiety-related behaviors, and social interaction during withdrawal and relapse. Rats assigned to the stress group were restrained in a plastic tube that did not allow for mobility with exposure to a scent (*stress*), while other rats were exposed to the odor in a neutral cage with no restraint (*sham*) for two hours. All animals underwent heroin or saline self-administration (SA), anxiety assessments, and extinction followed by non-cued and cued reinstatement testing. During SA, stress rats acquired heroin faster than sham rats indexed as days to reach criteria. Intake (mg/kg) did not differ between stress conditions, but females had higher intake than males. In subsequent analyses, data were collapsed across sex due to similar patterns of responding. Sham and stress rats did not differ on locomotor activity in a novel environment, object recognition or compartment choice on the elevated plus maze. In a defensive burying test in which the stress-conditioned odor was presented, stress exposure resulted in higher indices of defensive behavior in stress rats. A history of heroin exposure in stress rats resulted in more time interacting with a conspecific during abstinence and greater reinstatement to heroin seeking relative to sham controls. Our results suggest that stress and heroin may be acting on shared mechanisms mediating approach/avoidance and defensive behaviors that increase stress reactivity during drug

abstinence. Additionally, our data support the hypothesis that acute stress exacerbates the risk of increased drug taking and reinstatement of heroin seeking.

Title: Reduced opioid intake and stress-induced relapse in fatty acid amide hydrolase (FAAH) knockout rats

Authors: *A. KARNATI[1], J. E. SCHLOSBURG[2]
[1]Pharmacol., Virginia Commonwealth Univ. Hlth. Syst., Richmond, VA; [2]Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The number one focus, for both treatment and public policy, is the ongoing opioid epidemic. Overdose rates in the United States have more than tripled over the last decade, with total deaths nearing 70,000 in the past year alone. It has, therefore, become a priority to identify possible agents that could combat excessive opioid use. Fatty acid amide hydrolase (FAAH) is an enzyme responsible for regulating the levels of the endogenous cannabinoid, anandamide (AEA), and inhibition of FAAH has been shown to convey resilience to chronic stressors. Based on the theoretical concept that excessive drug use and withdrawal is a form of chronic stress, we examined whether rats with FAAH genetically inactivated (knockout) are less likely to escalate their intake in extended-access drug self-administration, as well as reduced sensitivity to reinstatement of drug-seeking behavior.
Using long-term self-administration sessions (12 hr) indicates that rats with FAAH genetically inactivated, both males and females, exhibit decreased opioid consumption following temporary periods of withdrawal, resulting in reduced escalation of heroin and oxycodone intake. This is despite the fact that FAAH knockout rats show no differences in seeking for natural reward. We then set out to determine the effects of factors such as stress, drug re-exposure, and drug-associated cues on reinstatement of drug seeking behavior. Yohimbine, an alpha-2 adrenergic antagonist, produced a sympathetic stress response capable of heroin reinstatement, which was significantly reduced in the FAAH knockout rats. Cue-induced reinstatement showed significant increases in responding behavior across both genotypes in comparison to extinction values, while heroin primed reinstatement behavior did not show any significant differences in responding

behavior. Going forward, we hope to examine how the stress response relates to drug withdrawal and the averseness of withdrawal in FAAH knockout rats.

Title: Chemogenetic activation of prefrontal cortex - thalamic projections in the augmentation of heroin seeking induced by chronic food restriction

Authors: *A. CHISHOLM, E. FORTIN, D. RIZZO, V. MOMAN, R. DAUTH, A. GHEZZO, N. QUTEISHAT, J.-P. MANOLIADIS, A. CASOLA, U. SHALEV
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Drug addiction is a chronic disorder that is characterized by compulsive drug seeking and involves switching between periods of compulsive drug use, abstinence, and relapse. In both human addicts and animal models of addiction chronic food restriction has been shown to increase rates of relapse. Previously, our laboratory has demonstrated a robust increase in drug seeking following a period of withdrawal in chronically food-restricted rats compared to sated rats. To date, the neural mechanisms that mediate the effect of chronic food restriction on drug seeking have not been elucidated. Previous evidence from our laboratory indicates that chemogenetic activation of the paraventricular nucleus of the thalamus (PVT) reduces heroin seeking in food-restricted animals. A major excitatory input to the PVT is from the medial prefrontal cortex (mPFC). Thus, the objective of the current study was to study the effect of chemogenetic activation of the mPFC-PVT neuronal pathway on heroin seeking under food restriction conditions.
Male Long Evans rats were injected with a viral vector carrying an excitatory Designer Receptor Exclusively Activated by Designer Drug (DREADD) into the mPFC, and implanted with a guide cannula aimed at the PVT. Next, rats were trained to self-administer heroin over the course of 10 days (0.1 mg/kg/infusion; i.v.). Following training, rats were removed from the operant conditioning chambers and placed into drug withdrawal for 15 days. Over the withdrawal period, rats were exposed to a mild food restriction (90% of baseline body weight) or were given unrestricted access to food. On the 15^{th} day of the withdrawal period, a drug-seeking test was conducted in which rats were intracranially injected with CNO (1.0 mM) into the PVT, to activate the mPFC-PVT pathway, or vehicle. Injectors' placement was verified using

immunohistochemistry.
All rats reliability learned to self-administer heroin. As expected, food-restricted rats demonstrated an augmented heroin seeking during the heroin-seeking test in comparison to sated rats. Preliminary results suggest that chemogenetic activation of the mPFC-PVT pathway does not attenuate heroin seeking in food-restricted or sated rats.
These results suggest that the excitatory input from the mPFC to the PVT does not play a role in cue-induced heroin seeking.

Title: Hippocampal mTORC1 and ERK co-regulate drug context-induced heroin-seeking behavior

Authors: *R. A. FUCHS[1], *R. A. FUCHS[1], R. WANG[1], T. A. BROWN[1], S. TAN[1], J. A. HIGGINBOTHAM[1], D. T. LYSLE[2]

Abstract: The dorsal hippocampus (DH) plays a selective role in reinstatement of drug-seeking behavior elicited by exposure to a drug-paired environmental context. This study examined the roles of mechanistic target of rapamycin (mTOR; an element of mTOR complex 1, mTORC1) and extracellular signal-regulated kinase (ERK) signaling in the DH in drug context-induced heroin-seeking behavior. Sprague-Dawley rats were trained to lever press for in-signaled heroin infusions (diamorphine hydrochloride, 50 µg/infusion then 25 µg/infusion, IV) in a distinct environmental context made up of multimodal sensory stimuli. Next, rats received extinction training sessions in a different context during a minimum of seven daily sessions, until their responding reached the extinction criterion (≤ 25 active lever responses/session during at least two consecutive sessions). At test, rats received bilateral microinfusions of the mTOR inhibitor, rapamycin (0.25 or 0.5 µg/0.5 µl/hemisphere), the ERK inhibitor, U0126 (1 µg/0.5 µl/hemisphere), or vehicle into the DH or the dorsally adjacent trunk region of the

somatosensory cortex (SStr, anatomical control region). The rats were then placed into the previously heroin-paired or the extinction context, where lever presses were assessed without drug reinforcement, or into a novel context, where motor activity was monitored. Exposure to the heroin-paired context reinstated extinguished drug-seeking behavior relative to exposure to the extinction context. Intra-DH, but not intra-SStr, administration of rapamycin or U0126 significantly attenuated heroin-seeking behavior relative to vehicle. The manipulations did not alter motor activity. Together, these findings suggest that mTORC1 and ERK signaling pathways are necessary for the motivational effects of drug-associated contextual stimuli. Based on evidence of ERK-mediated regulation of mTORC1 activity in other systems, ongoing studies explore the possibility that mTORC1 and ERK interact to regulate drug-seeking behavior.

Title: Pain-induced negative affect is mediated via recruitment of the nucleus accumbens kappa opioid system

Authors: *N. MASSALY[1], A. R. POE[2], B. A. COPITS[2], L. HIPOLITO[3], T. MARKOVIC[2], S. LIU[4], R. NEVE[5], C. M. CAHILL[4], K. I. SHOGHI[2], R. W. GEREAU, IV[2], J. G. MCCALL[2], R. AL-HASANI[2], M. R. BRUCHAS[2], J. MORON-CONCEPCION[2]

Abstract: Prolonged negative affect significantly impacts quality of life for patients suffering from pain. These maladaptive emotional states can lead to severe depression, suicide, involuntary opioid overdose, and related neuropsychiatric comorbidities. The nucleus accumbens

(NAc) shell, which integrates both the aversive and rewarding valence of stimuli, exhibits allostatic changes in the presence of pain. In discrete regions of this structure, activation of the kappa opioid receptor (KOR), either by dynorphin, its endogenous agonist, or pharmacological ligands, acutely decreases the reinforcing properties of rewards and induces dysphoria and aversive behaviors. Using a wide range of complementary techniques including pharmacology, optogenetics, chemogenetics, physiology, biochemistry and in vivo positron emission tomography (PET) imaging, our current findings demonstrate that *in vivo* recruitment of NAc shell dynorphin neurons, acting through KOR, is both necessary and sufficient to drive pain-induced negative affect. Furthermore, we reveal that the presence of inflammatory pain impacts patterns of consumption of fentanyl using an intra-venous self-administration paradigm. Those particular patterns, where rats in pain display bursts of consumption interrupted by periods of "rest", could lead to the occurrence of respiratory depression and subsequent involuntary overdose. Taken together, our results provide evidence that adaptations in the kappa opioid system within the NAc shell represent a functional target for therapeutic intervention in pain that could circumvent affective disorders and may prevent life threatening episodes.

Title: Cellular specificity of matrix metalloproteinase activation on accumbens medium spiny neurons during heroin relapse

Authors: *V. CHIOMA, P. KALIVAS
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Heroin abuse is a leading cause of drug overdose-related deaths in the United States, highlighting a need for further research elucidating effects of maladaptive neuroadaptations following prolonged heroin use. Activation of the tetrapartite synapse in the nucleus accumbens core (NAcore), which comprises of pre- and postsynapse, astrocytic processes, and surrounding extracellular matrix (ECM), has been linked to increased relapse vulnerability. Specifically, degradation of the ECM by activated matrix metalloproteinases (MMPs) is involved in

extracellular synaptic remodeling both constitutively and transiently. Following chronic cocaine self-administration, cocaine-extinguished rats exhibit enduring increases in MMP-2 activity in NAcore compared to controls, and MMP-9 activity is transiently increased during cued reinstatement. Interestingly, heroin-extinguished rats do not show constitutive MMP activity, however, transient increases were elicited after 15 mins of cued heroin seeking. Although increases in MMP-2,9 fluorescence can be localized to the soma and dendritic processes of medium spiny neurons (MSNs) in the accumbens, it is unknown which specific cell types harbor changes in MMP activity under heroin-extinguished and cued reinstatement conditions. We hypothesized that D1-receptor expressing MSNs express increased colocalization with MMPs during transient cued heroin seeking, while D2-receptor expressing MSNs express increased colocalization following extinction. We used an AAV cre-dependent mCherry virus to transfect accumbens MSNs in D1 and D2 cre-dependent rats and measured the colocalization of activated MMP-2,9 after FITC-gelatin microinjection under extinguished and reinstated conditions. For D1 MSNs, we observed increased MMP-2,9 colocalization with dendritic surfaces in both extinguished and reinstated animals compared to yoked saline controls. While D2 MSNs showed increased MMP-2,9 colocalization only in heroin-extinguished animals, but MMP-2,9 colocalization after 15 min reinstatement was reduced to yoked saline levels. These findings reveal how NAcore extracellular matrix signaling underlying constitutive and transient synaptic plasticity relies in part on specific cell-types.

Title: Operant oral oxycodone self-administration in inbred strains of rats

Authors: X. FAN[1], T. WANG[1], E. REDEI[2], *H. CHEN[1]
[1]Dept Pharmacol, Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Over two million people in the US are suffering from substance use disorder related to prescription opioid pain relievers in the current opioid abuse crisis. Most of these opioid abusers started with oxycodone. Rapid onset of CNS effects is commonly required for animal models of drug abuse. Thus many current rodent models of oxycodone abuse use intravenous drug self-

administration. However, oxycodone in general is taken orally. We therefore investigated the abuse liability of oral oxycodone using an operant licking procedure in rats. Young adult Lewis rats were used. We also tested the WMI and WLI strains, which were developed as a genetic model of depression. Self-administration was conducted using operant chambers equipped with two lickometers. Licking on the active spout meeting a fixed ratio 5 schedule triggered the delivery of 60 ul oxycodone solution to the tip of the spout. A cue light was triggered to coincide with drug delivery. This was followed by a 20 s timeout, which was signaled by a tone. Rats received five 1-h daily training sessions, which were followed by five 6-h sessions on alternate days. Rats were not deprived of water or food. Water was available during the 6-h sessions. Rats licked significantly more on the active than on the inactive spout ($F_{1,809}=505.4$, $p<2e-16$) across the strains. In Lewis rats trained on 0.025-0.1 mg/ml, the highest dose resulted in the highest intake. This dose difference was no longer significant when access was prolonged to 6-h. Instead, a significant sex difference emerged ($F_{1,23}=4.3$, $p<0.05$, female > male). These rats were then further tested for cross-session dose response. Oxycodone intake (0.70+/- 0.11 - 0.85+/-0.20 mg/kg/session) was stable between 0.1-0.4 ug/ml, indicating self-regulation in drug intake. WMI and WLI strains were trained using 0.1 mg/ml oxycodone. Significant sex difference was found ($F_{1,15}=15.2$, $p=0.001$, female > male). No strain difference was found during the 1-h sessions. There was a significant interaction between strain and sex during the 6-h sessions ($F_{1,16}=15,8$, $p=0.001$). Tukey HSD posthoc showed oxycodone intake was WMI > WLI in males and WLI > WMI in females. Together, these data demonstrated that oral oxycodone is readily self-administered by three inbred strains of rats without prior operant training. Ongoing studies will investigate whether they will develop addiction-like phenotypes with extended drug exposure.

Title: Evidence for the role of biased signaling at the kappa opioid receptor in reducing conditioned place preference to morphine

Authors: *S. KASKI[1], J. GROSS[2], A. SCHROER[2], K. WIX[2], D. P. SIDEROVSKI[2], V. SETOLA[2]

Abstract: Activation of the kappa opioid receptor (KOR) has been shown to reduce the rewarding properties of opioid drugs in pre-clinical studies. Yet, the dysphoric side-effects of KOR agonists have limited their therapeutic potential. Advancements in KOR ligand pharmacology have identified G protein-biased KOR agonists that elicit a reduced level of aversion in pre-clinical studies. As opioid-induced reward is linked to dopamine release in the nucleus accumbens, and G protein signaling by KOR is known to reduce the release of dopamine in the nucleus accumbens, we hypothesized that G protein-biased KOR agonists may reduce the rewarding properties of co-administered opioid analgesics, while avoiding the therapeutically limiting side-effects of traditional KOR agonists. We tested this hypothesis in C57BL/6J mice using conditioned place preference and conditioned place aversion assays to measure drug-induced reward and aversion, respectively, and open field locomotion to assess for any locomotor suppression. In addition, the hot plate assay was used to assess the possibility that co-administration of a KOR agonist with an opioid analgesic may alter analgesic efficacy. Our results suggest an important role for beta-arrestin signaling in counteracting the rewarding effects of opioid analgesics in mice.

Title: Activation of amylin receptors in the nucleus accumbens shell reduces voluntary oxycodone taking in rats

Authors: *Y. ZHANG[1], N. S. HERNANDEZ[2], C. A. TURNER[2], M. KAHNG[2], V. R. WEIR[2], H. D. SCHMIDT[3]
[1]Biobehavioral Hlth. Sci., [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Dept Psychiatry, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Prescription opioid abuse has reach epidemic-like proportions in the United States. There is a critical need for innovative research aimed at identifying novel mechanisms underlying opioid addiction that could serve as targets for new medications to treat prescription

opioid abuse. Amylin is a peptide hormone co-secreted with insulin from pancreatic β-cells. Amylin crosses the blood brain barrier and activates amylin receptors expressed throughout the brain. Central amylin signaling has been shown to regulate food intake. Specifically, activation of amylin receptors in the mesolimbic dopamine system has been shown to reduce the hedonic value of food. Given that the reinforcing effects of natural rewards and drugs of abuse are regulated by the mesolimbic dopamine system, these findings suggest that central amylin signaling may play an important role in addiction-like behaviors. The goal of these studies was to determine the role of amylin receptors expressed in the nucleus accumbens (NAc) shell in voluntary oxycodone taking behavior. Our results indicate that systemic administration of amylin (5 and 10 µg/kg, i.p.) significantly attenuates oxycodone self-administration under both fixed-ratio 5 and progressive ratio schedules of reinforcement, suggesting that amylin may reduce the reinforcing efficacy of prescription opioids. In addition, administration of amylin (0.4 µg/µl) directly into the NAc shell significantly attenuated oxycodone self-administration in rats, further supporting a novel role for central amylin receptors in opioid addiction. To phenotype amylin receptor-expressing neurons in the ventral striatum, AAV-DIO-YFP was injected directly into the NAc shell of transgenic rats expressing Cre recombinase specifically in medium spiny neurons (MSNs) expressing dopamine type 1 receptors (D1R-expressing MSNs) and dopamine type 2 receptors (D2R-expressing MSNs). Our results show that amylin receptors are expressed by both D1R- and D2R-expressing MSNs in the NAc shell. Taken together, these findings demonstrate an important role for central amylin receptors in preclinical models of prescription opioid addiction.

Title: Economic choice in squirrel monkeys for studying opiate reward

Authors: *S. O. BROWN[1], R. YANES[1], E. B. THORNDIKE[1], H. P. JEDEMA[2], C. W. BRADBERRY[1]
[1]NIDA Intramural Res. Program, NIH, Baltimore, MD; [2]NIDA, Baltimore, MD

Abstract: There is a growing need to develop translational animal models to better understand choice behavior and other complex phenotypes relevant to addiction. The objective of the present

study was to develop a touchscreen approach to assess economic choice in squirrel monkeys. Using a touchscreen to present behavioral tasks allows for the presentation of diverse stimuli and recording of responses. In this study, 14 male squirrel monkeys (*Saimiri sciureus*) were trained daily, using response shaping, to target a stimulus on the touchscreen for delivery of a highly-palatable milk reward (30% sweetened condensed milk). Animals were then trained to perform a choice task in which two stimuli were simultaneously presented, with the number of symbols in each stimulus representing relative milk reward volumes. Twelve subjects learned to discriminate and consistently chose the larger milk reward on at least 85% of trials of the choice task, across 34 sessions. Subsequently, drug-naïve animals will be outfitted with intravenous catheters and trained with a separate set of stimuli to intravenously self-administer remifentanil, a short-acting μ-opioid receptor agonist. A choice distribution between drug and non-drug reward will be established which will be a primary metric for evaluating candidate treatments and investigating the neurocircuitry involved in this reward-seeking behavior.

Title: Fentanyl demand decreases after activation or blockade of μ opioid receptors in male rats

Authors: *L. R. HAMMERSLAG[1], J. BECKMANN[1], R. S. HOFFORD[2], M. T. BARDO[1]
[1]Psychology, Univ. of Kentucky, Lexington, KY; [2]Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Individuals exhibiting high levels of economic demand for abused illicit opioids, such as fentanyl, in the month preceding treatment are more likely to use illicit opioids during medication-assisted therapy (MAT; Worley et al., 2015, Drug Alcohol Depend, 148:62-68). Thus, lower demand prior to MAT is associated with better treatment outcomes. Because MAT directly affects the reinforcing properties of opioids, it is possible that those who fail to achieve abstinence from illicit opioids will nevertheless eventually reduce their economic demand for opioids, and thus be more likely to achieve abstinence with continued treatment. In the current study, we examined demand for the opioid fentanyl in rats following s.c. pre-treatment with buprenorphine (0, 0.3, 1.0, and 3.0 mg/kg), naltrexone (0, 0.1, 0.3, and 1.0 mg/kg), or morphine

(0, 0.3, 1.0 and 3.0 mg/kg). Using adult male Sprague-Dawley rats (n=8), we obtained estimates of two measures of economic demand, elasticity and demand intensity, using a threshold procedure. After rats learned to earn 5 µg/kg fentanyl on an FR1 schedule we transitioned to the threshold procedure on an FR3, where in each session they earned progressively smaller quantities of drug for each infusion across eleven 10-min intervals. Thus, during the course of a session the price for 1.0 µg/kg of fentanyl increased from 0.6 to 190 responses. Rats received 14 sessions with the threshold procedure before the first drug pretreatment test. The design was within-subjects, with two retraining sessions between tests, and each rat received each drug/dose combination according to a Latin-square design. Although the drugs tested have different effects on µ opioid receptors, we found that each of the drugs dose-dependently increased elasticity. Morphine and naltrexone also decreased demand intensity. Buprenorphine did not affect demand intensity during the test session, but went on to dose-dependently decrease demand intensity for at least 48 hours following the test session. Taken together, the results suggest that fentanyl demand is highly sensitive to activation or blockade of µ opioid receptors. The protracted effects of buprenorphine on demand suggest that patients who do not achieve full abstinence from illicit opiates may still benefit from medication-assisted therapy.

Title: Effects of morphine abstinence on oxycodone self-administration in male and female rats

Authors: *T. LINTZ, M. MAVRIKAKI, B. ESAYEAS, S. PAGE, E. CHARTOFF
McLean Hosp., Belmont, MA

Abstract: Opioid abuse is a major public health concern, and abuse often begins after withdrawal from a prescribed regimen of opioid painkillers. Opioid withdrawal can include intense, short-lived physical symptoms and protracted stress-like psychological symptoms, which are thought to contribute to addictive behavior through negative reinforcement mechanisms. Accumulating evidence indicates that women are more likely than men to abuse opioids to self-treat negative affect and pain, suggesting that withdrawal-induced negative affective states would increase abuse risk more in women than in men. An unmet clinical need is

a way to predict vulnerability to opioid abuse in patients. One possibility is the use of distress intolerance—defined as the perceived inability to tolerate negative physical (e.g. pain) and emotional states. Opioid abuse is associated with heightened levels of distress intolerance, raising the possibility that distress intolerance measures can be used to predict the likelihood of initiating prescription opioid abuse. Here we used acoustic startle, warm water tail flick latency, and somatic withdrawal signs as proxies for distress intolerance in adult male and female Sprague Dawley rats after a non-contingent regimen of escalating dose chronic morphine (5 - 30 mg/kg, 2xd for 12d; N=15-18/group). After 2-weeks of withdrawal from morphine (or vehicle), rats were implanted with jugular vein catheters and allowed to self-administer oxycodone (0.06 mg/kg/inf). We found that morphine withdrawal was associated with decreased tail flick latencies in male, but not female, rats—indicative of hyperalgesia. In addition, somatic withdrawal signs were increased in both sexes, whereas no change in acoustic startle amplitudes was observed in either sex. We found that male, but not female, morphine-withdrawn rats initially self-administered more oxycodone than vehicle-withdrawn rats, suggesting that morphine withdrawal increases vulnerability to initiate prescription opioid abuse specifically in males. However, after extended exposure to 1-hr/d self-administration sessions, intake normalized across groups. Furthermore, subsequent dose response functions indicated that morphine-withdrawn male and female rats were less sensitive to the reinforcing efficacy of oxycodone. Individual distress intolerance measures (e.g., acoustic startle, tail flick latency) were correlated with acquisition of oxycodone self-administration behavior, supporting our hypothesis that distress intolerance may be useful in predicting vulnerability to initiating prescription opioid abuse.

Title: Individual vulnerability to traumatic stress predicts increased demand for heroin and cue-induced reinstatement: A novel preclinical approach to study individual differences underlying traumatic stress and heroin use comorbidity

Authors: *C. DONOVAN[1], T. KAZAN[1], N. STAFFORD[1], E. HART[1], M. FORD ORTIZ[1], K. TAYLOR[1], D. HERTIA[1], M. DURANKO[1], R. C. DRUGAN[2], S. CHARNTIKOV[3]

Abstract: Heroin use is a prevalent epidemic in the U.S. Long-term consequences of stress and high rates of comorbidity between substance abuse disorders and mood disorders are critical risk factors in use, relapse, and overdose. Individuals with stress-related disorders are 3-5 fold more likely to develop substance use disorders. High prevalence rates coupled with poor treatment outcomes indicate a need for improved understanding of how stress reactivity contributes to the mechanisms of substance abuse. Preclinical models of traumatic stress have provided key insights into the effects of stress on self-administration of drugs of abuse. However, there is a significant gap in our understanding of how ethologically relevant stressor exposure contributes to heroin self-administration. Moreover, there are no studies investigating individual differences underlying reactivity to stress and subsequent stress-induced heroin self-administration. We hypothesized that greater individual vulnerability to stress would predict higher demand for heroin self-administration in a rodent model of heroin use. To this end, rats were first exposed to an inescapable swim stress and stress reactivity was assessed via a panel of behavioral tests of anxiety (open field, social anxiety) and depression (forced swim). Individual demand for heroin was assessed using behavioral economics approach. Subsequently, all rats underwent extinction and reinstatement tests with stress, non-contingent cues, or yohimbine as triggers. For the first time, our results demonstrate that individual reactivity to an ethologically relevant traumatic stressor predicted subsequent demand for heroin. Specifically, rats most vulnerable to traumatic stress had higher demand for heroin. Furthermore, our results demonstrate that responding in extinction was more persistent among rats with the lowest demand for heroin. Additionally, we show that non-contingent cue presentation reinstated heroin seeking and was significantly related with individual reactivity to traumatic stress. More studies are warranted to better understand individual vulnerability to stress and how stress relates to substance use and abuse if the goal is to develop effective individualized prevention and treatment approaches.

Title: Morphine experience and expectations alter 50-55 kHz ultrasonic vocalization counts and acoustic characteristics

Authors: *C. L. DUVAUCHELLE[1], C. CERVANTES[1], J. BAILEY[2], A. MARTINEZ[3], H. TRINH[4], N. MITTAL[5], N. THAKORE[1], W. MADDOX[6]

Abstract: Intense craving for the drug is a critical feature of opiate addiction and a strong trigger for drug use and relapse. Though positive affective states in rodents can be monitored in real-time through ultrasonic vocalization (USV) emissions, few animal studies have determined the role of emotional status as a motivational factor for opiate abuse. Existing USV reports on this topic have yielded conflicting findings on USV emission rate through varied methodologies involving short duration studies and experimenter-administered opioid intake. Our laboratory has developed a reliable, high-speed analysis technique, called WAAVES, that extracts USV calls and quantifies a number of acoustic characteristic (specifically, mean frequency, duration, bandwidth, and power) associated with each call. WAAVES allows us to examine all data generated from long duration, multiple-session experiments and to utilize advanced statistical techniques to examine acoustic characteristic differences across experimental conditions. In the present study, we examined the influence of the timing and delivery of morphine availability during a multi-session morphine self-administration experiment. In this study, we recorded USVs from two groups (Chronic and Intermittent) male Wistar rats prior to (e.g. “Anticipation”) and during 10 morphine self-administration sessions (e.g. “Session”). Both groups received the same number of self-administration sessions, but Chronic animals received daily sessions (5 days/2wks) while morphine access for the Intermittent group was on a variable schedule (e.g., 5 days/3wks). To determine if the USV acoustic characteristics from animals in the Chronic group can be distinguished from animals in the Intermittent group we used discriminant analysis to determine if a linear combination of the acoustic characteristics can successfully distinguish animals in each group. Results revealed significant differences in acoustic characteristics between animals in the Chronic and Intermittent group with 80% accuracy. As 50-55 kHz USV emissions are mediated through mesolimbic dopaminergic activation these data indicate that expectations of impending opiate drug use can significantly alter the pharmacological effects of morphine. These findings further suggest that drug expectation and drug experience may be important factors in opiate addiction and accidental overdose.

Title: Sex differences in oxycodone preference choice task

Authors: *J. GERSON[1,2]
[1]Brain Res. Inst., UCLA, Goleta, CA; [2]Psychological and Brain Sci., UCSB, Santa Barbara, CA

Abstract: Aim
Due to the continuing rise in opioid addiction, it is critical to discover the underlying factors that play a role in drug abuse. Sex differences are a relatively new focus of study in the field of opioid addiction and it is essential to add to this growing body of research.
Methods
To add to the growing body of research on the role of sex in addiction vulnerability, we examined differences in oxycodone (0.03 mg/kg/infusion, IV) and food (45 mg banana pellets) reinforcement between male (n=7) and female (n=8) Sprague Dawley, rats. Each rat was implanted with a jugular catheter before undergoing behavioral testing using a two-lever operant chamber model of drug self-administration. Rats underwent both single-reinforcer progressive ratio sessions for both oxycodone and food separately, followed by discrete choice sessions where both reinforcers were concurrently available.
Results
During choice sessions, males and females selected food more frequently than oxycodone, showing a significant preference for food over oxycodone ($F(3,26)=24.35$, $p<0.0001$). There were no significant differences in food vs. oxycodone preferences between sexes when both oxycodone and food were concurrently available. Furthermore no rats showed a preference for oxycodone (selecting drug on over 50% of trials). In contrast, when only oxycodone was available under progressive ratio, female subjects displayed significantly higher breakpoints for oxycodone than males ($U=8.0$, $p<0.05$).
Conclusions
These results indicate females exhibit higher motivation for oxycodone than their male counterparts but, at this dose, there are no sex differences in the choice model of addiction. These results are in agreement with previous work which demonstrated a higher breakpoint for female rats self-administering heroin and morphine on a PR schedule (Cicero et al., 2003) as well as with female rodents showing a greater propensity to display higher intake, seeking, and reinstatement for drug reinforcement (Becker & Koob, 2016).

Title: The reinforcing properties of heroin vapor self-administration

Authors: *A. GUTIERREZ[1], M. A. TAFFE[2]
[1]Dept. of Neurosci., [2]Cmte Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: Abuse of opioid drugs has reached epidemic proportions. Although many research studies address the reinforcing properties of opioid drugs, there is a gap in understanding route-specific effects. Smoking is a common route of heroin administration and of those who inject the drug, a large percentage initially began using by smoking it. E-cigarette technology has been steadily increasing in popularity, especially among young people, and reports exist of this technology being used to self-administer illicit drugs. The novelty of this technology means that few data exist to address the reinforcing effects of vapor delivery of illicit substances, including heroin. The aim of this study was to assess whether self-administration was supported by vapor delivery of heroin to rats using e-cigarette-type technology. Operant vapor chambers made of transparent acrylic boxes with response levers on each side were used. Each lever had a stimulus light directly over it which illuminated immediately after the reward lever was press, indicating a 20 second time-out interval. Air was routed through a commercially available vapor canister, triggered by computer to deliver reinforcers, directed though an air inlet in the front of the box and a vacuum cleared the chambers through an outlet located on the far end of the box. Heroin was prepared in propylene glycol at concentrations ranging from 1.0 mg/mL to 50 mg/mL. Adult female Wistar rats were given 1 h sessions in operant vapor chambers where they could lever-press for a 1 second puff of the vaporized heroin under a Fixed Ratio (FR) 1 reinforcement schedule for 5 sessions. The animals were then trained using a 50 mg/mL heroin solution. The 50 mg/mL concentration was found to be efficacious at increasing and maintaining heroin self-administration. Experiments using a progressive-ratio schedule and drug-substitution testing were then used to further probe the efficacy of vaporized heroin as a reinforcer. The findings of this study will help establish a model of heroin vapor self-administration and will provide insight into the harm potential of e-cigarette technology misuse.

Title: Polyaminergic agents modulate extinction and reinstatement of conditioned place preference in mice

Authors: *M. A. RUBIN[1], B. A. GIRARDI[2], S. FABRIN[2], A. L. WENDEL[2], F. R. MELLO[2], C. F. MELLO[2]

Abstract: Morphine addiction is a chronic disease that involves biological, cognitive and behavioral changes developed after the repeated and compulsive use of the drug. Drug addicts constantly relapse to drug seeking after recall of memories linked to the drug experience. The glutamatergic system is critically involved in specific processes of memory, including the modulation of dopaminergic neurons for the formation and maintenance of drug-induced drug-related memories. Polyamines are endogenous modulators of the NMDA receptor and it is not known whether polyaminergic agents modulate the extinction and reinstatement of morphine-induced conditioned place preference (CPP). In the current study we determined whether spermidine, a polyamine ligands, modulate the morphine CPP extinction and reinstatement. Adult male albino Swiss mice received saline (0.9 % NaCl, intraperitoneally (i.p.)) or morphine (5 mg/kg, i.p.) and were respectively confined to a black or a white compartment for 30 min for four consecutive days for CPP induction. The effect of spermidine (10-30 mg/kg, i.p.) or ifenprodil (0.1-1 mg/kg, i.p.), antagonist GluN2B NMDAr and agonist of the polyamine-binding site at the NMDA receptor, on the extinction and reinstatement of morphine CPP was studied. Spermidine and ifenprodil facilitated the extinction of morphine CPP *per se*. The treatment with spermidine during the extinction period impairs the reinstatement induced by a noneffective dose of morphine (1.25 mg/kg). Ifenprodil (0.1 mg/kg) prevented the effect of spermidine on the extinction of morphine CPP but did not prevent the reinstatement of CPP induced by morphine. These results suggest that spermidine facilitated the extinction and prevented the reinstatement of morphine CPP by modulating the polyamine-binding site at the NMDA receptor.

Title: Incubation of oxycodone craving after conflict-induced voluntary abstinence

Authors: *I. FREDRIKSSON, A. MINIER-TORIBIO, J. M. BOSSERT, Y. SHAHAM
Behavioral Neurosci. Br., NIH, NIDA, IRP, Baltimore, MD

Abstract: A major problem of the current U.S. opioid addiction epidemic is high relapse rates. To date, preclinical studies on relapse to prescription opioids like oxycodone are limited, and in these studies, relapse was determined after experimenter-imposed or forced abstinence periods. In humans, however, abstinence is often self-imposed and drug-seeking episodes typically involve a conflict situation where addicts choose between the desire to experience the drug's rewarding effects and the adverse consequences of drug seeking. Here, we introduce a rat model of relapse to oxycodone seeking after conflict-induced voluntary abstinence. We trained male and female (n=12-14/sex) rats to self-administer oxycodone (0.1 mg/kg/infusion, 6-h/d) for 14 days. Next, we tested the rats for relapse to oxycodone seeking under extinction conditions on abstinence day 1. We then introduced an electric barrier near the drug-paired lever and increased the barrier shock intensity daily from 0.1 to 0.4 mA over days until the rats achieved abstinence (conflict phase). We tested the rats for relapse in the absence of shock or drug on abstinence day 15 or 30. The rats showed a time-dependent increase in drug seeking after conflict-induced voluntary abstinence indicated by higher lever presses on abstinence day 30 compared to day 1 or day 15 (incubation of oxycodone craving). There were no sex differences in either oxycodone self-administration or incubation of oxycodone craving. We introduce a conflict-induced voluntary abstinence procedure to study mechanisms of incubation of opioid craving after cessation of drug taking by adverse consequences associated with drug use.

Title: Relapse to fentanyl seeking after choice-based voluntary abstinence

Authors: *D. J. REINER[1], O. M. LOFARO[1], M. VENNIRO[2], Y. SHAHAM[3]
[1]IRP-NIDA, NIH, Baltimore, MD; [2]Natl. Inst. On Drug Abuse, Baltimore, MD;
[3]IRP/NIDA/NIH, Baltimore, MD

Abstract: Background: The current prescription opioid crisis is a major public health problem. A high relapse rate is a core feature of addiction to prescription opioids like fentanyl. To date, there are few preclinical studies of prescription opioid relapse, and these studies have used animal models in which the abstinence period prior to relapse is experimenter-imposed or forced. However, in humans, abstinence is often self-imposed, because the former drug user chooses nonaddictive alternative rewards while the drug is still available. We recently developed a rat model of choice-based voluntary abstinence and here we used the model to study relapse to fentanyl seeking.
Methods: We first trained male and female rats (n=14/sex) to self-administer palatable food pellets for 6 days (6-h/day) and fentanyl (2.5 microgram/kg/infusion, i.v.) for 12 days (6-h/day). We then assessed relapse to fentanyl seeking in extinction tests, after 1 and 14 abstinence days. Between tests, rats underwent voluntary abstinence, which was achieved through a discrete choice procedure between drug and palatable food (20 trials/day).
Results: We found no sex differences in fentanyl self-administration or in the preference for palatable food over fentanyl during discrete choice trials. In both sexes, there was no difference in fentanyl seeking during the relapse tests, indicating an absence of a time-dependent increase in fentanyl seeking (incubation of drug craving) following food choice-based voluntary abstinence.
Conclusions: Our data extend previous findings that food-choice voluntary abstinence prevents incubation of heroin craving. We currently explore brain mechanisms of relapse to fentanyl seeking after voluntary abstinence.

Title: Confirmatory factor analysis of drug self-administration in rats

Authors: *Y. SWAIN[1,2], M. GADES[1], P. MUELKEN[2], M. G. LESAGE[2,1], M. MCGUE[1], J. G. GEWIRTZ[1], A. C. HARRIS[2,1]

Abstract: Individual differences in susceptibility to addiction in humans have been widely studied through confirmatory factor analysis (CFA), a statistical method that identifies “latent” variables (variables that are not measured directly) that reflect the common variance among a larger number of related measures. Despite its widespread application in clinical research, CFA has been virtually unused in preclinical addiction models. The current study used CFA to examine the latent factor structure between six measures of i.v. morphine self-administration (SA) in rats (e.g., acquisition, demand elasticity, reinstatement). Because individual differences in multiple measures of abuse liability in humans have been shown to be best accounted for by one single latent factor, a one-factor model was fitted to the data. Results from a chi-squared test of overall model fit indicated that the one-factor model did not fit the data well. Standardized factor loadings for demand intensity (0.64) and morphine-induced reinstatement (0.74) were the highest, suggesting that these measures are the strongest indicators of the latent factor. However, extinction and stress-induced reinstatement loadings did not significantly differ from 0, suggesting that they are not related to the latent factor. These results contrast with human studies, which have indicated a common drug addiction factor underlying multiple measures of addiction propensity, and instead suggest specific factors contributing to some SA measures. Additional analyses are needed to explore and identify multi-factor models of drug SA measures. Further establishing CFA approaches in preclinical neuropsychopathology will provide more reliable core measures of disease vulnerability in animal models for further cellular, molecular, and genetic analysis, as well as a quantitative approach for studying predictors of individual differences in addiction vulnerability.

Title: Genetic variance in prescription opioid abuse: A comparison between 129 mouse substrains

Authors: *K. K. SZUMLINSKI, M. A. COELHO, S. FERDOUSIAN, N. STAILEY, S. M. JIMENEZ, E. K. F. FULTZ, 93106-9660
Univ. California-Santa Barbara, Santa Barbara, CA

Abstract: Genetic factors are theorized to contribute to the substantial inter-individual variability in opioid abuse/addiction. With intense concern over the high rate of prescription opioid abuse and related deaths, we have sought to advance the behavioral genetics of prescription opioid abuse by comparing oxycodone and/or fentanyl self-administration between inter-related 129 mouse substrains. When provided with the opportunity to consume low-dose solutions under both home-cage drinking and operant-conditioning procedures, our earlier studies identified the 129S1/SvlmJ (S1) and 129P3/J (P3) mouse substrains, respectively, as low and high opioid-taking. However, in follow-up studies, S1 mice failed to acquire sucrose self-administration under various operant-conditioning procedures, suggesting a motivational or operant-learning deficit in this substrain. Subsequent place-conditioning studies indicate robust oxycodone-induced place-preference in P3, but no conditioning in S1, mice. However, the lack of conditioning exhibited by S1 mice reflected a pronounced immobility during testing, which confounded data interpretation. Although S1 mice exhibited lower sucrose consumption in the home-cage, compared to P3 mice, both substrains exhibited an escalation of sucrose intake with repeated opportunities to drink. Intriguingly, S1 and P3 mice initially exhibited equivalent oxycodone and fentanyl consumption in the home-cage, however opioid intake escalated only in P3 mice with repeated opioid experience. No sex differences were observed for any of our measures. These data provide additional evidence for robust differences in opioid addiction-related behaviors between P3 and S1 substrains, suggesting that P3 mice harbor allelic variance that not only augments opioid reward/reinforcement but that promotes a loss of control over

prescription opioid intake. These findings argue further the utility of 129 mice for the study of the behavioral genetics of prescription opioid addiction.

Title: Distinct neural mechanisms of monetary and drug reward seeking decisions under uncertainty

Authors: C. HUTSLAR[1], R. POLK[1], E. ATKINSON[1], J. MACY[2], L. CHASSIN[4], C. PRESSON[4], P. FINN[1], *J. W. BROWN[3]
[1]Psychological & Brain Sci., [2]Sch. of Publ. Hlth., [3]Indiana Univ., Bloomington, IN; [4]Psychology, Arizona State Univ., Tempe, AZ

Abstract: A handful of studies have explored the neural effects of addictive drug administration during fMRI. Still, little is known about the neural mechanisms of choice and contingent drug reward with actual drug reward delivery during scanning. To explore this question, we used human fMRI to directly compare gambling under uncertainty for monetary reward vs. drug reward. Each subject was a heavy smoker who had abstained from nicotine prior to the scan session, as verified by exhaled carbon monoxide measures. The same subjects gambled for drug reward on one day and monetary reward on another day, with the order of days counterbalanced across subjects. They were presented on each trial with a gambling task, in which they had to make a two alternative forced choice between a risky decision with uncertain reward vs. a safe decision with a certain reward amount. The gambles varied independently in expected value, probability of failing to win reward, and the level of risk (i.e. variance of the gamble outcome distribution). Drug reward was administered via a novel MR-compatible electronic cigarette with a valve to control access and an airflow monitor to measure vapor intake. Greater drug reward was administered by opening the airflow valve for a longer period of time after each trial. Results: Greater variance of a gamble for nicotine was associated with greater activation in the dorsal anterior cingulate cortex (BA32), while gamble variance for monetary reward did not show a significant correlation in the same region. Furthermore, there was a striking reversal of error effects in money vs. nicotine reward: losing minus winning a monetary gamble was

associated with greater dorsal cingulate and bilateral anterior insula activation, but the effect was reversed for nicotine reward, such that winning was associated with greater activity than losing in the same regions. All results survived whole brain cluster correction. The results challenge the notion that monetary and drug reward are processed similarly in the brain and highlight the importance of studying drug use decisions directly with neuroimaging rather than using monetary reward as a proxy.

Abstract: The brain features of nicotine dependence have yet to be studied in a large sample of individuals using high-resolution MRI. Uncovering brain profiles of nicotine dependence will inform the nature of addiction and treatment. All participants (N=110) were daily smokers and categorized into three levels of nicotine dependence (mild, moderate, high) based on criteria established from a large representative study (Schnoll et al, 2013). Following overnight smoking abstinence, participants received an MRI assessing morphology, blood perfusion, and activation to three cognitive tasks (stop-signal, monetary incentive, and cue reactivity). The cue reactivity task required participants to respond to smoking and neutral images.MRI data were processed using pipelines from the Human Connectome Project (Glasser et al., 2013). Differences in reaction time and brain activations for smoking vs. neutral images were calculated. Behavioral data were analyzed using a one-way ANOVA with dependence as a between-subjects factor. Brain data were submitted to non-parametric permutation tests using a general linear model with significance set using a whole-brain correction $p<.05$ from 5000 permutations. Results indicated the dependence levels failed to differ on behavioral performance. However, brain activity to

smoking vs. neutral images differed across all levels with activations in visual, parietal, prefrontal, and insular cortices (Fig1A). Post-hoc tests indicated the high vs. low dependence groups differed in activations in bilateral inferior frontal cortices. Robust differences were evident in the high vs. medium dependence groups in bilateral orbitofrontal and right insular cortex (Fig1B&C). Analyses suggest that nicotine dependence modulates brain activity to smoking cues. Results point to a linear trend, such that the highest level of dependence is characterized by the highest activations in key regulatory and somatosensory regions. Future studies are needed on how treatments and tobacco regulation strategies targeting nicotine dependence may attenuate brain differences.

Title: Obese smokers show altered reward-related functional connectivity associated with level of nicotine dependence

Authors: *A. V. ELY[1], K. JAGANNATHAN[2], K. A. KETCHERSIDE[2], C. NUTOR[2], T. FRANKLIN[2], R. WETHERILL[2]
[1]Christiana Care Hlth. Syst., Newark, DE; [2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Background: Obesity and cigarette smoking are two of the leading causes of chronic illness and preventable death in the United States. Obese smokers are thus at particularly high risk for lower quality of life and shorter life span. Prior findings show obese smokers have altered smoking cue-potentiated brain responses compared to lean smokers; however, whether differences exist in functional connectivity that may contribute to these comorbid conditions remains unstudied.
Methods: This study used arterial spin-labeled (ASL) perfusion fMRI to compare resting state connectivity between 26 lean and 25 obese treatment-seeking individuals with nicotine use disorder (NUDs). Data were preprocessed in DPARSF toolbox, which is based on SPM8 within a MATLAB environment. *A priori* functionally-defined seed regions were used to identify differences in reward-related (ventral striatum, VS/orbitofrontal cortex, OFC) and inhibitory-related (middle frontal gyrus, MFG) connectivity. Self-report measures of nicotine dependence and craving were acquired.
Results: Controlling for age and sex, MFG connectivity did not differ significantly between groups. In contrast, obese NUDs showed significantly reduced VS/OFC connectivity with the bilateral anterior insula compared to lean NUDs. Among obese NUDs, greater connectivity between VS/OFC and left insula was related to a longer smoking history and higher scores on the Fagerstrom Test for Nicotine Dependence. Correlations were not seen among lean participants.
Conclusions: This differential pattern of functional connectivity is consistent with our research showing that obesity uniquely impacts neurobiology in NUDs. Results suggest obese individuals may fail to appropriately integrate interoceptive or motivational states with reward response. This may contribute to severity and maintenance of nicotine dependence. Future studies are necessary to elucidate the interaction between obesity and cigarette smoking, and impact on treatment outcome.

Title: Functional connectivity of the human ventral striatum during smoking abstinence and pharmacologic administration

Authors: *R. POUDEL[1], M. J. TOBIA[1], M. C. RIEDEL[1], A. R. LAIRD[1], T. J. ROSS[2], B. SALMERON[2], E. A. STEIN[2], M. T. SUTHERLAND[1]
[1]Florida Intl. Univ., Miami, FL; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Extensive animal and human research implicates the ventral striatum (VS) and its interconnected circuitry in reward processing and addiction. Dysregulated VS resting-state functional connectivity (rsFC) has been linked with nicotine use and a failure to maintain abstinence. However, differential rsFC of striatal subregions remains to be more fully characterized as a function of a smoking trait (smoker vs. nonsmoker) and pharmacological state (nicotine withdrawal vs. administration). As such, we performed seed-based rsFC assessments on fMRI data (8 min) collected from overnight abstinent smokers (n=24; 12 females; age=36 ±10) and nonsmokers (n=20; 10 females; age=30±7) following administration of nicotine (via patch), varenicline (via pill), both, or neither (placebo-controlled). We employed two bilateral VS seeds (right and left superior VS seeds [RVSs, LVSs] and right and left inferior VS seeds [RVSi, LVSi]) and assessed group effects (smoker vs. nonsmoker collapsed across drug sessions in independent samples t-tests) and drug effects (e.g., nicotine vs. placebo in a linear whole-brain mixed effects ANOVA using AFNI's 3dLME). Regarding group effects, smokers (relative to nonsmokers) showed significantly greater rsFC between the RVSi seed and the medial prefrontal cortex, parahippocampal gyrus, and anterior cingulate cortex, whereas the LVSs seed showed greater rsFC with the superior frontal gyrus (Fig. 1A.). Regarding drug effects, we observed that among smokers, nicotine (vs. placebo) administration significantly reduced the rsFC between the RVSs seed and a cluster encompassing the insula, putamen, and parahippocampal gyrus ($P_{voxelwise}<0.005$, cluster extent: 213 voxels, $P_{corrected}<0.05$) (Fig. 1B.). No effect of Varenicline was observed. Taken together, these outcomes indicate that the rsFC of VS subregions are differentially impacted as a function of a smoking trait (smokers vs. nonsmokers) and the current pharmacological state of a smoker (nicotine vs. placebo).

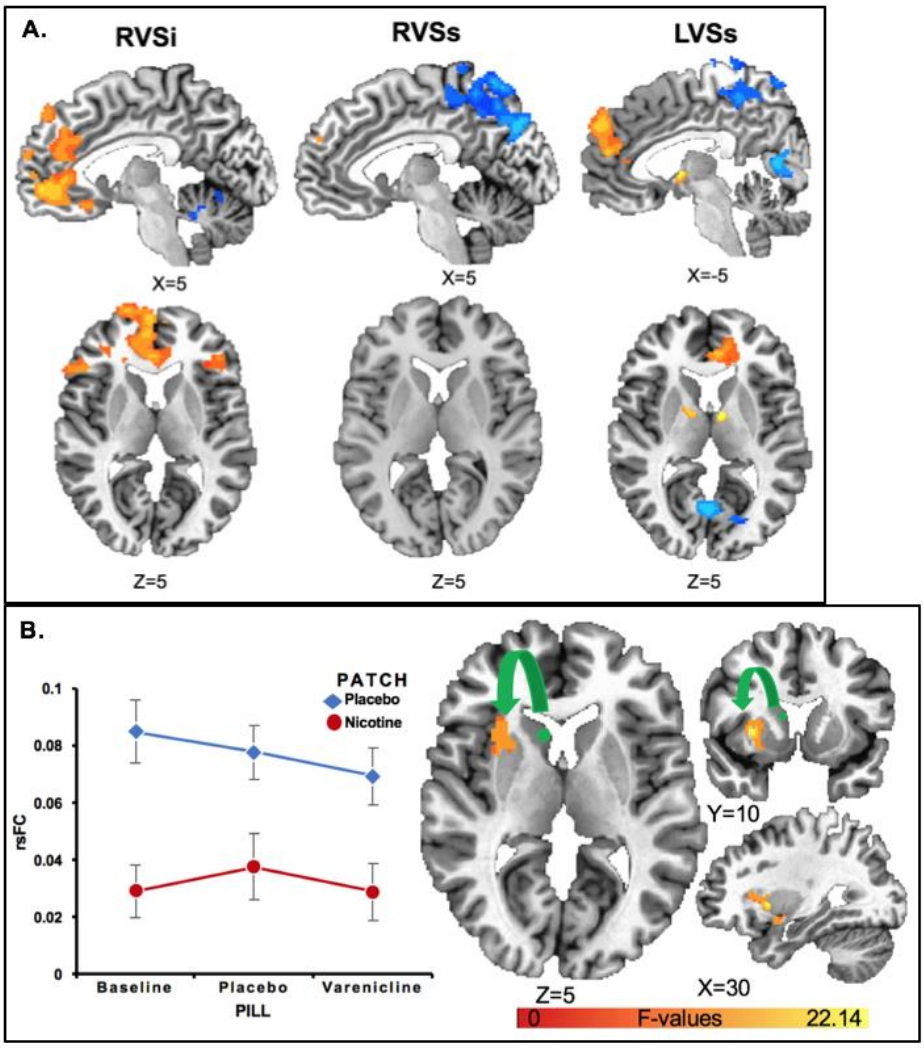

Fig. 1: Group difference and drug effects on rsFC of ventral striatum subregions. A. Group effect (smoker vs. nonsmoker): Significant whole-brain rsFC difference map for ventral striatal seeds: right ventral striatum inferior (RVSi), right ventral striatum superior (RVSs), left ventral striatum superior (LVSs). Orange (smokers > nonsmokers), blue (nonsmokers > smokers). Cluster corrected using ETAC. **B.** Drug effect (nicotine vs. placebo): Significant cluster showing effect of patch on RVSs (green circle) rsFC.

Title: WGBS reveals genome-wide differential methylation of occupational exposure to coal mining and tobacco smoking

Authors: *M. WANG[1], M. D. LI[2]
[1]Zhejiang Univ., Zhejiang Province, China; [2]Inst. NeuroImmune Pharmacol., Seton Hall Univ., South Orange, NJ

Abstract: DNA methylation is a crucial epigenetic modification that plays essential roles in multiple biological processes and is susceptible to many environmental factors, such as air pollution and smoking. Here, we conducted WGBS (whole genome bisulfite sequencing) on 120 samples, including 36 underground miners, 36 ground miners and 48 non-miners. Through the comparison of underground miners with non-miners, we identified 300 significant ($P < 0.1$, 1-step Šidák multiple-testing correction) differentially methylated regions (DMRs). Strikingly, we found more than expected (73.3%) significant DMRs showing gradient methylation levels among the three groups, i.e., the DMR methylation levels of ground miners were intermediate between the two other groups. Subsequent GO analysis of 176 genes associated with DMRs with gradient methylation levels revealed 21 significantly enriched biological process ($P < 0.05$, Benjamini-Hochberg correction), primarily related to oxidative stress (mitochondrion regulation, glutathione metabolic process and sulfur amino acid metabolic process) and immune response (interferon-gamma production and antigen receptor-mediated signaling). Considering the fact that the most enriched terms group was related to mitochondrion regulation, we investigated whether coal mining have an influence on mitochondrial DNA copy number (MtDNAcn), defined as the ratio of WGBS coverage of mitochondrial genome to nuclear genome. We found that MtDNAcn of underground miners and ground miners were significant more than non-miners ($P = 0.01$ and $P = 0.007$); however, there was no significant difference between underground miners and ground miners. In sum, our results showed the effects of detrimental occupational exposure on DNA methylation and revealed potential implicated biological processes.

Title: Implication of critical role of GluN3A in nicotine dependence by both genetic association and molecular functional studies

Authors: *C. J. LI[1], M. D. LI[2]
[1]Zhejiang Univ., Zhejiang, China; [2]Inst. NeuroImmune Pharmacol., Seton Hall Univ., South Orange, NJ

Abstract: Nicotine dependence (ND) is a chronic brain disease. The glutamate receptor gene, ionotropic N-methyl-D-aspartate 3A (*GluN3A*), is a crucial subunit of N-methyl-D-aspartate receptors (NMDARs), which plays an essential role at synaptic plasticity in the brain by regulating ion flow across membranes in response to glutamate signaling. Although both common and rare variants of *GluN3A* have been associated with ND in the European-American (EA) and African-American (AA) samples, no reported study has investigated the association between *GluN3A* and ND in Chinese smokers. We thus performed an association study of 16 single nucleotide polymorphisms (SNPs) in *GluN3A* with ND in 2,616 Chinese individuals. Individual SNP-based association analysis indicated that SNP rs1323423 was significantly associated with FTND score (P = 0.0026). Haplotype-based association analysis revealed that two major haplotypes, formed by rs1323423-rs10989591, were significantly associated with FTND score (P = 0.0183). Considering the critical role of *GluN3A* in regulating neurotransmission and its association with ND in human study, we used CRISPR/Cas9 technique to edit *GluN3A* in HEK293T cells, which showed that *GluN3A* expression level affects expression of other NMDA subunit receptors. Moreover, we demonstrated that nicotine at a concentration of 100 μM decreased expression of *GluN3A* in both SH-SY5Y and HEK293T cells at both the RNA and protein levels, respectively. Taken together, by using a combined approach of both genetic association and molecular studies, we provided novel evidence for the involvement of *GluN3A* in developing ND, suggesting that this gene has a great effect on the molecular mechanisms of ND-related behaviors.

Title: Role of a 3'utr polymorphism (rs2304297) in the human alpha 6 nicotinic receptor subunit gene in adolescent substance use

Authors: *A. CARDENAS[1], S. LOTFIPOUR[2]
[1]Pharmacol. Sci., [2]Emergency Medicine, Pharmacol. Sci., Univ. of California, Irvine, Irvine, CA

Abstract: The alpha 6 (<**α**;6>) nicotinic acetylcholine receptor (nAChR) subunit is expressed in the dorsal and ventral striatum as well as the ventral tegmental area and substantia nigra. <**α**;6> nAChRs exhibit peak expression during adolescence, which coincides with the initiation and use of nicotine and other drugs of abuse. Evidence has demonstrated that in adolescent humans, a single nucleotide polymorphism, rs2304297, in the 3-untranslated region (3'UTR) of the <**α**;6> nAChR gene, $Chrna6^{C123G}$, is associated with enhanced substance use and structural enlargement of the striatum. Given the localization of <**α**;6> nAChRs in reward circuitry and the developmental peak expression during adolescence, modifications in subunit quantity and/or function may significantly influence drug seeking behavior. The mechanisms underlying the functional role of the $Chrna6^{C123G}$ genetic variant are unknown. One hypothesis may be a reduction in mRNA stability via disruption of microRNA (miRNA) binding at the site of the $Chrna6^{C123G}$ polymorphism. To test this hypothesis *in vitro*, we used a 3'UTR-reporter assay containing the $Chrna6^{C123G}$ genetic variants fused to a luciferase reporter gene. We identified potential miRNAs that are predicted to bind to the $Chrna6^{C123G}$ genetic variants using *in silico* analyses. Our data illustrate that the $Chrna6^{C123G}$ genetic variant did not influence miRNA binding, suggesting that an alternative mechanism of action independent of miRNAs could be involved. To further investigate the mechanisms, our lab generated a viable 3'UTR humanized mutant rat line via CRISPR/Cas9 genomic engineering. Using our animal model, our study aims to understand the genetic, environmental, and neurobiological mechanisms mediating the effects of the $Chrna6^{C123G}$ genetic variant on adolescent substance use. Our findings could have a important impact in the scientific and public health communities which may contribute to the development of improved prevention and intervention strategies for addiction.

Title: Understanding the molecular basis of nicotine addiction by integrative functional genomic analyses in a rat model and hiPSC-derived DA neurons

Authors: *A. KOZLOVA[1,2], S. ZHANG[1,2], T. UJAS[2], M. STREIT[1], H. ZHANG[1], A. SANDERS[1,2], Z. PANG[3], P. GEJMAN[1,2], P. VEZINA[2], J. DUAN[1,2]
[1]Northshore Univ. Healthsystem, Evanston, IL; [2]Dept. of Psychiatry and Behavioral Neurosciences, Univ. of Chicago, Chicago, IL; [3]Dept. of Neurosci. and Cell Biol. and Child Hlth. Inst. of New Jersey, Rutgers Univ., New Brunswick, NJ

Abstract: Cigarette smoking is the largest preventable risk factor for mortality and a primary risk factor for many chronic diseases. Tobacco consists of more than 4,800 compounds, among which nicotine (NIC) is responsible for the addictive nature of smoking. Repeated exposure to NIC leads to NIC sensitization, which enhances the self-administration (SA) of NIC and other stimulants and is thus a key process in the development of NIC-related addictive behaviors in rats. NIC sensitization and SA in rats correlate with neurobiological changes in multiple brain regions, however, the molecular basis of these changes has yet to be determined. We aim to identify translatome profiles (RNA transcripts bound to ribosomes and actively involved in protein synthesis) in NIC addiction-relevant brain regions following NIC sensitization and in dopaminergic (DA) neurons derived from human induced pluripotent stem cells (hiPSCs). We are using F1 progeny of two inbred rat strains [Fischer-344 (F344) and Brown Norway (BN)] to analyze allele-specific NIC sensitization associated translatome changes. To this end, we have generated F1 F344/BN hybrid rats from F344/NHsd and BN/RijHsd breeding pairs using reciprocal crosses to account for confounding parental imprinting effects. We found that both male and female F1s show a dose-dependent increase in NIC-induced locomotion; however, only males exhibited NIC sensitization. We are in the process of performing the translatome profiling of F1 F344/BN hybrid rats in major brain regions relevant to NIC addiction, the ventral tegmental area (VTA) and nucleus accumbens (NAc). To determine whether the translatome profiles of NIC sensitization observed in rats are similar to those observed in hiPSC-derived NIC sensitized midbrain DA neurons, we evaluated, as a proof of concept, the transcriptomic similarity of these hiPSC-DA neurons to human postmortem brains from Genotype-Tissue Expression (GTEx) and BrainSpan projects. We found a strong expression correlation between iPSC-DA neurons and brain regions relevant to addiction. Interestingly, substantia nigra, a major

DA neuron enriched area, showed the highest correlation with iPSC-DA neurons for NIC/DA-related genes, supporting the validity of hiPSC-derived DA neurons in the transcriptomic study of NIC addiction. We are currently subjecting hiPSC-DA neurons to NIC sensitization. The NIC-induced translatome changes in iPSC-DA neurons will be assayed and compared to those observed in rat brain tissues. Identifying novel gene targets relevant to NIC sensitization will increase understanding of the neurobiology of human NIC abuse and inform the development of more effective therapeutics.

Title: Striatal cholinergic interneurons control behavioral sensitivity to nicotine

Authors: *B. KIM[1,2], J. WOO[1,2], C. LEE[1,2], H.-I. IM[1,2]
[1]Brain Sci. Inst. (BSI), Korea Inst. of Sci. and Technol. (KIST), Seoul, Korea, Republic of;
[2]KIST School, Korea Univ. of Sci. and Technol. (UST), Seoul, Korea, Republic of

Abstract: The effect of nicotine is driven in large part by striatal nicotinic acetylcholine receptors, but the role of striatal cholinergic interneurons (ChIs) in the behavioral sensitivity to nicotine remains unclear. Here, we demonstrate that RNAi-mediated inhibition of striatal ChIs leads to effective mitigation of nicotine preference and withdrawal signs in mice. Data mining through biological databases predicted a type of brain-enriched and evolutionarily conserved non-coding RNA (designated as ncRNA1) as a potential inhibitor of ion channel subtypes expressed in striatal ChIs. In hemizygous ChAT-Cre mice, AAV-mediated selective overexpression of ncRNA1 in striatal ChIs ($ChI^{ncRNA1\text{-}OE}$) resulted in ion channel knock-down and action potential threshold elevation, consequently lowering the action potential generation capacity of ChIs. In a comprehensive battery of behavioral tests, $ChI^{ncRNA1\text{-}OE}$ mice displayed diminished nicotine preference and somatic withdrawal signs without affecting general locomotion, anxiety, motor coordination, and long-term spatial memory. Interestingly, a neurotransmitter-wide LC-MS analysis revealed that $ChI^{ncRNA1\text{-}OE}$ led to paradoxical changes in striatal acetylcholine level after nicotine administration. Overall, our data indicate that RNAi can be utilized to inactivate neurons, and that striatal ChI inhibition can alleviate behavioral

sensitivity to nicotine in an unconventional manner. Further study is required with respect to the mechanism underlying $ChI^{ncRNA\text{-}OE}$-dependent changes in striatal acetylcholine level and the effect of $ChI^{ncRNA1\text{-}OE}$ in nicotine self-administration.

Title: Diversity in midbrain dopaminergic circuitry in response to drugs of abuse

Authors: *C. NGUYEN[1,2], S. TOLU[2], S. MONDOLONI[2], R. DURAND-DE CUTTOLI[2], F. MARTI[2], P. FAURE[2]
[1]Inst. de biologie Paris Seine, Univ. Paris Sorbonne, Paris, France; [2]Neurosci. Paris Seine, CNRS UMR8246, INSERM U1130, Paris, France

Abstract: Dopaminergic (DA) neurons of the ventral tegmental area (VTA) are at the core of the reward circuit. They play a crucial role in motivation, motor control, learning processes and reinforcement. Drugs of abuse target this system triggering maladaptive neurological modifications that may lead to addiction. Acute administration of nicotine, the main psychoactive compound of tobacco, increases DA cell firing and DA release in the VTA and in target structures such as nucleus accumbens (NAc), thereby initiating reinforcement and drug addiction.Contrasting with this classical view that suggests an activation of VTA DA cells, we recently identified a subpopulation of DA neurons, located in the medial part of the VTA, that are inhibited by nicotine. Yet, the mechanism by which nicotine inhibits DA neurons, and the consequences of such inhibition at the circuit and behavioral levels are unknown.
We first showed that despite different basic mechanisms of action at molecular and cellular levels, both nicotine and ethanol inhibit a subpopulation of VTA DA cells. The DA neurons that were activated by nicotine were also activated by ethanol and similarly most of DA neurons that were inhibited by nicotine were also inhibited by ethanol. Furthermore, using in vivo juxtacellular electrophysiological recordings combined with retrograde tracers (retrobeads), we also investigated the projection profiles of DA cells depending on their responses to nicotine.Thus, we demonstrated that NAc-projecting neurons are exclusively activated by nicotine, while inhibited neurons are mostly amygdala-projecting neurons.
Taken together, these results highlight the diversity of DA circuits in response to drugs of abuse and suggest a mechanism where opposing effects on two distinct neuronal populations triggers the nicotine effects.

Title: Insulin normalizes the decrements in dopamine transmission observed in diabetic rats

Authors: *B. CRUZ[1], L. M. CARCOBA[1], R. J. FLORES[1], E. J. ESPINOZA[1], A. NAZARIAN[2], L. E. O'DELL[1]
[1]Psychology, Univ. of Texas at El Paso, El Paso, TX; [2]Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Introduction: Pre-clinical studies in our laboratory have shown that the rewarding effects of nicotine are enhanced in diabetic rats. The neurochemical mechanisms that modulate nicotine reward involve dopamine release in the nucleus accumbens (NAc), a terminal region of the mesolimbic reward pathway. Given that the etiology of diabetes reflects a lack of insulin signaling, an important question is whether the neurochemical effects of nicotine are altered in diabetic rats in an insulin-dependent manner. To address this issue, the present study examined whether insulin supplementation normalizes nicotine-induced increases in the NAc of diabetic and healthy control rats. **Methods:** Rats first received vehicle or streptozotocin (STZ; 45 mg/kg), a drug that is toxic to pancreatic insulin-producing cells and increases plasma glucose levels. STZ-treated rats were then implanted with an insulin pellet or received a sham surgery. Two-weeks later, microdialysis probes were implanted in the NAc to measure dopamine release during baseline and following systemic administration of escalating doses of nicotine (0.3, 0.6, & 0.9 mg/kg). **Results:** Healthy control rats displayed an increase in NAc dopamine release following nicotine administration, and this effect was blunted in diabetic rats. Interestingly, the suppression of dopamine release observed in STZ-treated rats was normalized to control levels following insulin supplementation. **Conclusion:** These data suggest that insulin systems play an essential role in modulating the strong rewarding effects of nicotine observed in diabetic rats.

Title: Enhanced GABA release by projections from the nucleus accumbens to the ventral pallidum reduces nicotine self-administration in rats

Authors: A. L. SMITH, 37614[1], R. T. CHAPMAN[4], C. A. BRADLEY[2], H. W. SHELTON[3], *M. I. PALMATIER[2]
[1]Psychology, [3]Dept. of Biomed. Sci., [2]East Tennessee State Univ., Johnson City, TN; [4]Biomed. Sci., East Tennessee State Univerisy, Johnson City, TN

Abstract: Medium Spiny GABA neurons (MSN) project from the Nucleus Accumbens (NAc) to the Ventral Pallidum (VP) and play critical role in incentive motivation and reward. Rewards and reward-associated cues are thought to dynamically alter this pathway by suppressing GABA release to the VP. However, the role of the NAc to VP projection has never been investigated in nicotine self-administration. We hypothesized that increasing GABAergic signaling from the NAc to the VP would decrease the reinforcing effects of nicotine. To selectively increase GABA release in this pathway, a retrograde AAV was injected into the anterior (1.5 AP, ±1.8 ML, -7.9 DV)) and posterior (-0.5 AP, ±2.6 ML, -8.2 DV) VP to express CRE recombinase (AAV pmSyn1-EBFP-Cre, ADDGENE) of male CD rats (Charles River). After two weeks, a CRE dependent excitatory DREADD (pAAv-hSyn-DIO-hM3D(Gq)-mCherry, ADDGENE, n=14) or a control vector (pAAV-hSyn-DIO-mCherry, ADDGENE, n=5) was injected into the NAc (1.6 AP, ±1.3 ML, -7.3 DV) and rats were instrumented for intravenous nicotine self-administration. After recovery, the rats injected with the DREADD self-administered nicotine (30 ug/kg/infusion, DREADD+NIC, n=7) or saline (DREADD+SAL, n=7). The rats injected with the control AAV also self-administered nicotine (30 ug/kg/infusion). After responding for nicotine stabilized, clozapine was administered IP at doses below the threshold for activation of dopamine D2 receptors (0.03-0.75 mg/kg) during behavioral testing. Following testing, brains were collected and prepared for immunohistochemistry (IHC). Clozapine selectively reduced responding in rats injected with the DREADD, responding was not changed in rats injected with the control vector. Significant reductions in responding for nicotine and saline infusions were observed, but clozapine did not reduce responding on the inactive levers. This pattern suggests that the MSN projections from the NAc to the VP generally reduced reinforcement, although not specifically nicotine reinforcement. IHC confirmed DREADD expression in the NAc core and shell. Additional studies using microdialysis are being conducted to confirm that clozapine increases extracellular GABA in this model.

Title: Acute nicotine exposure alters ventral tegmental area inhibitory transmission and promotes diazepam consumption

Authors: *R. WITTENBERG, A. OSTROUMOV, B. A. KIMMEY, M. B. TAORMINA, W. M. HOLDEN, J. A. DANI
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Nicotine is the main addictive component of tobacco and e-cigarettes and its abuse continues to pose a serious public health problem. Not only is smoking the leading cause of preventable death worldwide, but exposure to nicotine also represents a prominent risk factor for further drug use. Recently, we found that an acute nicotine injection increased subsequent ethanol self-administration through a change in ethanol-induced GABA signaling in the ventral tegmental area (VTA). In this study, we show that this alteration in inhibitory signaling arises from a downregulation in the function of the potassium-chloride cotransporter, KCC2, in VTA GABA neurons. Impaired KCC2 function results in intracellular chloride accumulation and depolarizes the $GABA_A$ receptor reversal potential (E_{GABA}) in GABA neurons of nicotine-treated rats. Depolarized E_{GABA} switches diazepam-induced inhibition of VTA GABA neurons to paradoxical excitation. Increased activity of VTA GABA neurons leads to increased GABA release onto VTA DA neurons and blunts DA neuron firing. At the behavioral level, acute nicotine injection increased diazepam intake without altering saccharin consumption. Together these results demonstrate that nicotine may be a risk factor for subsequent diazepam abuse mediated by downregulation of KCC2 function in VTA GABA neurons. KCC2-targeted therapies, therefore, may present a novel treatment mechanism for disrupting nicotine-drug interactions which facilitate drug abuse.

Title: Extracellular dopamine release induced by co-presentation of nicotine and flavor conditioned reinforcers: Effect of nicotine dose

Authors: C. S. BAILEY[1], *G. A. DEEHAN, JR[2], C. A. BRADLEY[3], A. SMITH[4], M. I. PALMATIER[3]
[1]Psychology, East Tennessee State Univ., Watauga, TN; [2]Psychology, [3]East Tennessee State Univ., Johnson City, TN; [4]Psychology, East Tennessee State Univ., Elizabethton, TN

Abstract: Nicotine is a primary reinforcer that increases operant responding and increases dopamine release in the nucleus accumbens (NAc), an important terminal region in the mesocorticolimbic incentive motivation system. However, nicotine also serves as a reinforcement enhancer meaning that it increases responding for other reinforcers, including conditioned reinforcers (CRs). We have shown that tobacco flavor additives (e.g. licorice) increase nicotine self-administration in rats after they are established as CRs. However, no previous studies have investigated whether enhanced responding is associated with changes in extracellular dopamine in the NAc. To investigate this hypothesis, male Sprague-Dawley rats were randomly assigned to one of two groups: CR (n=12) or Neutral (n=11). For the CR group, 1% licorice root extract (LRE, v/v) was established as a CR via pairing with 20% sucrose. The Neutral group was exposed to 1% licorice root extract (unsweetened) but received 20% sucrose with grape kool-aid to equate conditioning. Rats in both the groups were then instrumented for nicotine self-administration. During self-administration contacts at a sipper tube were recorded and meeting the schedule of reinforcement on the active sipper resulted in oral delivery 1% unsweetened LRE solution and a iv delivery of 0.2 ml/kg/infusion of 20 or 40 ug/kg nicotine. Rats were tested under escalating fixed ratio (FR) schedules that increased from FR2 to FR10 across sessions. Subsequently all rats were tested under a progressive ratio (PR) schedule, in which each reinforcer earned incremented the schedule requirement for the next reinforcer according to an exponential formula. After behavioral manipulations, cannulas were implanted into the nucleus accumbens shell (AcbSh; AP+1.7, ML+2.4, DV-5.4). After recovery from surgery, microdialysis samples were collected according to the following schedule: washout (90 m), baseline (60 m), oral LRE (60 m), IV NIC + oral LRE (140 m). High pressure liquid chromatography of DA samples during this interval revealed an increase in extracellular DA for the CR rats during the LRE interval; no such increase was observed in the Neutral rats. Further

elevation in extracellular DA was detected during co-presentation of NIC and LRE for CR rats, but not for Neutral rats. The enhancement of extracellular DA release by flavor CRs suggest that they play a critical role in the maintaining tobacco use and may promote the transition from use to dependence.

Title: Nuclear factor kappa B signaling in the nucleus accumbens core mediates cue-induced nicotine seeking and modulates glutamate transporter 1 expression

Authors: *M. D. NAMBA, C. D. GIPSON
Dept. of Psychology, Arizona State Univ., Tempe, AZ

Abstract: Withdrawal from chronic nicotine self-administration is associated with enduring alterations in glutamatergic plasticity within the nucleus accumbens core (NAcore), including basal potentiation of dendritic spines on medium spiny neurons and dysregulation of glial glutamate transport. The nuclear factor kappa B (NF-κB) pathway, which is activated by IκB kinase (IKK) and mediates drug-induced neuroinflammation, is a key regulator of synaptic plasticity and may be a critical regulator of cue-induced neurobehavioral plasticity. Notably little is known about NF- κB's role in cue-induced nicotine seeking. Here, we assessed whether 1) NF-κB mediates cue-induced nicotine reinstatement and 2) if NF-κB signaling underlies the attenuating effects of the antioxidant and glutamatergic agent *N*-acetylcysteine (NAC) on cued nicotine seeking. Rats underwent nicotine self-administration (0.02 mg/kg/infusion) for a minimum of 10 days prior to 14 days of extinction training. On day 10 of extinction, rats received intra-NAcore microinjections of a herpes virus expressing constitutively active IKK (IKKca), a dominant negative mutant of IKK (IKKdn), or eGFP, as well as NAC (100 mg/kg/i.p.) or saline injections between days 10-14 of extinction. Following extinction, rats underwent cue-induced reinstatement (2hr) and were immediately sacrificed for NAcore tissue collection. IKKdn blocked cue-induced nicotine reinstatement and IKKca impaired NAC from attenuating reinstatement. Interestingly, IKKdn alone did not restore GLT-1 expression, while IKKca blocked NAC-mediated restoration of glutamate transporter 1 (GLT-1). These results indicate that NF-κB is regulates cued nicotine seeking behavior and is a key mechanism

underlying the therapeutic efficacy of NAC and its ability to restore GLT-1. These results also highlight a novel target for the development of new pharmacotherapeutics that have anti-inflammatory activity and suppress nicotine relapse.

Title: Extracellular vesicle integration in the rodent brain

Authors: *A. F. AHMED, V. LALLAI, C. D. FOWLER
Univ. of California Irvine, Irvine, CA

Abstract: Extracellular RNA-containing vesicles have recently been implicated in human disease. Our prior studies have found the presence of extracellular vesicles in high density within the cerebrospinal fluid (CSF) of the brain, potentially indicating that extracellular factors play a role in regulating neuronal signaling. The medial habenula, which contains cholinergic cells, is involved in mediating the aversive properties of nicotine and borders the dorsal third ventricle. Therefore, we hypothesized that CSF-derived extracellular vesicles from nicotine self-administering rats would integrate into habenular cholinergic cells *in vivo*. To visualize the integration of extracellular vesicles into neurons, CSF was extracted from a donor subject via the cisterna magna, and vesicles were isolated with ExoQuick-TC and labeled with ExoGreen. Thereafter, labeled vesicles were stereotaxically injected into the ventricles of rats and mice. Brain tissue was processed and examined with confocal microscopy. We document the presence of labelled vesicles in various regions of the brain, including the cholinergic region of the medial habenula. Together, these studies suggest that extracellular vesicles integrate into the neuronal parenchyma and may thereby alter neural function through the release of signaling factors.

Title: Extracellular vesicle release from the choroid plexus and small rna content modulated by nicotine

Authors: *V. LALLAI, A. F. AHMED, C. D. FOWLER
Neurobio. and Behaviour, UCI, Irvine, CA

Abstract: Cerebrospinal fluid (CSF), produced by the choroid plexus in the brain, contains extracellular vesicles carrying signaling molecules, including various RNA species. In previous studies, we have demonstrated functionally active cholinergic signaling mechanisms in the choroid plexus, in which nicotine differentially alters the expression of microRNAs both in the choroid plexus tissue and in the CSF. In this study, we extend these findings by examining whether pharmacological antagonism of cholinergic receptors prevents the release of miRNAs both *in vivo* and *in vitro*. For *in vivo* studies, subjects were administered the general nicotinic acetylcholine receptor antagonist, mecamylamine, prior to intravenous nicotine self-administration, and CSF was collected thereafter. To further validate these results, *in vitro* studies were conducted with primary cells of the choroid plexus from rats, and cell culture serum was collected following drug exposure. The expression of miRNAs in the CSF and serum were assessed with Taqman microRNA assays with qRT-PCR.
Our findings demonstrate the specific activity of nicotine on cholinergic receptor function in the choroid plexus and further implicate nicotine's actions in mediating extracellular vesicle signaling in the brain.

Title: Participation of metabotropic and endocytic mechanisms in nicotine-induced upregulation of α7 nicotinic acetylcholine receptors (nAChRs) in xenopus oocytes

Authors: *J. PANCHAL[1], M. ISLAM[3], K. DEBOEUF[4], J. B. ANDERSON[5], I. MCFATRIDGE[2], J. FARLEY[6]
[1]Neurosci., [2]Indiana Univ., Bloomington, IN; [3]Neurosci., [4]Psychology and Neurosci., [5]Psychological and Brain Sci., [6]Indiana Univ. Bloomington, Bloomington, IN

Abstract: The α7 nAChR is widely expressed throughout peripheral and central nervous systems and is implicated in many neuropathologies/syndromes (e.g., Alzheimer's Disease, inflammation, stroke, cancer, schizophrenia) and nicotine addiction. Functional/numerical upregulation of α7 Rs by many compounds has been reported and several different mechanisms have been suggested to participate. Prolonged nicotine exposure may upregulate α7 and contribute to nicotine addiction. We've previously shown ~ 2-fold functional and numerical upregulation of α7 Rs in oocytes following 12 hr of 100 μM nicotine and extensive washout. Nic-upregulation was dependent upon intracellular Ca2+ (being blocked by BAPTA-AM), but independent of Ca2+- influx from extracellular media. We further identified several Ca2+-signaling pathways involved in nic-upregulation. Because α7 R (like another Cys-loop LGIC, Gly R1) contains a canonical G-protein binding cluster (GPBC) in the M3-M4 intracellular loop, whose mutation abolishes GPCR-Ca2+-signaling of α7 Rs (King & Kabbani, 2015), we tested the involvement of this cluster in nic-upregulation. Mutation of GPBC (RMKR to AAAA), preventing interaction of endogenous Gαq/ Gβγ with GPBC and disrupting Gαq-PLC-IP3-Ca2+ release, abolished nic-upregulation of α7 Rs. Furthermore, when Gαq was exogenously co-expressed with wt α7 Rs, we saw ~2X upregulation similar to nicotine treatment. We also found that a calcineurin inhibitor cyclosporine A (CsA) produced 2X-upregulation of wt α7 Rs and occluded nic-upregulation. Endocytic inhibitors (Dynasore, PitStop 2) produced ~2X upregulation of both wt and mutant α7 Rs and occluded nic-upregulation. Brefeldin A (BFA, inhibitor of protein transport from ER to Golgi) failed to affect nic-upregulation. Interestingly, prolonged exposure to the membrane-permeable competitive antagonist methyllycaconitine (MLA) upregulated α7 Rs in a calcium-independent manner, and inhibition of MLA-induced upregulation by BFA supported a chaperone-role for MLA. Our results suggest that nicotine and MLA upregulate α7 Rs by different mechanisms. Nic-upregulation of α7 arises from sustained GPCR-Ca2+-signaling by α7 Rs, inhibiting basal/constitutive endocytosis of α7 Rs and not via stimulation of ER-Golgi trafficking (unlike MLA). Although GPCR-Ca2+ signaling is blocked in mutant α7 Rs channels, the downstream effects of calcineurin- and endocytic-inhibition are still produced pharmacologically in these mutant channels, reproducing the 2X nic-upregulation.

Title: Nicotine-induced behavior and gene expression in larval zebrafish

Authors: *H. SCHNEIDER, A. PEARSON, D. HARRIS
Dept. of Biol., Depauw Univ., Greencastle, IN

Abstract: Dependence on nicotine-containing products is a major cause of preventable diseases in the U.S. and worldwide. Current smoking cessation therapies with varenicline and bupropion have still a high rate of relapse. Behavioral tests that measure the response to nicotine following pretreatment with a chemical are used in animal models and could lead to the discovery and development more effective pharmacotherapeutics. Larval zebrafish represent an excellent model for the screening of chemicals that reduce the neurobehavioral response to nicotine. In addition, comparing gene expression dynamics before and after pretreatments and before and after nicotine application could provide new insight into the function of potential pharmacotherapeutics. When exposed to nicotine in the water, larval zebrafish respond with an increased movement activity. Previously, we have identified chemicals in the serotonin system that reduce the acute response to nicotine. Pretreatment with serotonin receptor agonists for serotonin receptors of type 2 (htr2cl1) and agonists and antagonists for the serotonin receptor type 2a (htr2aa) reduce the acute nicotine response significantly. Reverse transcriptase quantitative polymerase chain reaction (RT-qPCR) methods were used to explore gene expression profiles associated with the acute nicotine response including the htr2c and htr2a mediated change of nicotine responses. First experiments confirm a significant increase in cfos gene expression after 30 min of nicotine exposure. In contrast, htr2cl1 and htr2aa receptor gene expression appears to remain unchanged. The cfos gene activity returns to background levels within 2 hours after the start of nicotine exposure. No significant change in htr2cl1 and htr2aa receptor gene expression seems to occur within 24 hours of nicotine exposure. Higher levels of htr2cl1 gene activity have been measured compared to the htr2aa gene. The results indicate that nicotine itself does not appear to change gene expression levels of serotonin receptors htr2cl1 and htr2aa within 24 hours of nicotine exposure. In the future, experiments will explore gene expression profiles following pretreatment with serotonin receptor agonists and antagonists, that reduce the acute nicotine response.

Title: Overexpression of a stress peptide in the nucleus accumbens selectively increases nicotine self-administration in female versus male rats

Authors: *K. P. URIBE, R. J. FLORES, V. CORRERA, B. CRUZ, L. E. O'DELL
Psychology, The Univ. of Texas at El Paso, El Paso, TX

Abstract: Previous studies have shown that nicotine withdrawal produces a larger increase in the expression of the stress-associated gene, corticotrophin-releasing factor (CRF) in the nucleus accumbens (NAc) of female versus male rats. The present study expands this work by assessing sex differences in the rewarding effects of nicotine following over-expression of CRF in the NAc of female and male rats. A group of ovariectomized (OVX) females were also included to examine whether our behavioral effects are ovarian-hormone mediated. Extended access (23-hour) to nicotine self-administration was compared in female, OVX female, and male rats that received intra-NAc administration of an adeno-associated vector (AAV-CRF) that over-expressed CRF in this region. Control rats received intra-NAc administration of a control vector (AAV-GFP). The rats were then surgically prepared with a jugular catheter for subsequent self-administration of escalating doses of nicotine (0.015, 0.03, 0.06 mg/kg). After the final session, the rats were sacrificed and the NAc was dissected to verify over-expression of CRF using qRT-PCR methods. Our results revealed that over-expression of CRF in the NAc produced a selective increase in nicotine self-administration in intact female versus male rats. The effects of CRF-overexpression in the NAc appeared to be ovarian-hormone dependent, as OVX females did not display an increase in nicotine intake relative to intact females. Over-expression of CRF in the NAc produced a similar increase in CRF in the NAc of female and male rats relative to their respective GFP controls. However, over-expression of CRF produced a larger increase in the expression of CRFr1 and CRFr2 in females versus male and OVX female rats. In conclusion, these findings suggest that stress systems in the NAc play a key role in modulating sex differences in the reinforcing effects of nicotine

Title: Disruption of hippocampal NRG3-ERBB4 signaling ablates nicotine withdrawal-induced anxiety-like behaviors

Authors: *M. FISHER[1], E. ANDERSON[1], J. L. TWISS[2], J. R. TURNER[1]
[1]Col. of Pharm., [2]Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstract: Addiction to nicotine and the ability to quit smoking are influenced by genetic factors. Identifying altered gene networks and how those networks contribute to nicotine dependence and withdrawal will only accelerate therapeutic development of new smoking cessation aids. Previous work from our lab and that of our collaborators demonstrate that SNPs across the Neuregulin 3 (NRG3) gene and its cognate receptor, ERBB4, are associated with smoking cessation outcomes. These genes are critical in the maintenance of synaptic connectivity and plasticity during development and adulthood. Our studies show that during nicotine withdrawal both mRNA and protein levels of NRG3 and ErbB4 are upregulated in the hippocampus, a region that mediates affective withdrawal symptoms in mice, suggesting that aberrant hippocampal NRG3 signaling may underlie select withdrawal behaviors. Current studies aim to interrogate the functionality of this signaling pathway in the hippocampus during nicotine and withdrawal, and examine how nicotine-induced changes in NRG3 and ErbB4 may contribute to withdrawal-induced phenotypes in genetically modified mice. To do this we disrupted the pathway via conditional hippocampal ErbB4 deletion in ErbB4-floxed mice and evaluated nicotine withdrawal anxiety-like behaviors using the novelty-induced hypophagia test and the open field exploration task. We found that ErbB4 deletion on GABAergic interneurons results in the ablation of withdrawal-induced anxiety-like behavior, demonstrating a potential role of this signaling pathway in nicotine dependence. Ongoing studies are utilizing single molecule fluorescence in situ hybridization coupled with immunofluorescence to identify the underlying cell type and circuit-specific modulation of NRG3 signaling by nicotine within the hippocampus of these animals. Collectively, these data will provide insight into NRG3-ErbB4 dependent mechanisms underlying nicotine withdrawal-induced phenotypes.

Title: Sex-dependent behavioral effects of adolescent exposure to a cannabinoid agonist and nicotine in adult mice

Authors: *A. EUGENE[1], A. N. PUSHKIN[1], A. TORRES MENDOZA[1], C. D. FOWLER[2]
[1]Univ. of California, Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Recent studies suggest that adolescent exposure to substances of abuse, including nicotine or cannabis, may alter neuromaturation and neurocognitive function during adulthood. Nicotine acts in the brain via neuronal nicotinic acetylcholine receptors, whereas the main psychoactive component in cannabis, THC, acts on cannabinoid receptors. Here, we examined the effects of adolescent exposure to nicotine, a cannabinoid receptor agonist (WIN55-212,2), or co-exposure to both nicotine and WIN55-212,2 on operant learning, generalized locomotion, and anxiety- and reward-related behaviors in male and female mice. Our findings reveal differential effects of adolescent drug exposure on later anxiety and reward-related behaviors between males and females. However, significant differences were not found in operant learning or generalized locomotor/exploratory behaviors. Together, these data provide evidence that adolescent co-exposure to nicotine and cannabinoids can alter later affective and reward-related behaviors in a sex-dependent manner during adulthood.

Title: Traumatic stress enhances nicotine-induced locomotor sensitization in a rat model of PTSD

Authors: *F. GHODDOUSSI[1], T. GORE[2], M. J. LISIESKI[2], K. KARAVIDHA[2], D. K. KNOX[3], S. A. PERRINE[2]
[1]Anesthesiol. & Magnetic Resonance Core, Wayne State University, Sch. of Med., Detroit, MI; [2]Psychiatry & Behavioral Neurosciences, Wayne State University-School of Med., Detroit, MI; [3]Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: **Introduction**: Post-traumatic stress disorder (PTSD) is a debilitating psychiatric disorder characterized by anxiety, avoidant behavior, and hyper-reactivity to trauma-associated stimuli that affects nearly 25 million people in United States. Smoking is the leading preventable cause of death and nicotine dependence has a life time prevalence of 22.5% of the US population. Nicotine dependence is more prevalent in mental health disorders, including PTSD, than in non-clinical populations. Furthermore, clinical studies have linked enhanced symptoms in PTSD with smoking rates in PTSD. Trauma exposure, even in the absence of clinically diagnosed PTSD, is also associated with increased smoking rates and with physiological/behavioral associated outcomes. These reports suggest a link between trauma exposure and nicotine dependence, and raise the strong possibility that there are neurobiological mechanisms via which traumatic stress exposure leads to susceptibility to nicotine dependence. However, the mechanisms behind this comorbidity are not currently understood. In spite of this, there have been few studies that have studied this relationship. Proton-Magnetic Resonance Spectroscopy (1H-MRS) is a non-invasive clinically-relevant technique that we have used to show decreased glutamate signaling in the prefrontal cortex in a rat model of PTSD. Here we expand of these findings to study the mechanisms underlying the relationship between trauma and nicotine exposure. **Methods:** Single Prolonged Stress (SPS), a multimodal series of stressors, was used in rats to model PTSD. Sprague-Dawley rats were divided in 4 groups CTRL-Saline(n=6), CTRL-Nicotine(n=8) , SPS-Saline (n=8) , SPS-Nicotine (n=8). Effects of nicotine on behavior was measured by nicotine-induced locomotor sensitization. Brains were removed following behavioral testing and High Resolution Magic Angle Spinning (HR-MAS) 1H-MRS was performed on the cortical and striatal tissues. **Results:** Locomotion activity increased over the 5-day period in rats who received both SPS and nicotine and was significantly different from rats receiving SPS and saline ($p=0.0125$). Analysis of cortical and striatal, MRS measurable glutamate and GABA levels is currently underway. **Discussion:** Our preliminary results indicate that psychological trauma enhances nicotine induced locomotion sensitization. We hypothesize that decreased cortical glutamate is associated with enhanced nicotine sensitization in trauma-exposed animals.

Title: The effects of nicotine and withdrawal on sleep latency in C57BL/6J mice

Authors: *H. L. MATHEWS[1,2], V. IYER[3], J. A. STITZEL[4]
[1]Psychology & Neuroscience, IBG, Univ. of Colorado Boulder Dept. of Psychology and Neurosci., Boulder, CO; [2]Inst. for Behavioral Genet., Boulder, CO; [3]Univ. of Colorado - Boulder, Boulder, CO; [4]Inst. Behav Genet., Univ. of Colorado Boulder, Boulder, CO

Abstract: Increased sleep latency, a primary symptom of insomnia, is observed and reported during periods of nicotine consumption and withdrawal. Yet, there is no established animal model to study the effects of chronic nicotine use and withdrawal on this insomnia related phenotype. The present study used mice to characterize inactive phase sleep latency during periods of nicotine administration and withdrawal and to measure inactive phase corticosterone following a series of sleep latency trials. In experiment one (n=6), mice were implanted with EEG/EMG recording devices. During the pre-nicotine baseline condition, mice had free access to food and .2% saccharin water. To generate nicotine dependence, 200µg/ml of nicotine was added to the .2% saccharin water. After 14 days of nicotine exposure, withdrawal was induced by excluding the nicotine from the water. Multiple sleep latency testing (MSLT) consisted of three consecutive trials spaced one hour apart occurring under three conditions: baseline (BL), nicotine exposure day 8 (N8), and withdrawal day 1 (WD1). MSLT procedures were initiated at ZT 2 (n=3) or ZT 2.5 (n=3). During each trial, mice were kept awake for 5 minutes by means of gentle handling. Sleep latency was measured as the time (in seconds) it took to enter the first bout of sleep. Sleep/wake quantity and architecture was assessed for each 55min period following each trial and averaged. Relative to BL, sleep latency was not altered on N8. No difference was observed for measures of sleep/wake quantity and architecture between BL and N8. Compared to BL, sleep latency proceeding trial one was significantly increased on WD1, suggesting difficulty falling asleep. A significant decrease in total sleep, explained by a reduction in NREM sleep, was also observed during the WD1 condition. In the second experiment (n=4), an ELISA was used to assess plasma corticosterone immediately following a third sleep latency trial during BL, N8, and WD1 conditions. No main effect of condition was observed, however multiple comparisons tests revealed a significant decrease in corticosterone during WD1, relative to BL. In summary, these data suggest an impairment in the HPA axis during withdrawal which might contribute to the increased latency to sleep during WD1.

Title: Effects of chronic inhalation of electronic cigarette vapor containing nicotine on neurotransmitters in the frontal cortex and striatum of C57BL/6 mice

Authors: *F. ALASMARI[1,2], L. E. CROTTY ALEXANDER[2], A. M. HAMMAD[1], C. M. BOJANOWSKI[2], A. MOSHENSKY[2], Y. SARI[1]
[1]Pharmacol. and Exptl. Therapeut., Univ. of Toledo, Toledo, OH; [2]Dept. of Medicine, Div. of Pulmonary and Critical Care, Univ. of California at San Diego (UCSD), La Jolla, CA

Abstract: Electronic (E)-cigarettes are the latest form of nicotine delivery device, and are highly popular in the general population. It is currently unknown whether vaping E-cigarettes leads to nicotine addiction. Alterations in the levels of the neurotransmitters in the mesocorticolimbic areas have been reported to mediate the initiation and development of nicotine dependence. Therefore, to determine whether E-cigarettes activate the same addiction pathways as conventional cigarettes, we investigated the effects of daily inhalation of E-cigarette vapor-containing nicotine for six-months on the concentrations of these neurotransmitters in the frontal cortex (FC) and striatum (STR) of male C57BL/6 mice. We found that chronic inhalation of E-cigarette vapor-containing nicotine reduced dopamine concentration only in the STR. There were no changes in serotonin concentrations in the FC or STR. Chronic E-cigarette exposure also increased glutamate concentration in the FC alone, while glutamine concentrations were increased in both the FC and STR. We found that E-cigarette exposure also decreased GABA concentration only in the FC. These data suggest that chronic E-cigarette use alters homeostasis of several neurotransmitters in the mesocorticolimbic areas, which may result in the development of nicotine dependence in E-cigarettes users.

Title: Transcriptional changes extend far beyond forgetting of a long-term sensitization memory in *Aplysia* californica

Authors: *R. CALIN-JAGEMAN[1], U. PATEL[2], L. PEREZ[2], S. FARRELL[2], D. STECK[2], I. CALIN-JAGEMAN[3]
[1]Psychology, [2]Neurosci. Program, [3]Biol., Dominican Univ., River Forest, IL

Abstract: Most long-term memories are forgotten, becoming progressively less likely to be recalled. Still, some memory fragments may persist beyond forgetting, as savings memory (easier relearning) can persist long after recall has become impossible. What happens to a memory trace during forgetting that makes it inaccessible for recall and yet still effective to spark easier re-learning? We are addressing this question by tracking the transcriptional changes that accompany learning and then forgetting of a long-term sensitization memory in the tail-elicited siphon withdrawal reflex of *Aplysia californica*. First, we tracked savings memory. We found that even though recall of sensitization fades completely within 1 week of training, savings memory is still robustly expressed at 1 week and 2 weeks post training. Next, we used microarray to identify transcriptional changes that persist beyond the decay of recall; we identified 11 transcripts strongly regulated 1 week after training that validated with qPCR in an independent set of samples. Finally, we tracked these time-course of regulation of these 11 'savings-related' transcripts at 1 hour, 1 day, 5 days, and 2 weeks after the induction of sensitization. Some are regulated rapidly after induction and then persist for up to 1 week; others show a delayed but persistent regulation. Remarkably, 2 transcripts still show strong regulation of expression 2 weeks after training. Our results provide the first evidence of transcriptional fragments of a learning experience that persist far beyond the decay of recall.

Title: Differential contribution of protein kinase G to short-term and long-term behavioral plasticity induced by sensitization training in *Aplysia*

Authors: *R. MOZZACHIODI, R. CHATTERJI, E. SALAS, M. WAINWRIGHT
Dept. of Life Sci., Texas A&M Univ. Corpus Christi, Corpus Christi, TX

Abstract: In the mollusk *Aplysia*, exposure to aversive stimuli causes a learned enhancement of defensive responses, known as sensitization, and a concurrent suppression of feeding. Sensitization and feeding suppression are co-expressed across different training protocols and share common temporal domains (Acheampong et al. 2012; Shields-Johnson et al. 2013). In particular, a training protocol, consisting of a single trial of electric shocks to the body wall, induces short-term (15 min) concomitant sensitization of the tail-induced siphon withdrawal reflex (TSWR) and feeding suppression. An extended training protocol, consisting of four trials, spaced 30 min apart, induces more prolonged behavioral changes, with both sensitization and feeding suppression lasting at least 24 h. The strong relation in the temporal dynamics of sensitization and feeding suppression suggests that these two processes may share common signaling pathways.
In this study, we investigated the role of the protein kinase G (PKG) in the concomitant learning-dependent behavioral modifications in defensive and non-defensive responses induced by short-term and long-term sensitization training. The selective PKG inhibitor KT5823 (henceforth KT) was used (Michel et al. 2011). Animals were injected *in vivo* with 1 mL per 100 g of body weight of either KT (6.5 µM in 1% DMSO) or vehicle solution (1% DMSO; Michel et al. 2011). In both the single-trial and the four-trial protocols, four groups of animals were used: trained/injected with KT, untrained/injected with KT, trained/injected with vehicle, and untrained/injected with vehicle. TSWR duration and feeding were measured prior to (pre-test) and at given post-test time points (15 min or 24 h) after training.
We first examined the role of PKG in the short-term behavioral changes induced by the single-trial protocol. KT did not prevent the expression of either sensitization or feeding suppression 15 min after training, suggesting that PKG does not contribute to the short-term behavioral plasticity

induced by sensitization training. Next, we investigated whether PKG plays a role in the long-term behavioral changes induced by the four-trial protocol. KT prevented the expression of both sensitization and feeding suppression 24 h after training, suggesting that PKG contributes to the long-term behavioral modifications induced by sensitization training.
Overall, these findings suggest that a PKG signaling pathway is necessary for the induction of both long-term sensitization and feeding suppression, but not for the induction of short-term behavioral changes.

Title: Regulation of context memory maintenance during reconsolidation with serotonin precursor and epigenetic regulators

Authors: *P. M. BALABAN, A. VINARSKAYA, A. ZUZINA
Inst. Higher Nervous Activity & Neurophysiol. RAS, Moscow, Russian Federation

Abstract: In the present study we tested possible ways of modification of the long-term context memory using the reconsolidation process as a tool for memory labilization. Recently it was shown that the reinforcing neurotransmitter serotonin is necessary for successful repeated reconsolidation of context memory in terrestrial snails, and we used injection of the serotonin precursor 5-HTP for reinstatement of memory after its impairment during reconsolidation with a protein synthesis blocker or with a specific inhibitor (ZIP) of atypical proteinkinase PkMzeta shown to be involved in memory maintenance. It was observed that application of 5-HTP known to increase the serotonin concentration or just reminding did not restore the context memory, while combination of 5-HTP+reminder effectively reinstated the impaired context memory. Application of an epigenetic regulator, histone deacetylase inhibitor sodium butyrate (NaB), was not as effective as serotonin, and the reminder+NaB reinstated memory only partially after impairment with ZIP, while additional session of training under NaB effectively reinstated the impaired memory. Application of an inhibitor of DNA methyltransferases RG108 erased context memory, and the memory was not reinstated by reminder or additional training session, while NaB+reminder and NaB+training partially reinstated the memory. Obtained data confirmed the assumption that serotonin/reinforcing transmitter is necessary for successful reconsolidation,

demonstrated possible ways of memory regulation during the reconsolidation process by the epigenetic factors.

Title: Learning and circuit-dependent replacement of memory

Authors: M. CROSSLEY, G. KEMENES, *P. R. BENJAMIN, I. KEMENES
Univ. Sussex, Brighton, United Kingdom

Abstract: Temporary lapses in memory recall during consolidation of long-term memory have been observed in many species, including humans, raising questions about their function in the phenomenon of memory lability. These lapses could represent windows of opportunity for one memory to be replaced by another. To examine this hypothesis, we induced a memory and then examined the effects of the formation of a second memory using the model molluscan system *Lymnaea*. When the second training was applied at a lapse-point, the original memory was replaced by the new memory. However, when applied at a non-lapse point, both memories were retained in the case of appetitive followed by aversive training whereas only the first memory was consolidated if two different appetitive paradigms were used. We further demonstrate that aversive and appetitive conditioning induce training-specific cellular changes. We provide evidence that the fate of the second memory is dependent on whether the two memories are encoded within the same or different memory circuits.

Title: Successful and unsuccessful attempts to swallow regulate *aplysia* feeding responses in a reduced *in vitro* preparation

Authors: *A. J. SUSSWEIN[1], J. M. MCMANUS[2], H. J. CHIEL[3]
[1]Bar-Ilan Univ., Ramat-Gan, Israel; [2]Biol., Case Western Reserve Univ., Cleveland, OH; [3]Case Western Res. Univ., Cleveland, OH

Abstract: Cyclic behaviors in behaving animals are modulated by feedback from effectors and by learning and memory. We examined modulation of cyclic *Aplysia* feeding activity in a reduced preparation in which the buccal and cerebral ganglia are attached to the buccal muscles effecting feeding. We challenged this system with either edible or inedible foods, loads causing learned changes in behavior. We examined how the preparation responds to the loads, and whether such loads produce learned changes in response. Repetitive feeding responses were induced by bathing the cerebral ganglion in the cholinomimetic carbachol (CCh). Comparing the effects of CCh in preparations with and without the buccal musculature showed that presence of the muscles speeded up the maximal response rate, and also produced a mixture of feeding responses more like that in intact animals, presumably via feedback from the effectors. Repetition of the CCh exposure after 1 h produced a decrease in responses. Challenging the system with edible strips of food produced an increase in the maximal response rate during the first CCh exposure, and on repetition of the procedure after 1 h memory was expressed as a lack of decrease in the maximal response rate that would have been caused by the CCh alone. Challenging the system with inedible food had no effect on any of the parameters of feeding responses during the initial exposure to CCh+inedible food, or during the repetition of this procedure 1 h later. All preparations were exposed a third time to CCh alone, 1 h after the 2nd test of CCh effects. During this test, there were no differences in response parameters between preparations previously challenged with CCh alone or with CCh+edible food, indicating that memory was dependent on a repetition of the presence of the edible food. However, there was a decrease in response to CCh alone in preparations previously challenged with CCh+inedible food. This decrease suggests that memory arises in part via a post-synaptic decrease in response to CCh in cerebral ganglion neurons excited by cholinergic taste afferents. Since no changes in response were present during training, these findings also indicate that changes in response during learning with inedible food do not appear to determine memory formation.

Title: Sleep deprivation inhibits early steps in the induction of associative memory

Authors: *L. C. LYONS[1], H. C. KRISHNAN[1], E. J. NOAKES[1], L. M. CANCIO[2]
[1]Dept. of Biol. Science, Program in Neurosci., [2]Florida State Univ., Tallahassee, FL

Abstract: Acute sleep deprivation and chronic sleep loss constitute a rising public health problem in teenagers and adults. Sleep deprivation causes significant impairments in memory and performance resulting in substantial risks to health and society through increased occupational errors and traffic accidents. However, our understanding of the molecular impacts of sleep deprivation remains limited. The marine mollusk *Aplysia californica* is an excellent model for studies of sleep and represents a well-established model for non-associative and associative memory. Recently, we demonstrated that acute and chronic sleep deprivation inhibits the induction of short and long-term operant memory using the learning that food is inedible paradigm (LFI). In the current research, we tested the hypothesis that sleep deprivation prior to training disrupts early steps in memory formation. We investigated the effects of sleep deprivation on the immediate induction of MAPK activity following LFI training, a necessary shared step in the formation of both short and long-term memory. We found that sleep deprivation suppressed the activation of training-induced MAPK activity. Moreover, the induction of MAPK activity following training was still significantly inhibited even when training occurred 24 hours after the period of sleep deprivation, suggesting a molecular mechanism through which sleep deprivation persistently blocks memory formation. To identify the underlying molecular changes caused by sleep deprivation, we examined the effects of sleep deprivation on protein synthesis and protein degradation. Using the SUnSET assay, we found that acute sleep deprivation significantly decreases protein synthesis. Interestingly, we also found that sleep deprivation increases protein ubiquitination specifically in the buccal ganglia, which has previously been shown to be the site of training-induced MAPK signaling necessary for LFI memory. Furthermore, we found that pharmacological inhibition of proteasome activity reverses the effects of sleep deprivation on short and long-term memory, although inhibition of proteasome activity in the absence of sleep deprivation blocks long-term memory. These results suggest that the effects of sleep deprivation on protein synthesis and protein degradation impair the induction of associative memory and that these molecular impacts of acute sleep deprivation persist for at least 24 hours.

Title: Ribosomal S6 kinase (RSK) is essential for long-term synaptic facilitation (LTF) at sensorimotor (SN-MN) synapses of *Aplysia*

Authors: *R.-Y. LIU, Y. ZHANG, L. J. CLEARY, J. H. BYRNE
Dept. of Neurobio. and Anat.,, McGovern Med. Sch. of UTHSC At Houston, Houston, TX

Abstract: RSKs are a family of serine-threonine kinases that are activated by mitogen-activated protein kinase (MAPK) and consequently phosphorylate and activate cAMP response element-binding protein (CREB). Although the RSK2 gene has been identified in *Aplysia* (NCBI Reference Sequence: XP_005094788.1), and a recent study indicates activation of RSK via the ERK (a MAP kinase isoform) pathway (Philips et al. 2013), the complete signaling pathways and their roles in long-term synaptic facilitation (LTF) have not been fully examined. In the present study, we used immunocytochemistry to measure the phosphorylation of RSK induced by serotonin (5-HT), a neurotransmitter mediating sensitization in *Aplysia*, and found that a standard LTF-inducing treatment with 5-HT leads to a complex dynamics of RSK phosphorylation observed over 24 h in isolated sensory neurons (SNs) (See companion poster). This effect depended upon the MEK-ERK pathway as evidenced by the attenuated phosphorylation produced by the MEK inhibitor U0126 (U0). Moreover, inhibiting either the activation of ERK by U0 or the downstream effects of RSK by its specific inhibitor BI-D 1870 (BID), attenuated 5-HT-induced phosphorylation of CREB1. These results suggest an important role for ERK/RSK in the activation of CREB1. To elucidate the roles of RSK in synaptic plasticity, we employed siRNA knockdown to inhibit the expression of RSK protein, and then measured CREB1 phosphorylation and LTF. 5-HT-induced increases in phosphorylated CREB1 were reduced by RSK siRNA injection. Moreover, either injection of RSK siRNA into the SN from SN-MN co-culture or inhibition of RSK using BID resulted in a significant reduction of LTF. These data suggest that RSK is required for the induction of LTF. The reduction in RSK and LTF after RSK siRNA injection suggests that knock down of RSK by siRNA may constitute a single-cell analogue of Coffin-Lowry syndrome (CLS), a cognitive disorder that is associated with deficits in learning and memory caused by mutations in the RSK2 gene. Interestingly, the impairment in both phosphorylation of CREB1 and LTF can be restored by a computationally designed

Enhanced Protocol, which was previously demonstrated to augment normal LTF and long-term memory (LTM) (Zhang et al. 2012). These results reveal that *Aplysia* RSK is a critical upstream kinase for CREB1 and required for LTF. Moreover, this study indicates that a computationally-designed Enhanced protocol not only improves normal LTF and LTM, but also rescues deficits in LTF in a single-cell CLS analogue.

Title: Biphasic regulation of MAPK pathways contributes to dynamics of CREB1 and CREB2 after serotonin treatment

Authors: *Y. ZHANG, R.-Y. LIU, L. J. CLEARY, J. H. BYRNE
McGovern Med. Sch. of UTHSC at Houston, Houston, TX

Abstract: Serotonin (5-HT)-induced long-term synaptic facilitation (LTF) of the *Aplysia* sensorimotor synapse depends on the activation of transcription activators such as CREB1 and inactivation of transcription repressors such as CREB2 (Bartsch et al., 1995,1998). Levels of CREB1 and CREB2 mRNA and proteins and phosphorylation of CREB1 exhibit complex dynamics after induction of LTF (Liu et al., 2008, 2011). Processes that underlie these dynamics are not well characterized, however. To address this issue, we examined three elements of the MAP kinase cascade that are critical for activation of CREB1 and CREB2: extracellular signal-regulated kinase (ERK), p38 mitogen-activated protein kinase (p38 MAPK) and p90 ribosomal S6 kinase (RSK). LTF requires activation of the ERK MAPK isoform that relieves CREB2-mediated repression of CREB1 activity and activates CREB1 via RSK (See companion poster). Activation of the p38 MAPK isoform inhibits LTF by activating CREB2 and suppressing ERK (Guan et al., 2002, 2003; Zhang et al., 2017a). We treated isolated *Aplysia* sensory neurons with five 5-min pulses of 5-HT and examined the phosphorylation of ERK, p38 MAPK and RSK at the same time points used previously to investigate CREB1 and CREB2 dynamics (Liu et al., 2008, 2011). Compared to vehicle control measurements at the same time points, 5-HT treatment induced a rapid increase in phosphorylated p38 MAPK at 1 h after treatment (+19.6 ± 7.2%, n = 9), which returned to basal levels at 2 h (-9.8 ± 8.3%, n = 9), but subsequently increased a second time at 5 h (+16.2 ± 5.0%, n = 10), eventually returning to basal level at 24 h (+3.6 ± 6.4%, n = 9) (Zhang et al. 2017b). Complex dynamics of RSK phosphorylation were also observed over 24

h. Phosphorylated RSK (pRSK) was elevated by +21.1 ± 8.9% (n = 10) at 1 h after treatment, followed by a decrease to -4.6 ± 9.8% (n = 8) at 2 h. A second increase in pRSK levels was evident at 5 h (+19.1± 8.1%, n = 11), and pRSK levels returned to basal levels at 24 h (+7.1% ± 7.6%, n = 8). In contrast, 5-HT induced a significant increase of phosphorylated ERK (pERK) immediately after treatment (+57.3% ± 9.9%, n =10), which gradually declined thereafter but remained significantly elevated at 2 h after treatment (+31.9% ± 11.7%, n = 11). Levels further decreased to +15.0% ± 7.3% at 5 h (n = 6), and returned to the basal level at 24 h (-3.6% ± 9.8%, n = 9). These data suggest that complex regulation of MAPK pathways contribute to the dynamics of CREB1 and CREB2, which in turn are important to understanding the efficacy of training protocols to form LTF. Further investigation is needed to investigate the interaction between these kinases and quantify the relationship between MAPK signaling and CREB1/CREB2 dynamics.

Title: Differentiating the molecular mechanisms underlying short-term behavioural plasticity

Authors: *A. J. YU[1], E. L. ARDIEL[1], C. H. RANKIN[2]
[1]Grad. Program in Neurosci., [2]Psychology, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Non-associative learning, including sensitization and habituation, is ubiquitously observed in a wide range of species following presentation of stimuli of certain patterns and properties, that allows organisms to modulate their responses to subsequent stimuli. The experience-dependent behavioural plasticity can be expressed in forms of increase or decrease in response, corresponding to sensitization and habituation. Several other processes can also mediate short-term behavioural plasticity in conjunction or interaction with non-associative learning. For example, in dishabituation, a novel strong stimulus can produce recovery (dishabituation) or facilitation (dishabituation and sensitization) of the habituated response. The serotonergic signalling pathway underlying sensitization in Aplysia has been delineated for decades; however, other mechanisms mediating these behavioural plasticities remain poorly understood at cellular and molecular levels.

In this study, we analyzed different forms of short-term behavioural plasticity in the tap withdrawal circuit of *Caenorhabditis elegans*. The tap withdrawal circuit is well annotated at the synaptic level, and genes expressed in these neurons are known. Through a mutant screen and our optogenetic behavioural assays, we found that several peptidergic signalling pathways play a substantial role in mediating various forms of short-term behavioural plasticity. We identified the cellular and molecular components in at least one peptidergic signalling pathway underlying tap-induced sensitization that is not involved in dishabituation. Similarly, another peptidergic signalling pathway has been found to mediate only dishabituation and not sensitization. Additionally, we showed that different training paradigms can differentially produce sensitization or dishabituation. Thus, two forms of behavioural plasticity that both increase responsiveness in the same response can be differentiated at cellular and molecular levels. Several theoretical implications can be extrapolated from our findings. The findings both support, and provide a new interpretation of the classic Dual-Process Theory of non-associative learning. The results also highlight the importance of extra-synaptic signals in plasticity in the nervous system.

Title: High-throughput phenomic characterization of ASD-associated genes reveals a functional gene network underlying hypersensitivity and impaired habituation

Authors: *C. H. RANKIN[1], T. MCDIARMID[3], M. BELMADANI[4], K. HAAS[5], P. PAVLIDIS[2]
[2]Psychiatry, [1]Univ. British Columbia, Vancouver, BC, Canada; [3]Grad. Program in Neurosci., [5]Brain Res. Ctr., [4]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: A primary challenge facing Autism Spectrum Disorder (ASD) genetics is the large and growing number of genes and gene variants of unknown functional significance. Here, we used *Caenorhabditis elegans* to systematically functionally characterize ASD-associated genes *in vivo*. Using our custom machine vision system we characterized 26 quantitative phenotypes spanning morphology, locomotion, mechanosensory responding, and habituation learning in 87 strains of *C. elegans* each carrying a mutation in an ortholog of an ASD-associated gene. This research has generated a large number of novel genotype to phenotype relationships that range from severe developmental delays and uncoordinated movement to subtle deficits in sensory and

learning behaviours. Clustering based on multi-parametric phenomic profiles revealed a set of 12 genes that all result in a strikingly similar profile characterized by hypersensitivity and impaired habituation learning. Current epistasis experiments are aimed at determining whether the phenomic similarity among members of this cluster results from previously undiscovered functional interactions. One of the genes in this cluster is the sole *C. elegans* ortholog of neuroligins, *nlg-1*. Transgenic pan-neuronal expression of human *NLGN3* in *nlg-1* mutant *C. elegans* rescued their sensory and learning impairments; confirming functional conservation. The wealth of *in vivo* phenomic functional data generated in this work will inform more targeted studies in vertebrates and offers novel positive and negative pathway components as therapeutic targets for ameliorating the effects of ASD.

Title: Investigation into the role of motor response performance in associative learning in *C. elegans*

Authors: M. R. PRIBIC[1], J. T. BYLIN[1], L. C. LAWRENCE[2], M. N. BISHOP[2], *J. K. ROSE[3]
[1]Biol., [2]Behavioral Neurosci., [3]Psychology, Western Washington Univ., Bellingham, WA

Abstract: *Caenorhabditis elegans* can detect and respond to stimuli in their environment and form associations (e.g., worms will migrate towards a chemical or temperature previously associated with the presence of food). To test the potential role activation of motor circuitry has on learning, an associative conditioning protocol previously described by our lab was employed. Briefly, this assay utilizes the combined activation of two distinct sensory circuits that typically trigger opposing locomotor responses when presented alone (reversal for one stimulus and forward motion for the other). In wild type *C. elegans*, after five stimulus pairings delivered at a 60 s interstimulus interval, an altered motor response is seen at test when a single stimulus is presented; worms pause (a cessation in motion) more frequently at test stimulus onset compared to naive worms ($p<0.01$). This change in response lasts for at least 10 minutes post-conditioning. To determine if motor response performance is necessary for this alteration in response following stimulus pairing, transgenic strains expressing channelrhodopsin in cholinergic motor neurons ($_p$unc-17::ChR2), GABAergic motor neurons ($_p$unc-47::ChR2) or muscle ($_p$myo-3::ChR2) underwent the same stimulus-pairing procedure. In these worms, exposure to blue light alone was sufficient to generate the previously reported channelrhodopsin-mediated motor

responses; $_{p}$unc-17::ChR2 and $_{p}$myo-3::ChR2-expressing worms showed shortening of the body due to light-activation of the cholinergic motor neurons or body wall muscle resulting in contraction. $_{p}$unc-47::ChR2 worms displayed an overall cessation of movement. Initial conditioning trials with blue light to simultaneously activate channelrhodopsin during stimulus pairings indicate $_{p}$unc-47::ChR2 do not show the same altered motor response as seen with wild-type. Results from this study will elucidate if motor circuit activation influences signalling at upstream neural circuits involved in learning.

Title: Exploring the role of the chloride channel CLH-1 in salt chemotaxis learning in the nematode *C. elegans*

Authors: *C. PARK[1], Y. SAKURAI[3], Y. IINO[2], H. KUNITOMO[4]
[1]Fac. of Sci., The Univ. of Tokyo, Bunkyo-ku, Japan; [2]Dept. of Biol. Sciences, Grad. Sch. of Sci., The Univ. of Tokyo, Tokyo, Japan; [3]Dept. of Biol. Sci., Sch. of Science, Univ. of Tokyo, Tokyo, Japan; [4]Sch. of Science, Univ. of Tokyo, Department of Biological Sciences, Japan

Abstract: *Caenorhabditis elegans* is an excellent model organism to study the neural substrate of behavior thanks to its well documented and simple nervous system as well as amenability to genetic manipulations. Also, *C. elegans* shows a behavioral plasticity in NaCl chemotaxis, which is regulated by food availability. Animals are attracted to the salt concentration at which they have been previously fed, while avoid the salt concentrations they have been starved at (hereinafter referred to as salt chemotaxis learning). The insulin/PI3-kinase signaling in the ASER salt-sensing neuron regulates starvation-induced behavioral change (Tomioka et al. 2006, Ohno et al. 2014). However, PI3-kinase pathway mutants showed no discernable defect in food-associated salt-concentration preference, suggesting that the mechanism of food-associated salt chemotaxis learning is at least partially different from that of starvation-induced salt chemotaxis learning (Kunitomo et al. 2013). Recent studies show that anion channels play important roles in synaptic transmission by regulating the excitability of neurons. ClC chloride channels are conserved across various animal species, and they are expressed in most tissues, including neurons. ClC channels have been the subject of many studies, due to their malfunction being

implicated in various diseases in humans. Roles of ClC channels in learning and memory, however, are not fully understood. Here, we show that ClC chloride channel CLH-1 acts in food-associated salt chemotaxis learning of *C. elegnas*. We screened for mutants that show defects in food-associated learning but not in starvation-induced learning, and obtained two mutants JN572 and JN577. Both mutants had a missense mutation in *clh-1* that encodes a ClC chloride channel. CLH-1 is known to function as a bicarbonate transporter in pH homeostasis of glial cell in *C. elegans* (Grant et al. 2015). Interestingly, *clh-1* null mutants did not show behavioral defects in food-associated learning. This result suggests that the missense mutations are neomorphic. Tissue-specific rescue experiments indicated that CLH-1 acts in ASER.

Title: Honey bees form separated memory traces after experiences containing appetitive and aversive consequences

Authors: *M. KLAPPENBACH[1], F. F. LOCATELLI[2]
[1]IFIBYNE-CONICET, FCEN-UBA, Argentina; [2]IFIBYNE-CONICET, FCEN-UBA, Buenos Aires, Argentina

Abstract: In natural situations animals must be able to acquire information from experiences that combine appetitive and aversive consequences. How learning derived from those experiences is stored and retrieved to produce adaptive behavior is a major question in neurobiology. Honey bees have been lengthily used to study olfactory learning and memory processes triggered upon olfactory conditioning of the proboscis extension response. In its appetitive version, the odor is presented with sugar solution and the bees learn to extend the proboscis in response to the odor. In the aversive version, the odor is presented with a salty or a bitter solution, and the behavior observed is the withdrawal of the proboscis in response to the odor. In the present study we performed a series of experiments aimed at evaluating in which extend these two forms of learning interact when appetitive and aversive stimuli take part in the same training protocol. First of all, we established a testing protocol focused on measuring the occurrence and duration of the aversive olfactory-gustatory memory. During the training session, bees receive paired presentations of the odor and a quinine bitter solution. Aversive learning

becomes evident just during the testing phase, in which the same odor is paired with sugar solution and the bees show deficit in appetitive conditioning. We found that multiple trials of aversive conditioning endow a memory that lasts 24 but not 48 h. Afterwards, we demonstrate that honey bees are able to recognize the aversive conditioned odor when during the test it is presented as component of a binary mixture. Then, we performed a differential conditioning protocol, alternating presentations of two odors that were paired with the appetitive and the aversive reinforcements respectively. When the memory test was performed separately for each odor, we observed that bees responded accordingly to the learned appetitive or aversive valences. Finally, the bees that had undergone differential conditioning were challenged in a test session in which the appetitive and the aversive odors were combined in a mixture. We found that confronted to this decision bees behaved either according to the appetitive or the aversive odor depending on their satiation level. Starved bees responded as detecting the appetitive trained odor, while fed bees responded as if they detect the aversive odor. In summary, bees are able to learn and remember the association between different odors and different reinforcements acquired during the same experience, and use this information according to the motivational state during retrieval.

Title: Sequencing of entire brains at the single-cell resolution: Principles of molecular classification (neurosystematics) and periodic system of neurons

Authors: *L. L. MOROZ[1,2], A. KOHN[1]
[1]The Whitney laboratory for Marine Biosci., Univ. of Florida, Saint Augustine, FL; [2]Neurosci., McKnight Brain Inst., University of Florida, FL

Abstract: There is more than one way to develop cell and tissue complexity, and animals frequently use different molecular toolkits to achieve similar functional outcomes (=convergent evolution). However, the genomic bases of convergent evolution are largely unknown. Here, we used a combination of microfluidic and massive-parallel single-cell RNA-seq (scRNA-seq) to

capture more than one million cells in representatives of 13 animal phyla. These species also represent major transitions in the formation of mesoderm, muscle and neural organizations as well as origins of complex organ systems (from comb jellies to cephalopods). First, we revisited the animal phylogeny and start to develop a metric to quantitate each cell's type transcriptional relationships as well as criteria for cell-/neuronal homologies. Second, we showed that for many species tested, virtually all neurons are unique in their RNA modifications, non-coding RNAs, and secretory molecules, providing the foundation for the natural neuronal classification or NEUROSYSTEMATICS. The discovered molecular complexity of the numerically "simpler" neural systems and the emerging single-cell data suggest the hypothesis: neurons are different not only because they have different functions, but also because neurons and circuits have different genealogies, and perhaps independent origins at the broadest evolutionary scale from ctenophores and cnidarians to mollusks and chordates. Origins of neurons (and synapses) from different types of ancestral secretory cells might have occurred at least three times during Metazoa evolution. It appeared that mesoderm and muscles, including striated muscles, evolved independently. Also, our reconstructions suggest 9-12 independent events of nervous system centralizations from a common bilaterian/cnidarian ancestor with diffuse-like neural systems. Thus, using examples of convergent evolution, we set up a foundation toward natural genealogical classification of neuronal classes across phyla. Perhaps, there is a type of the Periodic System of Neurons, which might be an analog of the Periodic System of chemical elements, with a predictive power for cellular phenotypes.

Title: Reprogramming of feeding behavior by diet

Authors: *T. PARDO, C. MAY, A. VAZIRI, M. DUS
Neurosci., Univ. of Michigan, Ann Arbor, MI

Abstract: While we understand how changes in the environment such as temperature and light direct animal behavior by acting acutely on neural circuits, we know less about how the environment can lead to persistent changes in brain and behavior. Tackling this question has been challenging because it requires having a circuit-based understanding of the behavior and a mechanistic way to study how neural connections are changed by the environment. The reshaping of circuits that regulate food intake by a hyper-caloric diet in *Drosophila melanogaster* provides an attractive model for studying this question because the circuits are mapped, the

behavior is easily quantifiable, and the environmental variables are simple to measure. We found that animals fed a Western style high-calorie diet show profound deregulation of feeding states: they incorrectly process the nutritional value of food, eat more, and become obese. We will present data showing how these behaviors are mediated by the metabolic-transcriptional reprogramming of distinct feeding circuits by diet and how their effect is persistent even after animals are returned to the control diet.

Title: Mother knows the threat: Neural mechanisms of wasp-induced oviposition depression in *Drosophila*

Authors: *M. K. SADANANDAPPA, G. BOSCO
Dept. of Mol. and Systems Biol., Dartmouth Col. Geisel Sch. of Med., Hanover, NH

Abstract: In addition to mounting an immunological response after endoparasitoid wasp infection, fruit flies have developed various behavioral adaptations to protect themselves as well as their progeny from the impact of infection. In presence of larval endoparasitoid wasp, *Drosophila* females either reduce their egg lay or prefers to lay their eggs in food containing toxic levels of alcohol. This preferential alteration in ethanol-seeking behavior self-medicates the larvae against wasp infection, thereby prevents wasp adults emerging from fly pupae. Despite its importance, the neuronal and molecular mechanisms that underlie wasp-induced physiological changes in female fruit flies remains to be elusive.
To address the above question, we have combined the behavior assays with the neurogenetics and immunohistochemistry approaches. When adult flies (5 females and 2 males, 12-24 replicates) are exposed to wasps for 24hrs, the flies decrease their mean egg lay compared to naïve flies. Interestingly, either in the absence of visual (nina B^1 mutants) or olfactory inputs ($Orco^1$ mutants), female flies fail to depress their eggs upon exposure to wasps. Strikingly, this observed oviposition depression is specific to larval endoparasitoid, but not to pupal endoparasitoid wasps. Together, these findings point that the adult fruit flies have developed a behavioral immunity specific to larval endoparasitoid based on the search images that distinguish between the larval endoparasitoid from pupal endoparasitoid.

Furthermore, as the neuropeptide F (NPF) and its receptor mutants (NPFR) display defects in wasp-induced oviposition response, we are currently dissecting the neural circuits that are upstream and downstream of the NPF neurons. Additionally, given that the decreased egg lay is associated with transient retention of matured eggs in wasp-exposed females, we are also investigating how do the neuronal inputs modulate the female germline physiology.

Title: Associative olfactory learning in *Drosophila* induces synaptic de-correlation of axonal Kenyon cell boutons

Authors: *A. FIALA[1], B. GEURTEN[2], F. BILZ[1]
[1]Univ. Goettingen, Goettingen, Germany; [2]Cell. Neurobio., Univ. of Goettingen, Goettingen, Germany

Abstract: Plastic changes in synaptic transmission represent a neuronal substrate underlying learning and memory formation. Since sensory stimuli are typically encoded as sparsely distributed activity across assemblies of many neurons, it is challenging to determine which and how individual synaptic connections change to acquire a stimulus-specific memory. Here we used *in vivo* calcium imaging in *Drosophila* to monitor learning-induced synaptic plasticity. Fruit flies can learn to avoid an odor stimulus that is temporally paired with a punitive electric shock. We trained fruit flies positioned under a two-photon microscope using this classical aversive olfactory conditioning regime, and monitored odor-evoked calcium activity through a window cut in the head capsule. One odor (CS+) was presented in coincidence with a punitive electric shock. A second odor (CS-) was subsequently presented without punishment. Control animals received the same odorant stimulation, but without the electric shock. The MARCM technique was used to express the calcium sensor GCaMP in single γ-lobe Kenyon cells of the mushroom body, a brain region to which the acquisition of associative olfactory short-term memory could be localized. We measured odor-evoked activity in synaptic boutons along individual axons and across many neurons. Using a subsequent immunohistochemical staining we could assign axonal boutons to specific γ-lobe sub-compartments. A comparison of calcium activity before and after associative learning revealed that albeit associative learning induced bi-directional changes in synaptic bouton activity, their overall calcium activity across all boutons remained constant.

However, odor-evoked synaptic bouton activity within and across single Kenyon cells de-correlated as a result of associative learning, and specifically for the CS+. No de-correlation between boutons was observed for the calcium activity evoked by the CS- or the control odor. This reveals a novel principle of how associative memories can be differentially encoded across assemblies of neurons and axonal compartments.

Title: Distinctive roles of pre- and post-synaptic DD2Rs in *Drosophila* larval olfactory learning

Authors: C. QI[1], *D. LEE[2]
[1]Biol., [2]Ohio Univ., Athens, OH

Abstract: Dopamine (DA) plays a critical role in associative learning by activating excitatory D1- or inhibitory D2-like receptors. In Drosophila larvae, postsynaptic D1 receptors (dDA1) are known to mediate olfactory learning. However, whether Drosophila D2 (DD2R) plays a crucial role in olfactory learning hasn't been fully investigated. DD2Rs are comprised of pre- and postsynaptic receptors, which are likely involved in larval olfactory associative learning. In olfactory learning, the presynaptic neurons are dopaminergic neurons (DAN), and the postsynaptic neurons are in mushroom body (MB), the key structure for fly learning. Therefore, if DD2Rs are expressed in MB neurons or DANs, it strongly indicates their important role in larval learning. Former studies showed that DANs in DL1 clusters innervating the vertical lobes of MB are necessary for aversive olfactory learning, while those in the pPAM clusters innervating the medial lobes of MB are important for appetitive learning. In this study, we aimed to examine whether DD2R are expressed in MB and different DAN clusters, and whether these DD2Rs are involved in *Drosophila* olfactory learnings. By using a GFP-tagged DD2R strain, expression patterns of DD2R were explored in both MB neurons and DANs. In pPAM cluster, DD2R exists in all four DANs. In DL1 cluster, DD2R is expressed in 5 out of 7 DANs. As distinct DANs innervate different compartments on MB lobes, this result indicated DD2Rs in distinct DANs may have unique roles in specific learning tasks. To investigate this, we drove expression of DD2R-RNAi under tissue-specific drivers. The olfactory learning assay showed both appetitive and aversive learning are completely impaired in larvae with DD2R-RNAi expression under 30Y-GAL4 or 201Y-GAL4 driver, showing DD2Rs in MB neurons are necessary for both kinds of larval learning tasks. As to DD2Rs in DANs, aversive learning is completely impaired in larvae with DD2R knockdown under a DA-specific driver TH-GAL4

(including DL1, not pPAM), while the appetitive learning is partially impaired. This is consistent with our results of DAN-to-MB GRASP using TH-GAL4. Intensive GRASP signals were observed in the vertical lobes showing functional synapses formed between DL1 and vertical lobes of MB. These results demonstrate DD2Rs in the DL1 have an important role in larval aversive learning. In contrast, knockdown of DD2R under a pPAM-specific driver (R58E02-GAL4) completely impaired appetitive learning, which indicates DD2Rs in pPAM clusters have an important role in appetitive learning. Our findings revealed DD2R in different brain structures have distinct functions in *Drosophila* larval olfactory learning.

Title: Discovery of long-lasting context-dependent olfactory memory in *Drosophila*

Authors: *B. ZHAO, X. ZHANG, Q. LI, Y. ZHONG
Tsinghua Univ., Beijing City, China

Abstract: How much memory is recollected depends largely on the circumstance. People always retrieve memory better in the context where they have ever learnt, termed as 'Context Effect'. However, we still lack a biologically mechanistic understanding of how context facilitates memory retrieval. Here we find that a single aversive olfactory conditioning in *Drosophila*, which was believed produce memory lasting for only one day, can yield context-dependent memory lasting for more than two weeks. Such context-dependent memory is resistant to protein synthesis inhibitor and cold shock treatment. Moreover, we found that silencing neurons of mushroom body, a classical center for olfactory learning and memory, did not affect context-dependent memory retrieval. Instead, outputs of several sensory input brain regions were required. Correspondingly, we found that context-dependent memory can be retrieved only when all external conditions are consistent with learning situation, since any alteration of perceptible context condition, such as temperature and light, led to failure of this memory retrieval. Taken together, our data indicate that behaviorally observed memory may not be actually formed memory for such memory recall can be improved by providing learning context again.

Title: Fruit flies integrate reward history into foraging decisions

Authors: *S. E. SEIDENBECHER[1], J. SANDERS[2], D. KVITSIANI[3]
[1]Aarhus Universitet, Aarhus C, Denmark; [2]Sanworks LLC, Stony Brook, NY; [3]DANDRITE, Aarhus Univ., Aarhus C, Denmark

Abstract: Foraging, or searching for food, is a fundamental behavior exhibited by all moving animals throughout evolution. Every behavior, including foraging, is fundamentally steered by decision-making processes. One particularly interesting type of foraging decision is the decision to return to a spot in the environment that was previously experienced as profitable. We are interested in the basic principles underlying this type of decision. To break down the decision behavior and gain access to these foraging decision principles, we use mathematical models that objectively describe the behavior. These models can give us a set of parameters that can be related to single genes driving this behavior. If all moving animals make foraging decisions according to these principles then we can hypothesize that certain behaviors of foraging and their genetic basis are conserved among different species. We developed an experimental setup to study foraging decisions in male fruit flies using optogenetic rewards and investigated the animal's behavior for different reward probabilities. In particular, we are interested in behavioral changes to varying uncertainty in the environment. Our results so far suggest that, on a population level, the flies base their decisions to return to a rewarded spot more strongly on previous rewards, when the reward probability is low while they become less sensitive to the reward history for higher probabilities. In the long run, our aim is to find computational models for fly foraging decisions and to uncover the key molecular players, by relating single genes and behavior through these models.

Title: A computational model for a spatial map in the fan-shaped body of *Drosophila* based on neuroanatomical evidence mined from the FlyCircuit database

Authors: *A. J. COPE[1], A. B. BARRON[2], J. A. R. MARSHALL[3]
[1]Univ. Sheffield, Sheffield, United Kingdom; [2]Macquarie Univ., Sydney, Australia; [3]Univ. of Sheffield, Sheffield, United Kingdom

Abstract: In invertebrates the central complex (CX) is an ancient, highly preserved, structure implicated in a wide range of behaviours (e.g. mating, locomotion, pattern recognition). Intriguingly it is also unique in spanning the brain midline. Despite this its role in the brain is poorly understood. Here we present an investigation of the role of the CX using the rich data sets available for the Drosophila brain. We performed a systematic review of the FlyCircuit.tw database for the CX fan-shaped body (FSB) using the NAT R package. This review involved an initial search to return all neurons with arborisation in the FSB over a fixed threshold. These were categorised based on morphology and large sets of heavily stereotyped neurons were identified. This morphological categorisation was validated using searches constructed to extract each large set. We hypothesised that these sets formed the parts of one circuit. Connectivity was inferred from arborisation overlap and neuron count extrapolated from the number in each set, assuming even sampling in the database. Following this bottom-up review a top-down approach was used to identify potential roles of these neurons. This approach strongly identified a potential role for the FSB in part as a 3D Cartesian spatial map. A computational model of these circuits was constructed based on three orthogonal linear attractors (see Figure). Activity through the attractor links is gated by progressive and regressive motion signals via the noduli, and by the heading of the fly via neurons which map to four heading quadrants. Landmark information is associated onto this network through a pathway via the anterior optic tubercle, the superior protocerebrum, and a separate layer of the FSB. Associative connections to the nodes of the linear attractors are via a very large set of interneurons. Our computational model is capable of driving movement towards a remembered location in a virtual environment. A spatial map

indicates a role for the CX for representing invertebrates' place in the world, providing a site for context across disparate fixed and learned behaviours.

Title: Biased randomness: A connectivity mechanism for associative brain centers

Authors: *S. J. CARON, E. AMEMATSRO, K. ELLIS
Dept. of Biol., Univ. of Utah, Salt Lake City, UT

Abstract: Uncovering fundamental mechanisms of neuronal connectivity that enable associative brain centers to learn efficiently is an important goal of neuroscience. In the *Drosophila melanogaster* mushroom body, the constituent Kenyon cells receive input from olfactory projection neurons. Each projection neuron connects to one of the fifty glomeruli in the antennal lobe, the primary olfactory processing center. We and others have shown that these connections are random in that there are no sets of glomeruli converging preferentially onto a given Kenyon cell. However, we found that the glomeruli are not represented with equal frequency among Kenyon cell inputs. Certain glomeruli form many more connections than expected under a uniform distribution, whereas other glomeruli form far fewer connections than expected. We are testing the idea that this non-uniform distribution, which we termed 'biased randomness', serves an important biological function, namely to predispose the learning ability of the mushroom

body towards certain ethologically pertinent stimuli. To test this idea, we built two mathematical models of the mushroom body: one model was built using the biased distribution of input that we measured experimentally, while the other model uses a uniform distribution of input. Both models generate very similar representations for most of the tested odors. However, we found that each model generates strikingly different representations for a few ethologically relevant odors. Odors activating overrepresented glomeruli activate many more Kenyon cells than odors activating underrepresented glomeruli do. Consequently, although both models show overall similar learning performance, they perform differently in tasks involving these ethologically relevant odors. We are proposing that overrepresentation serves a biological function, namely to enable odors that must be learned in many different contexts, pheromones for instance, to be represented by a large number of Kenyon cells. In contrast, underrepresentation might be used as a strategy to prevent the mushroom body from representing — and possibly learning — odors with strong innate valence. We are currently testing this idea further by measuring the biases in connectivity in the mushroom body of other *Drosophila* species that have evolved in different ecological niches and therefore have different olfactory preferences. Altogether, our work supports the idea that 'biased randomness' is a wiring mechanism that predisposes associative brain centers to learn efficiently.

Title: Hippocampal damage causes retrograde memory loss and delayed cue-place memory acquisition in a two-platform water task in rats

Authors: *J. Q. LEE[1], R. J. MCDONALD[2], R. J. SUTHERLAND[3]
[1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Dept. of Neurosci., Univ. Lethbridge, Lethbridge, AB, Canada; [3]Univ. Lethbridge, Lethbridge Alberta, AB, Canada

Abstract: Hippocampal (HPC) damage is known to cause retrograde amnesia (RA) for a broad range of long-term memory (LTM) tasks in rodents, including those dependent on cue- and place-memory guided behaviour. By contrast, HPC damage does not cause anterograde amnesia (AA) for cue memory, but causes AA for some aspects of spatial memory. In the present experiments, we examined cue and place aspects of LTM in parallel using a two-platform water task in rats with HPC damage made before or after training. We have found that HPC damage

before training causes a delay in expression of cue-place behaviour, followed by task performance that is comparable to control animals, including spatial aspects of memory performance. By contrast, HPC damage after learning causes robust RA for cue-place memory. Our findings support a view whereby the hippocampus is essential for an unexpectedly wide range of memory types if it is intact during a learning episode. Based on alternation of cue- and place-preferred strategies in over-trained control animals, we further hypothesize that cue and place information develop competitive associative strengths within the HPC system when both aspects of LTM are conditionally relevant to task performance.

Title: Development of the reconfigurable maze - Various shapes of maze in a single environment

Authors: *S. HOSHINO, K. IDE, S. TAKAHASHI
Doshisha Univ. Grad. Sch. of Brain Scine, Kyoto, Japan

Abstract: Several shapes of maze have been used for elucidating the neuronal mechanism on cognitive functions such as spatial navigation, working memory and decision-making. However, conventional maze has only a few experimental variables because the position of parts of the maze such as paths, walls, gates and feeders cannot be easily changed after construction. A novel maze system which is able to easily change the shape in a single environment, enables us to investigate the neural mechanisms more multi-directionally. Here, we realized such a maze system for small animals, called reconfigurable maze, in which the parts of the maze can be systematically reconfigured. In addition, to change scheduling of sensors and/or actuators in the maze in association with examining experimental variables, we developed a controller on an Arduino microcontroller and a user interface using Matlab programming language. To evaluate efficacy of reconfigurable maze, we produced several shapes of maze such as figure-eight maze and cross-to-square maze and recorded activity of place cells from the hippocampus CA1 of rats during some behavioral tasks. It is possible that the gap between paths in the maze hinders the animal's behavior. However, the rats could run through the maze at a speed comparable to that of the conventional mazes. Moreover, the size and shape of the place field are similar to those

previously reported in the conventional maze. Previous studies reported that while the animal briefly paused, place cells are sequentially reactivated as if they represent recently traveled trajectory; when a rat travels across the place field of a place cell, the firing timing shifts earlier in phase relative to the theta rhythm of the local field potential; the place field can be remapped in response to the morphing of square or circular walls. We thus checked whether the replay, phase precession and remapping of the place field can be observed in the maze. The results suggest that our reconfigurable maze system has compatibility with conventional maze. Our reconfigurable maze together with single cell recordings produces a complementary effect among the current maze tests and might provide a novel insight into the neural underpinnings of spatial navigation.

Title: Effects of partial hippocampal lesions in rats on the traveling salesman problem

Authors: *E. A. PETTY, G. COLLINS, K. LONG-IYER, J. PAUL, R. BLASER, J. B. HALES
Psychological Sci., Univ. of San Diego, San Diego, CA

Abstract: The Traveling Salesman Problem (TSP) is a spatial navigational task that differs from many other behavioral techniques because it allows the observation of behavior in a more naturalistic setting. The goal of the task is not to verify if an animal can do a certain behavior, but to record how the animal behaves in natural foraging conditions. This task may involve a variety of cognitive functions, such as spatial processing, memory, attention, route planning, and decision making. Given the established role of the hippocampus in both spatial processing and spatial memory, we examined how hippocampal damage affects rats' performance in the TSP. The rats were pretrained on the TSP, which involved learning to retrieve bait from targets in a variety of spatial configurations. Matched for performance, rats were then divided into two groups, receiving either a partial hippocampal lesion or a control sham surgery. After recovering from surgery, the rats were tested on eight new configurations. A variety of behavioral measures were recorded, including distance traveled, number of revisits, span, and latency. The results showed that the sham group outperformed the lesion group on most of these measures, with the

lesion group demonstrating more pronounced impairment on the more complex configurations. Based on histological tissue analysis of each group, we determined that the hippocampus appears to be involved in finding efficient routes, particularly in complex versions of the TSP.

Title: The effects of lesions to the head direction cell circuit on behavioural demonstrations of direction learning in rats

Authors: *D. M. SKINNER, M. A. WASEF, V. C. J. HARVEY, C. M. THORPE
Psychol, Mem. Univ. of Newfoundland, St John's, NL, Canada

Abstract: To navigate successfully an animal must have knowledge of its location and directional heading. These two components of navigation are well represented in a spatial network in the mammalian brain that contains place cells, grid cells, and head direction (HD) cells. It has been suggested that the HD signal originates sub-cortically in the reciprocal connections between the dorsal tegmental nucleus (DTN) and the lateral mammillary nucleus (LMN). Lesions to the LMN or DTN have been shown to disrupt HD cell firing in downstream structures, such as the anterior dorsal nucleus of the thalamus (ADN) and the postsubiculum. Lesions to the DTN have also been shown to produce severe impairments in directional heading on a foraging task and in directional learning in a water maze. In the present study, rats with bilateral electrolytic lesions of the LMN were compared to sham controls on a battery of spatial tasks that involve directional heading. LMN-lesioned rats were impaired, relative to sham controls, on water and dry-land versions of the direction problem, a foraging task, and a spatial discrimination on a radial arm maze. These results build on previous behavioural and cell-recording research and demonstrate the importance of the HD system to spatial learning. Current studies are examining the effects of discrete lesions to components of the HD system on response reversal learning. We have previously shown that a change in the orientation of the apparatus when the response contingency changes facilitates reversal learning to the same extent as a change in rooms. Whether this effect depends on the integrity of the HD circuit remains to be determined.

Title: Modeling of multiscale spatial navigation in complex environments

Authors: *A. WEITZENFELD[1], P. SCLEIDOROVICH[1], B. HARLAND[2], J.-M. FELLOUS[3]
[1]Computer Sci. and Engin., Univ. of South Florida, Tampa, FL; [2]Psychology, Univ. of Arizona, Tucson, AZ; [3]Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Studies suggest that spatial navigation is supported by the multiscale neural system of the hippocampus and associated structures. The dorsal hippocampus (DH) has a critical role in spatial learning and memory, but most of the supporting experiments were conducted using simple spatial tasks in small arenas. Such conditions may have not equired the integration of spatial representations at different scales along the dorso-ventral axis of the hippocampus, and hence may have not relied on ventral hippocampal (VH) computations. Our overall hypothesis is that the interactions of spatial maps at multiple scales along the dorso-ventral axis of the hippocampus allows for spatial navigation in large and complex environments. We are currently developing a computational model to simulate goal-directed navigation tasks in a large environment with different density of obstacles. The current work will present preliminary results related to this computational model and evaluation with autonomous robotic systems.

Title: Testing the hippocampus' role in a rapidly-acquired, novel spatial sequence task in rats

Authors: *S. KILIANSKI, R. E. HOKENSON, A. SAHAGIAN, B. L. MCNAUGHTON
Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: It is thought that the hippocampus generates an "index code" that contains pointers to neocortical modules storing the content of a memory. In this model, the hippocampus coordinates reactivation of new memory traces distributed across the neocortex during sleep, and these reactivations support the gradual development of corticocortical connections that allow for eventual memory retrieval independent of the hippocampus. To test the hypothesis that the hippocampus coordinates neocortical reactivation, an experimental subject must encounter a new experience and thus generate a new index code that can be reactivated during sleep. To this end, we developed a 4-element spatial sequence task in which subjects must learn a novel sequence in a novel environment every day. We shaped water-restricted rats (n = 3) to continuously run a 4-element sequence of cued arms in an 8-arm radial maze for sweetened-water reward. Cued sequences were interleaved with noncued sequences, during which the blinking LED cue indicating the correct arm was on an 8 second delay so rats had to navigate to the correct arms from memory. All rats were trained on at least 36 new sequences, each in a new environment. To investigate the role of the hippocampus in this task, we inactivated it by infusing the $GABA_A$ agonist, muscimol, or saline before training on alternating days. All three rats learned the novel sequences in a single 45-minute training session under both muscimol and saline infusion conditions. In two rats, hippocampal inactivation retarded, but did not abolish, learning of the new sequence. While these results suggest that hippocampal inactivation might retard acquisition of the spatial sequence task, all 3 rats showed a significant improvement in performance across a single session irrespective of infusion condition. Given the rats' ability to rapidly acquire these sequences and the apparent role of the hippocampus in this process, this task is viable for use in future experiments probing the role of the hippocampus in neocortical reactivation of new memory traces. Ongoing experiments aim to investigate the role of the hippocampus in consolidation of memory for this task using a 2-day training/testing paradigm and inactivating the hippocampus immediately following initial training.

Title: Representation of borders, velocity and speed in the goldfish brain

Authors: *E. VINEPINSKY, O. BEN-SHAHAR, O. DONCHIN, R. SEGEV
Ben Gurion Univ., Beer Sheva, Israel

Abstract: Navigation is one of the fundamental cognitive skills found in many animals across the animal kingdom. This ability is important for finding food, shelter, and mates in order to survive. However, almost nothing is known about the neural representation of space in the brain of animals outside the mammalian class. Goldfish, which is part of the largest animal class, the bony fish, also have the cognitive ability to navigate, using both allocentric and egocentric cues. In the goldfish brain, there is a specific region, the lateral pallium, which is associated with allocentric navigation and is a possible homolog of the mammalian hippocampal formation. Using a novel wireless recording system, we measured the activity of single cells in the lateral pallium while fish swam freely. We found three unique cell types: border cells, velocity cells and speed cells. Border cells are cells which are active when the fish is near the boundary of the environment. Velocity cells encode swimming direction and speed, while speed cells encode only the speed independent of direction. Those cells types resemble cell types which are found in the mammalian hippocampal formation and believed to be the building blocks which drive the navigation system. Our study sheds light on how spatial information is encoded in the fish brain and whether the mechanisms of the neural navigation system are preserved across evolution.

Title: A feedback circuit shaping spatial and reward expectation during visually guided locomotion

Authors: *E. M. ADAM, M. SUR
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: The ability to build up expectations, and hence predict and anticipate, is at the heart of cognition. This ability is enabled by assimilating prior experience, and, in light of it, completing acquired partial information, which is reincorporated as experience to build future expectations. We are interested in how this interaction is biologically implemented and how it is leveraged through feedback mechanisms to drive expectation and anticipation. We have developed a behavioral task where head-fixed mice run on a treadmill through a virtual linear track, then stop and wait at fixed visual landmarks to collect specified rewards. Mice learn to perform the task reliably, by moving quickly through the track and recognizing landmarks. By altering reward contingencies, we dissociate spatial information from reward information, thereby setting up rule-specific expectations. We hypothesize that the task biologically recruits an interplay of two pathways: one relaying spatial information, mediated through retrosplenial cortex (RSC), and one relaying reward information, mediated through prefrontal cortex (PFC). Retrograde tracing experiments reveal reciprocal connections between caudal anterior cingulate cortex (ACC), a subdivision of medial PFC, and both rostral and caudal RSC, as an anatomical basis for this interplay. Preliminary two-photon calcium imaging in caudal RSC and caudal ACC reveals neural population activity that is locked to locomotion activity during task performance. The low-dimensional dynamics of the population activity contain significant information reflecting the animal's speed. Using projection-specific in-vivo two-photon imaging, coupled with causal optogenetic manipulations, we are further investigating the information content and functional role of these feedforward and feedback pathways, with the goal of understanding their specific contributions to experience and expectation.

Title: Super-active and ultra-sparse neurons: Hippocampal neurons with persistently high and low propensities for representing space across environments and time

Authors: *J. LEE, J. BRIGUGLIO, S. ROMANI, A. K. LEE
HHMI / Janelia Res. Campus, Ashburn, VA

Abstract: Hippocampal CA1 neurons exhibit clear location-specific (place field) activity. In a small environment, most CA1 pyramidal neurons are active at a single location or not active at all. In a large environment (48-meter-long track), Rich et al. (Science 345: 814-7, 2014) found that most CA1 pyramidal neurons have a few or no place fields, but a small population of CA1 neurons has many (e.g., >10) place fields, and that the distribution of place fields per cell across the population was well-described by a gamma-Poisson model. However, it was not known whether a neuron's place field propensity was specific to each environment and/or point in time. Therefore, we used 2-photon calcium imaging and a head fixed-virtual reality system to follow the spatially tuned activity of >500 simultaneously imaged CA1 cells over a month in mice that explored multiple, distinct 40-meter-long virtual environments. We found that the number of place fields of individual hippocampal CA1 neurons was stable across days within each environment. The number of place fields of each neuron was also stable across different environments while place field maps were remapping. These results imply that a neuron's place field propensity is a stable feature of the cell and likely reflects pre-existing differences between CA1 cells that have a large impact on how the hippocampus represents space.

Title: Effects oflesionsoftheretrosplenialcortexontracingalearned routethat includes asmallchange inspatial structure

Authors: T. HAYASHI[1], *N. SATO[2]
[1]Psychological Sci., [2]Kwansei Gakuin Univ., Nishinomiya, Hyogo, Japan

Abstract: It has been thought that the retrosplenial cortex plays an important role in spatial navigation and spatial learning. Here, we investigated the function of the retrosplenial cortex of rats in route learning. We used a lattice maze which consists of five vertical and five horizontal paths. We used twenty-one male rats as subjects. Of the rats, eleven had excitotoxic lesions of the retrosplenial cortex and nine had sham lesions. The rats were required to go to a goal box from a start box in the lattice maze. In the learning phase, there were 5 trials in a daily session. We trained the rats until they could reach the goal without any mistakes in the consecutive 8 trials (2 days). After the rats fulfilled the criterion, we conducted tests. In the test phase, there are 6 trials in a daily session. The first trial was the same procedure as the learning phase. In the remaining trials, we added one of seven novel bypassing routes to the learned route, and the rats were required to go to the goal box from the start box. We focused on the behavior when the rats faced the bypassing route. In the learning phase, there were no significant difference in the number of sessions to reach the criterion between the retrosplenial cortex lesion and sham groups. In the test phase, the rats with lesions of the retrosplenial cortex tended to make the greater number of deviations from the learned route than the control group. This result suggests the rats with lesions of the retrosplenial cortex cannot trace the learned route without mistake, and that the retrosplenial cortex may be related to tracing a learned route.

Title: Modeling egocentric bearing selectivity in the rat parahippocampal region

Authors: *P. A. LACHANCE, J. S. TAUBE
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Head direction cells, grid cells, and other spatially responsive neurons (including conjunctive cells) have been shown to be intermingled with one another in the postsubiculum (PoS), parasubiculum (PaS), and medial entorhinal cortex (MEC) of the rat. Population analyses across these regions reveal a rough transition from direction to location encoding, with PoS cells largely encoding head direction and MEC cells primarily encoding location information. These functional differences are consistent with the anatomical connectivity of these areas, as PoS receives projections from the head direction circuit and MEC provides dense inputs to the hippocampus where place cells are found. However, mechanisms underlying the functional transition from direction to position encoding have not been fully characterized.
We developed a method for modeling aspects of this direction-location transformation by analyzing the encoding of egocentric place bearing (EPB) in parahippocampal cells. A subset of cells in the posterior parietal cortex fire in response to an animal's directional heading relative to a salient environmental cue (Wilber et al. 2014). It is therefore possible that cells could provide information about egocentric bearing relative to arbitrary places within an environment (i.e. egocentric place bearing), such that a navigating animal is constantly aware of how it is oriented with respect to its surroundings. The parahippocampal region, with its unique mixture of direction and location encoding, provides a potential substrate for this representation. Preliminary evidence suggests that EPB is indeed represented by parahippocampal neurons in a manner independent of allocentric head direction or location, with a general increase in EPB selectivity from PoS through PaS to MEC. Such area-specific differences could provide critical insights into fundamental mechanisms behind the transformation from direction to location encoding in the mammalian brain.

Title: How does the cerebellum modulate hippocampal coding?

Authors: *A. TORRES HERRAEZ[1], L. RONDI-REIG[2]
[1]Sorbonne Universites, UPMC, IBPS, Paris, France; [2]Neurosci. Paris Seine, IBPS-UPMC, Paris, France

Abstract: The cerebellum is involved in many cognitive processes through its interaction with different association areas in the brain. In particular, it has an important role in shaping the hippocampal place code during self-motion based navigation thus evidencing the existence of cerebello-hippocampal interactions. However, little is known about the organization and functioning of the circuits supporting such interactions.
By using a retrograde tracing strategy the team has recently identified three polysynaptic pathways from the cerebellum to the hippocampus (HPC) involving lobule VI-caudal fastigial nuclei, Crus I-dentate nuclei and paraflocculus-vestibular nuclei. We have later explored the electrophysiological relevance of these pathways in behaving mice by measuring the levels of coherence between simultaneously recorded local field potentials from the HPC and the cerebellar cortex in the lobule VI, Crus I and lobule II/III as a control. We have consistently found higher levels of coherence in the theta range (6-12 Hz) between lobule VI and/or Crus I and the HPC compared with the control. In particular, Crus I-HPC coherence dynamically changed depending on the behavioral and sensorial context, being maximal during goal-directed behavior. However, in order to further investigate the role of the cerebellum in shaping the hippocampal spatial code we need a causal approach that allows us to address direct modulation of the hippocampal activity by specific manipulation of the cerebellum.
To optogenetically control the activity of discrete cerebellar circuits, we are using transgenic mice expressing channelrhodopsin specifically in the cerebellar Purkinje cells (L7-ChR2 mice), the only output of the cerebellar cortex. Using a virtual reality (VR) setup, we are now performing acute-like experiments in head-fixed mice with craniotomies exposing the cerebellar cortex and the cortex above HPC. We are using silicon probes to record the laminar profile of LFPs and units in the dorsal HPC while we stimulate precise spots on the cerebellar cortex with an optic fibre. Stimulation at specific hotspots generates heterogeneous hippocampal responses, either inhibitory or excitatory, at single cell level. We now aim at recording stable place cells in the VR and at testing the effect of cerebellar manipulation on their activity. Using this strategy we plan to explore to which extent and through which sensory information cerebellar manipulation can affect the hippocampal place code.

Title: Turning direction and image selectivity of hippocampal neurons during virtual reality navigation

Authors: *D. FETTERHOFF[1], C. LEIBOLD[1,2]
[1]Dept. Biol. II, Ludwig-Maximilians-Universität München, München, Germany; [2]Bernstein Ctr. for Computat. Neurosci. Munich, München, Germany

Abstract: Virtual reality is useful to study spatial navigation because it enables environmental manipulations that would be unfeasible in real world setups. In our study, male Mongolian gerbils (Meriones unguiculatus) were exposed to two different virtual hallways that could be identified based on both turning direction and sequence of images on the walls of straight hallways. Specifically, maze A had two right turns and images of zebra skin, stars and targets, while maze B had two left turns and images of moons, pyramids and leaves. One objectives of this study was to identify activity of place cells during navigation of a maze with a well-known sequence of images compared to one which had images shuffled between two different image sequences. By shuffling between image sequences, identification of neuronal activity corresponding to spatial location versus image selectivity will be possible.
After learning how to navigate mazes with well-known sequences, a microdrive with eight individually movable tetrodes was implanted into hippocampal CA1 and CA3 regions and single units and local field potential recordings were made before, during and after virtual maze navigation. On testing days, gerbils were exposed initially to 20 laps with the well-known images, while the last 20 laps contained the initial image from one maze type but the final 2 images from the opposite maze type (i.e., mixed maze A contained zebra skin, pyramid and leaf; mixed maze B contained moon, stars and targets.)
Behavioral results showed that gerbils learned how to navigate virtual mazes. Analysis of electrophysiological data collected when images were shuffled between mazes showed that hippocampal principal cells fired specifically to either spatial location, turning direction or to specific images, while some cells only fired during the initial maze but not after shuffling. The results show that specific hippocampal cells respond to spatial location based on turning direction, to images or to a specific combination of the two.

Title: Lesions of the head direction cell system impair directional discriminations

Authors: *A. E. SMITH[1,2], O. A. CHEEK[1], E. L. C. SWEET[1], P. A. DUDCHENKO[2], E. R. WOOD[1]
[1]Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Univ. of Stirling, Stirling, United Kingdom

Abstract: Previous work has shown that rats are better able to discriminate otherwise identical maze compartments when these face different directions, compared to when the compartments all face the same direction (Grieves et al., 2016). Additionally, hippocampal place cells show repetition of place fields between compartments that are parallel to one another, but not in the same compartments arranged at a 60^{o} angle to one another. This suggests that both place cell fields and spatial discrimination abilities are influenced by a directional input. Consistent with the former, lesions to the lateral mammillary nuclei (LMN, part of the head direction network) lead to place field repetition in the maze compartments facing different directions (Harland et al, 2017). In the current study we tested the hypothesis that a directional input is similarly necessary for rats to discriminate, behaviourally, maze compartments facing different directions. Adult, male Lister Hooded rats were randomly assigned to undergo either bilateral ibotenic acid lesions of the LMN (LMNx group, n=8) or a sham surgery (sham group, n=6). Once recovered from surgery, animals were mildly food deprived and trained on a four-way odour-location task in a maze with four radially arranged compartments. In this task, every compartment contained four sand wells, each scented with a different household spice. The same scented wells were replicated in each compartment, but a food reward (a buried cereal piece) was associated with a different sand well in every compartment. Thus, the rats' task was to discriminate between the otherwise identical maze compartments in order to dig in the correct sand well in each. The location and identity of rewarded odours was counterbalanced between groups, and experimenters were blind to the condition of the animals at the time of testing. Only 4 of 8 LMNx animals reached learning criterion for the four-way odour-location task, whereas all sham animals (6 of 6) reached this criterion. In addition, LMNx animals took significantly longer to reach criterion in an early stage of acquisition of the task which involved discrimination between two compartments, although group differences were not as evident in later stages of training. Analysis of probe trials indicated that neither group used the scent of the food reward to detect rewarded wells. These preliminary findings suggest that directional input may contribute to the ability to discriminate behaviourally between maze compartments facing different directions.

Title: Learning efficient search for reward by CA3 recurrent network model

Authors: *T. HAGA, T. FUKAI
Ctr. for Brain Sci., RIKEN, Wako-Shi, Saitama, Japan

Abstract: Sequence learning is one of the essential functions of hippocampus. During run, sequential activities of place cells along the path is observed in every theta oscillation cycle (theta sequences), and place-cell sequences during run are replayed during immobility. These hippocampal firing sequences correlate with future paths of rats during exploration, and often designate paths to the predictable reward. In one-dimensional tracks, replay in the reversed order (reverse replay) is often observed when rats are consuming reward. Because reward modulates its occurrence frequency, reverse replay presumably contributes to goal-directed path learning in hippocampus. In contrast, in a two-dimensional open field, it has been reported that firing sequences triggered at the rewarded position are not biased to reverse replay of the recent path. The mechanism how hippocampus realize this goal-directed path learning, and the role of reverse replay in one-dimensional environments and unbiased firing sequences in two-dimensional environments are still unknown. In this work, we built the CA3 recurrent network model with the combination of Hebbian plasticity and short-term depression (or afterdepolarization). In our model, a firing sequence selectively potentiates synaptic transmissions in the reverse direction. Therefore, after a traversal on a one-dimensional track, this model generates reverse replay from goal to start, which realizes goal-directed learning by potentiation of forward synaptic transmission from start to goal. Notably, reverse replay in our model sometimes deviates from recent path and bifurcates into previously experienced paths, by which the network can optimize many possible goal-directed paths through one rewarded experience. Such “joint replay” has been also observed in experiments and our model suggests their importance in generalization of spatial memory. When we applied our model to a two-dimensional open field, firing sequences triggered at reward sites isotropically propagate over the space, and they create bias of sequence propagation to reward from any point in the space. This property of our model suggests that we can extend the role of one-dimensional reverse replay for goal-directed learning to unbiased

sequence propagation in two-dimensional space. We demonstrate that this model can quickly learn efficient search for reward in the task similar to Morris water maze. Our hippocampal model proposes the experimentally testable mechanism for goal-directed path learning in one-dimensional and two-dimensional environments.

Title: Hippocampal sharp-wave ripples precede high-effort movements

Authors: *A. G. HOWE[1], G. J. BLAIR[2], H. T. BLAIR[2]
[1]NSIDP/Psychology, [2]Psychology, UCLA, Los Angeles, CA

Abstract: Sharp-wave ripples (SWR) are an electrophysiological local field potential (LFP) phenomenon found in the hippocampus during periods of waking stillness and sleep. SWRs have been proposed to participate in a variety of cognitive processes such as deliberative planning, memory consolidation, and credit assignment during reinforcement learning. Here, we investigated the role of SWRs in deliberative planning by recording LFP signals from area CA1 in freely behaving rats as they acquired and expressed a simple T-maze task with a fixed reward location. We identified episodes of movement initiation during which the rat was continuously still (speed < 5 cm/s) for at least 3 s, and then transitioned to a period of movement (speed > 10 cm/s) lasting for at least 3 s. We observed a bimodal distribution of speeds during movement episodes, allowing for behavioral discrimination between low-effort (10-25 cm/s) versus high-effort (35-55 cm/s) movement episodes. Preliminary analyses indicate that during the 3 s of stillness preceding movement onset, SWRs occurred at a significantly higher rate prior to high-effort versus low-effort movements. Furthermore, the probability of SWR events peaked approximately 1 s prior to high-effort movement initiation. As a complementary analysis, we categorized the movement traces during these episodes of transition from stillness to movement into those preceded by one or more SWR and those preceded by no SWR. Statistical comparison

of the average speed trace for each category revealed that the average speed trace for episodes preceded by one or more SWR is significantly higher than the average speed trace for episodes preceded by no SWR, which is consistent with the first analysis. Based on these results, we hypothesize that SWR rate increases prior to the execution of effortful actions, as would be expected if SWR events are involved in deliberative planning of goal-directed actions that are subsequently executed with vigorous effort.

Title: The causal role of oxidative kynurenine metabolism in mediating cognitive impairment by remodeling actin cytoskeleton structure in a model of chronic inflammation

Authors: *M. MITHAIWALA, A. M. GARRISON, J. C. O'CONNOR
Neurosci., UT Hlth. San Antonio, San Antonio, TX

Abstract: Cognitive impairment is a comorbidity associated with multiple neurological conditions accounting for reduced quality of life and significant socioeconomic burden. Currently, there is no FDA approved therapy for cognitive dysfunction and the pathogenic mechanisms remain poorly understood. Inflammation-induced disruption in the kynurenine pathway (KP) of tryptophan metabolism has been implicated in mediating behavioral dysfunction. In the hippocampus, a pronounced shift toward oxidative metabolism of kynurenine occurs during inflammatory conditions, and this shift appears to mediate hippocampal-dependent cognitive deficits caused by inflammation. We hypothesized that increased oxidative KP metabolism during inflammation leads to increased production of QA in the hippocampus that is responsible for cognitive impairment. In this study, we infected WT and 3-Hydroxyanthranillate-3,4-dioxygenase (3-HAAO; enzyme that produces QA) null mice with the Bacillus of Calmette-Guérin (BCG) to induce chronic inflammation. BCG challenged WT mice exhibit significant deficits in hippocampal-dependent spatial learning and a significant reduction in spine density CA-1 basal and dentate gyrus neurons. These impairments were absent in 3-HAAO null mice. Chronic direct administration of QA (10μM) to primary hippocampal neuronal cultures for 5 days significantly decreased the number of dendritic spines. Interestingly, we also observed an increase in the levels of the actin-severing protein-cofilin in hippocampal tissue lysate in WT-

BCG mice that was absent in 3-HAAO null mice. Together, these data indicate that inflammation-induced increases in hippocampal QA production contribute directly to cognitive impairments, likely via structural remodeling of hippocampal dendritic structure and alterations in synaptic plasticity.

Abstract: Episodic memories are encoded by a sparse population of hippocampal neurons. In mice optogenetic manipulation of this memory "engram" established these neurons are necessary and sufficient for memory recall. However, nothing is known about their *in vivo* activity or precise role in memory. Here we find that during memory encoding only a fraction of the CA1 place cells are engram neurons, distinguished by firing repetitive bursts paced at the theta frequency, a pattern effective in strengthening synapses. During memory recall these neurons remained highly context specific, yet demonstrated preferential spatial remapping of their place fields. These data demonstrate a dissociation of precise spatial coding and contextual indexing by distinct hippocampal ensembles and suggest the hippocampal engram serves as an index of memory content.

Title: Interactions of taste and place coding in the hippocampus

Authors: *L. E. HERZOG, L. PASCUAL, D. B. KATZ, S. P. JADHAV
Program in Neurosci., Brandeis Univ., Waltham, MA

Abstract: The hippocampus plays a key role in spatial learning and memory, and hippocampal place cells respond to specific locations as animals explore their environment. Place cells have also been shown to respond to non-spatial stimuli such as odors, visual cues, textures and tones, forming a mental map based on environmental context and task demands. However, little is known about how place cells respond to tastes, which is surprising, given that one of the most important purposes of having a mental map is to find food. To characterize how the hippocampus responds to tastes, we recorded from neurons in the dorsal CA1 hippocampal region of freely behaving male Long-Evans rats (n=5) as they received different taste solutions delivered via intra-oral cannula either randomly or at specific locations on a linear track. We identified a subset of hippocampal neurons (~20% of recorded cells) that included both putative principal cells and interneurons that responded to as well as discriminated between tastes. Out of these taste-responsive cells, those classified as place cells discriminated between tastes exclusively when stimuli were delivered within their place field. Taste experience in specific locations on the linear track also led to an increased number of cells with place fields that represented locations of tastant delivery. Together, these results suggest that hippocampal taste responses allow animals to form associations between tastes and contexts, using past experience to locate food sources. These findings add to a growing body of literature indicating that place cells do not just respond to locations—rather, they form a mental map that encompasses both spatial and non-spatial aspects of an animal's environment. Future work will further assess the taste and place components of hippocampal responses, and examine the reactivation of taste-responsive cells during sharp-wave ripples.

Title: Odor-place associative memory in the hippocampal-prefrontal network

Authors: *C. A. SYMANSKI, S. K. GUHA, E. KULLBERG, S. P. JADHAV
Brandeis Univ., Waltham, MA

Abstract: Rodents use olfactory cues to learn and remember information about their environment. This requires forming associations between odors and locations, and then recalling these associations to guide future behavior. The physiological mechanisms by which these odor-place associations are formed, retrieved, and maintained during spatial behavior are thought to involve a brain-wide network that includes the hippocampus and the prefrontal cortex (PFC) (Tse 2007; Fujisawa 2011; Igarashi 2016; Rangel 2016). Recent evidence suggests that activity in the hippocampus and PFC, and especially the coordination between the two regions, is important for associative memory, memory formation and recall, and memory-guided decision making (Churchwell 2010; Spellman 2015; Shin & Jadhav 2016). We therefore investigated how coordination between these two regions, along with the olfactory bulb, supports the retrieval of learned odor associations to guide spatial decision making in an odor cue-guided T-maze task. In this task, rats (n = 6) recalled familiar associations between odors and reward locations on the maze arms (75-90% performance accuracy). Multi-site tetrode recordings were used to simultaneously monitor neural activity in the olfactory bulb, medial PFC, and dorsal hippocampal CA1 in freely-behaving rats as they performed this task. We measured local field potential (LFP) activity in all regions, as well as spiking activity of ensembles in CA1 (n = 494 neurons) and PFC (n = 181) to investigate the physiological basis of the recall and maintenance of odor-place associations. During the period of acute olfactory sampling and recall, beta oscillations (15-35 Hz) were prominent in olfactory bulb, CA1, and PFC; further, beta coherence was enhanced between the three regions. Inter-regional phase locking of hippocampal and PFC neurons to beta oscillations was also observed, suggesting beta-driven coordination of these regions as part of a functional network. Individual neurons in both CA1 and PFC also exhibited odor/choice-selective responses, implicating their involvement in recall of odor-place associations. These results point to an olfactory-hippocampal-prefrontal network underlying the recall of olfactory-place associations. In particular, beta oscillations may organize spiking patterns conveying task-related information in the hippocampal-prefrontal circuit. Future

investigations will address ensemble mechanisms in this network for recall and maintenance odor-place associations during the memory-guided decision-making task.

Title: Hippocampal theta supports distinct prefrontal representations on a behavioral timescale

Authors: *M. C. ZIELINSKI[1], J. D. SHIN[1], S. P. JADHAV[2]
[1]Grad. Program in Neurosci., [2]Neuroscience, Psychology & Volen Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Rhythmic coordination of network activity between the rodent hippocampus (CA1) and medial prefrontal cortex (PFC) supports working memory guided decision-making. Theta (6-12 Hz) oscillations are one such prominent mode of rhythmic hippocampal activity, seen during active, goal driven behavior. Theta cycles pattern the firing of hippocampal place cells, as well as temporally organizing PFC activity; a majority of PFC cells fire at distinct hippocampal theta phases during spatial behavior (*Siapas et al., 2005; Jones & Wilson, 2005; Jadhav et al., 2016*). In addition to coding of spatial location, the firing of place cells during theta cycles are hypothesized to support cognitive processes such as planning and evaluation of paths in space and time, with theta-paced PFC responses likely facilitating these processes (*see Zielinski et al. 2017 for review*). In support of this, sequences of place cells that sweep away from the animal's current position during theta have been described (*Wikenheiser & Redish, 2015; Amemiya & Redish, 2018*), but the potential role of PFC in these patterns and the dynamics of these phenomena during behavior are still unknown. To address this relationship, we simultaneously recorded neural ensembles in PFC and CA1 during performance of a W-track spatial alternation task, known to require spatial working memory and dependent on interactions between these two areas (*Wang & Cai, 2006; Maharjan et al., in preparation*). We observed that population dynamics in PFC can encode the animal's current position on a theta cycle timescale, and that prefrontal representations aligned with concurrent representations in CA1. Incorporation of corresponding hippocampal theta phase improved PFC ensemble decoding of space. Furthermore, on approach to goal locations, we observed spatially distant, non-local

representations of place in CA1 on a theta cycle timescale, which aligned with non-local representations of place in PFC. These non-local representations often represented recent or future goal locations. These findings show that PFC coordinates with CA1 at a theta cycle timescale during active behavior, that the hippocampal theta phase locking of PFC activity is relevant to coordinated representations of space, and that concordant non-local representations between the two regions can serve as hallmarks of goal-oriented cognitive processes.

Title: Investigating thalamic contributions to abnormal hippocampal oscillatory activity in a mouse model of schizophrenia

Authors: *R. NANU[1], C. LIN[2], D. B. KATZ[3], S. P. JADHAV[3], H. PI[3], J. LISMAN[3]

Abstract: Schizophrenia (SZ) patients show an elevation in the power of delta frequency (1-5 Hz) EEG oscillations in the awake state (Venables et al., 2009; Clementz et al., 1994). This elevation is unique to the diseased state of SZ and isn't seen in first-degree relatives of patients. Furthermore, optogenetic studies in rodents suggest that waking hippocampal delta oscillations may be causal in producing some of the symptoms of SZ (Duan et al., 2015). Previous studies from our lab have found that thalamic T-type Ca^{2+} channels support this delta abnormality in an NMDAR antagonist model of SZ (Zhang et al., 2012); however, NMDAR antagonists do not fully capture the development and progression of the disease. A stronger model is provided by the Df(16)1/+ (Df1) mouse which mimics the largest known genetic risk of SZ (~33%), human 22q11 deletion syndrome. These mice have already been found to exhibit many of the behavioral phenotypes associated with animal models of the disease (Karayiorgou et al., 2010), but in order to further establish this experimental system to study underlying neural mechanisms, it is necessary to determine if these mice also show waking delta abnormalities. In a key a first step, here we test whether delta is elevated in the Df1 mice. To this end, we use in-vivo electrophysiology to record from hippocampal area CA1 in 3-9 month old Df1 mice and WT

littermate controls. We then use EMG data to classify behavioral states as moving, quiescent waking or sleeping, and the baseline spectral properties of the local field potentials are compared between groups and states. Our preliminary data suggests a large variation among Df1 animals with some animals exhibiting an elevation in low-frequency oscillatory power compared to controls. Ongoing studies seek to confirm these results and investigate possible phenotypes to identify Df1 animals with delta elevations. We aim to establish an experimental system that fully encapsulates SZ development and can be used to thoroughly study the mechanisms underlying SZ pathophysiology. Our long-term goal is to establish whether the mechanisms responsible for delta elevations in the NMDAR antagonist model, thalamic T-type Ca^{2+} channels, are still valid and can be targeted for possible treatment of SZ.

Title: Dual-phase-locking in the hippocampal-prefrontal network

Authors: *R. YOUNG[1], J. D. SHIN[1], S. P. JADHAV[2]
[1]Grad. Program in Neurosci., [2]Neuroscience, Psychology and Volen Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Network interactions among neural ensembles in distributed circuits are necessary for cognition and behavior. It is still unclear how groups of neurons organize information transmission, but rhythmic patterns are thought to coordinate activity to form functional networks (*Palmigiano et al., 2017*). Brain rhythms reflect synchronized activity across large ensembles of neurons, believed key for coordination during many cognitive tasks. It has been shown that neurons in local networks will anchor their spikes within different local field rhythms, and that rhythms can synchronize across communicating structures (*Fries, 2015; Rangel et al., 2016)*. Multiple network activity patterns are prominent features in hippocampal and prefrontal areas during memory-guided navigation (*Shin & Jadhav, 2016*). Coordination of theta rhythms, and theta-gamma coupling, is observed in hippocampal-prefrontal circuits during spatial memory tasks, accompanied by local phase-locked spiking to theta and gamma rhythms

(*Tamura, et al., 2017; Shin & Jadhav, 2016*). Here, we report an interregional phase-locking pattern between prefrontal spikes and two hippocampal rhythms at once, beta and theta, during a spatial alternation memory task. A similar pattern has been observed before within the hippocampus (phase-locking of hippocampus to its own rhythms; *Lansink et al., 2016*), but here we examine a novel inter-regional phenomenon with prefrontal cells phase-locking simultaneously to hippocampal beta and theta rhythms. Importantly, this dual-phase-locking pattern undergoes a phase shift between distinct sections of the spatial memory task that have different cognitive demands, forming two inverse phase-locking modes we call "Type A" and "Type B". Both types appear in working memory and non-working memory phases of the task. However, only one of the two modes, Type B, is greatly attenuated and disordered during error trials that require working memory. Further, both phase-locking modes strengthen with degree of task performance. The precise manner in which spikes of the distant prefrontal cortex coordinate to this pair of hippocampal rhythms is striking and are indicative of different circuit-level operations, utilized differentially in behavior.

Title: Learning-associated changes in awake replay content in the hippocampal-prefrontal network

Authors: *W. TANG[1], J. D. SHIN[1], S. P. JADHAV[2]
[1]Neurosci. Program, [2]Neuroscience, Psychology and Volen Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: The hippocampus replays place-cell sequences reflecting behavioral experiences during sharp-wave ripple (SWR) events in awake and sleep states. Awake replay can recapitulate past trajectories as well as predict future paths, suggesting both retrospective and prospective roles in memory consolidation, retrieval and planning. Additionally, we have previously shown that these hippocampal replay events are coordinated with prefrontal cortical (PFC) activity for memory reactivation (*Jadhav et al., 2016*; *Tang et al., 2017*). However, it remains unclear whether replay serves specific functions in different learning states, and how PFC cells

participate in replay.
To address these questions, we continuously monitored the activity from same neuronal populations in both hippocampal area CA1 and PFC using high-density tetrode recordings throughout the duration of learning of a W-track spatial alternation task (n = 4 rats). Consistent with previous studies (see *Zielinski et al. 2017*, *Tang and Jadhav, 2018* for review), we observed that sequences of CA1 activity were reactivated both in the order as experienced (forward replay) and in the opposite order (reverse replay) during awake immobility. Interestingly, the order of replay sequences (forward or reverse) has a specific relationship to possible past and future trajectories during correct choices, but not during incorrect choices. Furthermore, the content of forward and reverse replay differentially changed as learning progressed: reverse replay was retrospective for past paths only during early learning; whereas forward sequences were predominantly related to prospective paths only during late learning. Additionally, PFC cells reactivated more coherently with CA1 cells during the replay of current relevant trajectories (i.e., the immediate past or future) than during that of irrelevant trajectories. This coordinated reactivation was stronger during initial learning compared with well-learnt periods, consistent with our previous study (*Tang et al., 2017*). Thus, our results show that the content of hippocampal replay systematically changes during learning. These suggest a shift in the role of replay from retrospective evaluation during initial learning to prospective planning of upcoming trajectories during later performance. Moreover, the coordinated hippocampal-PFC reactivation may play a crucial role in learning through selective replay of task-relevant content during memory-guided behaviors.

Title: Development of hippocampal-prefrontal representations in parallel with behavioral learning

Authors: *J. D. SHIN[1], W. TANG[1], S. P. JADHAV[2]
[1]Neurosci. Program, [2]Neuroscience, Psychology & Volen Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Coordinated activity between the hippocampus and prefrontal cortex (PFC) is critical for many aspects of cognition. The development of task-related neural representations within this network is thought to provide the neural substrate that underlies many memory-related processes (Frank et al., 2000; *Wood et al., 2000; Baeg et al., 2003)*. In any given environment, hippocampal place cells have specific spatial firing patterns that tile all locations, forming a cognitive map that provides a substrate for the formation of salient associations. Similarly, PFC cells also exhibit spatially modulated firing patterns, and we have recently shown that spatial correlations within the hippocampal-prefrontal circuit during the initial stages of learning may facilitate the emergence of representational similarities in these two regions (*Tang et al., 2017*). The development of stable representations in this network can support memory formation and retrieval. However, the specific nature of these task-relevant representations, the relative timescales at which they emerge in the hippocampus and PFC during learning, and how they support subsequent stable performance is still unclear.
To address these questions, we continuously recorded neural ensembles simultaneously in PFC and CA1 region of the hippocampus across behavioral and sleep sessions using high-density tetrode recordings in rats (n = 6) during learning of a novel spatial working memory task in a single day. This single-day learning paradigm allows us to track the same population of cells over the entire learning process, enabling characterization of changes in representations and dynamics in parallel with behavioral learning. We found that over the course of learning, populations in the hippocampus and PFC rapidly develop stable, task-modulated firing patterns. These stable representations dynamically represent behavior on a trajectory-by-trajectory basis during memory-guided performance. Furthermore, our results indicate that changes in neural dynamics in PFC occur at a similar behavioral timescale as the hippocampus. Spatially stable representations, as well as direction selectivity, emerged in parallel in both regions. Additionally, choice selective representations developed in the hippocampal-prefrontal network in parallel with learning and became predictive of past and future choices. The emergence of these stable, task-related representations may reflect the establishment of hippocampal-prefrontal associations that are important for learning in novel environments, and can therefore provide the neural basis to support memory guided behavior.

Title: Visualizing and modulating memories during voluntary aerobic exercise

Authors: *K. DORST[1], O. P. MCKISSICK[2], S. RAMIREZ[3]
[1]Grad. Program in Neurosci., [2]Psychological and Brain Sci., Boston Univ., Boston, MA; [3]Ctr. for Brain Sci., Harvard Univ., Boston, MA

Abstract: Aerobic exercise improves physical health as well as various aspects of cognition. Moreover, the structural and functional integrity of the hippocampus—a key site for episodic memory-related processes—are markedly enhanced after chronic bouts of running. However, the underlying circuitry mediating interactions between an episodic (e.g. contextual) memory and voluntary aerobic exercise remains unclear.
Here, we selectively label cells within the dentate gyrus (DG) and basolateral amygdala (BLA) that are preferentially activated during the encoding of a positive, negative, or neutral memory. Our preliminary data suggest that both the DG and BLA become active during bouts of voluntary running, as indicated by c-fos expression. However, the ensemble within the DG that was previously active during the encoding of a positive, negative or neutral memory does not become preferentially reactivated during bouts of voluntary exercise. Conversely, BLA cells previously activate during the formation of negative, but not neutral or positive memories, become preferentially reactivated during bouts of voluntary exercise.This suggests that the DG may be encoding a different context when mice are voluntarily running, while BLA cells processing fear may become preferentially engaged during such behavior.
Lastly, our current experiments focus on closed-loop optogenetic reactivation of DG- or BLA-mediated negative or positive memories specifically during bouts of running to test for potential suppression or enhancement-like effects on subsequent memory expression.Together, our experiments reveal a putative neuronal and behavioral interaction between discrete memory-related processes and aerobic exercise.

Title: Visualization and modulation of ensembles in the hippocampus and amygdala during fear reinstatement

Authors: *W. MAU, Y. ZAKI, A. HAMIDI, E. DOUCETTE, S. L. GRELLA, N. J. MURAWSKI, E. MERFELD, M. SHPOKAYTE, S. RAMIREZ
Boston Univ., Boston, MA

Abstract: Post-traumatic stress disorder (PTSD) is a condition that precipitates from a highly aversive experience and is manifested by overgeneralized fear in innocuous situations. Interestingly, a striking proportion of patients who undergo exposure therapy - which can lead to the suppression, or "extinction," of the original fear memory - are highly vulnerable to relapse, especially when the conditioned stimulus is delivered outside a clinical context. Here, we interrogated the neural substrates supporting the acquisition of fear as well as the subsequent extinction of fear to gain a causal understanding of its underlying neural components. We used a combination of activity-dependent labeling of neuronal ensembles in multiple brain regions associated with fear-related behaviors (basolateral amygdala, BLA; dorsal dentate gyrus of hippocampus, dDG) and further manipulated these ensembles using optogenetics to probe the changes that a fear memory undergoes during extinction and during fear reinstatement.
We first tagged BLA or dDG cells during the acquisition of a contextual fear memory in mice. All subjects then underwent extinction learning, and then received a shock in an unconditioned context (serving to reinstate the original context-specific fear). We inhibited the tagged fear ensemble during reinstatement or during a fear recall test in the original conditioned context the day after. We found that inhibition of the fear ensemble in BLA or dDG during the recall test actively disrupted fear expression in the conditioned context. This suggests that the original fear ensemble in BLA and dDG contributes to a context-dependent fear response following shock-induced reinstatement, providing key evidence that the neural correlate of fear reinstatement may be a reemergence of the original fear memory trace. Next, we employed *in vivo* calcium imaging using miniaturized microscopes to visualize ensemble dynamics within and across fear conditioning, extinction, reinstatement, and recall sessions. Preliminary results from CA1 and BLA suggest that population activity can predict freezing bouts, opening up the possibility to investigate which cells are involved with fear expression at different time points in extinction and recall. We also observed sequences of cell activity related to the shock stimulus. Future work will examine how these sequences evolve over extinction and reinstatement.

Title: Population and projection-specific segregation of fear and reward in the ventral hippocampus

Authors: *M. SHPOKAYTE[1], O. MCKISSICK[2], S. X. LIU[3], S. L. GRELLA[2], E. DOUCETTE[2], E. MERFELD[2], N. J. MURAWSKI[2], Y. ZAKI[2], A. B. FINKELSTEIN[4], S. RAMIREZ[2]
[1]Dept. of Psychological Brain Sci., [2]Boston Univ., Boston, MA; [3]Whitehead Inst., Cambridge, MA; [4]Sch. of Life Sci., Arizona State Univ., Boston, MA

Abstract: The ventral hippocampus(vHPC) codes both contextual information as well as rewarding and aversive experiences. Still, the behavioral, anatomical, and molecular vHPC activity associated with rewarding and aversive experiences has not yet been fully characterized. Here, we utilize an activity dependent, inducible, all-virus cfos-tTA system for tagging cells processing rewarding or aversive memories in vCA1 projecting onto the basolateral amygdala (BLA) of c57BL/6 mice. We optogenetically manipulate vCA1 to BLA terminals and provide evidence of the their capacity to "switch" from driving reward-related behaviors to aversive-related behaviors and vice versa. Furthermore, we use fluorescence-activated cell sorting (FACS) to pull down cells from the vCA1 responsible processing either fear or reward as well as those that have had their terminals "switched." Using Gene Set Enrichment Analysis (GSEA), a computational method that determines whether a defined sets of genes are statistically significant between two biological states, we find that vCA1 fear and reward cells upregulate genes associated with Alzheimer's Disease and neuroprotection, respectively. To further characterize this cellular population, we provide evidence that vCA1 recruits two segregated populations of cells in response to either a rewarding or aversive stimuli using a novel dual memory tagging strategy that combines our c-fos-tTA doxycycline-regulated viruses with a transgenic fos-Cre tamoxifen-regulated line. Our ongoing experiments focus on anatomically tracing projection-specific targets in vCA1 cells using retrograde, clearing, and physiological strategies. Understanding how the hippocampus regulates gene expression, processes and stores reward and

fear, and recruits valence specific information may have clinical value for the treatment of psychiatric disease-related states.

Title: Optogenetic induced extinction-like behaviors in ethanol withdrawn mice

Authors: *C. CINCOTTA[1], N. J. MURAWSKI[2], S. L. GRELLA[2], E. DOUCETTE[2], E. MERFELD[2], M. SHPOKAYTE[2], Y. ZAKI[2], A. HAMIDI[1], K. DORST[3], S. RAMIREZ[2]
[2]Psychological and Brain Sci., [3]Grad. Program in Neurosci., [1]Boston Univ., Boston, MA

Abstract: Withdrawal from chronic alcohol impacts the brain's stress and memory systems, which may underlie individual susceptibility to persistent drug seeking and stress-induced relapse. Preclinical studies demonstrate impaired fear memory processes in rodents withdrawn from alcohol, including abnormally heightened fear responses that are resilient to subsequent attenuation by extinction training. The underlying neural circuits mediating, and sufficient to intervene with, impaired extinction following alcohol withdrawal have remained elusive. First, we demonstrate that mice withdrawn from chronic ethanol show impaired fear extinction and heightened fear renewal relative to controls. Next, control mice that received a brief reactivation session prior to extinction showed enhanced extinction and lower reinstatement relative to non-reactivated controls; ethanol-withdrawn mice did not demonstrate this putative reconsolidation-extinction enhancement. We next labeled neural ensembles in the dentate gyrus (DG) with an inducible and activity-dependent virus cocktail which allows expression of channelrhodopsin-2 (ChR2) or a control protein (eYFP) in cells active during the formation of a contextual fear memory in mice withdrawn from chronic alcohol. Mice were placed into a distinct context and received chronic light stimulation directed at the DG over five consecutive days. Chronic reactivation of fear ensembles led to context-specific reductions in fear responses in control mice

expressing ChR2 (but not eYFP). This paradigm was successful in producing optogenetic induced extinction-like behavior effects in ethanol withdrawn mice. These results show how chronic reactivation of fear ensembles in the hippocampus may offer a means to facilitate extinction following withdrawal from chronic alcohol exposure. A mechanistic understanding of fear processes following drug withdrawal will aid in the development of therapies to attenuate stress-related cognitive dysfunction following drug withdrawal.

Title: Reactivating hippocampus-mediated memories to disrupt the reconsolidation of fear

Authors: *S. L. GRELLA, A. H. FORTIN, J. H. BLADON, N. J. MURAWSKI, Y. ZAKI, E. DOUCETTE, E. MERFELD, M. SHPOKAYTE, S. RAMIREZ
Ctr. for Memory and Brain, Boston Univ., Boston, MA

Abstract: Background: Fear conditioning has been used to model memory and stress-related behaviors in rodents. While fear is often adaptive, dysregulation of fear circuits can lead to maladaptive states comprising mood and anxiety disorders. A promising prospect of attenuating the strength of fear memories is through the disruption of reconsolidation - a process by which activated memories are susceptible to modification. In previous studies, interventions such as protein synthesis inhibitors and beta-blockers have been used to target and disrupt conditioned fear during the reconsolidation process. Here, we propose a novel intervention based on the hypothesis that optogenetic reactivation of a previously formed, hippocampus-mediated memory during reconsolidation will disrupt the original fear memory, thereby reducing the behavioral expression of fear. **Method:** We combined the use of the activity-dependent inducible c-Fos-tTA system for neuronal tagging in c57BL/6 mice to tag dorsal dentate gyrus (dDG) cells active during a positive, neutral, or negative experience, and channelrhodopsin 2-mediated optogenetics. Mice were fear-conditioned and given a 20-minute recall session the following

day. During recall, we optically stimulated the dDG during the first or last 10 minutes of the session to reactivate the tagged dDG-mediated positive, neutral, or negative memories. Mice then received extinction training and were tested for stress-induced reinstatement on subsequent days or spontaneous recovery two weeks later. **Results:** Artificial reactivation of a positive memory during the last ten minutes of the recall session resulted in real-time decreases in freezing whereas reactivation of a neutral and negative memory did not produce similar decreases in freezing. Artificial reactivation of positive, neutral, and negative memories during the first ten minutes of the recall session resulted in faster rates of extinction learning and the attenuation of stress-induced reinstatement as well as lower levels of spontaneous recovery. Since these effects were observed when stimulation occurred during the first half of the recall session, it suggests that artificial memory reactivation may induce a priming effect or a general system perturbation serving to interfere with reconsolidation (and /or other) memory processes. We are currently investigating how widespread, non-specific hippocampal activation using a CAMKIIa promoter affects reconsolidation. **Significance:** This work highlights the therapeutic value of memory modulation as a viable treatment for the suppression of fear responses, implicating dDG cells as specific nodes of intervention.

Title: Chronically reactivating positive and negative memories to modulate hedonic and social behaviors

Authors: *E. DOUCETTE, E. MERFELD, J. LOGAN, Y. ZAKI, S. L. GRELLA, N. J. MURAWSKI, M. SHPOKAYTE, A. HAMIDI, S. RAMIREZ, K. DORST, A. FINKELSTEIN
Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: Chronic stress in mice induces a variety of anxiety- and depressive-like phenotypes at the neuronal, circuit, and behavioral levels. More specifically, social and hedonic-like states are dramatically impaired across many psychiatric disorders, though the underlying mechanisms sufficient to precipitate or alleviate such impairments remain largely unknown.
Here, we utilize an activity-dependent and inducible tagging strategy to modulate hippocampus (HPC) cells processing positive, neutral, or negative memories prior to chronic immobilization stress exposure. We hypothesized that chronic negative memory stimulation would impair social behavior and decrease hedonic-like activity, while positive memory stimulation would promote social behavior and increase hedonic-like activity.
We find that chronically stimulating hippocampal cells processing a valence-specific experience is sufficient to affect social but not anxiety-like behaviors. Furthermore, chronic reactivation of positive and negative memories modulates the behavioral response to chronic stress. We also find that chronic memory stimulation followed by chronic immobilization stress differentially affects body weight.
Our current experiments aim to delineate the underlying cellular activity during a variety of behavioral assays following chronic memory stimulation. In addition, our ongoing research focuses on interrogating the neural circuitry underlying affected behaviors, particularly examining functional connectivity between the hippocampus and the basolateral amygdala. Together our results connect chronic memory modulation with discrete maladaptive behavioral states and simultaneously provide a mechanistic basis for inducing a defined set of behavioral impairments.

Title: Manipulating a social ensemble to modulate socially induced reinstatement of a contextual fear memory

Authors: *A. B. FINKELSTEIN[1], A. HAMIDI[2], Y. ZAKI[2], E. MERFELD[2], S. L. GRELLA[2], N. J. MURAWSKI[2], M. SHPOKAYTE[2], S. RAMIREZ[2]

Abstract: Social interactions provide some of the most influential experiences in a social animal's life. The basolateral amygdala (BLA) and ventral hippocampus (vHPC) are two brain regions implicated in fear, anxiety, and social behaviors. Lesions to the BLA have been shown to decrease anxiety and increase social behaviors in novel environments. In social defeat paradigms, mice that underwent an aggressive attack exhibited increased BLA activity, and decreased vHPC activity. Finally, work by Ortiz and Tye has demonstrated that excitatory projections from the BLA to vHPC mediate changes in social behaviors. Collectively, these studies highlight the complementary and important role that the BLA and vHPC play in mediating anxiety and social behaviors. Here, we show that social interaction with a mouse that has received a foot shock induces non-generalized reinstatement of an extinguished fear memory in a portion of cagemates. Optogenetic excitation of basolateral amygdala (BLA), but not dentate gyrus (DG), cells that were previously active during the social encounter causes freezing in social reinstators but not non-reinstating cagemates and in a frequency-specific manner. However, activation of this ensemble is not necessary for reinstatement, as optogenetic silencing does not prevent reinstatement. Future experiments will test whether chemogenetic inhibition of the fear memory during the social encounter reduces reinstatement, and will explore overlap in cellular representation of the social and fear memories.

Title: Effect of combined adult vitamin D deficiency and social stress on spatial cognition in BALB/c mice

Authors: *M. AL AMIN, R. SULLIVAN, S. ALEXANDER, T. H. BURNE
Queensland Brain Inst., Brisbane, Australia

Abstract: Background
Vitamin D (VD) deficiency is prevalent in adults and is associated with cognitive impairment. However, it has not been established that VD deficiency is a causal factor leading to adverse health outcomes. It is possible that those VD deficient individuals are exposed to an additional insult leading to the progression of brain diseases. Therefore, the main aim of this study was to determine if AVD deficiency would exacerbate the effects of a secondary exposure, in this case social stress, in BALB/c mice.
Methods
Adult male BALB/c mice (10 weeks old) were fed a control or VD deficient diet for 10 weeks. To induce social stress, we further divided the animals into two groups, separated (SH) or socially defeated (SD). SH mice were housed 2 per cage separated with a perforated Plexiglass divider. SD mice were subjected to ten days of social defeat stress with a CD-1 mouse for 10 min/day. We then tested mice in a social preference test, and on the active place avoidance test to measure social preference and spatial learning and memory formation respectively. We performed Golgi-cox staining to measure the spine morphology of hippocampal CA1 (proximal branches) and Dentate gyrus (DG) neurons.
Results
We found that AVD-deficient mice were more susceptible to the effect of social stress in the social preference test; SD mice interacted more than the SH mice. SD mice had a longer latency to enter the shock zone in the APA test. We observed a lower mushroom spine density in AVD-deficient mice in the CA1 neurons. Moreover, the head extension and head extension to the centre was reduced in AVD-deficient mice. Interestingly, we found an increased in the number of thin spines in SD mice.
Conclusions
Our results support the hypothesis that VD deficiency may alter behavioral outcomes in mice susceptible to social stress. Spatial learning of SD mice could be correlated with increased formation of a thin spine in the CA1 neuron. However, reduced mushroom spine formation may affect spatial learning in AVD deficient mice. We suggest that pharmacological and genetic approaches be used to investigate the role VD deficiency and social stress in hippocampal-dependent spatial learning deficits in future studies.

Title: Effects of LEC-specific P301L tau on object recognition memory

Authors: *S. SETTI, R. T. HESLIN, Y. DU, M. N. REED
Drug Discovery and Develop., Auburn Univ., Auburn, AL

Abstract: Alzheimer's disease (AD) is biologically characterized by accumulation of beta-amyloid plaques, neurofibrillary tangles containing hyperphosphorylated tau protein, and pervasive neuronal damage ultimately leading to neuronal death. Because of the irreversible nature of the neuronal death, early detection of AD is important for any treatment aiming to halt or prevent neuronal damage. Currently, there are no existing cognitive screening tasks for AD optimized to assess function of one of the first brain regions affected in AD, the lateral entorhinal cortex (LEC). Tasks aimed to assess LEC function, as it is the first area to exhibit tau pathology, would aid in early detection of AD, thereby offering a better prognosis for affected individuals. In this study, we used a viral vector to introduce mutant P301L tau into the LEC of otherwise healthy male mice. Then, after 4 weeks, we assessed performance on an object recognition task previously identified to be sensitive to LEC lesions. Afterwards, we determined the presence of AD-associated pathology by using immunohistochemistry. Results indicate that tauP301L mice exhibit early stage-specific tau pathology and subtle learning and memory deficits when compared to control mice. Thus, our task is sensitive to AD pathology occurring within the LEC. Additionally, the literature suggests that neuronal activity alterations may mediate cognitive deficits in AD and promote the spread of tau pathology. Therefore, our next steps include examining whether using optogenetics to manipulate neuronal activity in the context of tau pathology can rescue cognitive deficits in this model.

Title: Prenatal cannabinoid exposure results in learning and memory deficits in rodent adolescent offspring: Elucidation of the mechanism and identification of a therapeutic target

Authors: *P. D. PINKY, J. BLOEMER, S. E. SETTI, R. T. HESLIN, M. N. REED, V. D. SUPPIRAMANIAM
Drug Discovery and Develop., Harrison Sch. of Pharmacy, Auburn Univ., Auburn, AL

Abstract: Cannabis use during pregnancy has increased by 62% from 2002 through 2014 and is now the most commonly used illicit drug during pregnancy with use ranging from 2-5% in most studies but as high as 15-28% among urban, low-income pregnant women. Human brain imaging studies show that functional network activity underlies the typical cognitive and behavioral processes reportedly altered by prenatal cannabinoid exposure (PCE), and that aberrant connectivity is linked to atypical functional development in other disorders. However, very little is known about the effects of prenatal cannabinoid exposure on early brain development in human infants, or on the formation of early functional networks that may underlie the cognitive and behavioral deficits reported in studies of exposed children. Here, we have investigated the impact of PCE in adolescent offspring in hippocampal dependent spatial learning and memory preforming a series of behavioral, electrophysiological and immunochemical studies. An osmotic pump filled with either N-Methyl Pyrulol (NMP) or the cannabinoid receptor full agonist WIN55,212-2 (2 mg/kg body weight/day) was implanted subcutaneously in Gestational Day-3 (GD-3) which delivered the drug at a constant rate until the delivery of the pups. Contextual Fear Conditioning (CFL) and Morris Water Maze (MWM) were performed to investigate the hippocampus based spatial memory which revealed significant deficits in the PCE animals. Electrophysiological experiment in Schaffer Collateral Pathway of Hippocampus also revealed significant impairment in NMDA mediated synaptic plasticity. In line with this, Immunochemical and Western blot data has shown increased Cannabinoid Receptor Type 1(CB1) expression followed by reduced Neural Cell Adhesion Molecule (NCAM) expression which postulates the observed behavioral deficits might be due to altered NMDA mediated glutamatergic neurotransmission in the hippocampus of these animals leading to impaired synaptic plasticity causing significant learning and memory deficits.

Title: Non-invasive sensory stimulation targets deep brain structures in awake mice

Authors: *A. L. PAULSON[1], S. M. PRINCE[2], M. K. ATTOKAREN[3], L. ZHANG[3], A. C. SINGER[1]

Abstract: Rhythmic brain activity is thought to be important for temporally precise coordination of neural activity to support a variety of brain functions. In the hippocampus, a deep brain region essential for spatial and episodic memory, rhythmic activity is thought to play a key role in learning and memory by modulating spiking across neurons and hippocampal subregions. Furthermore, in neurogenerative disease, such as Alzheimer's disease, there are deficits in rhythmic activity, particularly in the gamma band (30-50 Hz, also known as slow gamma). However, determining the causal role of rhythmic activity in hippocampal function or disease has been limited because of a lack of methods to drive such activity non-invasively in deep brain structures. Therefore, we developed a novel sensory stimulation technique to non-invasively drive rhythmic neural activity in deep brain regions. Prior work has shown that flickering light or sound stimulation drives rhythmic activity in primary sensory regions, visual cortex and auditory cortex, respectively, entraining neural activity to the frequency of the flickering stimulus. Surprisingly, we found that sensory flicker stimulation entrains activity beyond primary sensory areas. Using silicon probes, we recorded neural activity from awake, behaving mice as they were exposed to auditory or auditory-visual flicker stimulation at multiple frequencies between 20-100 Hz. We found that sensory flicker stimulation entrains single unit spiking activity not only in auditory cortex, but also in hippocampal area CA1 and prelimbic cortex, the mouse homolog of prefrontal cortex. Due to the non-invasive nature of this stimulus, driving rhythmic neural activity with sensory stimulation has a variety of applications, from understanding the role of rhythmic brain activity in cognitive functions, to developing therapeutics to treat neurodegenerative disease.

Title: CA1 neural activity during spatial navigation in the 5XFAD mouse model of Alzheimer's disease

Authors: *S. M. PRINCE[1], A. L. PAULSON[2], L. ZHANG[3], M. K. ATTOKAREN[3], S. AMIGUES[3], J. H. TIPTON[3], A. C. SINGER[2]

Abstract: Extensive research has revealed protein accumulation, synapse loss, and neurodegeneration in Alzheimer's disease, the most common form of dementia. However, it remains unclear how these changes lead to disruption of neuronal activity and cognitive impairment. Alterations in electrophysiological activity have been found in both humans with Alzheimer's disease (AD) and animal models of AD. Previously, we have shown decreases in gamma (30-100 Hz) power and gamma-modulated spiking activity in a well-established mouse model of Alzheimer's disease (5XFAD). These deficits were found specifically during hippocampal sharp-wave ripples, high frequency oscillations that are essential for spatial learning and memory. Not only is the hippocampus affected early in AD, but these neural deficits were also found before behavioral deficits emerged. These results, combined with proposed role of gamma in learning and memory, suggest that altered gamma activity contributes to memory deficits in Alzheimer's disease. Yet, the mechanism underlying these deficits in gamma activity during behavior remains unknown. In order to determine how neural circuits produce aberrant neural activity in a 5XFAD mouse model of Alzheimer's disease, we examined the contributions of different cell types to gamma activity during spatial navigation. We hypothesized that deficits in gamma oscillations occurred in 5XFAD mice due to changes in interneuron activity. To test our hypothesis, we designed a virtual-reality spatial navigation task that could be performed by both 5XFAD and wild-type (WT) animals. We then used silicon probes to record local field potential and single unit spiking activity from hippocampal subregion CA1, where gamma activity has been well characterized. All recordings were performed in awake, behaving, male 5XFAD mice and WT littermates during spatial navigation, and experimenters were blinded to genotype. Using spike rate, width, and autocorrelograms to classify putative cell types, we determined how spiking activity of putative pyramidal cells and interneurons differs between 5XFAD and WT mice. This work has broad applications in revealing how neural circuits for memory are disrupted in mouse models of Alzheimer's disease, and in bridging the gap between molecular pathology, neural activity, and cognitive deficits.

Title: OLM interneuron activity during goal-directed behaviors in a mouse model of Alzheimer's disease

Authors: *L. PENAZZI, J.-B. BOTT, C. LEGRAND, B. RIVARD, S. WILLIAMS
McGill University-Douglas Inst., Verdun, QC, Canada

Abstract: Oriens lacunosum-moleculare (OLM) cells represent a key class of GABAergic interneurons in controlling hippocampal network state and downstream behaviors. Their activitiy is associated to successful learning of new information. Recent reports demonstrate that OLM cells may be active in response to specific events such as aversive stimuli delivery (e.g. shock or air-puff) or to the locomotion state of the animal. However, it is still unknown whether functionally distinct OLM interneurons are selectively engaged during one of those events or both. In the pathology of Alzheimer's disease (AD), altered excitatory network activity is associated with cognitive deficits. Whether an impairment of OLM interneuron activity contributes to abnormal hippocampal function during learning and memory has not yet been determined.
We aim to characterize OLM activity patterns during distinct behavioral events underlying procedural and reference memory processes. To maximize the diversity of behaviors to investigate OLM activity, we performed calcium imaging in freely moving mice using the miniscope imaging technique. We used the Chrna2-cre mouse line to identify and control specifically OLM interneurons. To determine whether abnormal OLM cells contribute to the neuropathological feature of AD, we generated a novel transgenic Alzheimer mouse model Chrna2-J20 over-expressing a mutant form of human amyloid precursor protein with Swedish and Indiana mutations. OLM activity was analyzed during a diversity of behavioral events such as "avoidance" of aversive area, uptake of the sucrose-sweetened water, "reactivity" to aversive stimuli delivery, "locomotion" and "immobility".
This study using calcium imaging will help to reveal some of the key roles played by OLM interneurons in hippocampal function during goal-directed behaviors.

Title: Characterization of sex differences in hippocampus-dependent learning and memory

Authors: J. M. STRAUSS[1], K. D. STEVANOVIC[1], N. H. WU[2], *J. D. CUSHMAN[1]
[1]Neurobio. Lab., Natl. Inst. of Envrn. Hlth. Sci., Durham, NC; [2]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Basic neuroscience research currently has a deficit in awareness of sex differences in neurobehavioral function; stifling translation to the human population. The current project is intended to characterize sex differences in hippocampus-dependent behavioral tasks and examine the underlying mechanisms. We assessed spatial, contextual and temporal learning using a battery of tests in two-month-old C57Bl6Tac mice: spontaneous alternation, novel context recognition (exploratory habituation), object recognition and tone and contextual fear conditioning. There were no sex differences in percent alternation, indicating similar spatial working memory, however females showed an overall increase in the number of arm entries. Males and females showed similar levels of exploratory behavior over two days of exposure to the same open field environment, including the typical reduction in exploratory behavior on the second day (referred to as exploratory habituation or novel context recognition). Novel object recognition was similar in males and females, with both showing a preference for investigating the novel object 24 hours after the familiarization phase. In the object location task males showed increased exploration of the displaced object after a 24 hour delay, whereas females did not. For tone fear conditioning we assessed hippocampus-independent delay, hippocampus-dependent trace and two non-associative controls: explicitly unpaired and sensitization (no tone present during training). Delay conditioning was similar; however, trace fear conditioning was enhanced in males. Females showed increased freezing in the sensitization group, responding fearfully to a novel tone after context-only fear conditioning. Overall these findings show task-specific sex differences indicative of a relative enhancement in hippocampus-dependent spatial and temporal learning in males. The enhanced non-associative sensitization learning has important implications as non-associative controls are rarely used, thus differences could be erroneously assumed to be due to altered associative learning when they are in fact due to non-associative changes. In addition, this finding could serve as a basis for modelling increased anxiety disorders in women. These findings are not only informative about general sex differences, to be studied in their own right; but they also set the baseline for interpreting data in transgenic models and advanced in vivo techniques.

Title: The role of medial septal glutamate neurons in CA1 principal cell activity during freely behaving navigation investigated with both calcium imaging and optogenetic silencing in mice

Authors: *J.-B. BOTT[1], L. PENAZZI[2], A. KY[1], S. WILLIAMS[3]
[1]Dept of Pyschiatry, McGill University, Douglas Ins, Verdun, QC, Canada; [2]McGill University-Douglas Inst., Verdun, QC, Canada; [3]Dept Psych, McGill Univ., Verdun, QC, Canada

Abstract: Recent evidence suggests that medial septum (MS) glutamatergic neurons through their projections to hippocampus may code for ongoing locomotion velocity. Since these results were obtained in head-fixed mice running on a treadmill, the role of MS glutamatergic cells in more cognitive-demanding behavior such as navigation remains underexplored.
Using miniscope calcium imaging, we characterized the spontaneous activity of identified glutamatergic neurons during navigation tasks in freely behaving mice. MS glutamatergic neurons form heterogeneous subpopulations of cells that are differentially active in relation to specific behaviors. MS glutamate neurons do not code for locomotion *per se* but rather for the spatial destination of both future and ongoing trajectories. The consequences of optogenetic silencing MS glutamatergic neurons before the onset of active navigation on both the precision of the navigation and CA1 principal cells activity was further explored using a combination of optogenetic and calcium imaging on the same freely-behaving mice.
Our results suggest that one subpopulations of medial septum glutamatergic neurons are indispensable for goal directed navigation.

Title: Investigating replay activity during Slow-wave and REM sleep in freely behaving mice

Authors: *J. CHOI[1], G. ETTER[3], S. WILLIAMS[2]
[2]Dept Psych, [1]McGill Univ., Verdun, QC, Canada; [3]Douglas Mental Hlth. Inst., Verdun, QC, Canada

Abstract: Several studies have pointed out the importance of sleep in memory functions. Periods of sleep can further be divided into rapid eye-movement (REM) periods characterized by prominent hippocampal theta (~8Hz) oscillations, and non-REM sleep that display slower hippocampal oscillations and occasional ultra-fast oscillations termed ripples. A large body of evidence indicates that ripple events observed during non-REM sleep are crucial for memory consolidation as they replay neuronal activations observed during wakefulness. Moreover, previous studies have pointed out increased ripple frequency after novel experience. More recent studies from our laboratory show however that altering hippocampal activity during REM sleep can induce a significant reduction in memory consolidation. We combined in vivo electrophysiology and calcium imaging using the miniscope technique to see whether wakefulness-related neuronal activity could be replayed during ripple-events but also during REM periods. In addition, we determined whether the temporal organisation of the cell assemblies during sequences is preserved between REM and wakefulness brain states. This would support previous studies that suggest that hippocampal temporal firing is governed by internal, intrinsic properties, rather than external stimuli only. Importantly, we observed that the proportion of the cells that were reactivated during REM sleep increases after the mouse is running the open field. This study sheds light on the mechanisms that underlie memory consolidation during different sleep stages.

Title: Sex-specific effects of locus coeruleus norepinephrine loss on hippocampus-dependent learning

Authors: *I. EVSYUKOVA[1], N. PLUMMER[1], J. STRAUSS[2], K. SMITH[1], K. STEVANOVIC[2], N. RIDDICK[3], S. MOY[3], J. CUSHMAN[2], P. JENSEN[1]
[1]Neurobio. Lab. - Developmental Neurobio. Group, [2]Neurobehavioral Core Lab., Natl. Inst. of Envrn. Hlth. Sci., Research Triangle Park, NC; [3]UNC Carolina Inst. for Developmental Disabilities, Mouse Behavioral Phenotyping Core, Univ. of North Carolina, Chapel Hill, NC

Abstract: Locus coeruleus norepinephrine (LC-NE) signaling is involved in the modulation of diverse behaviors and physiological processes, including anxiety and learning. Yet, little is known about the long-term effects of embryonic loss of LC-NE on these behaviors, primarily due to the inability to selectively target the LC. Global synthesis of NE can be disrupted by mutating the dopamine β-hydroxylase (*Dbh*) gene, but *Dbh* null mice die *in utero*. While the embryonic lethality can be rescued by supplying pregnant dams with a synthetic precursor of NE, the prenatal treatment obscures any developmental phenotypes and does not permit dissection of brain-specific functions. To overcome these limitations, we generated a conditional knockout allele of *Dbh* (*Dbh cKO*). To specifically target the LC, we crossed *Dbh cKO* with $En1^{cre}$ (LC-NE mutants). LC-NE mutants survive to adulthood, allowing us to evaluate the consequences of embryonic disruption of LC-NE on adult behavior. We examined the performance of mutant and littermate control mice in a series of behavioral tasks. As previously reported for *Dbh* null mutants, LC-NE mutants showed normal levels of anxiety in the elevated plus maze and in the open field, as well as deficits in context-dependent, but not cue-dependent fear conditioning. Unlike the *Dbh* null mice, however, context-dependent learning was affected only in male LC-NE mutants, suggesting that early disruption of LC-NE affects hippocampus-dependent memory in a sex-specific manner. Moreover, while the deficits in contextual learning were no longer observed in *Dbh* null mice two weeks after training, those exhibited by LC-NE males persisted. This finding suggests that the contextual fear deficit in LC-NE males is not specific to short term retrieval. Mutant males also showed deficits in pre-exposure-dependent contextual fear conditioning, which has previously been shown to depend on LC input to hippocampal area CA3. In addition, LC-NE mutants exhibited sex-dependent changes in other aspects of hippocampal-dependent learning, including novel context and object recognition tasks.

Together, these findings suggest that embryonic disruption of LC-NE has selective, sex-specific effects on hippocampus-dependent memory and confirm the utility of our *Dbh cKO* allele for investigating the long-term consequences of early disruption of NE signaling.

Title: Essential role of acetylcholine in memory consolidation during REM-sleep

Authors: *S. WILLIAMS[1], J. KANG[2], J.-B. BOTT[3], G. ETTER[4], F. MANSEAU[4]
[1]Dept Psych, McGill Univ., Verdun, QC, Canada; [2]Psychiatry, Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [3]Dept of Pyschiatry, McGill University, Douglas Ins, Verdun, QC, Canada; [4]Douglas Mental Hlth. Inst., Verdun, QC, Canada

Abstract: Spatial memory has been recently shown to be consolidated during rapid eye movement (REM) sleep since disrupting normal theta activity specifically during this state through the optogenetic silencing of medial septum (MS) GABAergic neurons impaired spatial and contextual fear memory (Boyce et al., 2016). In this study, we have examined the effects of MS cholinergic neuron inhibition on hippocampal activity during REM sleep following fear conditioning learning.
Viral delivery of the inhibitory opsin ArchT (n=7) or control eYFP (n=7) were done targeting the MS of ChAT-Cre mice. An optic fiber was implanted in the MS and tungsten electrodes were placed in the CA1, CA3 and subiculum of the hippocampus to record local field potentials. Three weeks later, mice received contextual fear conditioning (30s of cue tone followed by 50uA of electric foot shock) and were then returned to their home cage. Optogenetic silencing was performed specifically during REM sleep for a 4hr period following conditioning. On the following day, contextual and cue memory were tested by measuring the freezing duration. We found that silencing MS cholinergic neurons specifically during REM sleep modulated theta-gamma cross-frequency coupling. Following fear conditioning, phase-amplitude coupling between theta (5-12 Hz) and gamma band (30-60 Hz) significantly increased in the CA1 of eYFP control group during REM sleep (118±10%, Modulation Index compared before and after

learning). However, such an increase was suppressed in the ArchT mice group where cholinergic neurons were silenced (85±8%). This reduction in the modulation index was specific to the CA1 area and was not observed in CA3 or subiculum.
Our study demonstrates that MS cholinergic neurons play an essential role for hippocampal-dependent contextual memory consolidation during REM sleep. In addition, the present results propose that the modulation of cross-frequency coupling is an important mechanism underlying how acetylcholine promotes memory consolidation.

Title: Role of medial septum parvalbumin neurons in supporting hippocampal predictive coding in normal and Alzheimer's disease conditions

Authors: *G. ETTER[1], B. RIVARD[2], S. WILLIAMS[3]
[1]Douglas Mental Hlth. Inst., Verdun, QC, Canada; [2]Res. Ctr., Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [3]Dept Psych, McGill Univ., Verdun, QC, Canada

Abstract: The exact role of the hippocampus in spatial learning and memory is still not fully understood. Earlier work and the discovery of place cells has comforted the existence of a cognitive map that relies on distance and direction codes that arise from entorhinal cortex grid cells which represent one of the main input to hippocampal principal neurons. Alternative theories support the role of the hippocampus in predictive coding, both online, during exploration through phase precession (firing of place cells ahead of their place fields) and offline, during sharp-wave ripples (preplay of trajectories to be explored). More recent models inspired by reinforcement learning frameworks propose that the hippocampus codes for representations that maximize future reward by performing continuous predictions (Stachenfeld et al., 2017). Importantly, hippocampal sequences can only be reliably observed in environment involving a memory task (Pastalkova et al., 2008) and medial septum pharmacological inactivations are associated with perturbed place cells offline, but not online processing (Wang et al., 2014). Importantly, place fields persist (Koenig et al., 2011) and can emerge in new environments (Brandon et al., 2014) under pharmacological medial septum inactivations that are associated with reduced hippocampal theta oscillations and grid fields abolition. However, since

these experiments were performed in an environment that was devoid of a memory task, it is difficult to conclude on the impact of decreased theta on hippocampal predictive coding. We propose that hippocampal theta rhythms that are supported specifically by medial septum parvalbumin interneurons activity contribute to offline predictions of the future behaviourally relevant locations to be explored. We combined chronic recordings of large CA1 hippocampal cell assemblies (>1000 neurons per subject) in mice performing in a spatial working memory task that involved enriched multimodal sensory cues. Because of the neurochemical complexity of the medial septum, we combined our calcium imaging recordings with targeted optogenetic modulation of medial septum parvalbumin cells to transiently modulate or abolish theta rhythms. In parallel and as a negative control, we performed calcium imaging in an APP mouse model in similar tasks to verify the relationship between CA1 predictive coding and spatial working memory performances.

Title: Encoding of elapsed time in the order of minutes by hippocampal pyramidal neurons

Authors: *Y. SHIKANO, T. SASAKI, Y. IKEGAYA
Pharmaceut. Sci., Univ. of Tokyo, Tokyo, Japan

Abstract: The hippocampus is involved in the formation of episodic memories including spatial and temporal contexts. While it has been well established that hippocampal pyramidal neurons encodes spatial information, little has been tested about how hippocampal neurons represent temporal contexts. Recently, several studies have demonstrated an interplay across brain regions to process seconds-range time intervals with tens of seconds. However, neural correlates of time periods in the order of minutes by hippocampal pyramidal neurons have not been extensively examined. Here, we developed a novel behavioral task in which rats were placed in a test chamber (25 cm x 25 cm) with a feeding port at a specific location. The animals were rewarded if they poked a reward port to collect single 45-mg food pellets that were presented for 2-3 s every five-minute waiting time period. Trained animals showed a gradual increase in their frequency of nose-poke behavior in individual five-minute waiting time periods. Chronic in vivo

electrophysiological recordings using tetrode assemblies from the dorsal hippocampal CA1 area revealed that about half of hippocampal neurons showed a gradual increase or decrease in their firing rates, so-called ramping activity, during the waiting time periods. The firing rates of these neurons were specifically correlated with elapsed times without being affected by poke behavior, animal's positions, and animal's head direction. Our results suggest that hippocampal neurons periodically and repeatedly show ramping activity to cover a duration on a time scale of minutes.

Title: Transcriptome analysis of state-dependent memory transition from recent to remote

Authors: *V. JOVASEVIC[1], F. SANANBENESI[3], A. FISHER[3], J. RADULOVIC[2]
[1]Pharmacol., [2]Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL; [3]German Ctr. for Neurodegenerative Dis., Göttingen, Germany

Abstract: Overwhelming stressful experiences can lead to mental illnesses known as dissociative disorders. They are thought to arise when normally integrated functions of consciousness, such as memory, perception, and identity awareness become disrupted. Dissociative symptoms are often debilitating, and persist for a long time after the initial stress has ended. While many dissociative symptoms are intrinsic to human sufferers, and therefore cannot be studied in rodents, this is not the case with dissociative amnesia, which can be modeled in rodents using state-dependent learning. Fear-inducing memories can be state-dependent, meaning that the retrieval of a memory is most efficient when occurring under the same state of consciousness as when the memory was encoded. We have previously demonstrated that encoding of state-depended memories required a distinct molecular mechanism from encoding under normal conditions. State-dependent memories are long-lasting and they retain their state-dependence, suggesting that distinct mechanisms initiated at encoding are maintained during consolidation and transition from recent to remote. Here we analyzed the global changes in gene expression using high throughput RNA sequencing to identify individual genes and cellular pathways contributing to the transition or fear-inducing memories from recent to remote under normal and state-dependent conditions. For these analyses, mice were fear conditioned under normal or state-dependent conditions, and samples collected 1 day (recent) or 30 days (remote) later. Our results show that consolidation of memories and their transition from

recent to remote under normal and state-dependent conditions occurs through the same cellular pathways, yet involving mostly distinct sets of genes belonging to these pathways. These results suggest that changes of cognitive states require alterations of the activity of distinct sets of genes within conserved pathways.

Physiol. and Pharmacol., Texas A&M Univ., College Station, TX

Abstract: New experiences are initially encoded as labile short-term memories and then converted into stable long-term memory by gene transcription-dependent processes. Gene expression after learning involves a transient wave of transcription that is critical for memory consolidation. Following early transcriptional activity, learning induces persistent long-lasting transcriptional changes that are reported to be involved in the storage of long-term memory. Increased transcript levels of 13 nuclear receptors, including all 3 members of the Nr4A subfamily, have been identified after learning. In this study, we show that transgenic mice expressing a dominant-negative form of Nr4A (Nr4ADN) in forebrain excitatory neurons have impaired long-term spatial memory. Following a spatial object recognition task, we removed dorsal hippocampi from Nr4ADN mice and wildtype controls and performed single-neuronal nuclear RNA sequencing (Sn-Nuc RNA seq). This employs a Drop-Seq based method to allow nuclei from single neurons to be processed individually. We found significant downregulation of genes related to long-term spatial memory and synaptic plasticity in CA1 and CA3 excitatory

neurons. Differentially expressed genes were validated at the single-cell level using the *in situ* hybridization technique RNAscope. Although no cellular ligands have been identified for the Nr4A sub-family of transcription factors, we and others have observed that synthetic molecules like C-DIM drugs bind to Nr4A and modulate its transactivation function. In additional studies, we found that C-DIM12, a putative NR4A2 ligand enhances spatial memory and Nr4A regulated genes in adult mice. These results further underscore the importance of Nr4A during hippocampus dependent memory storage.

Title: Characterising the function and transcriptional regulation of a cluster of genes core to hippocampal memory consolidation

Authors: *S. ABDULMALEK[1], L. MCDONNELL[2], K. J. MURPHY[2]
[1]Conway Inst., [2]Univ. Col. Dublin, Dublin, Ireland

Abstract: Memory formation and recall are fundamental processes that involves information processing and consolidation that control cognitive function. Understanding the molecular background underlying normal cognition would provide insights to identify impairments underpinning range of neurodegenerative and neuropsychiatric disorders. During the learning event, a cascade of molecular signals are initiated recruiting genes that translate to proteins to mediate morphological alterations of synapses in the hippocampus, a central region for memory consolidation. Previous studies suggest that the early phase (0-6h) of memory consolidation involve several waves of gene expression regulation and subsequent protein expression change that drives synaptic restructuring involving formation of new synaptic connections. This growth phase seems to be followed by selective retention and pruning of synapses to restore the circuit to the baseline level of connectivity. Much of the molecular underpinnings of these events remain poorly elucidated.
Recently, we have revisited a temporal microarray study we conducted looking at increasing time points following either water maze or passive avoidance learning. We found 609 and 700 genes to be transcriptionally regulated across 24h post-learning following spatial learning and

passive avoidance conditioning, respectively. Comparing those gene lists, we were able to find an overlapping cohort of 135 genes regulated following both tasks. This cohort could identify a core memory consolidation-specific program that is recruited regardless of the nature of the task. We have begun to characterise the function and transcriptional regulation of these genes. Using primary hippocampal cultures, we were able to characterise morphological changes exerted by two members of the cluster, midkine and klotho, which seem to mediate distinct effects on the growth of neuronal processes. Furthermore, we have been able to show that the plasticity-associated neurotransmitter glutamate can control the expression of klotho but not midkine suggesting the need for convergent signals during actual memory formation to regulate the cognition cluster as a coordinated whole. Finally, we have used genomatix promotor analysis software to identify several potential transcriptional regulators of the cognition-associated genes and have confirmed the classic, memory-associated transcription factor CREB to be a regulator of several genes in the cognition-associated cluster. These studies begin to dissect the function and transcriptional regulation of a core cognition-associated gene cluster regulated during memory consolidation.

Abstract: Arc/Arg3.1, an immediate early gene and molecular coordinator of synaptic plasticity, is transcriptionally and translationally regulated by network-wide activity. The temporal expression of Arc protein is largely mediated through the ubiquitin-proteasome pathway, yet the importance of such turnover is currently unknown. We created an Arc knock-in mouse (ArcKR) wherein the predominant Arc ubiquitination sites were mutated. Arc mRNA and protein expression are altered in ArcKR mice, leading to reduced mGluR-LTD threshold and enhanced mGluR-LTD amplitude. ArcKR mice had intact spatial learning but showed specific deficits in selecting an optimal strategy during reversal learning. Alterations in reversal learning suggest a global deficit in cognitive flexibility and is likely a result of underlying changes in neural coding mediated through proper turnover of Arc.

Abstract: Protein synthesis in neurons is essential for long-term memory formation, in which dendritic mRNA transport and local translation are believed to play roles. However, molecular mechanisms involved are not fully understood. In this study, we focused on RNG105/caprin1, a major RNA-binding protein in RNA granules that are responsible for mRNA transport and local translation, because RNG105-deficient mice display impaired long-term memory formation.
We comprehensively identified mRNAs whose dendritic localization was dependent on RNG105. In this identification, the hippocampal CA1 region, in which somas of pyramidal neurons are aligned in the stratum pyramidale (SP) and dendrites elongate in the stratum radiatum (SR), was used. We microdissected and isolated SP and SR from 12-week-old mice, extracted mRNAs from the isolated layers, and subjected them to RNA-seq. We identified 1,122 SR-enriched mRNAs (dendritic [D-] mRNAs) and 2,106 SP-enriched mRNAs (somatic [S-] mRNAs) in control mice (*Rng105*$^{f/f}$). Comparison between control and RNG105 conditional knockout (cKO) mice (*Camk2a-Cre; Rng105*$^{f/f}$) revealed that a considerable subset of D-mRNAs was reduced in the SR of RNG105 cKO mice. GO enrichment analysis of the RNG105-dependent D-mRNAs found that a category of "Regulation of Arf (ADP-ribosylation factor) protein signal transduction", which included Arf regulators GEFs and GAPs, had a high-fold enrichment score. RNG105-dependent dendritic localization of Arf GEF and GAP mRNAs was confirmed by imaging of mRNAs fused to the MS2-binding sequence with MS2-GFP in primary cultured cerebral neurons from wild-type and RNG105 KO mice. These results indicated that RNG105 was a key regulator of dendritic localization of mRNAs for the Arf regulators.
Arf is known to be involved in AMPAR recycling in dendrites. In addition, fEPSP amplitude of hippocampal CA1 neurons was markedly reduced in RNG105 cKO mice. Given these results, we analyzed AMPAR (GluR1) surface expression in primary cultured neurons with immunostaining. The number of surface GluR1 puncta in dendrites was significantly reduced in RNG105 KO neurons compared with wild-type neurons. Taken together, these results suggested that RNG105-dependent dendritic localization of mRNAs for regulators of AMPAR distribution, such as Arf regulators, is an underlying mechanism for synaptic potentiation and long-term memory formation.

Abstract: Local translation in neuronal dendrites plays an essential role in synaptic plasticity. Local translation is mediated by RNA granules, large RNP complexes containing mRNAs, ribosomes and RNA-binding proteins. However, the relevance of RNA-binding protein components of RNA granules to long-term memory in vertebrate animals remains elusive. In this study, we show roles of RNG105/caprin1, a major RNA binding protein in RNA granules, in structural spine plasticity and long-term memory formation. By applying the glutamate-uncaging technique to control neurons (*Rng105*$^{flox/flox}$) and RNG105 conditional knockout (cKO) neurons (*CMV-Cre*; *Rng105*$^{flox/flox}$), we found that RNG105 was required for the late phase of structural spine plasticity, but not for the initial phase. Furthermore, in the hippocampal neurons of RNG105 cKO mice (*CaMK2a-Cre*; *Rng105*$^{flox/flox}$), the proportion of the number of large spines to total spines was significantly reduced as compared with neurons of control mice (*Rng105*$^{flox/flox}$). We then examined whether RNG105 is involved in learning and memory. In Morris water maze, spatial memory was markedly impaired in RNG105 cKO mice. Furthermore, in contextual fear conditioning tests, 5-minute memory was normal, but one-day or longer memory was affected in RNG105 cKO mice. These results demonstrated that RNG105 regulates the structural plasticity of spines and is required for long-term memory formation.

Title: Enhancer RNAs are necessary and sufficient for gene transcription and neuronal function

Authors: *N. CARULLO[1], A. J. SALISBURY[3], R. C. SIMON[2], K. D. BUNNER[2], J. S. REVANNA[4], K. E. SAVELL[2], F. SULTAN[2], J. J. DAY[2]
[2]Neurobio., [1]Univ. of Alabama at Birmingham, Birmingham, AL; [3]Neurobio., [4]Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Enhancer elements in the DNA regulate gene expression programs important for cell fate and function in the developing and adult brain. The majority of DNA sequence variants linked to neuropsychiatric diseases and intellectual disabilities fall in non-coding DNA regions, and numerous variants have been linked to altered enhancer function. Moreover, enhancer activity drives transcription changes in response to a variety of signals. A significant fraction of regulatory DNA regions, like enhancers, are subject to bidirectional, RNA polymerase II-dependent transcription that results in non-coding enhancer RNAs. However, the potential role of eRNAs in neuronal function and activity-dependent responses remains unclear. Here, we used primary cortical neuronal cultures to investigate enhancers and eRNAs in the rat genome. We first identified actively transcribed enhancers using RNA sequencing from non-polyadenylated RNA fractions. This revealed thousands of active enhancers, with enrichment near genes involved in neurodevelopment, synaptic communication, and neuropsychiatric disease. We validated enhancer function at selected candidate enhancer-promoter pairs using a CRISPR-dCas9 system in which dCas9 is fused to a strong transcriptional activator (VPR) to allow for targeted activation of specific genomic loci. CRISPR-VPR mediated activation of enhancers promoted eRNA synthesis and produced corresponding increases in mRNA in all candidate pairs, whereas activation of promoters increased target mRNA but not eRNA. To explore the potential role of eRNAs in more detail, we focused on specific eRNAs arising from enhancers surrounding *Fos* (or *c-Fos*), an immediate early gene that codes for a transcription factor implicated in neuronal plasticity and cognitive processes. Transcription of *Fos* eRNAs is dynamically modulated by various forms of neuronal activity, requires RNA polymerase II, and

precedes activity-dependent *Fos* mRNA induction. Single-molecule FISH revealed nuclear localization of eRNAs, activity-dependent increases in eRNA arising from the most distal *Fos* enhancer and *Fos* mRNA, as well as a positive correlation between eRNA and mRNA within the same cells. Anti-sense based *Fos* eRNA knockdown decreased *Fos* mRNA expression, whereas mRNA knockdown did not affect eRNA levels. In contrast, CRISPR-targeted delivery of eRNA to a *Fos* enhancer elevated mRNA induction following neuronal depolarization. Finally, we show that knockdown of a single *Fos* eRNA is sufficient to alter neuronal activity patterns in vitro using a multi electrode array system. Overall, these findings indicate that eRNAs modulate gene expression and neuronal physiology.

Title: Micro-RNA130b-3p and its targets in the recognition memory of imprinting in domestic chicks

Authors: *R. O. SOLOMONIA[1], G. MARGVELANI[1], M. MEPARISHVILI[1], T. KIGURADZE[2], B. J. MCCABE[3]
[1]Inst. of Chem. Biology, Ilia Tbilisi State Univ., Tbilisi, Georgia; [2]I.Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia; [3]Sub-Dept Animal Behaviour, Dept Zoology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Visual imprinting is a learning process whereby young animals come to recognize a visual stimulus by being exposed to it (training) and subsequently prefer it to other objects. Much evidence has implicated a restricted forebrain region, the intermediate medial mesopallium (IMM), in memory for visual imprinting in the domestic chick. Learning-related, time-dependent molecular changes occur in the IMM after imprinting, indicating molecular regulation during memory formation. We have inquired whether certain micro-RNAs (miRNAs), which typically suppress protein translation, are involved in such regulation. Twenty-four hours after training, miRNA spectra in the left IMM were compared between chicks termed good learners, characterised by high preference score (a measure of memory strength), and chicks with low preference scores (poor learners); a μParaflo™ microarray assay was used**.** Using criteria of effect size and expression level, we chose gga-miR-130b-3p for further study and inquired

whether amount of miRNA was correlated with preference score. In left and right IMM, amount of gga-miR-130b-3p decreased significantly with preference score, but only when learning was observed. No effects were detected in the posterior pole of the nidopallium (PPN), a brain region not involved in imprinting. In both left and right IMM, residual variance from the regression with preference score was significantly lower than the variance of untrained chicks. Since the variances of trained and untrained chicks did not differ significantly from each other, the correlations were attributable not to training but to a predisposition, i.e. propensity to learn, independent of training.
We studied two gga-miR-130b-3p targets, cytoplasmic polyadenylation element binding proteins 1 (CPEB1) and 3 (CPEB3), in two subcellular fractions (P2 membrane-mitochondrial and cytoplasmic) of IMM and PPN. Only in the left IMM was a learning-related change observed: a positive correlation between amount of membrane CPEB3 and preference score, with protein amount increasing only when learning occurred. Residual variance from the regression with preference score was not significantly different from the variance of untrained chicks. Taken together, the results suggest that the increase in membrane CPEB3 with preference score was a results of training and specific to learning.
Our results indicate that animals predisposed to learn well possess reduced miR-130b-3p activity in the IMM. One of this miRNA's targets, membrane CPEB3, is up-regulated by training, reflecting the learning that occurs. This effect is lateralised, being restricted to the left IMM.

Title: Cell-specific knockdown of TSC1 increases mTORC1 signaling and facilitates late LTP induction in somatostatin interneurons, and promotes long-term hippocampal memory

Authors: *J. ARTINIAN, E. HONORE, A. W. JORDAN, A. KHLAIFIA, I. LAPLANTE, J.-C. LACAILLE
Dept of Neuroscience, Univ. of Montreal, Montreal, QC, Canada

Abstract: Long-term synaptic plasticity is a prime candidate as cellular substrate for learning and memory which remains largely unexplored in inhibitory interneurons. In the hippocampal CA1 region, excitatory synapses onto somatostatin interneurons (SOM-INs) show cell type-specific metabotropic glutamate receptor 1 (mGluR1)-mediated long-term potentiation (LTP) that regulates hippocampal network plasticity, persist 24h and requires translation via Mechanistic Target Of Rapamycin Complex 1 (mTORC1). We previously showed that impaired mTORC1 signaling in SOM-INs prevents learning-induced LTP in SOM-INs, reduces CA1 network metaplasticity and decreases contextual fear and spatial memories, indicating that mTORC1-mediated LTP in SOM-INs is necessary for intact hippocampal memory (Artinian et al., SfN 2017 abstract 428.21).
In this study we investigated if mTORC1 activity in SOM-INs is sufficient to modulate translation-dependent interneuron LTP and hippocampal memory, by using a knockdown of Tuberous Sclerosis Complex 1 (TSC1), an upstream repressor of mTORC1, selectively in SOM-INs (SOM-TSC1$^{+/-}$ mice).
We first determined that basal ribosomal S6 protein phosphorylation, a downstream effector of mTORC1, was increased in SOM-INs of SOM-TSC1$^{+/-}$ mice and that repeated treatment with mGluR1a agonist failed to further increase S6 phosphorylation in SOM-TSC1$^{+/-}$ mice. Whole-cell recordings revealed normal intrinsic properties of SOM-INs. A single treatment with mGluR1 agonist was sufficient to induce late-LTP (increased minimally-evoked excitatory transmission) in SOM-INs of SOM-TSC1$^{+/-}$ mice, whereas repeated treatment was necessary in WT mice, indicating that TSC1 knock-down upregulates mTORC1 activity and facilitates late-LTP induction in SOM-INs. At the behavioral level, SOM-TSC1$^{+/-}$ mice showed slightly decreased locomotion and normal anxiety in the open-field test. They showed improved long-term spatial reference memory in the Barnes maze, as well as stronger contextual fear memory and context discrimination deficits. Short-term contextual fear and long-term cued-fear memories were intact. These results indicate that increasing mTORC1 function in SOM-INs is sufficient to promote hippocampal memory consolidation.
Our findings show that cell-specific knockdown of TSC1 in SOM-INs is sufficient to increase mTORC1 signaling and facilitate mGluR1-mediated late LTP induction in SOM-INs, and to promote long-term hippocampal memory. Thus mTORC1 activity in SOM-INs appears necessary and sufficient for learning-induced persistent LTP in SOM-INs, up-regulation of CA1 network plasticity, and hippocampal memory precision.

Title: Mimicking age-associated Gadd45γ decline results in memory impairments in young mice

Authors: *D. VILHENA CATARINO BRITO, J. KUPKE, K. GÜLMEZ KARACA, B. ZEUCH, A. MM OLIVEIRA
Univ. of Heidelberg, Neurobio., Heidelberg, Germany

Abstract: With an increasingly aged population age-associated cognitive decline is a major health and socio-economic burden. Understanding the mechanisms underlying progressive cognitive loss is required to develop future therapies. The underlying causes of age-associated cognitive decline are largely unknown. We found that Gadd45γ expression is decreased during basal conditions and spatial learning in the hippocampus of old male mice, compared to young adult mice. This decrease is selective, as other family members are expressed at comparable levels in young adult and aged mice.
We hypothesized that if Gadd45γ would be involved in age-associated cognitive decline, then abolishing its expression in the hippocampus of young mice should promote memory deficits. Indeed, we found that knocking down Gadd45γ in the hippocampus of young adult male mice, generates age-like memory deficits in long-term and short-term memories. Abolishing the expression of other family members did not produce the same phenotype. Hence, our findings show a selective role of Gadd45γ in memory formation, which may underlie memory deficits observed during ageing. Next, we identified signaling pathways regulated by Gadd45γ that may mediate its activity during synaptic plasticity. Specifically, decreasing the expression of Gadd45γ disrupted MAPK signaling and downstream targets in dissociated hippocampal neurons. Importantly these alterations were not due to altered stimulus-dependent intracellular calcium dynamics.
This data suggests that age-associated decrease in Gadd45γ expression may be associated with age-dependent cognitive deficits.

Title: Learning triggered Dnmt3a2 overexpression within hippocampal neuronal ensembles is sufficient to enhance memory

Authors: K. GÜLMEZ KARACA[1], J. KUPKE[2], B. ZEUCH[3], *A. M. OLIVEIRA[4]
[1]IZN Neurobio., Univ. of Heidelberg, Heidelberg, Germany; [2]Univ. of Heidelberg, Germany, Germany; [3]Univ. of Heidelberg, Heidelberg, Germany; [4]Univ. Heidelberg, Heidelberg, Germany

Abstract: It is currently thought that memories are stored within neuronal ensembles in the brain. Although it has been shown that the recall of memories depends on the reactivation of neurons active at the time of learning, the molecular and cellular mechanisms within the neuronal ensembles that underlie their formation and stabilization are not known. Epigenetic mechanisms play a critical role in memory storage, therefore appear like good candidates in the regulation of these processes. However, until now, neuronal ensemble-specific manipulations aimed at the elucidation of the molecular mechanisms underlying their formation and stabilization have not been performed. Here, we hypothesized that Dnmt3a2, a *de novo* DNA methyltransferase critically involved in cognition, improves the formation and stabilization of the neuronal ensembles engaged in hippocampus-dependent memory, and its overexpression within neuronal ensembles is sufficient to strengthen memory. To address this, we used a synthetic, neuronal activity dependent promoter, E-SARE, to manipulate the levels of Dnmt3a2 specifically within the neuronal ensembles formed in the DG of the hippocampus of adult male mice upon contextual fear learning. We found that overexpressing Dnmt3a2 in the DG neuronal ensembles after a hippocampus-dependent fear learning was sufficient to enhance long-term fear memory. Furthermore, we showed that this cognitive enhancement required an ensemble-specific Dnmt3a2 upregulation, as overexpressing Dnmt3a2 in a similarly sized but random subset of neurons in the DG did not improve long-term fear memory. Currently, we are investigating the mechanisms underlying the cognitive enhancement triggered by Dnmt3a2 overexpression within the ensembles associated with spatial memory. Overall, in this study, we performed for the first time a neuronal ensemble-specific manipulation of a DNA methyltransferase and show that this is sufficient to impact memory storage. This study brings a novel perspective on how epigenetic factors may contribute to cognitive function and opens up a new venue to explore memory storage mechanisms at a neuronal ensemble level.

Title: Involvement of calmodulin kinase IIalpha in hippocampus- vs. amygdala-dependent memory revealed by kinase-dead knock-in mouse

Authors: *Y. YAMAGATA[1,3], Y. YANAGAWA[4], K. IMOTO[2]
[1]Div. Neural Signaling, Natl. Inst. Physiol Sci., Okazaki-Shi, Japan; [2]Natl. Inst. Physiol Sci., Okazaki, Japan; [3]SOKENDAI (The Grad. Univ. for Advanced Studies), Okazaki, Japan; [4]Gunma Univ. Grad. Sch. of Med., Maebashi, Japan

Abstract: Ca^{2+}/calmodulin-dependent protein kinase IIα (CaMKIIα) has been thought to be a key mediator of activity-dependent neuronal modifications and play a key role in the molecular mechanisms of learning and memory. So far, several types of CaMKIIα knock-in and knock-out mice have confirmed its essential role in hippocampal synaptic plasticity and behavioral learning. However, it is still not clear how CaMKIIα is involved in different types of memory. To better understand its involvement in amygdala-dependent memory as compared to hippocampus-dependent memory, here we performed biochemical analyses and behavioral memory tests using the kinase-dead CaMKIIα (K42R)-knock-in mouse (Yamagata et al., J Neurosci, 2009). In the Morris water maze tasks, homozygous mutants performed well in the visible platform trials, while they failed to form spatial memory in the hippocampus-dependent hidden platform trials. In fear conditioning, these mice were impaired but showed a certain level of amygdala-dependent cued fear memory that lasted as long as four weeks, while they showed virtually no hippocampus-dependent context discrimination memory. Neither stronger stimulation nor repetitive stimulation compensated for their memory deficits. The differential outcome of hippocampus- and amygdala-dependent memory in the mutant mouse was not due to differential expression of CaMKIIα between the hippocampus and the amygdala, because biochemical analyses revealed that both kinase activity and protein levels of CaMKII were indistinguishable between the two brain regions. These results indicate that kinase activity of CaMKIIα is indispensable for hippocampus-dependent memory, but not necessarily for amygdala-dependent memory. There may be a secondary, CaMKIIα activity-independent pathway, in addition to the CaMKIIα activity-dependent pathway, in the acquisition of amygdala-dependent memory.

Title: ErbB4 signaling in the infralimbic cortex regulates fear extinction

Authors: *Y. CHEN[1], L. BI[2], S. ZHANG[2], T. GAO[2]
[1]Southern Med. Univ., Guangdong, China; [2]Southern Med. Univ., Guangzhou, China

Abstract: Many psychiatric diseases such as post-traumatic stress disorder (PTSD) are characterized by abnormal processing of emotional stimuli particularly fear. The medial prefrontal cortex (mPFC) is critically involved in fear extinction, which is defined as the learned reduction of fear. However, the molecular mechanisms underlying this process are largely unknown. ErbB4 receptors, the only tyrosine kinase that can both bind to NRG1 and become a functionally active homodimer, are abundant in parvalbumin (PV)-expressing interneurons in the PFC. In this study, we aimed to determine how NRG1/ErbB4 signaling in the mPFC modulates fear extinction and found that fear extinction increased NRG1 expression in the mPFC. Fear extinction was impaired following neutralization of endogenous NRG1 and specific inhibition or genetic ablation of ErbB4 in the infralimbic (IL) cortex but not in the prelimbic cortex. Furthermore, ErbB4 deletion specifically in PV neurons impaired fear extinction. Notably, overexpression of ErbB4 in the IL cortex is sufficient to reverse impaired fear extinction in PV-Cre;ErbB4− / −mice. Together, these findings identify a previously unknown signaling pathway in the IL cortex that regulates fear extinction. Our study may shed new light on the pathophysiology of this disorder and help to improve its treatments.

Title: Inositol polyphosphate multikinase mediates extinction of fear memory

Authors: J. PARK[1], F. LONGO[2], *S. KIM[1], S. PARK[1], S. LEE[1], M. BAE[3], J.-H. HAN[1], E. SANTINI[4], E. KLANN[2], S. H. SNYDER[5]

Abstract: Inositol polyphosphate multikinase (IPMK), the key enzyme for the biosynthesis of higher inositol polyphosphates and phosphatidylinositol 3,4,5-trisphosphate, also acts as a versatile signaling player in regulating tissue growth and metabolism. To elucidate neurobehavioral functions of IPMK, we generated mice in which IPMK was deleted from the excitatory neurons of the postnatal forebrain. These mice showed no deficits in either novel object recognition or spatial memory. IPMK conditional knockout mice formed cued fear memory normally but displayed enhanced fear extinction. Signaling analyses revealed dysregulated expression of neural genes accompanied by selective activation of the mTOR regulatory enzyme p85 S6 kinase 1 (S6K1) in the amygdala following fear extinction. The IPMK mutants also manifested facilitated hippocampal long-term potentiation. These findings establish a novel signaling action of IPMK that mediates fear extinction.

Title: Plasmalogens enhance spatial memory by increasing synaptic plasticity

Authors: *M. HOSSAIN[1], T. FUJINO[2]
[1]Dept. of Neuroinflam. and Brain Fatigue Sci., Kyushu Univ., Fukuoka-Shi, Japan; [2]Inst. of Rheological Functions of Food, Fukuoka, Japan

Abstract: It was previously known that the plasmalogens (Pls) are reduced in the Alzheimer's disease (AD) brains. Pls are the type of ether phospholipid characterized by the presence of a vinyl ether linkage at the sn-1 position. To understand how these lipids are reduced in the brain, we previously reported that aging, inflammation and stress signals downregulate the gene encoding a Pls-synthesizing enzyme, *Gnpat* (Glyceronephosphate O-Acyltransferase). We also reported that the reduction of Pls in the brain increased the glial activation. However, the role of Pls in the synaptic plasticity and memory function was mostly elusive. The clinical study showed that the oral intake of sPls (Pls extracted from the scallop) improved the cognition among mild AD patients. In the microarray study, we noticed that various synaptic function related genes were upregulated when the neuronal cells were stimulated by the sPls. To examine the role of Pls in the memory and cognition, we reduced the Pls in the murine brain hippocampus by shRNA against *Gnpat* (shGNPAT) and observed a significant reduction of spatial memory ($p<0.01$, n=7). This evidence suggest that Pls have an important role in the hippocampal dependent memory and it may be due to the increased expression of memory related gene expression. This was further supported by our recent findings that Pls drinking for three months in adult B6 mice improved memory by enhancing the BDNF-TrkB signaling which was associated with an increased expression of synaptic related gene expression. The Pls treatments increased the dendritic spines in the cultured neuronal cells. The golgi cox staining also showed that the Pls drinking increased the dendritic spines in the murine hippocampal neurons which is believed to be associated with the increased synaptic potential. We still do not know how the Pls can increase the gene expression. However, our previous study showed that Pls can activate ERK and Akt signaling, which may play a role behind the gene regulation. The future study will be conducted to investigate the detail mechanism of Pls-mediated memory related gene expression. Our research outcome may help us to understand the sPls-mediated cognition improvement among the mild AD patients.

Title: M1 muscarinic receptor-dependent protein signaling underlying visual recognition in monkey

Authors: *B. A. CORGIAT[1], C. MUELLER[2], R. C. SAUNDERS[4], J. L. OLDS[3], L. LIOTTA[2], M. MISHKIN[5], J. N. TURCHI[6]
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]George Mason Univ., Manassas, VA; [3]Krasnow Inst. for Advncd Study, George Mason Univ., Fairfax, VA; [4]Lab. Neuropsychol, [5]NIMH, Bethesda, MD; [6]LN, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Visual recognition memory is critically dependent upon the perirhinal cortex (PRh). More specifically, visual memory formation requires cholinergic activation of PRh M1 muscarinic receptors and is also characterized by enhanced multiunit activity in the upper middle and deep PRh layers. However, the M1 muscarinic-dependent intracellular signaling pathways underlying the critical synaptic changes induced during visual memory formation remain unknown. Here, we used a proteomic approach to assess M1-dependent protein signaling in specific PRh layers and in other implicated brain regions after visual recognition memory training.
Experimentally naïve monkeys (n=4) first learned the delayed non-matching-to-sample (DNMS) rule in a Wisconsin General Testing Apparatus using 1200+ junk objects as stimuli. Once criterion was met, they received forebrain commissurotomies plus unilateral optic tract transections. Once recovered, animals were retrained on DNMS and the stimulus list-lengths (LL) and trials completed per day were gradually increased. The mnemonic difficulty of the DNMS task was tailored to each animal and variable LLs (range: 3-10) were used so each animal performed at criterion (above 75% correct in 78-80 trials). After a testing session, monkeys were quickly sedated, euthanized, and specific brain structures were excised and snap-frozen in bilateral pairs. Samples from two behaviorally naïve control subjects receiving the same surgery were collected in the same manner 7 months post-op.
Layers III and V/VI of ventral part of anterior area TE (TEav) and PRh, layers II/III and V/VI of entorhinal (ERh), and the pyramidal cell layer of hippocampal subregions CA1, subiculum, and the dentate gyrus were microdissected and then lysed. Along with the microdissected lysates, whole region lysates created from TEav, PRh, ERh, hippocampus, tail of the caudate nucleus, primary visual cortex, posterior parietal cortex, and prefrontal regions (areas 11/13, area 45, area 9, lateral area10) were printed onto reverse phase protein microarrays (RPPAs). We stained RPPAs with antibodies against M1-dependent signaling proteins and compared the phosphorylation states in the hemisphere which received more extensive visual mnemonic training to the contralateral control hemisphere.

Title: Proteomic analysis determines molecular pathway differences between tDCS current intensity groups in rats

Authors: *J. WAGNER[1], S. H. JUNG[4], C. N. HATCHER-SOLIS[5], Q. V. QUALLEY[7], M. P. JACKSON[8], R. J. MOORE[2], N. A. BECHMANN[3], J. A. MARTIN[6], R. JANKORD[5]
[1]Applied Neurosci., Infoscitex, Wpafb, OH; [3]Applied Neurosci., [2]Infoscitex, WPAFB, OH; [4]Applied Neurosci. Br., U.S. Air Force Res. Lab., WPAFB, OH; [5]Air Force Res. Lab., WPAFB, OH; [6]Air Force Res. Lab., WAPFB, OH; [7]UES, WPAFB, OH; [8]ORISE, WPAFB, OH

Abstract: Previous studies have demonstrated the positive effects of transcranial direct current stimulation (tDCS) on cognitive performance; however, no study has been conducted to determine the molecular processes involved in the modulation of behavior, specifically protein expression in the hippocampal synapse. tDCS at anodal current intensities of 250µA and 500µA was applied to Sprague Dawley rats for 30 minutes prior to both training and testing of a passive avoidance test (PAT); hippocampal tissue was harvested and synaptic proteins were profiled. Multiple bioinformatics methods were employed to analyze the protein regulation difference between the two current intensity groups. Interestingly, pathway analysis between 250µA and 500µA showed differences; highlighted processes of interest are: cadherin signaling pathway, glutamate receptor pathways, G-protein mediated pathways, wnt signaling pathway, oxidative stress response, and some neuronal diseases. DAVID Annotation clustering analysis identified multiple clusters, including mitochondrial membrane (enrichment score: 2.3), prenylation (1.6), immunoglobulin domain (1.24), etc. The Ingenuity Pathway Analysis (IPA) network analysis created 12 networks, and the 6 networks with a networks score greater than 20 are mainly associated with cell death, metabolisms, molecular transport, protein trafficking, and free radicals. Further analysis regarding canonical pathways of IPA networks analysis found similarly related functions such as: mitochondrial dysfunction, some neuronal diseases, protein trafficking, cell death and survival, free radial scavenging, and cell morphology. Based on the IPA Upstream Analysis of causal networks and IPA results of brain-associated diseases and functions we are able to show that the anodal 500uA of tDCS are related to negative molecular and functional changes in hippocampal synapse: e.g., decreases in growth of neurites, neuronal density and cell viability and increases in inflammatory signaling, apoptosis of neurons, and cell death. The upstream analysis of IPA causal networks identified multiple upstream candidate regulators,

including lrrc4, fbxw8, prkcz, bdnf, il3, thpo, mir-214, etc. In conclusion the data has successfully shown significant findings utilizing a shot gun proteomic experiment, focusing on hippocampal synapse, which has further elucidated mechanisms involved in the behavioral effects of tDCS in rats.

Title: A unique mouse model of early-life exercise enables lasting hippocampal synaptic plasticity and memory

Authors: T. YU[1], E. A. KRAMÁR[3,4], S. PARIEVSKY[2], T. L. VU[2], M. A. WOOD[3,4], *A. S. IVY[1,4]
[1]Dept of Pediatrics, [2]Ayala Sch. of Biol. Sci., Univ. California-Irvine, Irvine, CA; [3]Neurobiol & Behavior, Univ. of California Irvine, Irvine, CA; [4]Ctr. for Neurobio. of Learning and Memory, Irvine, CA

Abstract: Exercise in adulthood is a powerful regulator of cognitive function. Molecular mechanisms underlying exercise's effects on hippocampus-dependent learning and memory have been extensively characterized in rodent models. Less known is whether exercise taking place during early-life periods of hippocampal development can regulate its function later in life. It is well established that exogenous experiences occurring during early-life developmental periods can have long-lasting effects on memory and neuronal function. We address the hypothesis that aerobic exercise occurring during specific periods of postnatal hippocampal maturation can have enduring consequences on hippocampus-dependent memory and synaptic plasticity. In addition, we explore molecular and epigenetic mechanisms that may give rise to the persistent changes in neuronal function engaged by early-life exercise. Wild-type C57Bl/6J mice were placed in cages with either locked or unlocked running wheels on day of weaning (postnatal day (P) 21) for three exercise durations: a 3-week juvenile-adolescent period (P 21-41); a 1-week juvenile period (P21-27), and a 1-week period of later adolescence (P35-41). Subthreshold and threshold training durations for long-term memory formation were identified in the Object Location Memory

(OLM) task in a separate group of age-matched sedentary mice. Between P43-P50, mice from running-wheel exposed groups were then tested in the OLM task or were used to examine long-term potentiation (LTP), a form of synaptic plasticity, in hippocampal CA1 Schaffer collateral pathway. Both the 3-week exercise group and the 1 week juvenile-exercise group formed long-term memory for novel object location when exposed to a typically subthreshold training duration for memory acquisition. LTP was increased in adolescent mice that underwent early life exercise during the juvenile-adolescent period. Notably, input/output curves generated in the Schaffer collaterals showed greater fEPSP responses in early-life exercised groups compared to sedentary controls. Neuronal gene expression and histone modifications after OLM training of exercised mice will be measured by RT-qPCR and ChIP-qPCR, respectively, for candidate genes identified by transcriptome sequencing. These preliminary results suggest that early-life exercise can improve spatial memory and synaptic plasticity and identifies a juvenile, critical period of hippocampal plasticity during which an exercise experience can have a lasting effect on memory function.

Title: Molecular profiles in the brain are involved in fear memory induced by physical and psychological stress

Authors: *J. H. WANG[1], W. LU[2]
[1]The Inst. of Biophysics, CAS, Beijing City, China; [2]Qingdao Univ., Qingdao, China

Abstract: Fear memory induced by physical and/or psychological stress influences human's life, which may lead to anxiety or depression. The removal of fear memory is important to reduce the occurrence of psychological disorders. Molecular mechanisms underlying fear memory remain to be elucidated. We have used the intruder/resident model to investigate the alternation of molecular profiles in the brain areas related to sensation, emotion and cognition from mice that have experienced physical and/or psychological stress, in which mRNA and microRNA profiles have been analyzed by high throughput sequencing. The strength and maintenance of fear memory induced by physical and psychological stress are higher and longer than those induced

by psychological stress alone. Numerous mRNAs and microRNAs are differentially expressed among the prefrontal cortex, nucleus accumbens, amygdala, visual cortex and somatosensory cortex in the mice that experience physical/psychological stress versus psychological stress. Genes of encoding molecules are engaged in the following signaling pathways, such as dopaminergic synapse, cholinergic synapse, serotonergic synapse, GABAergic synapse, glutamatergic synapse, calcium signaling, Wnt signaling, MAPK signaling, PI3K-Akt signaling, axon guidance, cell adhesion molecules and so on. Through these analyses, we are able to figure our molecular profiles related to fear memory induced by physical and psychological stress in brain region-specific manner, which should be helpful to attenuate and remove fear memory.

Title: Secreted amyloid precursor protein alpha overexpressing neural stem cells increase cognition in healthy mice

Authors: *G. W. GLAZNER[1], B. AULSTON[1], G. L. ODERO[2]
[1]Div. Neurodegen Disorders, Winnipeg, MB, Canada; [2]St. Boniface, Winnipeg, MB, Canada

Abstract: Secreted amyloid precursor protein alpha (sAPPα) is a neurotrophic factor that plays a pivotal role in learning and memory acquisition. Numerous studies demonstrate that sAPPα administration in the brain can enhance cognition in multiple species of animals and decreased sAPPα levels are hypothesized to contribute to cognitive impairment associated with Alzheimer's disease. Here, we tested the hypothesis that sAPPα overexpressing neural stem cells (sAPPα-NSCs) could improve cognition in healthy in mice. sAPPα-NSCs and wild-type NSCs (Wt-NSCs) were engrafted into the hippocampi of 7-month old SAMR1 mice and cognition evaluated 6 weeks later using the Morris water maze (MWM). Both types of NSCs survived implantation and differentiated primarily into astrocytes. Strikingly, sAPPα-NSC injected mice performed better in both the acquisition trials and in the probe trial compared to Wt-NSC injected mice and artificial cerebrospinal fluid (ACSF) treated controls. These datum demonstrate that NSCs can be utilized to improve cognition via clinically available methods and warrant additional studies examining the therapeutic potential of sAPPα-NSCs

Title: Neuropeptide s ameliorates pathological damages and spatial memory impairment in the app/ps1 mouse model of Alzheimer's disease

Authors: *P. ZHAO, X. QIAN, N. SUN, C. WEI, Y. NIE, G. CHAI
Dept. of Neurol. of Disease, Anat., Wuxi Med. School, Jiangnan Univ., Jiangsu, China

Abstract: Alzheimer's disease (AD) is a common neurodegenerative disorder with the characteristics of a progressive deterioration of memory and cognition. However, there is no effective cure for this devastating disease at present. Neuropeptide S (NPS) is an endogenous peptide in central nervous system which has comprehensive functions. Central administration of NPS produces anxiolytic-like effects, promotes arousal, inhibits food intake, and plays an important role in learning and memory processes. The mechanisms by which NPS modifies cognitive processes and the potential therapeutic roles of NPS in AD have not been determined. In the present study, we examined the effects of NPS on the pathological changes and spatial memory impairment of eight month-old amyloid precursor protein/presenilin 1 (APP/PS1) transgenic AD mice. The results showed that NPS intracerebroventricular (i.c.v) injection (1nmol) for a week ameliorated spatial memory deficits and promoted dendrite ramification and spine generation in hippocampal CA1 neurons, which was accompanied by the upregulation of postsynaptic density protein 95, synapsin1 and synaptophysin. We also found that i.c.v injection of NPS decreased cerebral amyloid plaques through the up-regulation of γ-secretase activity and by decreasing the phosphorylation of APP at Thr668. Furthermore, application of NPS reversed the deficits in hippocampal late-phase long-term potentiation. These findings suggested NPS attenuated cognitive deficits by reducing pathological features in APP/PS1 mice and NPS might be a potential therapeutic agent for Alzheimer's disease. (1387)

Title: The role of the basolateral amygdala complex in consolidation of second-order conditioned fear

Authors: *N. M. HOLMES[1], K. CLEMENS[1], A. SHVETCOV[1], M. MIRZAEI[2], F. WESTBROOK[1]
[1]Univ. of New South Wales, Sydney, Australia; [2]Australian Proteome Analysis Facility, Sydney, Australia

Abstract: *Background.* This study pursued our recent findings that consolidation of a second-order fear memory requires DNA methylation, but not de novo protein synthesis, in the basolateral amygdala complex (BLA). It specifically used an animal model (fear conditioning in rats) to examine whether the BLA gene and protein networks that have been implicated in the consolidation of first-order conditioned fear (e.g., established through tone-shock pairings) are also involved in the consolidation of second-order conditioned fear (established when tone-shock pairings in stage 1 of training are followed by light-tone pairings in stage 2). The genes of interest were analysed using RT-PCR: they were selected for their relevance to kinase signalling pathways (e.g., PKA, PKC, CaMKII, CaMKIV, MAPK1, MAP2K7) and nuclear processes (e.g., CREBBP, EGR-1 and DNMT3A) that have been differentially implicated in consolidation of first- and second-order conditioned fear. The protein networks were analysed using TMT-10plex LC-MS/MS.
Results. Relative to controls that received tone-shock pairings in stage 1 and context alone exposures in stage 2, rats that underwent second-order conditioning (i.e., that received tone-shock pairings in stage 1 and light-tone pairings in stage 2) exhibited a unique profile of gene and protein changes in the BLA. There were three major findings. First, all genes included in our analyses were upregulated in the control group that was re-exposed to the conditioned context. Second, after second-order conditioning, the majority of these genes were NOT upregulated; and a network of proteins was explicitly downregulated. Third, this dowregulated network of proteins included Mapk1, Map2k7, Mras and Rasa1, which we have previously shown to play a limited role in consolidation of second-order fear.
Conclusions. Taken together, these results provide molecular support for our recent findings that consolidation of second-order fear does not require ERK/MAPK signalling or de novo protein

synthesis in the BLA. They are discussed with respect to the established roles for CaMK signalling and DNA methylation in consolidation of second-order fear and other types of memory.

Title: Molecular dissection of active forgetting in *Drosophila*

Authors: *Y. GAO, Y. PENG, X. ZHANG, Y. ZHONG
Shool of Life Sci. Tsinghua Univ., Beijing City, China

Abstract: A highly flexible nervous system requires not only the generation of memories but also forgetting. The pioneering studies have identified two small G proteins, Rac1 and Cdc42, which separately regulate active forgetting of labile anesthesia-sensitive memory (ASM) and consolidated anesthesia-resistant memory (ARM) in *Drosophila*. It remains unclear how the two proteins actively regulate forgetting of different memory components. Here, the current study reveals downstream molecular signaling pathways underlying Rac1- and Cdc42-dependent active forgetting mechanisms respectively: WAVE acts as downstream of Rac1 in ASM forgetting, while WASP functions as the downstream of Cdc42 in ARM forgetting. These two proteins contribute to both natural memory decay and interference-induced forgetting. Knocking down them in mushroom body neurons leads to slower memory decay and significant resistance of interference-induced forgetting. Conversely, overexpressing them accelerates memory decay. Surprisingly, Arp2/3 complex, which is widely reported to be a shared downstream effector, is only required in ARM forgetting, but not in ASM forgetting. Furthermore, we also provide an explanation of active forgetting of labile memory at synaptic level. Thus, learning itself activates two pathways to actively erase the formed memory: Rac1/WAVE pathway for labile memory lasting for hours and Cdc42/WASP/Arp2/3 pathway for consolidated memory lasting for days. Such two pathways may manage forgetting through different actin remodeling mechanisms which determine presynaptic structure changes.

Title: Specification of a remote memory cell ensemble during cortical tagging

Authors: *R. KIM, Y. KONDO, T. KAWASHIMA, M. INOUE, Y. ISHII, K. INOKUCHI, K. SAKAI, M. NONAKA, M. SAKAMOTO, H. OKUNO, H. BITO

Abstract: Formation of long-term memories (LTM) for episodes and events require two distinct mechanisms of consolidation. Initially, recent memories are rapidly acquired in the hippocampus through synaptic plasticity, and then strengthened via a cellular consolidation process through new gene expression and protein synthesis. Subsequently, however, via a time-dependent mechanism referred to as systems consolidation, these LTM are slowly consolidated into the neocortical network through dynamic interaction between the hippocampus and the neocortex. Although molecular and genetic mechanisms for cellular consolidation have been intensively investigated, mechanistic insights on systems-level memory consolidation still remain elusive. In this study, we introduce a novel transgenic mouse line that can permanently label and manipulate a temporally-defined active neuronal ensemble. Using this, we investigated the cellular and molecular basis of the memory dynamics that underlies time-dependent systems-level memory consolidation. We found that a cortical "proto-engram" is generated during encoding, in parallel to the formation of a hippocampal engram. Memory engram transfer from the hippocampus to the neocortex was in fact accounted for by a functional awakening of this silent cortical "proto-engram", which was specified during cortical tagging. How can a proto-engram remain resistant to recall during a recent memory phase, but subsequently slowly mature into an "engram" that is activatable during remote memory retrieval? To address this question, we have investigated several activity-dependent pathways implicated in memory consolidation mechanisms. Altogether, our results indicate that a cellular consolidation-like process critically governs key steps of systems consolidation.

Title: Proteomic modification in hippocampal synapse following noninvasive brain stimulation

Authors: *S. H. JUNG[1,2], A. QUALLEY[2], J. WAGNER[2], R. MOORE[2], N. BECHMANN[2], M. JACKSON[2], J. MARTIN[2], C. HATCHER[2], R. JANKORD[2]

Abstract: Transcranial direct current stimulation (tDCS) is known to enhance cognitive performance and neuroplasticity, but its underlying mechanisms in the brain are still unknown. The purpose of this study was to investigate effects of tDCS on protein regulation in the hippocampal synapse. Two different current intensities (anodal 250uA and 500uA) of tDCS were applied to Sprague Dawley rats (male, 9-10 weeks old) for 30 min for 2 days, just before training and testing of passive avoidance test (PAT). Hippocampal synaptic proteins were profiled by the Waters Acquity UPLC M-class LC and normalized proteomic data were analyzed by multiple bioinformatics methods. Compared to the sham group, anodal 250uA tDCS upregulated 26 proteins, and 17 protein expression were down-regulated. The expression levels of only 20 proteins were significantly modified by anodal 500uA of tDCS when compared to the sham group. Multiple signalings were identified by GO enrichment analysis. From both tDCS intensities, membrane (GO:0016020) and synapse (GO:0045202) were significantly detected. Multiple terms associated with mitochondrial function were identified only from the anodal 500uA. Pathway analysis identified both shared and unique pathways between 250uA and 500uA. Inflammatory pathway (P00031) detected from both current intensities. Annotation clustering analysis identified some unique annotations, including PDZ domains (Enrichment score: 2.3 & 1.2, respectively). Multiple IPA networks were created for anodal 250uA and 500uA. The networks for both intensities are associated with Protein Synthesis and Cellular Development, Growth and Proliferation. Neurological Disease is the top disease detected from the comparison of 500uA and sham. Only one module created by WGCNA was significantly correlated with PAT latency, and 3 proteins (*gdi1*, *ran* & *ndufs6*) resulted in the most weighted connections in the module. Expression levels of these proteins were significantly associated with PAT latency. Best subset regression method to compare all possible regression models for both

PAT latency and current intensity compared more than 800 models and identified 2 and 6 models for the variables of current intensity and PAT latency, respectively. *Fabp7* were detected from all 8 regression models, and significantly inverse correlation between the expression of *fabp7* and PAT latency were detected while a negative trend was observed with the increased intensity of tDCS. In conclusion, our data provide molecular evidence for effects of tDCS on the hippocampal synapse and suggest candidate synaptic molecules in the hippocampus that are modulated by anodal tDCS.

Title: Mediators of spatial and verbal working memory decay across the adult life span

Authors: *S. CANSINO[1,2,3], F. TORRES-TREJO[1], C. ESTRADA-MANILLA[1], J. G. MARTÍNEZ-GALINDO[1], E. HERNÁNDEZ-RAMOS[1], M. AYALA-HERNÁNDEZ[1], T. GÓMEZ-FERNÁNDEZ[1], M. D. RAMÍREZ-GONZÁLEZ[2], S. RUIZ-VELASCO[3]

Abstract: Working memory abilities significantly decrease with advancing age; hence, the search for factors that may increase or mitigate this decline is critical. Several factors have been identified that influence working memory beside age, such as education, socioeconomic status, nutrient intake and health status, among many others. However, the influence of these variables has mostly been analyzed separately and rarely together with other factors in the same sample. The aim of the present study was to identify factors that jointly act as mediators of working memory decay across the adult life span. We examined a total of 120 variables that included sex; education; income; nutrient intake; alcohol and drug consumption; medication intake; health status; glucose, cholesterol and triglyceride levels; heart rate; physical, cultural and mental activities; and self-perception of memory ability. A lifespan sample of 1652 healthy adults (831 women) between the ages of 21 and 80 participated in the study. The n-back task was used to

evaluate working memory in the spatial and verbal domains. Structural equation modeling analyses were conducted to search for potential mediators that intervened between age and working memory. Age was treated as an exogenous variable and all the rest of the variables were included as mediators. All models were found to have a power of 1 when the alpha level was set to .05, the null RMSEA to .05 and the alternative RMSEA to .08. The study is exploratory because to be able to estimate the effects of numerous factors on memory it is necessary to employ observational methods. Only 14 and 10 variables reliably mediated spatial and verbal working memory, respectively. Some factors positively mediate the effects of age on working memory decay in both domains (education, Mini Mental State Examination, believes about their own memory capacity, alcohol intake, computer use and social activities), while others negatively mediate these effects (anxiety related to memory performance; palmitic acid consumption). Bootstrapped test of mediation revealed that bias-corrected confidence intervals were significant for each of the individual indirect effects, and for the total indirect effects in both models. We identified the factors that are sufficiently powerful to influence working memory decline when they jointly interact, as in everyday living.

Title: Frontoparietal theta tACS enhances verbal working memory in healthy humans with high working memory capacity

Authors: *Z. HU[1], A. J. WOODS[1], C. RANA[1], I. B. SAMUEL[1], S. MEYYAPPAN[1], R. GAO[2], M. DING[1]
[1]Univ. of Florida, Gainesville, FL; [2]Huazhong Agr. Univ., Wuhan, China

Abstract: Theta oscillations are hypothesized to play an important role in working memory by mediating the interaction between frontal and parietal structures. To date, evidence supporting the hypothesis has mainly come from correlative studies; the causal relation between theta oscillations and working memory remains to be better established. In this study, we stimulated the frontoparietal network at individual theta frequencies via two 4x1 electrode arrays centered at F3 and P3, respectively, in three schemes: in-phase, anti-phase, and sham. Twenty healthy

subjects performed a Sternberg verbal working memory task with three levels of memory load (load 2, 4 and 6), imposing three levels of cognitive demand, during stimulation and after stimulation. High-density EEG (128 channel) were recorded throughout the experiment. Individual differences in working memory abilities were assessed by working memory capacity (WMC) derived from the OSPAN task. Analyzing behavioral and EEG data from the after-stimulation session, we report two results. First, in-phase stimulation improved task performance only under the high memory load (load 6) condition as compared to sham stimulation in subjects with high WMC. Second, in-phase stimulation enhanced frontoparietal theta synchronization relative to sham stimulation during working memory retention under the high load condition in subjects with high WMC. Taken together, the present findings suggest that under high cognitive demand, in-phase theta tACS of the frontoparietal network using two high-definition stimulation arrays enhanced neuronal communications between prefrontal and parietal structures in healthy subjects with high WMC, and the enhanced frontoparietal communications may underlie improved task performance.

Title: Elderly with high aerobic fitness maintain working memory via right ventrolateral prefrontal activation: A functional near infrared spectroscopy neuroimaging study

Authors: *K. HYODO[1], T. JINDO[1], H. SOYA[2], T. NAGAMATSU[1]
[1]Physical Fitness Res. Inst., Meiji Yasuda Life Fndn. of Hlth. and Welfare, Hachioji-shi, Japan; [2]Univ. Tsukuba, Tsukuba-city, Japan

Abstract: BACKGROUND: Prefrontal cortex (PFC) - mediated working memory (WM) declines with aging. On the other hand, several studies have reported that higher aerobic fitness is associated with greater WM performance in the elderly. However, the underlying neural mechanisms of the relationship are still not well understood. With aging, the brain activity pattern during a cognitive task becomes less lateralized in the PFC, and this change is thought to compensate for the neural dysfunction specific to task demand. Thus, the compensatory brain mechanism might be involved in the association between aerobic fitness and WM in elderly

people. In this study, we aimed to clarify the neural mechanisms underlying the relationship between the aerobic fitness and WM performance in elderly by using functional near infrared spectroscopy (fNIRS) neuroimaging method. **METHODOLOGY:** Twenty two healthy elderly women (mean age 68.8 ± 2.4 years) participated in a graded exercise test using a recumbent ergometer, and computer-based verbal WM task on separate days. During the exercise test, respiratory gas was measured and ventilatory threshold (VT) was analyzed as an indicator of submaximal aerobic fitness. As the WM task, verbal N-back task with letter stimuli was used in this study. The task consisted of three conditions: 0-back (no memory load), 1-back (low memory load), and 2-back (high memory load). Correct reaction time (RT) and correction rate (CR) in each condition were measured. During the task, we monitored prefrontal activation with multichannel fNIRS. fNIRS probes were set to cover lateral PFC activation foci, and neighboring channels were combined for the dorsolateral PFC (DLPFC), ventrolateral PFC (VLPFC), and frontopolar area (FPA) in each hemisphere using virtual registration. **RESULTS:** Compared to the 0-back and 1-back condition, RT was slowed and CR was declined in 2-back condition. The fNIRS data showed bilateral PFC activation during only 2-back condition. Partial correlation analyses revealed that there were significant relationships among higher VT, shorter RT in 2-back condition, and greater right-VLPFC activation during 2-back condition, with controlling age as covariates. **CONCLUSION:** Our results suggest that aerobic fitness is associated with high-loaded verbal WM performance via right-VLPFC activation in the elderly. Because verbal WM task recruits the left PFC predominantly, it is possible that the elderly with high aerobic fitness could maintain working memory by increasing compensatory brain activation.

Title: Visual working memory processes for objects' material properties in the human prefrontal cortex

Authors: *M. FUJIMICHI[1,2], H. TSUDA[1], H. YAMAMOTO[1], J. SAIKI[1]
[1]Kyoto Univ., Kyoto-Shi, Japan; [2]Japan Society for the Promotion of Sci. (JSPS), Tokyo, Japan

Abstract: We previously investigated neural bases of visual working memory for objects' material properties (VWMM) in the human visual cortex, and found VWMM-related activities in the higher-order ventral visual pathway and intraparietal sulcus. It remains unclear how the brain

regions other than the visual cortex are related to VWMM. We hypothesized that VWMM is accomplished by the interplay between the visual cortex and the prefrontal cortex (PFC) that has been shown as a critical site for VWM. To test this, we conducted an fMRI experiment where participants repeatedly performed delayed material discrimination tasks in a 3T scanner. Two kinds of material discriminations were performed, one for glossiness and another for roughness. In each trial, participants first judged which of the two tasks to be performed by detecting which dimension material property of two sequentially presented samples were varied (material discrimination phase). For example, samples varied in glossiness, participants judged this task to be glossiness memory task. After the presentation of the samples, a numerical cue indicating which sample to memorize was presented. After an 11s delay (delay phase), a probe object was presented and participants indicated whether the probe object had higher glossiness (lower roughness) than the memorized one. A multi-voxel pattern analysis (MVPA) was applied to predict which task participants performed from the fMRI activities in the anatomically defined prefrontal regions, dorsolateral PFC (DLPFC), ventrolateral PFC (VLPFC), and frontal pole (FP). The results of MVPA in each phase were different in the three regions. FP was near chance accuracy in both phases. In DLPFC, accuracy was not significantly higher than chance level in the material discrimination phase. The accuracy significantly exceeded chance in the mid-delay phase and fell to chance in the late-delay phase. VLPFC showed above chance accuracy in the material discrimination phase, in contrast, only marginally significant accuracy throughout the delay phase. In comparison with the visual cortex, a similar pattern of MVPA results was obtained in VLPFC and the higher-order ventral visual cortex. Furthermore, in the mid-delay phase, the accuracies in DLPFC and in intraparietal cortex varied in a similar fashion. These results suggest that visual working memory for objects' material properties is supported by the interplay between the visual cortex and lateral PFC.

Title: Are unattended memory items under cognitive control? Electrophysiological evidence

Authors: *J. M. FULVIO[1], B. R. POSTLE[2]
[2]Psychology and Psychiatry, [1]Univ. of Wisconsin - Madison, Madison, WI

Abstract: In our variant of the dual-serial retrocuing (DSR) paradigm, two sample items are presented simultaneously at the beginning of each trial, and recognition is tested twice in succession, each time after a delay-period retrocue has indicated (with 100% validity) which of the two items will be tested (thereby giving the probed item the temporary status of "attended memory item"; AMI). Importantly, the intitially-uncued item cannot be forgotten because it may be tested by the second memory probe, and so it temporarily takes the status of "unattended memory item" (UMI). Previous work has shown that multivariate pattern analysis (MVPA) evidence for an active representation of the UMI often drops to baseline, raising the possibility that the UMI may not be held in working memory, but instead may be transferred to long-term memory (LTM) and then retrieved from LTM on trials when it is cued by the second retrocue. Initial evidence that the UMI is held in working memory, not LTM, came from the demonstration that it can be "reactivated" by a single pulse of transcranial magnetic stimulation (spTMS): 1) spTMS transiently reinstated the MVPA decodability of the UMI from the concurrently measured electroencephalogram (EEG); and 2) spTMS increased false-alarm responses when the UMI was presented as the recognition memory probe (i.e., as a lure; Rose et al., 2016). Here, we tested predictions made by the model that an active representation of the UMI's spatial context is held in a dynamically reconfigurable parietal salience map: Behavioral and EEG reactivation of an uncued item with spTMS targeting IPS2 would only occur on DSR trials when the uncued item was a UMI, but not on single-probe trials, when the uncued item could be dropped from working memory ("dropped memory item"; DMI). (Critically, the temporal lag between sample presentation and retrocue was identical for DSR and single-probe trials.) Results supported these predictions, showing UMI reactivation effects - in behavior and in the EEG - only during the first delay of DSR trials and not on single-probe trials. The specificity of reactivation effects for UMIs, but not for DMIs, confirms that information about the UMI is held in working memory. The presence, and strength, of elevated effective connectivity between a frontoparietal salience map (including IPS2) and the posterior networks that can represent a recently presented stimulus may govern whether or not that stimulus remains "in working memory."

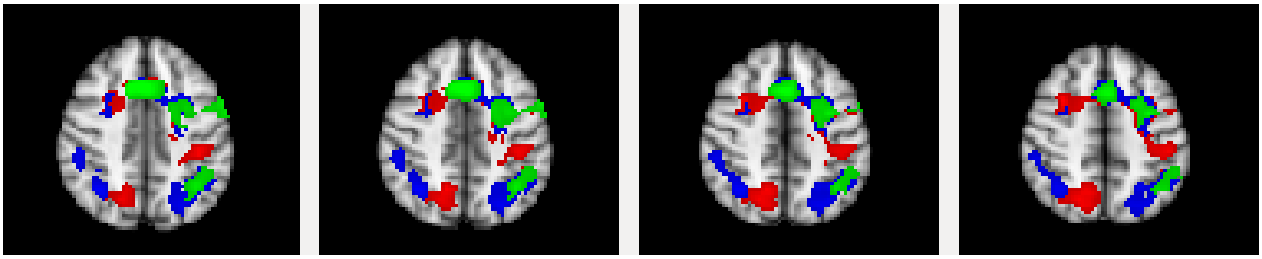
Title: Longitudinal brain connectivity changes in response to a working memory task

Authors: *A. BRZEZINSKI RITTNER, S. ALCAUTER, F. A. BARRIOS
Inst. de Neurobiología, Univ. Nacional Autónoma De México, Queretaro, Mexico

Abstract: Working memory (WM) consistently activates specific brain regions (Owen, et al, 2005). Some of these structures, such as the dorsolateral prefrontal cortex (DLPFC), part of the cingulate cortex and certain parietal regions are included in the Central Executive Network (CEN), (Bressler and Menon, 2010). It has been shown that practice in WM tasks can induce functional changes in neural activation patterns (Jolles, et al, 2010), presumably due to learning effects.

We tested if the brain activation and functional brain connectivity change when someone performs the same cognitive task along different time periods. Eight subjects (mean age 24.4 years) performed a N-back task (2-back) with visual stimuli during three fMRI sessions. The sessions where distributed with the second one taking place one week after the first, and three weeks before the last one. We found a decrease in BOLD signal extension comparing the average activation maps from each session. Then we performed a psycho-physiological interactions (PPI) analysis to study the functional connectivity; based on the BOLD signal average obtained from the third session, we selected different regions of interest (ROI) and created spherical masks to use them as seeds for the PPI analysis.

We found that, compared to the first session, the functional connectivity between the areas associated with the CEN and PPI connected structures grew stronger on the second session; for the third session, there was a decrease connectivity in certain of these areas. These PPI connectivity regions were mainly localized in frontal regions and the cingulate cortex. Overall, both in activation and connectivity, there was a left lateralization, since there was smaller activation in the right hemisphere. We think these findings are caused to a learning process over time considering that at the beginning, subjects started at a certain effort level to perform the task, and as they repeated it, they invested less resources to solve.



PPI maps for a seed ROI placed in the cerebellum. Maps from the first (red), the second (blue) and the third sessions (green) are overlapped.

Title: Decoding working memory load from high density EEG

Authors: *C. RANA, Z. HU, S. MEYYAPPAN, I. B. H. SAMUEL, R. GAO, K. BO, A. J. WOODS, M. DING
Univ. of Florida, Gainesville, FL

Abstract: Working memory (WM) is an essential cognitive function. Manipulating working memory load and observing corresponding brain responses is a commonly applied technique for uncovering the neural mechanisms of WM. In this study we applied multivariate pattern analysis to high-density EEG data to examine the formation and development of WM representations in the brain. 128-channel EEG were recorded from twenty healthy subjects performing a Sternberg verbal working memory task with three levels of memory load (2, 4 and 6). On each trial, a memory array (cue), containing either 2, 4 or 6 letters to be remembered, was presented for 2000 ms (encoding period); to equalize the intensity of visual stimulation across memory load the non-letter positions in the array were filled with meaningless symbols. A time period (retention period) 3000 ms followed cue offset, and at the end of the time period, a probe letter was displayed for 1000 ms (retrieval period). Subjects responded via a button press to indicate whether this letter was contained in the cue array. Following EEG preprocessing, multivariate pattern classifiers were trained to decode load 2 condition versus load 6 condition during encoding, retention, and retrieval. There were four key findings. First, during encoding, decoding accuracy began to increase after cue onset, reached the highest level at ~500 ms, and decreased back to chance level at ~1500 ms. Second, during retention, following cue offset, decoding began to increase again, reached the highest level at ~500 ms after cue offset, and declined back to chance level at ~1100 ms after cue offset. Third, during retrieval, after probe onset, decoding accuracy once again began to increase, reached the highest level at ~500 ms after probe onset, and declined back to chance level at ~1500 ms after probe onset. Fourth, for the periods of encoding and retention when decoding accuracy was at chance level, we replaced voltage values by functional connectivity values as feature input into the classifiers, and found that the decoding accuracy became significantly above chance level. These results suggest that (1) the formation and development of the neural representations of WM is a highly dynamic process and (2) multivariate patterns of electrical activity and multivariate patterns of functional connectivity reflect different aspects of WM representations.

Title: Working memory and falls risk in older adults

Authors: *M. WONG[1], L. S. NAGAMATSU[2]
[2]Kinesiology, [1]Univ. of Western Ontario, London, ON, Canada

Abstract: RATIONALE: The aging population is rapidly increasing, where currently the population of older adults (ages 60+) outnumbers the population of children. Falls risk is major concern for older adults, as falls can impair instrumental activities of daily living. No studies have investigated the differences between fallers, non-fallers, and individuals who are at moderate risk for falls. Thus, understanding the factors that attribute to falls risk is vital. Cognition function, specifically global cognition and executive function have shown to be impaired in fallers. However, working memory has not been examined as a falls risk factor, and the effects of impaired working memory across fallers, non-fallers, and moderate risk for falls. PURPOSE: To examine if there is a differences behaviourally and electrophysiologically in working memory between non-fallers, fallers, and moderate risk for falls in older community-dwelling adults. METHODS: Older adults (n=44, female=27) aged 60-80 years (m=68.6, SD=4.7) completed two sessions. The first session incorporated a battery of cognitive tests, Tinetti's Mobility Test, and general questionnaires that obtained demographic information and falls history. Participants were classified as a faller, non-faller, or a moderate risk for falls, based on Tinetti's Mobility Test (TiMT) scores, and their falls history. The second session had participants engaged in 3 versions (0, 1, 2) of the n-back test. Electroencephalograms (EEG) and behavioural performance were recorded. RESULTS: A one-way ANOVA with a post-hoc Tukey analysis was used to detect differences between groups. No significant differences between age, sex, or education were seen between groups. However, fallers group had a significantly higher physical activities score in comparison to the non-fallers group and moderate risk group. The moderate risk for falls group performed significantly ($p<0.05$) poorer in comparison to both the fallers and non-fallers with reaction time and error ($n^2=0.133$). The P3 component at the Fz electrode site displayed a significant difference in peak latency between non-target and target by classification. As well, peak latencies in the N2 and P3 component were significantly different in the 1, and 2-back test at the Fz. CONCLUSIONS: The moderate risk for falls group per is associated with poorer behavioural and electrophysiological performance on higher order

working memory tasks, specifically with cognitive processing and conflict resolution. The implications of this study suggests that those who are at risk for falling should be investigated and further research should consider the link between working memory and falls risk.

Title: Quantitative electroencephalographic features of early postmenopausal women with low and high performance in a working memory test

Authors: *M. SOLIS-ORTIZ[1], E. GONZALEZ-PÉREZ[2]
[1]Inst. Invest Med, Univ. Guanajuato, Leon, Mexico; [2]Med. Sci., Univ. of Guanajuato, Leon, Mexico

Abstract: Working memory is an executive function which is key for effective cognitive performance. Several studies have found that this memory displays deficits in early postmenopausal women, although the results are inconclusive. An electroencephalographic (EEG) approach during the application of a working memory test may aid in understanding these cognitive deficits. The aim was to explore EEG features of postmenopausal women through the execution of a test demanding working memory. EEG activity was recorded through the execution of the Wisconsin Card Sorting Test in the frontal, central, parietal and occipital leads in twenty-five early postmenopausal healthy women. The women were divided into two groups according to their execution in the test. A low execution group (n=11) and a high execution group (n=14) were established for comparisons. The criterion was based on the number of trials needed to reach the first category of the test. A large number of trials and 2 categories performed were indicative of low performance. Delta, theta, alpha1, alpha2, beta1, beta2 absolute power, the number of completed categories, correct responses (trials), perseverative errors and test errors were analyzed between two groups. When compared to the high execution group, the low execution group displayed lower number of completed categories ($p = 0.0001$), a higher number of trials to complete the category) ($p = 0.003$), a higher number of perseverative errors ($p = 0.02$) and greater number of errors committed ($p = 0.0001$) in the test, with a large size effect. The quantitative EEG analysis did not reveal significant differences between the groups, although the high execution group showed a tendency to have higher delta, alpha2, beta1 and beta2 absolute power. These findings indicate that the EEG activity was similar between the two groups, which

suggests that the women of low execution group used the brain resources to perform the test in a manner analogous to the high-performing group.

Title: Network profiles of the dorsal anterior cingulate cortex in obsessive compulsive disorder during motor control and working memory

Authors: *T. D. MERAM[1], A. Z. CHOWDURY[1], P. EASTER[1], T. J. ATTISHA[1], E. KALLABAT[1], G. HANNA[2], P. ARNOLD[3], D. R. ROSENBERG[1], V. A. DIWADKAR[1]
[1]Wayne State Univ. Sch. of Med., Detroit, MI; [2]Univ. of Michigan Med. Sch., Ann Arbor, MI; [3]Univ. of Calgary, Calgary, AB, Canada

Abstract: Background
Obsessive-Compulsive Disorder (OCD) is a mental disorder characterized by recurring rituals or reoccurring thoughts (Coluccia, 2017). Interest on its biological correlates has focused on network profiles of the dorsal Anterior Cingulate Cortex (dACC; Rosenberg et al., 2004). This interest is motivated by the dACC's hypothesized role as a principle control region (Paus 2001), dysfunction in which may be relevant for OCD. Previous studies have described dysfunctional network profiles of the dACC during working memory (Diwadkar et al., 2015) and motor control (Friedman et al., 2017). Here we compared the *relative* impairments in these profiles across these two task-active states.
Methods
fMRI data (3T Siemens Verio) was collected from 28 OCD (10 male) and 27 Health Control (HC) (10 male) subjects (Right-handed; $12 \leq Age \leq 22$). Groups were matched for age, handedness, and gender. Subjects underwent fMRI while performing working memory (WM, 2-back) and motor tasks. During WM, subjects maintained information on stimuli in a sequence presented for brief periods of time (presentation time: 500 ms; ISI: 2500 ms; 10 letters per run). During the motor task, subjects tapped their right forefinger in response to a flashing white probe (.5 or 1 hz, 30 s Epochs). Data were modeled using standard methods in SPM12 (Wellcome Trust Center). Psychophysiological Interactions (PPI) were employed with a seed in the dACC to examine the region's modulatory effects. 2nd level analysis utilized a two-factor design with Group (OCD/HC) and Task (Memory/Motor) as non-independent factors ($p<.005$ for all

analyses).
Results
A main effect of Group was observed in the precuneus, cuneus, occipital cortex, and left postcentral gyrus, with OCD characterized by greater modulation. The motor task induced greater dACC modulation in OCD in multiple regions including the occipital lobe, cuneus, insula, and precentral gyrus. Effects during the memory task were more circumscribed, observed in the inferior frontal gyrus and middle occipital cortex.
Discussion
Dysfunctional network profiles of the dACC are exaggerated in OCD across tasks. This effect is more salient during motor function, implying a relationship between task characteristic and expression in network dysfunction. Previous studies have characterized the dACC as being ideally positioned to translate intentions to actions, placing a heavy emphasis on the link between cognition and motor responses (Paus, 2001). Our findings support the primacy of the dACC in motor over memorial processes (Diwadkar et al., 2017) and indicate that this primacy is revealed in the pathology of brain network function in OCD.

Title: Differences in alpha band along maintenance and manipulation of information in working memory

Authors: *T. V. ROMAN-LOPEZ[1], S. CISNEROS-LUNA[1], J. A. FRANCO-RODRIGUEZ[1], M. MENDEZ DIAZ[2], O. PROSPERO-GARCIA[2], A. E. RUIZ-CONTRERAS[1]

Abstract: Working memory (WM) is defined as the ability to maintain (Mt) and manipulate (Mp) information to guide subsequent behavior. The Mt refers to the ability to keep in mind information even if is not present. The Mp of information is the modification or processing of the

information that is being maintained. Delay-Match to Sample Task (DMST) allows the evaluation of different phases of the information processing in WM: encoding, delay period, and retrieval. The aim of this study was to evaluate the event-related synchronization (ERS) or desynchronization (ERD; by Hilbert transform) of alpha-band, along Mt and Mp processes. Two conditions of DMST were used: the Mt condition required keeping in mind two features (color and shape) of irregular figures; meanwhile, the Mp condition required the mental rotation (180º plane rotation) of these irregular figures. A higher percentage of correct responses and shorter reaction times was found for Mt *vs.* Mp ($p<0.001$). For encoding, a higher ERS was observed for Mt *vs.* Mp from 0-300ms, regardless region; also a higher ERS was observed at Occipital *vs.* Frontal and Central sites ($p<0.05$). Also, from 300-1000ms an ERD higher for Mp *vs.* Mt ($p<0.05$) was found. For delay period, in occipital site a ERS was larger for Mt than for Mp at 500-1000 ms. Also, an effect for region was found, occipital and parietal sites had larger ERS than frontal-central sites from 0 to 2500ms; and occipital had larger ERS than parietal *f*rom 0-1500ms occipital ($p<0.05$). Finally, in retrieval phase it was observed a higher ERD for Mt than for Mp at parietal and occipital regions ($p<0.05$); also, a higher ERD in parietal and occipital regions compared to frontal and central regions ($p<0.05$), regardless of the condition. Our results confirmed behaviorally and electrophysiologically that Mp is more difficult than Mt, associated with a higher desynchronization during encoding and the retention delay, predominantly in posterior regions, which could be related with differences in suppression of relevant features of the stimuli. Meanwhile, higher desynchronization for Mt than for Mp during retrieval could be associated with a more active searching process for comparing the actual stimulus which required a transformation.

Title: Neural circuit maintains simultaneously or sequentially presented multiple items in working memory

Authors: *D. WANG[1], Y. ZHANG[2], J. ZHOU[2]
[1]Sch. of Systems Science,Beijing Normal Universit, Beijing, China; [2]Dept. of Physics, Beijing Normal Univ., Beijing, China

Abstract: There are two streams of computational model in theoretical study on working memory. One claims that WM information is represented as persistent firing of neurons and the other argues that WM information is represented as brief bursts of spiking and stored in dynamic synapses. The working memory with simultaneously presented multiple items has been implemented by persistent firing model and the working memory given sequential multiple items has been implemented using brief bursts of spiking models. However, the brief burst model can not hold simultaneously presented information and the persistent firing model also has not been shown to maintain sequential presented information. Here we constructed a spiking neural network to maintain the simultaneously or sequentially presented multiple items in working memory. We use the prefer direction to label pyramidal cell with three compartments and placed them on a ring according to its prefer direction. We also include three different types of interneuron into the model. We adopt a structured connectivity between neurons. NMDA and AMPA receptors mediate the excitatory synaptic currents and GABA mediates inhibitory synaptic currents. Each item will evoke one localized activity bump which is a persistent gamma oscillation nested by beta oscillation during delay period. The population activity shows a persistent firing pattern but single neuron activity show a gamma oscillation nested by beta oscillation which is similar to the brief burst model. Importantly, our model can hold simultaneously presented information as well as sequentially presented information.

Title: Distinct neural coding schemes of anterior and posterior brain regions in forming cluster representations in visual working memory

Authors: *M.-S. KANG[1,2], B.-I. OH[1], Y.-J. KIM[3]
[1]Dept. of Psychology, Sungkyunkwan Univ., Seoul, Korea, Republic of; [2]Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci., Suwon, Korea, Republic of; [3]Ctr. for Cognition and Sociality, Inst. for Basic Sci., Daejeon, Korea, Republic of

Abstract: We investigated neural codes reflecting how sensory representations are transformed into visual working memory. We capitalized on two recent advances. In visual cognition,

evidence indicates that sensory signal is abstracted to form a cluster representation around the mean of multiple items (Brady & Alvarez, 2011). Methodologically, the temporal generalization (TG) enables us to distinguish dynamic from stable neural coding (King & Dehaene, 2014): If a decoder built at each time generalizes only to the same time, it implies that different neural populations dynamically code a representation. However, if it generalizes to a long period, it means that same neural populations stably form a representation. Twenty people (9 females, mean age = 24.6) were included in the analysis after oculomotor artifacts rejection. They remembered 20 oriented bars and performed an old/new judgment for a probe bar after a 1.6-s delay while EEG was recorded. We built an orientation decoder with an inverted encoding model from the homogeneous block where all orientations were the same. Since all orientations are identical to their mean, the decoder should reflect both sensory and cluster representations. We then generalized the decoder to the heterogeneous block where four orientations (e.g., −30°, −10°, 10°, and 30° from the mean) were repeated five times. Since the decoder's orientation was identical to their mean orientation but different from the individual orientations, successful generalization should reflect only cluster representations. All analyses were separately performed for anterior and posterior electrodes to investigate neural coding schemes of each region. Subjects formed a cluster representation, as indicated by the largest, old responses at the mean orientation in the heterogeneous block. When TG analysis was performed within the homogenous block, the anterior decoder stably generalized over 200-800 ms, while the posterior decoder generalized to the time when the decoder was built, suggesting a stable coding in anterior regions and a dynamic coding in posterior regions. When TG analysis was performed over the heterogeneous block, only the anterior decoder successfully generalized (300 - 700 ms), implying the stable coding for cluster representations in that regions. Further, a behavioral measure of a cluster representation correlated with the decoding sensitivity across subjects only in the anterior regions. These results suggest that different posterior neural populations dynamically transform the sensory signal into cluster representations in visual working memory, while same anterior neural populations maintain the representations over time.

Title: Event-related phase-amplitude coupling for assessing the EEG correlates of auditory working memory load

Authors: T. HUANG[1], H.-M. DING[1], *Y.-L. TSENG[2]
[2]Dept. of Electrical Engin., [1]Fu Jen Catholic Univ., New Taipei City, Taiwan

Abstract: Phase-amplitude coupling, also known as cross-frequency coupling, is a well-established concept to evaluate the neuronal encoding in brain regions and has been shown to be able to track learning and memory mechanisms. Previous study has presented that neural coding structure of memory retrieval is formed by the oscillations of gamma and theta brain signals. Although many studies have addressed the neural mechanisms underlying working memory, most of these studies have focused on the visual modality. In the past few years, neurologists suggested that different chords and tones can influence or induce the brain activations from the frontal, parietal, and temporal regions. In this study, we used auditory stimulation and focused on the relationship between activation of brain oscillations and working memory load using electroencephalography (EEG). The 32-channel EEG signals of 11 participants were measured while they were performing an auditory WM task. For the auditory n-back task, there were three experimental conditions, including two n-back task conditions of stimuli memorization with different memory load and a condition of passive listening to the stimuli. The independent components from frontal and parietal regions were further analyzed by event-related phase-amplitude coupling (ERPAC). ERPAC is used to calculate the degree of coupling between phase and amplitude in a single brain region. Different from other traditional methods with only spatial resolution, ERPAC can assess an index at each sampling point, and thus achieve better temporal resolution. The results suggested that there is significant theta-beta and theta-gamma ERPAC observed in the parietal region during auditory working memory. Furthermore, pronounced ERPAC has been found later (800 ms after the stimulus onset) during high working memory load than the lower conditions (400 - 800 ms after the stimulus onset). In conclusion, the findings demonstrate the existence of phase-amplitude coupling in the parietal regions during an auditory working memory task, and support the viewpoint of theta-gamma coding schemes that the amplitudes of high-frequency oscillations are modulated by the phase of low-frequency oscillations during the memory and learning processes.

Title: Sensory acquisition functions of the cerebellum in verbal working memory: An fMRI investigation

Authors: *Y. LIANG[1], J. PETERBURS[2,1], D. T. CHENG[3,1], J. E. DESMOND[1]
[1]Dept. of Neurol. Div. of Cognitive Neurosci., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Biol. Psychology, Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany; [3]Psychology, Auburn Univ., Auburn, AL

Abstract: **Objectives:** Several fMRI studies have shown that the superior cerebellum exhibits load-dependent activations during encoding of letters in a Sternberg verbal working memory (VWM) task. It has been hypothesized that the cerebellum regulates the acquisition of sensory data across all modalities (Bower, 1997), and thus, (1) VWM load activations may reflect high- vs low-load differences in sensory acquisition demands, and (2) increased difficulty in sensory data acquisition should elicit greater activation in the cerebellum. We tested sensory acquisition in VWM by presenting visually degraded and non-degraded stimuli with high and low memory loads, identifying load-dependent regions of interest in the cerebellum, and then testing if these regions showed greater activation for degraded stimuli. **Methods:** 15 healthy subjects (10 F, 5 M; mean age 31.6 years; age range 22-54 years), received 192 Sternberg VWM trials during fMRI scanning. Each trial was either high- (4 letters) or low-load (2 letters), and letters were either visually-degraded or non-degraded. Eye movements were recorded, and fMRI analyses in SPM8 focused on the encoding phase of the task. **Results:** Consistent with previous studies, load-dependent cerebellar activation was observed in hemispheric right and left VI, as well as in vermis Crus II. Using small volume correction, the degraded vs non-degraded contrast revealed significant activation in the vermis. However, significant activation was not found in the hemispheres. Eye movements for degraded vs non-degraded stimuli were not significantly different. Whole brain (corrected) analysis for the degraded vs non-degraded contrast revealed greater activation for degraded stimuli in left fusiform and right inferior occipital regions, indicating that the degradation manipulation successfully increased sensory acquisition demand. **Conclusion:** We found partial support for the sensory acquisition hypothesis in a load-dependent region of the vermis, which showed significantly greater activation for degraded relative to non-degraded stimuli. Because eye movements did not differ for these stimulus types, this activation appears to be related to perceptual rather than eye movement demands. In contrast to the vermis, hemispheric regions of the cerebellum that also exhibited load-dependent activation did not show increased activation for degraded stimuli. To explain these findings, an overall function of association-based prediction may underlie general cerebellar function, with perceptual prediction of stimuli from partial representations occurring in the vermis and articulatory prediction occurring in the hemispheres.

Abstract: From reading a book to remembering items at the grocery store, our capacity to temporarily store and manipulate information is critical to our interactions with the world. While previous fMRI work has characterized neural correlates of working memory (WM; Magnuson et al., 2015; McNab & Klingberg, 2007) and predicted WM precision (Galeano et al., 2017), brain-based measures have yet to be used to predict WM performance. Using a data-driven technique known as connectome-based predictive modeling (CPM; Finn et al., 2015; Rosenberg et al., 2016; Shen et al., 2017), we here built models to predict individual WM performance from whole-brain functional connectivity (FC) patterns. FC patterns between each pair of 268 nodes of the brain (Shen et al., 2013) in 502 subjects (mean age 28±3.6) of the Human Connectome Project were used to construct CPMs predicting individual WM performance (2-back accuracy). We built two CPMs, one using WM (n-back) fMRI task data and one using resting state data. In leave-one-out cross validation, CPMs built from n-back or rest data successfully predicted previously unseen individuals' 2-back acc. (correlation between predicted/observed scores: task: $r=0.36$, $p=7.3*10^{-16}$; rest: $r=0.20$, $p=1.1*10^{-5}$). Model predictions also correlated with measures of fluid intelligence (gF; Penn's Progressive Matrices: $r=0.30$, $p=7.7\times10^{-12}$) and, with less strength, sustained attention (Short Penn Continuous Performance: $r=0.13$, $p=9.3*10^{-3}$). Analogously built CPMs of gF can predict WM score ($r=0.42$, $p=1.7\times10^{-20}$), as can CPMs of sustained attention, again with less strength ($r=0.22$, $p=1.4\times10^{-6}$). This reflects the documented, strong relationship between WM and gF (Colom et al., 2002, 2004) and weaker relationship between WM and sustained attention (Barrett et al., 2004). Anatomical feature analysis likewise revealed significant overlap (30.8% of connections) between WM/gF models, particularly in utilization of prefrontal and parietal regions, while overlap between WM/sustained attention models was observed in just 5.7% of connections. Indicating that our models characterize WM abilities in general rather than 2-back acc. in particular, the same CPMs of WM generalized to predict memory deterioration (Ahn et al., 2010; $r=0.32$, $p=5.4\times10^{-5}$) in an independent dataset of 157 older adults (mean age 68.7±9.6; 48 healthy, 54 amnestic mild cognitive impairment, 55 Alzheimer's disease) recruited from the Samsung Medical Center (Seoul, Korea). The present results indicate for the first time that whole-brain FC is a broadly applicable indicator of WM capability across the lifespan, correlating as expected with constructs such as gF and sustained attention.

Title: Tracking stimulus representation across a 2-back visual working memory task

Authors: *Q. WAN, Y. CAI, J. SAMAHA, B. R. POSTLE
Univ. of Wisconsin Madison, Madison, WI

Abstract: In the dual serial retrocueing (DSR) task, after two items are encoded into working memory, a retrocue indicates which of the two will be the first to be tested (thereby designating it the "attended memory item" (AMI). Because there is a *p* of .5 that the initially uncued item will be tested later in the trial, it temporarily takes the status of "unattended memory item" (UMI). Although previous studies using multivariate pattern analysis (MVPA) often find that evidence for an active representation of the UMI drops to baseline levels (e.g., Rose et al, 2016), more recent studies employing multivariate inverted (or "forward") encoding modeling (IEM) suggest that the UMI may be held in an active state, but in a representational format that is different from the AMI (Yu & Postle, 2018). One question that remains unclear is whether the differential coding of AMI vs. UMI reflects a general property of varying attentional state, or, rather, is idiosyncratic to the DSR task. Here, we used a task in which memory items are also held in differing states of attentional priority, but one that lacks overt cuing, and for which the *p* of a UMI-to-AMI transition is 1 - the 2-back task. If subjects know with certainty that a memory item will be needed later during the trial, is it nonetheless recoded into a different format than the AMI, or is it held in the same state (as would be the case for, e.g., a conventional load-of-2 delayed-recognition (DR) task)? Stimuli were drawn randomly, with replacement, from 6 black-and-white gratings of 6 orientations. IEMs were successfully trained on EEG voltages from a 1-item DR task, with k-fold cross-validation, although the failure of cross temporal generalization indicated that the representational format at encoding differed from that during the delay. IEM reconstruction of stimuli during the 2-back task also revealed a dynamic representational trajectory: 1) After stimulus offset, when an item became a UMI, it could be reconstructed with the delay-period IEM, but not the encoding IEM; 2) after the offset of the subsequent item in the 2-back sequence, however, the opposite was true. These results suggest that a general principle of neural coding during working memory may be that information is recoded into a format that is different from visual perception while it is being retained for later use, then recoded back into a

perceptual format when needed to guide behavior (e.g., with a recognition decision or a recall response).

Title: Interactions between working memory and perceptual or predictive task demands on an adaptive oculomotor delay response task

Authors: *K. SCHAPIRO[1], J. I. GOLD[2]
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Dept Neurosci, Univ. Pennsylvania, Philadelphia, PA

Abstract: An ongoing question in neuroscience is how expectations inform decisions. Bayesian approaches have been used successfully to understand how prior expectations are used to improve accuracy and shape even low-level perceptual decisions. However, the majority of this work has focused on the effects of stable priors formed in static environments, whereas many decisions are made in more volatile conditions that require dynamic updating of the prior. In principle, this dynamic process relies upon the ability to represent and manipulate relevant information in working memory (WM). Information held in WM is subject to storage limitations and degradation over time. Thus, different task demands, such as whether to make a perceptual (retrospective) or predictive (prospective) inference, may differentially dictate what information is maintained and how it is manipulated to best perform within the constraints of WM. The goal of this study is to understand how different temporal delays affect decisions involving a dynamic prior under both perceptive and predictive task demands.
We used a novel adaptive Oculomotor Delay Response (ODR) task with noisy and volatile structure in the sequence of visual target locations to examine the effects of response delay and task demands on adaptive decision-making. This work builds on extensive work using the ODR task without this explicit sequential structure to understand visual-, memory-, and motor-related processing in the brain. Our task required subject to report, after each sample, either the perceived location of the previous sample or the predicted location of next sample after a varied delay period. Preliminary results show that the perceptual report was dominated by the most recent sample rather than the prior. Conversely, the effect of the most recent sample on the

prediction report decreased as the number of samples in the stable environment increased. These results suggest that the degree to which new information is represented and incorporated into an updated decision is dependent upon both environmental statistics and on task demands. Additionally, increased reporting delay in both decision conditions resulted in decreased average accuracy. This result suggests that at least part of the perceptual and predictive adaptive inference processes are executed in a WM framework that is subject to degradation over time. Possible differential effects of delay on perceptual and predictive adaptive inferences and the representation and modulation of these processes in the brain are the subjects of ongoing research.

Title: Training-induced changes to brain functional connectivity during cognitive tasks and rest

Authors: *J. EREZ[1,2], C. MACE[2,1], E. S. NICHOLS[2,1], A. M. OWEN[2,1], B. B. STOJANOSKI[2,1]
[1]Brain and Mind Inst., London, ON, Canada; [2]Western Univ., London, ON, Canada

Abstract: The primary goal of many ‘brain training’ games is to improve working memory (WM), thought to be a core component of higher cognitive function. The central tenet is quite appealing; by increasing one’s working memory capacity, other higher cognitive functions, such as planning and reasoning, might benefit as well. Yet, support for this idea remains inconsistent; although prolonged practice on one cognitive task yields significant improvements on that particular task, there is little evidence that this improvement transfers to unpracticed tasks that tax other cognitive domains. It is also not well understood whether these different aspects of higher cognitive function share common neural resources, and what degree of plasticity they have. Finding the neural mechanism of this limitation is a key question in cognitive neuroscience. In this study, 10 healthy young adults completed a series of ‘brain training’ sessions using tasks from a validated cognitive assessment tool (http://www.cambridgebrainsciences.com). Participants were assigned to one of two groups: the first group trained on a visuospatial working memory task (“Token Search”), while the second group trained on a reasoning task (“Double Trouble”). Each participant completed approximately 12-15 hours of training across 20 days, and was scanned 5 times over the training period (before,

after, and 3 times between training sessions, following every 2.5 hours of practice). fMRI scans were done as participants performed the tasks, as well as during a short period of rest before and after each scanning session (improvements in WM following training have been shown to be associated with increased neural connectivity at rest). This paradigm allowed us to (1) establish the neural network recruitment of each task before training, (2) investigate plasticity based changes to neural networks due to training, and (3) track whether network connectivity at rest changes as a function of cognitive training. Results revealed that 'brain training' on the two cognitive tasks produced domain-specific functional connectivity profiles (involving the frontoparietal network), but also produced domain-general effects consistent across both tasks (e.g. improved behavioral performance was associated with higher functional connectivity within the default mode network). In addition, prolonged cognitive training affected how these networks were represented in the resting state; that is, the neural profile during training became more divergent. These results provide key evidence as to the nature of the brain networks that are responsible for cognitive training.

Abstract: The limit capacity is a hallmark of working memory (WM). Previous studies demonstrated that 3 to 4 visual spatial items can be stored in WM, and 7 plus/minus 2 digits can also be hold in WM. Little is known about the WM capacity of tactile stimulus. Considering that tactile is an important sense and its neural coding is different from visual spatial stimulus and digit, we carried out three delayed match-to-sample experiments to investigate the capacity and maintenance mechanisms of vibrotactile WM. In Exp 1, vibrotactile stimuli were delivered to the fingertips of all five fingers of the left hand. In each trial, the sample and probe were delivered to

the same finger. Results showed that accuracies of five fingers were not significantly different, which suggested that regions of corresponding somatosensory cortex of each finger contribute equally to vibrotactile working memory. In Exp 2, two, three, four or five different vibratory frequencies were simultaneously delivered to two, three, four or five fingers of participants' left hand and randomly chose one of these fingers to test whether the participant memorized the delivered stimulus. Accuracy in the two frequencies condition was 63%, and performance in the three, four, and five frequencies conditions were near chance. The results suggested that there was interference when multiple frequencies were delivered to different fingertips simultaneously, and the sensory cortex can not process multiple vibratory stimuli simultaneously during vibrotactile working memory.Exp3 was designed to examine the capacity of vibrotactile working memory when subjects memorized sequentially presented vibratory frequencies. Vibrotactile stimuli were delivered to the left index finger. Participants were presented with two, three, four, or five 1000ms different vibratory frequencies, separated by an unfilled 1000ms period. Results showed that performance for all four conditions were above chance, and mean accuracies were 0.80, 0.75, 0.71, and 0.71 respectively. The mean capacity of vibrotactile working memory was 2.11. These results indicated that vibrotactile working memory can store multiple frequencies. Overall, our results suggest that the somatosensory cortex is equally recruited for each finger of the left hand in vibrotactile working memory tasks. However, the somatosensory cortex can not process multiple vibratory stimuli simultaneously. And the vibrotactile working memory can store about 2 vibratory frequencies.

Title: Active tracking of sound textures: A human intracranial study

Authors: *A. J. BILLIG[1], P. E. GANDER[2], W. SEDLEY[3], M. CHAIT[1], H. KAWASAKI[2], C. K. KOVACH[2], M. A. HOWARD, III[2], T. D. GRIFFITHS[3]

Abstract: A network consisting of auditory cortex, hippocampus, and inferior frontal gyrus has been proposed to support auditory working memory (Kumar et al., J Neurosci 36:4492-4505, 2016). However, human intracranial recordings are yet to reveal hippocampal high gamma activity, a neural spiking correlate, during memory for tones. Recordings from the rat hippocampal complex indicate that cells that support navigation can also form discrete firing fields for particular sound frequencies (Aronov et al., Nature 543:719-722, 2017). Critically, this is the case only when the animal adjusts a sound to match the frequency of a remembered target, but not during passive listening. For humans performing such a task, recruitment of navigation circuits may stem from a cognitive association between height in pitch and in physical space (Rusconi et al., Cognition 99:113-129, 2006). Here, we study the neural underpinnings of memory for and tracking of sound textures that vary continuously in a single dimension but have no such spatial association. Stimuli were concatenated chords, each containing between 4 and 100 simultaneous 200-ms tones randomly distributed in frequency over a 4-octave range. Fixing the number of simultaneous tones ("density") while varying their frequencies from chord to chord gave rise to textures that were more "beep"-like at lower densities and more "noise"-like at higher densities. In each active trial, human subjects (patients implanted with electrodes to localize epileptic activity) listened to a 2-s sound of fixed target density, which they were to remember over a subsequent 2-s retention period. They then heard a 15-s texture, the density of which they adjusted using button presses to match the density of the target. Preliminary analyses of sound-induced neural activity revealed robust (high) gamma responses in Heschl's gyrus and superior temporal gyrus, with concurrent low frequency (4-30 Hz) power decreases over a range of frontal, temporal, and parietal sites. (High) gamma responses were also observed in right hippocampus and right inferior frontal gyrus; these were greater during active adjustment than in a passive listening condition with similar auditory stimulation. Activity at one hippocampal site was also present during target presentation and the subsequent silent retention period. Ongoing work includes conducting motor and attention control experiments, and using multivariate analyses to study the link between behaviour and the strength of target representations across the putative auditory working memory brain network.

Title: Remapping of working memory across eye movements in early visual cortex

Authors: *T. HE[1], A. R. VANDENBROUCKE[2], M. EKMAN[1], F. P. DE LANGE[1]
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands; [2]Dutch national research agenda, Den Haag, Netherlands

Abstract: Saccadic remapping, the mechanism that visually responsive neurons increase their activity to stimuli that will be brought into their receptive fields by an upcoming eye movement, may play a critical role in visual stability. Previous studies have demonstrated remapping of stimulus representations during perception. However, our brain can also process stimuli that are not directly available to our eyes. A working memory buffer allows us to access visual information even after it vanished from our visual field, and further guides behavior over a period of seconds. It remains unclear if saccadic remapping also occurs for stimuli that are held in working memory. In the current study, we investigated whether visual working memory representations are remapped. To this end, we directly compared the contents of visual working memory in early visual cortex for saccade and no-saccade conditions. Participants memorized one of two orientation gratings presented in the left or right visual field, and on some trials, subsequently made a saccade. Then, after a retention period participants reported whether a probe stimulus was tilted clockwise or count-clockwise with respect to the grating held in working memory. We used multivariate pattern analysis of fMRI data to probe item-related working memory representations of the remembered grating orientation from contralateral and ipsilateral early visual areas (V1 - V3). Preliminary results suggest that contralateral visual areas contain an item-specific memory trace that corresponds to the retinotopic location of the remembered item during working memory period. Importantly, after participants made a saccade to the opposite visual field, working memory representations appeared to shift from contralateral regions to ipsilateral regions. These results indicated that working memory representations may indeed be remapped after eye movements, suggesting that the storage of working memory, like perception, is dynamically updated with eye movements.

Abstract: MAS and VP contributed equally to the study.
MMVH and AS share senior authorship.
Although working memory (WM) is part of many cognitive functions, its mechanism is still elusive. A popular way to assess WM function is with the N-Back task: subjects are asked to report whether the current stimulus matches one presented N stimuli earlier. While the basic structure of the N-back task is consistent across literature, the used stimulus type and task features vary considerably, such as duration, ISI, feedback, and response contingencies, and little is known about their effect on the neural correlates of WM. To investigate the latter, 36 healthy adults (18 males, 18 females) were recruited to perform different versions of the same N-back task while simultaneously recording their EEGs: Three different experimental set-ups (stimulus durations, ISI, feedback response contingencies) and three different stimuli types (colored circles, pictures, and syllables), crossed into nine different combinations. Preliminary results suggest that neural signatures differ for different versions of the N-Back task. Within each set-up, stimuli type seems to play an independent role modulating the P300 event-related potential (ERP) component. This shows that care must be taken when comparing study outcomes in particular when it comes to stimulus type.

Title: Effects of temporal lobe epilepsy on cognitive abilities: An automated memory assessment with eye tracking

Authors: *L. FENG[1], Q. WANG[2], J. WANG[1], K. YANG[1], S. HUANG[1], B. LI[3], B. XIAO[1], D. LIU[4]
[1]Dept. of Neurol., Xiangya Hospital, Central South Univ., Hunan, China; [2]Yale Sch. of Med., NEW HAVEN, CT; [3]computer science department, Univ. of Washington, Seattle, WA; [4]Dept. of Neurol., The Third Xiangya Hospital, Central South Univ., Hunan, China

Abstract: Cognitive dysfunction is a very common comorbidity of epilepsy with a severe influence on daily living quality for epileptic patients, which calls for early neuropsychological diagnostics. To increase the robustness and reproducibility, we created an automated computer-based memory assessment with eye tracking (Tobii Glass II), which provides game-like interaction and simultaneously a visual attention tracking system. In this automated assessment, one to four memory targets is presented for 10 seconds along the middle horizontal line of the computer screen for participants to memorize. After that, the memory targets disappear and 12 potential answers are presented on the screen. The participant must select the target(s) from the previous screen in order to proceed to the next, more difficult level. We invited 31 patients (13 males, age of 30.65 ± 9.89) with temporal lobe epilepsy and 28 age-matched healthy controls (12 males, age 32.93 ±10.01). In classical assessment of Digit Span Backward of the Wechsler Memory Scale, with linear mixed model with clinical diagnosis as the factor and age as the covariate, we found that the patients have significantly less number memorized items than the control group ($F(1,40) = 7.91$, $p = .008$), covaried age is significant ($F(56)=4.91$, $p = .031$). With automated computer-based assessment with eye tracking, the patients took significantly longer time to find the memorized items ($F(1,55)= 12.03$, $p= .001$). Eye tracking data show patients have longer total looking duration ($F(1,55) = 9.86$, $p= .047$), more visit counts ($F(1,55)=5.04$, $p = .029$). The patient group showed a strong correlation between the Wechsler memory performance and the number of visit count ($r(28) = -0.41$, $p = .014$) while none of correlation in control group. There is also marginal correlation between the Wechsler memory performance and the task accomplished time ($r(28) =-0.34$, $p =.068$) and the total looking time ($r(28) = 0.34$, $p =.067$). With our automated computer-based cognitive assessment platform, even though the patients with temporal lobe epilepsy showed no sign of attentional deficits, they might demonstrate significant memory deficit than healthy controls, which was consistent as Wechsler Memory Scale. This platform demonstrated its advantage in automated assessment, quantitative analysis and controlled for visual attention. Future direction would focus on investigating the underlying electrophysiological mechanisms responsible for memory impairment in the patients with temporal lobe epilepsy.

Title: Validation of a translational virtual experiential foraging task for humans

Authors: *N. C. SCHMITZER-TORBERT[1], T. HUYNH[1], K. ALSTATT[1], M. TREBING[1], S. V. ABRAM[2]
[1]Dept. of Psychology, Wabash Col., Crawfordsvlle, IN; [2]Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: Foraging tasks provide valuable insights into decision-making, as animals make decisions about how to allocate limited resources (such as time). In the "Restaurant Row" task, rodents obtain food rewards at several sites. In the "Web-Surf" task, humans are offered short videos from different categories. In both tasks, rewards are available after a variable delay. While rodents physically move between reward sites, humans transition to the next video type by pressing a button. Rodents and humans show similar patterns of behavior on these tasks, supporting their use to study decision-making across species. We tested a new human task ("Movie Row"), which combines elements of the Restaurant Row and Web-Surf tasks.
In the Movie Row task, participants navigate through a 3-d virtual environment on a rounded track. A movie screen is positioned at each corner of the track, where 4-sec video clips are available from one of four categories (kittens, bike accidents, landscapes, and dancing). As participants arrive at a screen, the category and loading time (delay) is presented. Participants accept offers by stepping onto a platform and looking at the screen, or skip an offer by moving to the next reward site. Delays range from 3 to 29 seconds (though longer delays were possible in the second version).
Two versions of the task were tested, the first in a sample of 30 male undergraduates who completed the Movie Row task in a laboratory. The second version was tested in an online sample of 51 participants (30 females, mean age = 42.2 years) recruited through Amazon's Mechanical Turk.
Behavior on the Movie Row was similar to that of the Web-Surf task. Revealed video preferences, assessed by delay thresholds (the delay below which they would accept, above which they would skip an offer) were positively correlated with stated preferences, with more than 64% of participants having a correlation greater than +0.75 with the average video rankings and with post-experiment rankings of each video category. Decision consistency (the proportion of offers where participants deviated from their delay threshold) was lower on the first (in-person) version ($M = 0.12$, $SD = 0.05$) than the second (online) version ($M = 0.20$, $SD = 0.11$), higher than the reported mean for the Web-Surf task ($M = 0.07$), but similar to the Restaurant Row task ($M = 0.12$).
These data support the Movie Row task as translational tool to study foraging behavior in humans, providing convergent results with a rodent navigation task and a human stay/go foraging task. And, by including a virtual navigation component, the task may be useful in testing if behavioral measures identified in the rodent Restaurant Row task translate to human virtual navigation.

Title: Greater willingness-to-pay for real foods (but not food images) that are perceived to have higher caloric content

Authors: *C. A. ROMERO, J. C. SNOW
Univ. of Nevada, Reno, Reno, NV

Abstract: Laboratory studies of human dietary decisions have been based almost exclusively on studies of computerized two-dimensional (2-D) images. In contrast, food choices in everyday life are typically made in the context of real foods —solids that afford grasping and have actual caloric content. Contrary to the assumption that 2-D images are appropriate proxies for real foods in the study of food valuation, we recently found that willingness-to-pay (WTP) increases by ~6% for food items that were displayed as real objects versus planar high-resolution colored images. Here, we examined whether effects of display format on valuation are modulated by the actual or perceived caloric content of the foods, and whether the stimuli were physically accessible at the time of choice. Participants placed monetary bids on everyday snack food items that were displayed either as real objects or 2-D images. Critically, although all of the stimuli were presented within reaching distance of the observer, on half of the trials the stimuli were displayed behind a clear Plexiglass barrier that prevented in-the-moment access to the stimuli. Linear mixed-effects modeling analysis revealed that although the presence of the barrier reduced WTP for preferred foods, this effect was comparable for real foods and food images. However, for real foods (but not images) WTP increased for items that were perceived by observers to have greater caloric content. There were no other higher-order interactions between the factors. These results suggest that although humans place greater value on foods that are perceived to yield higher caloric return, this only occurs when the decision is made in the presence of a real food.

Title: Similarities and differences in the representation of real objects versus 2-D planar images and 3-D augmented reality displays: Insights from inverse multidimensional scaling

Authors: *D. HOLLER[1], S. FABBRI[2,1], J. C. SNOW[1]
[1]Psychology, Univ. of Nevada, Reno, Reno, NV; [2]Psychology, Univ. of Groningen, Groningen, Netherlands

Abstract: Images of objects are commonly used as proxies to access the organization of conceptual knowledge in the human brain. However, recent studies from our laboratory have highlighted differences between images and real objects at the level of their neural representation, as well as in their contribution to memory, attention and decision-making. Asking an observer to make judgments about the similarities among a set of objects can provide unique insights into the nature of the underlying neural representations of those objects in human cortex (Mur et al, 2013). Here, we used inverse multidimensional scaling (Kriegeskorte and Mur 2012) to investigate the subjective properties that observers use to characterize objects during free-sorting, when the stimuli are displayed as 2-D images of objects, 3-D augmented reality objects, and real objects. Observers were asked to arrange 21 different items so that the distances between them reflected their perceived dissimilarities. One group of participants sorted 2-D images on a computer monitor using a mouse drag-and-drop action; another group manually sorted AR displays of the same objects; the remaining group manually arranged real-world objects. Critically, participants were free to use any dimension they liked to group the items, and were asked to report their sorting principle to the experimenter prior to sorting the stimuli. By correlating models based on the various sorting criteria, and the dissimilarity matrix obtained by the behavioral ratings, we identified the properties that observers used to separate the items in each format. Using stepwise linear regression, we found that both common and different criteria were used to arrange the stimuli across formats. For example, for all formats, the location where the item is typically encountered in everyday life was a salient dimension, as was elongation. However, unlike 2-D images, real objects and AR stimuli were sorted based on their physical size. Critically, only real objects were sorted based on their weight. These results suggest that although images and real objects are represented similarly with respect to their semantic properties, images lack the representational richness of their real-world counterparts.

Title: Evidence for response-boundary adaptation in two-choice decision tasks across probability conditions in three sensory modalities

Authors: *J. NADEL, P. SIMEN
Dept. of Neurosci., Oberlin Col., Oberlin, OH

Abstract: A key aspect of cognitive tasks is the tradeoff between speed and accuracy. When faced with extraction of a stimulus in noisy environments, organisms must choose between a) increasing the certainty of the stimulus's identity and b) rapid action without full certainty. Despite being a well-documented phenomenon in speeded response tasks, the factors leading to the setting of a particular tradeoff remain unclear. Evidence from a variety of lines of research have indicated that the Drift-Diffusion Model (DDM) accurately describes human behavior in such tasks. The drift diffusion model is a continuous sequential sampling model, in which evidence is accumulated in favor of one option or the other until a boundary is reached and a decision is made.
We previously proposed a diffusion model that heuristically approximates the optimal parameter values, and that can adapt speed-accuracy tradeoffs rapidly. This model predicted specific patterns of response time autocorrelation, along with negative cross-correlations between response times and estimated reward rates. To test the predictions of the model, human participants performed two-alternative forced choice tasks in visual (n = 4 subjects, 18 sessions), auditory (n = 4, 13), and tactile (n = 4, 18) modalities. Each session consisted of ten five-minute blocks. Additionally, to examine the effects of different probabilities of one choice being correct on response behavior, two blocks of five probability conditions were included in each session. The probability conditions were 85% rightward, 70% rightward, 50%, 70% leftward, and 85% leftward. Our results were consistent with the prediction of our previously proposed model; specifically, we observed strong autocorrelations and negative cross-correlations across modalities. Additionally, HDDM (hierarchical drift-diffusion model) fitting with all parameters but starting point held constant showed that participants' starting point shifts according to probability condition, such that left-biased blocks lead to starting points closer to the left boundary, and vice versa. Interestingly, cross-correlation patterns across probability conditions displayed an inverse "U" shape, such that more biased probability conditions had weaker relationships between reward rate and response time. This suggests that increases in bias may decrease the importance of the speed-accuracy tradeoff.

Title: Does raising the stakes reduce mistakes? Reward affects some, but not all, suboptimalities in a perceptual evidence accumulation task

Authors: *S. M. COOK, W. KEUNG, R. C. WILSON
Univ. of Arizona, Tucson, AZ

Abstract: Many decisions require us to integrate evidence over time. For perceptual decisions, such evidence accumulation involves integrating noisy sensory information to make a decision about some characteristic of the stimulus (e.g. whether dots are drifting left or right). While there is strong evidence that humans and animals actually perform such evidence accumulation, this process is subject to a number of suboptimalities including: (1) sensory noise, (2) uneven integration of evidence over time, (3) order effects such as repeating the last action and (4) irrational preferences in favor of one option over another ("side biases"). In this study we asked whether any or all of these suboptimalities can be modulated by reward. That is, by raising the stakes can we reduce mistakes? To measure the effect of reward on suboptimal perceptual decision making, we used a modified version of the Poisson Clicks Task developed by Brunton et al. (Science 2013). In this task, (N = 82) participants were presented with a stream of auditory clicks in both ears, and they were asked to simply respond which side had more clicks, right or left? Critically, on some, "high stakes", trials the potential reward for a correct choice was high, and on other, "low stakes", trials the potential reward for a correct choice was low. On all trials, they were not rewarded if they answered incorrectly. A simple analysis of accuracy showed that raising the stakes did indeed reduce mistakes in this task from 21% to 19% ($p < 0.001$). To understand which suboptimalities were affected by stakes we used a simple regression model which allowed us to quantify all four suboptimalities. Results show that on high stakes trials, only the average weight given to each click was affected (by about 12%, $p < 0.001$). This suggests that only the relative effect of sensory noise is modulated by stakes such that there is a higher signal to noise ratio on high stakes trials. This further suggests that some, but not all suboptimalities can be modulated in the service of maximizing reward.

Title: Modeling memory systems interactions during the development of decision-making expertise

Authors: *B. REUVENI, B. FEINSTEIN, P. J. REBER
Northwestern Univ., Chicago, IL

Abstract: Becoming an expert in a complex decision making task can produce a learning curve that is non-monotonic (U-shaped) as the learner switches among competing strategies. Here we observe a non-monotonic learning curve in a visual categorization task as participants are encouraged to switch strategies by model driven stimulus selection. The model, PINNACLE 2.0 (Nomura & Reber, 2012; Reuveni & Reber, *in prep*), is based on memory systems theory and provides a framework for understanding the roles of implicit / explicit memory and their interplay during learning. When initial performance is based on a partially effective explicit rule, early task accuracy will be modestly better than chance. If optimal expertise depends on a more complex representational structure gradually extracted from environmental statistics the learner must move beyond these initial rules. In this case the expert will exhibit intuitive decision making based on implicit learning. The mechanism underlying this transition is not well understood. We examined this process using a visual category learning task based on trial and error with feedback. Participants were initially taught a simple explicit rule before revealing that the true category structure required a more complex one typically learned implicitly. Computational modeling was used to provide online estimates of strategy and memory system use based on patterns of recent choice behavior. Model estimates were used to guide the participants through the strategy shift by selecting stimuli to encourage implicit learning. Successfully modeling behavior in a two memory system framework counter intuitively required hypothesizing that learning happens in parallel across systems on every trial, raising questions about the neural feedback learning mechanisms when systems compete. Conflict resolution between systems was captured with a simple mechanism, but which required a metacognitive analog to confidence, even for implicit (nonconscious) learning. The accuracy of the mechanisms used to fit human behavior can potentially be tested with neuroimaging data that connects neural activity changes to model mechanisms. Dynamic identification of strategy use over 400 trials of learning revealed a gradual shift from a simple rule to intuitive decision making punctuated by periods of rapid switching between strategies (thrashing). This process is inconsistent with

simple models of expertise that assume gradual transformation and improvement of task knowledge that would produce monotonically improving performance. Our model provides a preliminary account of the operation and interaction of these memory systems as expertise develops.

Title: Physiological measures link clinical states to impulsive decision-making in opioid use disorder

Authors: *S. LOPEZ-GUZMAN[1,2], A. B. KONOVA[2], J. MESSINGER[2], N. BANAVAR[2], K. LOUIE[2], J. ROTROSEN[3], P. W. GLIMCHER[2]
[1]Escuela de Medicina y Ciencias de la Salud, Univ. del Rosario, Bogota, Colombia; [2]Ctr. for Neural Sci., [3]Psychiatry Department, Sch. of Med., New York Univ., New York, NY

Abstract: Objective: Impulsive decision-making is characteristic of addictive disorders and is associated to changes in the brain valuation network due to chronic substance abuse. Computations in this network have been shown to be strongly context-dependent and to explain variation in decision-making behavior in healthy subjects. We hypothesized that changes in clinical states — particularly high-craving states — and other symptomatology may similarly lead to contextual changes in impulsive choice computations that could precipitate a return to drug use. However, inconsistent findings on the relation between self-reported symptom severity and relapse to drug use suggest that measuring psychophysiological manifestations may add precision to the evaluation of current clinical states. We addressed these questions in a group of opioid users receiving standard treatment in an outpatient urban clinic. We explored whether different levels in reported craving, withdrawal symptoms, and anxiety, as well as heart rate variability, skin conductance, and facial electromyography were related to changes in choice behavior in a delay discounting task.
Methods: Individuals with Opioid Use Disorder (OUD) who endorsed recent craving for heroin or other opioids were recruited to participate in 2 sessions. One was conducted before the participant received their medication and the other was conducted after. The order of the two

sessions was randomized across subjects. On each session, we employed validated instruments to assess craving, subjective withdrawal symptom severity, and current levels of anxiety. Participants then completed a 12-minute real-monetary-incentive delay discounting task. Heart rate variability (HRV), galvanic skin response (GSR), and corrugator and zygomatic surface electromyography (EMG) were measured during the task.
Results: In preliminary results (n=22), we find that there were on average no significant differences in symptomatology or impulsive choice between the 2 sessions. However, discount rates in both sessions were significantly explained by anxiety levels and the number of craving episodes in the last 24 hours, and were inversely proportional to the length of those episodes. Interestingly, HRV during the task was negatively correlated to craving intensity reported right before it, suggesting craving may have a physiologically measurable influence on impulsive decision-making. Current efforts in this study focus on increasing our sample size and establishing whether this and other psychophysiological measures are related to subjective value computations during the task.

Title: Evidence accumulation and optimal stopping in stochastic economic choice: Challenging the DDM

Authors: *S. F. BUCHER, P. W. GLIMCHER
Ctr. for Neural Sci., New York Univ., NY, NY

Abstract: Drift-diffusion models (DDM) have had empirical success in fitting both behavior and electrophysiological recordings during binary choice tasks. They model response times along with choice probabilities and permit insights into the processes from which (perceptual or value-based) decisions originate. In the recent theoretical literature, the DDM has been shown to arise as the optimal solution to a tightly limited class of learning problems. DDMs however are only one representative of the class of bounded accumulation or sequential sampling models. Unfortunately, based on choices and response times alone, it is almost impossible to distinguish between different models of this class, and the assumption of optimality remains untested. We address this problem in a behavioral experiment in which we use a new task to directly measure how choice accuracy evolves with time as evidence accumulates, and compare our findings to choices made under unrestricted time. Our incentive compatible paradigm attempts to, in

essence, reveal the evolving decision variable modeled by the DDM in real-time. In each of about 360 trials, subjects are shown 100 dots, some red and some blue, and are asked whether the majority of these are red or blue. In fixed-time trials the dots are masked after a given time that varies between trials (from 0.1 to 6s), and subjects then must select red or blue within 2s. After subjects choose red or blue we elicit their probabilistic beliefs (or confidence) that their previous choice was correct. Subjects thus report their best guess and their confidence in that guess. Reaction-time trials, which serve as a control, are identical but of unlimited duration and presented without a mask. As expected and previously demonstrated, the accuracy of choices increases as a function of the time during which the dots are displayed. However, our preliminary results show surprising patterns in how accuracy and confidence evolve with time that appear to be inconsistent with predictions of the DDM. The reported confidence is largely consistent with the accuracy of the decisions, and provides further empirical restrictions on how the underlying stochastic process modeled by the DDM evolves with time. While our results are preliminary, it is surprising that our measurement of the evolving decision variable in an economic task does not accord well with the predictions of the DDM in this task. This experimental methodology thus promises empirical insights that permit to refine bounded accumulation models in a way that is not possible relying on decisions and response times alone.

Title: Computational evidence for impulsive responding when expectation for inhibitory control is low in cocaine use disorder

Authors: *J. R. HOWLETT[1], K. M. HARLE[2,3], M. P. PAULUS[4]
[1]UCSD, San Diego, CA; [2]VA San Diego Healthcare Syst., San Diego, CA; [3]UCSD Psychiatry, San Diego, CA; [4]Dept Psychiatry, Laureate Inst. for Brain Res., Tulsa, OK

Abstract: Substance use disorders are among the most disabling conditions among young adults worldwide, yet their underlying pathophysiology is poorly understood. Recent computational approaches have provided new insights into cognitive and behavioral process dysfunctions in substance use disorder. Based on a Bayesian Dynamic Belief Model (DBM), we have found that individuals with stimulant use disorder show poorer tracking of the expectation to engage in inhibitory control (p(stop)). In this investigation, we combined a between-trial learning model (DBM) and a within-trial reaction time model (Hierarchical Drift Diffusion Model (HDDM)) to further delineate computational processing dysfunctions in subjects with cocaine use disorder.

We aimed to determine whether stimulant users, as we have observed in healthy comparison subjects, adjust reaction times as a function of p(stop). We applied a two-level modeling approach, in which p(stop) based on DBM determines the within-trial drift rate (rate of information accumulation) in a HDDM. 35 individuals with cocaine use disorder and 34 controls completed a stop-signal task. Trial-level p(stop) calculated using a DBM was entered as a regressor in a HDDM to examine the main effect of p(stop) on drift rate and interaction between group and p(stop). Cocaine use disorder subjects made more stop trial errors compared to controls based on LME controlling for stop signal delay ($p<.05$). There was a significant main effect of p(stop) on drift rate with a negative slope (slower drift rate when p(stop) was high) (posterior $P<.001$). There was a significant group-by-p(stop) interaction on drift rate, with a more negative slope in cocaine use disorder subjects than controls (i.e. cocaine use disorder subjects were more sensitive to p(stop)) (posterior $P<.001$). Drift rate intercept was negatively correlated with the slope of the effect of p(stop) on drift rate in both groups (cocaine use disorder: $R=-.74$, $p<.001$; controls: $R=-.53$, $p=.001$), indicating individuals who were more sensitive to p(stop) exhibited faster drift rates when p(stop) was low. The results suggest that cocaine use disorder is associated with greater behavioral sensitivity to the probability of a stop. Cocaine use disorder subjects also made more errors on stop trials, possibly due to relatively fast processing when p(stop) was low (despite relatively intact slowing when p(stop) is high). The combination of altered expectation to engage inhibitory processing and increased impulsive responding may be a critical process to target for interventions to reduce relapse in subjects with cocaine use disorder.

Title: The impact of framing effects and ADHD on intertemporal choice in adolescence

Authors: *J. B. SCHWEITZER[1], P. MUKHERJEE[2], C. FASSBENDER[3], A.-M. IOSIF[5], M. B. MENOR[3], J. BURNS[4], A. J. ROGAWSKI[6], A. MLODNICKA[4], J. F. DIXON[4], S. M. MCCLURE[7]
[1]Dept Psychiatry & Behav Scienc, Univ. of California Davis Dept. of Psychiatry and Behavioral Sci., Sacramento, CA; [2]Dept. of Psychiatry and Behavioral Sci., Univ. of California Davis Med. Sch., Sacramento, CA; [4]Psychiatry, [3]UC Davis Sch. of Medicine, MIND Inst., Sacramento, CA; [5]Univ. of California, Davis, Davis, CA; [6]MIND Inst., Univ. of California, Davis, Sacramento, CA; [7]Psychology, Arizona State Univ., Tempe, AZ

Abstract: *Objective*: To explore the effect of contextual (i.e., timing; rounded vs. decimal numbers) and individual variables (i.e., ADHD or not; IQ) on intertemporal choice for monetary outcomes in adolescents (n=129). *Rationale*: Opting for the sooner, smaller (SS) rewards over more delayed, larger (DL) rewards is associated with poor outcomes, such as substance use disorders, poorer physical health and greater economic problems. This project explores variables that might influence decision-making for monetary rewards varying in amount and delay to delivery. *Methods*: Typically developing (TD) and adolescents diagnosed with ADHD chose between 62 intertemporal choices, with half of the trials using rounded values (e.g., $11.00 today or $21.00 in 6 weeks - rounded condition) and half of the trials using decimal conditions (e.g., $10.87 today or $20.74 in 6 weeks - decimal condition). In addition, we explored the effect of the timing of the smaller, sooner reward (e.g., immediate vs sometime in the future - later) versus larger, much later in time on choice. Finally, we analyzed the effect of diagnosis (e.g., ADHD or TD) and IQ on choice. *Results*: Adolescents were more impulsive (i.e., chose SS) on the rounded versus decimal trials ($p = .007$) and when the SS trials were later (e.g., in 2 weeks) than when the SS were immediate (e.g., today; $p = .0001$). ADHD diagnosis was associated with selecting more SS over DL; $p = .05$), in the immediate condition (not the DL condition), however, choice in the TDs was more affected by the length of time to the SS than in the ADHD group ($p = .01$). There was emerging support for sex by group differences ($p = .096$) with females with ADHD demonstrating less impulsivity across conditions and their behavior approximating the TD females. As choice of the SS over the DL choices appeared to be driven by the ADHD male group (i.e., ADHD female choice approximated TD female choice) we further analyzed the effect of cognitive factors on male choice ($n = 83$). Higher IQ resulted in fewer impulsive choices (i.e., greater choice of DL over SS) in the TD group ($r=-.5$; $p = .003$), but not in the ADHD group ($r=.15$; $p = .3$). *Conclusion*: Framing effects should be considered in developing interventions to decrease impulsivity.

Title: Changes in perceived time of intention and movement onset in arbitrary and deliberate decisions

Authors: *U. MAOZ[1,3,5], S. WONG[2], N. ZIARI[3], M. J. SAMAD[4], X. ZHANG[4]
[1]Psychology & Brain Inst., [2]Computaional and Data Sci. & Brain Inst., Chapman Univ., Orange, CA; [4]Psychology, [3]UCLA, Los Angeles, CA; [5]Caltech, Pasadena, CA

Abstract: Libet (1985) showed that information about action onset exists in the brain before participants report forming the intention to act. This led to claims that all decisions are made unconsciously, challenging pillars of human social order, like free will and moral responsibility. In that paradigm, intention onset and movement onset were timed using an external clock (W and M time, respectively). Importantly, the decisions in these studies were arbitrary (e.g., raising the left or right hand). Here we investigated the extent to which W and M time generalize to deliberate decisions.
Participants (n=31) first tasted 10 different drinks—from appetitive ones like lemonade to aversive ones like diluted soy sauce—and rated their palatability. Then, on each trial, they made a choice between two drinks by pressing a button. Our clock was a rapidly changing stream of letters (inter-letter interval 200 ms) for both W time and M time. The experiment included 3 types of decisions in a counterbalanced, blocked design (10 trials per block). In *deliberate-decision* blocks, participants selected the drink they preferred. To motivate deliberate decisions, one trial in each block was randomly selected, and participants had to sip the drink they chose in that trial at the end of the block. *Arbitrary-different* blocks were the same except that participants had to drink both drinks in the randomly selected trial at the end of each block, regardless of their selection. In *arbitrary-same* blocks, participants were presented with the same drink twice, differently motivating arbitrary selection. Randomly interleaved memory catch trials motivated subjects to pay attention throughout the experiment. Participants consistently reported earlier W times in deliberate decisions compared to both arbitrary ones, whereas M time was reported earliest for deliberate decisions, incrementally later for arbitrary-different, and later still for arbitrary-same decisions. In a follow up study of subjects prescreened for high OCI-R scores (indicative of obsessive-compulsive disorder, OCD), W time moved increasingly towards movement onset with higher OCD scores for arbitrary-different decisions. We also found that W time was consistently about 200 ms earlier for all decision types when M and W were measured in the same experimental session, than when W time alone was measured. A preliminary drift-diffusion model that we constructed explains this result via nonlinearities stemming from the number of thresholds imposed on the model. Our results challenge the generalizability of the Libet results from arbitrary to deliberate decisions and could suggest a link between OCD and the report of intention onset.

Title: Executive fatigue and time pressure show dissociable effects on decision-making

Authors: *A. WIEHLER[1], M. PESSIGLIONE[1,2]
[1]Motivation Brain Behavior, ICM - Hop. Pitie Salpetriere, Paris, France; [2]Inserm U1127, CNRS 7225, Paris, France

Abstract: The ability to overcome time and effort costs is an important predictor of higher education and professional success. This ability has been related to the intervention of the executive control network, including lateral prefrontal and parietal regions. Recently, it has been shown that fatigue of the executive control system leads to an increased preference for immediate rewards, over larger but delayed rewards (Blain, Hollard, & Pessiglione, 2016). However, the executive control system may also be involved in the choice process itself, ensuring precise selection of the best option. We thus tested whether executive fatigue would specifically change the preference about options (i.e., exert a bias on which option is selected) or change the amount of control exerted on the choice process itself (i.e., altering the accuracy of decision-making).To better dissociate these two possibilities, we compared the effects of executive fatigue and time pressure, in two separate experiments. In both experiments, participants made choices between no-cost options (immediate, sure and free rewards) and costly options (delayed rewards, probabilistic rewards and rewards in exchange for performing an effort, either cognitive or physical). In the first experiment (n=24), we induced executive fatigue in participants by 6 hours of difficult executive control tasks (working memory and task-switching). In the second experiment (n=27), participants had to make the same choices with and without time pressure (timeout set at 70% of self-paced response time). Choice behavior was fitted with standard discounting models including 3 parameters (bias toward no-cost option, weight on cost level and choice stochasticity).Comparison of fitted parameters revealed distinct effects of executive fatigue and time pressure. Executive fatigue increased the bias towards no-cost options (without affecting choice accuracy) when opposed to delayed and effortful options. By contrast, time pressure increased the choice stochasticity (without affecting choice preference), for all types of options. Thus, we conclude that executive fatigue changes preferences about time and effort, but does not disrupt the choice process itself.

Title: Exploring the neural basis of metacognition in perceptual decision-making

Authors: *W. RYS[1], G. LOUGHNANE[2], D. P. MCGOVERN[2], C. JUDD[2], S. KELLY[3], R. G. O'CONNELL[1]
[1]Trinity Col. Dublin, Dublin, Ireland; [2]Trinity Col., Dublin, Ireland; [3]Sch. of Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland

Abstract: Computational modelling and neurophysiological recordings suggest that perceptual decision-making involves integrating noisy sensory evidence up to an action triggering threshold. Theoretical work and single-unit recording studies have also suggested that the same evidence integration process plays a central role in facilitating graded representations of choice confidence. The present study examined this possibility in human subjects during motion discrimination judgments. Participants were presented with a patch of coherently moving dots and, at random intervals, were presented with a response cue prompting them to simultaneously indicate the dominant motion direction and their confidence in that choice. The task was administered under two separate conditions requiring either saccadic or left/right hand button press responses. Analyses centred on two recently characterised non-invasive electroencephalographic signatures of decision formation: the Centro-Parietal Positivity (CPP) which traces the accumulation of sensory evidence for perceptual decisions irrespective of the sensory or motor requirements of the task, and effector-selective premotor beta-band activity which reflects the translation of the decision into a specific motor plan. Here, the CPP exhibited a gradual build up during presentation of the coherent motion stimulus and the amplitude it reached at the time of response cue presentation exhibited a strong positive correlation with confidence reports and choice accuracy. Meanwhile, premotor beta activity indicated that higher choice confidence was associated with reduced preparation of the unchosen effector, consistent with models in which choice confidence reflects the relative activation of the chosen and unchosen response alternatives (i.e. stronger response conflict would lead to lower confidence). These results suggest the neural representation of cumulative evidence provides the necessary information for the emergence of a graded representation of choice certainty.

Title: On the capacity of recurrent inhibition models for Bayesian updating and control of behavior

Authors: *S. W. EGGER[1], N. LE[2], M. JAZAYERI[3]
[1]McGovern Inst. for Brain Res., [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [3]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: Humans and animals face the challenging task of producing precise motor outputs to match task demands in a dynamic environment. This problem can be formalized under a Bayesian framework in which sensory information acts to mitigate uncertainty arising from changes in external states and internal sources of noise. While experimental psychophysics support the hypothesis that the brain performs Bayesian inference, the implementation at the level of neural circuits is poorly understood. Here, we develop a model based on a simple circuit motif, mutual inhibition, that can emulate the key characteristics of Bayesian updating to control motor output. We begin by considering a simple timing task in which the model has to initiate an "action" after a specified interval. A pair of mutually inhibitory units can be configured to generate an output that ramps up at different rates depending on the strength of a common input. By applying a fixed action-triggering threshold, this model can flexibly control action initiation time. However, internal noise can lead to significant variability in threshold crossing times. This variability can be offset by integrating additional temporal cues. To test whether the model can emulate this integration, we created a cascade of mutually inhibitory modules. Modules are activated sequentially and each generates ramp-like activity between a specific pair of consecutive temporal cues. When a cue is received, the output of the current module adjusts input into the subsequent module. Iteration of this process allows each module to counter deviations due to previously accumulated noise. The final module generates ramp-like activity to threshold and controls motor initiation time. Consistent with Bayesian updating, variability of cascade output decreases with increasing number of temporal cues. Importantly, parameters of

the model are robust (i.e., do not need adjustment) to both input levels and variations in noise, allowing for near-optimal integration with fixed circuit properties. The success of this simple model motivated the development of extensions in the form of linear and circular bump attractors. Using similar updating principles, these networks represent and update beliefs about the position and speed of a moving object by integrating intermittent spatiotemporal cues. Together, these results provide a plausible neural substrate for performing complex probabilistic inferences about the dynamic states of objects and events in the environment.

Abstract: Methods for measuring the confidence with which people make decisions, have traditionally relied on post-decision self-reports. We wanted to: 1) develop a new experimental paradigm that aims at measuring the confidence in a decision without participants having to explicitly rate their confidence, 2) characterize their decision using fMRI, and 3) show transfer of confidence through observation using the said paradigm.
In our experiment, the participants have to move a cursor around a circle to catch particles moving from the centre to the edge of the circle. The direction of the particles is block-wise determined by a mean and its standard deviation from that mean. The participants can change the size of the cursor, and the amount of points rewarded for each catch is inversely proportional to the size of the cursor.
The paradigm was tested in several deceit-free behavioural psychophysics experiments and analysed using computational modelling.
To test that the task actually measures confidence, we added a condition in which blocks of trials were followed by a confidence rating scale. The model estimated trial-by-trial particle variance correlated strongly with the normalized ratings given by the participants. Similarly, the computational modelling found each participant's trial-by-trial estimation of the particle variance to be correlated with the width of the cursor on the given trial.
fMRI results show strong correlations between expected decision making and learning areas

adding validity to the task.
Finally, to investigate if it is possible to transfer confidence between participants, we ran an experiment where participants could observe the cursor width chosen by previous participants. Results show that participants that observed a player with higher base confidence chose a significantly smaller catcher than the group observing a player with lower base confidence, an effect that persisted after the other player's choices were no longer displayed.
In conclusion, we have developed a novel task that allows for measuring choice confidence implicitly, and used this task to show that participants adapt an observed level of confidence to their own choices, a level that persists even after observations are no longer available.

Title: Ramping risk-taking: Progressing value function increases gambling in humans

Authors: *G. J. PAGNIER, A. WESTBROOK[1,2,3], M. J. FRANK[3]
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands; [2]Dept. of Psychiatry, Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [3]Cognitive, Linguistics, & Psychological Sci. Dept., Brown Univ., Providence, RI

Abstract: Anticipating a reward is critical for guiding behavior. Recent work has hypothesized that mesolimbic dopamine (DA) levels, distinct from phasic DA reward prediction errors, encode this anticipation by signaling the value of work (Hamid et al., 2016). In an instrumental task, rats exhibit a gradual ramping up of extracellular mesolimbic DA tone in proportion to the distance to, and magnitude, of the reward. But while previous accounts suggest that such DA ramps only invigorate responding, our theoretical models of striatal DA (Collins & Frank, 2014) suggest that higher endogenous DA levels would also bias decisions toward options that have higher perceived reward even if they also have higher cost. Here, we test the prediction that humans are more likely to gamble for a potential, larger reward at the expense of losing a certain reward, the closer they are to receiving that certain reward (i.e., as the value function ramps). We developed a novel gambling task in which participants were promised a certain amount of money at the end of a fixed interval on every trial, with progress indicated by a continuous progress bar. As the progress bar was filling up, participants were sometimes presented with the choice to either stay

with the guaranteed amount, or to gamble for a potentially larger reward. We describe implications of these results and test whether increased vigor and/or modified reward and cost perception affect an individual's decision to gamble. Preliminary results indicate that participants potentially gamble more the closer they were to the end of the fixed trial period, and only when the benefit of gambling was sufficiently large. These results suggest that participants are possibly more sensitive to rewards versus costs as they approach a rewarding outcome, potentially independent of the increased vigor associated with increased DA, and are also consistent with the hypothesis that striatal DA tone ramps in humans during an instrumental task.

Title: A pilot study of a novel reinforcement learning task: The value of cognitive control task

Authors: *S. BELL[1], K. T. KISHIDA[1,2]
[1]Dept. of Physiol. and Pharmacol., [2]Dept. of Neurosurg., Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Background: Value-based decision making is critical to adaptive behavior and is disrupted in substance use disorder and other neuropsychiatric disorders. Substance use disorder is hallmarked by exploitative reward seeking with a lack of regard for inherent cost. Computational reinforcement learning theory provides a useful framework for investigating value-based decision-making. We have designed a novel "Value of Cognitive Control (VoCC) Task," to investigate how learning about future "costs" associated with present choices guides behavior. The present study with n=35 healthy participants (16 M, 19 F, mean age = 27.8) aims to determine whether the VoCC task elicits behavior consistent with value-based decision-making that accounts for costs, represented by varying levels of required cognitive control, and monetary rewards. Methods: The VoCC task is a computer based decision-making game. At the beginning of each trial participants must choose one of three options. Each option leads, respectively, to 'low', 'medium', or 'high' difficulty problems from Cattell's Culture Fair Intelligence Test. Participants earn $1 for every problem answered correctly. If a particular option is exploited and "depleted", the task is programmed deliver the most difficult problems to

encourage exploration. The optimal strategy is to learn and exploit options that give the easiest problems in order to maximize reward. We employed binary logistic regression to examine, at each trial, predictors of switching options in the following trial. We hypothesized that incorrect responses and higher difficulty levels would be associated with a higher likelihood of subsequent switching (exploration). Analyses were performed on the full sample across both genders; gender differences will be examined in the future. Results: As hypothesized, problem difficulty positively predicted exploratory switching behavior during the task (mean coefficient = 0.74, p = 0.016) and correct responses were negatively associated with subsequent exploration (mean coefficient = -3.21, p = 0.016). Conclusions: Our results suggest that the VoCC task elicits choices that appear to be based on both rewards and cost. Future directions include employing the task in substance-using populations, modeling behavior using temporal difference reinforcement learning framework, and examining the neural substrates of optimal task performance using fMRI.

Title: Generalisation of human random behaviour

Authors: *S. WONG[1], U. MAOZ[2], G. MERHOLZ[3]
[1]Computat. and Data Sci., Chapman Univ., Orange, CA; [2]Psychology & Brain Inst., UCLA, Orange, CA; [3]Ecole Normale Superior, Paris, France

Abstract: Human endogenous random-number generation (RNG) has been shown to be systematically biased towards underestimating the likelihood of long runs of repeated entries (e.g., a run of 0-0-0-0 is underrepresented in binary (0/1) random-series). However, this bias can be reduced in a competitive environment. We investigated whether participants could transfer this learning back to a non-competitive environment. Participants (n=153) carried out a 3-part experiment where they: (Part A) created random sequences of Rock (R), Paper (P), Scissors (S) to establish baseline bias, (Part B) played a competitive game of R-P-S against a computer, then (Part C) again created random sequences of R-P-S as in part A, to measure any post-learning transfer effects.
This experiment had 3 between-subjects conditions, varying by computer algorithm and instruction to the participants in part B. In conditions 1 and 2, the computer searched for patterns in each participant's response and win/loss/tie history to predict the participant's next move. Thus, a participant's game responses needed to be as random as possible to win. In condition 3,

the computer generally followed a simple R-P-S-R-... pattern, where the corresponding winning strategy for the participant was P-S-R-P-.... Furthermore, in conditions 1 and 3, participants were only instructed to play to win against the computer, while in condition 2 they were specifically informed about the computer search algorithm and that they had to be as random as possible to win.
We computed each participant's randomness score using the Wald-Wolfowitz runs test, confirming that participants indeed produced more random sequences and longer runs in part B than in parts A or C. Their patterns in part B were not statistically different than Matlab's pseudo-random number generation. While participants' randomness in part B of conditions 1 and 2 were not reliably different, only those in condition 1 showed transfer learning from part B to C, despite not being informed about the computer's algorithm. Our results suggest that humans can learn to become relatively random in a competitive situation with feedback and maintain that randomness for other tasks, but only if the ability is learned implicitly.
Future directions include putting this experiment on mTurk to collect more data for more sophisticated analysis. We will also be varying the features of the game situation to explore the extent to which improvement in random sequence generation is due to the competitive environment or feedback provided by the game.

Title: The neurocognitive architecture that underlies the redundant signal effect in audio-visual target detection: An EEG study

Authors: *J. M. EGAN[1], R. G. O'CONNELL[2], S. KELLY[1]
[1]Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland; [2]Trinity Col. Dublin, Dublin, Ireland

Abstract: When two signals are redundant, such that either signal alone is sufficient to elicit a response, we can respond to their co-occurrence faster than we can respond to either of the signals presented in isolation. This is known as the 'Redundant Signals Effect' (RSE), and although many studies have inferred from response behaviour that convergent processing of the signals must be involved, the neurocognitive architecture that underlies the RSE has not been firmly established. Specifically, while studies on perceptual decision making show that we

translate noisy sensory information into appropriate responses by accumulating the information over time, it is not known whether information from redundant signals is accumulated in parallel, or whether the information first converges to a common pool and is then accumulated by a single accumulator. In order to determine the neurocognitive architecture that underlies the RSE in a simple target-detection task, we recorded EEG data from participants who were asked to report periods of coherency in otherwise incoherent auditory and visual stimuli. The participants performed two variants of this task in separate blocks: In half of the blocks participants were asked to report either visual or auditory events, or their co-occurrence [OR condition]; in the other half the participants were asked to only report the co-occurrence of auditory and visual events [AND condition]. The CPP (Centro-parietal positivity; a signal that reflects evidence accumulation), reached different peak amplitudes for auditory and visual events during the OR condition, despite the response time distributions being very similar, suggesting that auditory and visual information does not converge to a single modality-independent accumulator. However, CPPs elicited by the co-occurrence of auditory and visual events in the OR condition - which produced an RSE - did not reach the amplitude that was predicted by simulating an entirely independent race between two parallel modality-specific accumulators to initiate a response. Furthermore, CPPs were elicited by auditory or visual events alone in the AND condition, suggesting that information from each source is accumulated separately and is not bound into a distinct multisensory construct prior to accumulation. We believe that an architecture that involves parallel processing of information until at least an evidence accumulation stage, followed by online convergence of information at a later stage (eg. motor planning), provides the simplest explanation of our results, and we are currently conducting further EEG studies to test this proposition.

Title: Manipulation of initial dynamics of value-biased sensorimotor decision mechanisms

Authors: *K. AFACAN[1], S. KELLY[2]
[1]Dept. of Biomed. Engin., City Col. of New York, New York, NY; [2]Sch. of Electrical & Electronic Engin., Univ. Col. Dublin, Dublin, Ireland

Abstract: In daily life when we must quickly respond to sensory cues, sensorimotor decisions must be biased towards more valuable options for reward maximization. We recently reported that under such circumstances, humans show behavioral and electrophysiological patterns consistent with an initially non-selective, temporally increasing evidence representation in addition to a value-based shift in "drift rate" of an accumulate-to-bound decision process, contrary to dominant, "starting-point bias" mechanisms that best explain deliberative, perceptual judgments (Afacan-Seref et al 2018). In our Dynamic Shift of Influence model, the underlying principle is that feature-tuned neural populations initially respond non-selectively, but their selectivity increases over time, and when the population tuned for the higher value feature is boosted relative to the lower-value color coding population, the differential evidence driving an evidence-accumulation process initially favors the high-value option regardless of what is presented. Thus, on presentation of a low-value cue, differential evidence (and hence drift rate) initially favors the incorrect, higher value alternative but over time switches to favoring the correct alternative, resulting in a turn-around in cumulative evidence that is reflected in choice error patterns and electroencephalographic signatures of motor preparation. Here we extend our study to investigate the hypothesis that cues with a more intense and longer-lasting initial nonselective phase will enhance this dynamic shift of influence effect. In our task, subjects perform rapid, suprathreshold color discrimination reported through left/right hand button clicks within a very strict deadline, with one alternative rewarded more points than the other if correct. In randomly interleaved half of the trials, the cue begins with a sudden bright but non-discriminating flash and then fades to one of the color alternatives in ~50ms in order to evoke a more intense and longer-lasting initial nonselective phase. Preliminary analysis of data collected so far indicate that the shift of influence from value to sensory information driving action choices is delayed in the "flash" condition compared to the regular color cue trials. Preliminary behavioral modelling suggests that drift rate bias models with increasing evidence, as previously, provided a better fit of the data for both cue conditions. We will show further results from electrophysiology and modeling examining the role of such rapid drift rate bias mechanisms in value-biased sensorimotor decisions.

Title: Probability estimation and decision with limited knowledge of uncertainty

Authors: *K. OTA[1,2,3], J. PHILLIPS[1], L. T. MALONEY[1,4]
[1]Dept. of Psychology, New York Univerisity, New York, NY; [2]Dept of Technol., Tokyo Univ. of Agr. and Technol., Tokyo, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan; [4]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Bayesian decision-theoretic models predict actions maximizing expected gain in stochastic tasks. BDT presupposes (1) that the visual system has estimates of probability (density) that conform to laws of probability and (2) that it correctly combines probability with value. We test these assumptions in two visual tasks, *estimation* and *decision*. Methods: In the estimation task observers were shown a Gaussian sample of size 5 or 30 on a display. They were then shown an interval marked on the display and asked to estimate the probability p[I] that the next dot from the same distribution would fall in the interval. Observers received feedback. Correct performance in this *interval estimation* task is equivalent to correct use of sample information in estimating probability density. There were three types of intervals: symmetric S around the mean and the other two being the upper SU and lower SL halves of S. These triples allowed a test of *density additivity*:P[S] = P[SU] + P[SL]. We varied interval width so that p[I] spanned the range 0.1 to 0.9. In the decision task, observers were shown similar samples but now with a penalty boundary (PB) marked on the display. Observers moved the visible sample to any location on the screen translating the mean of the Gaussian. Then a new dot from the translated Gaussian distribution determined a score in the trial. If the point was above the PB they suffered the penalty, if below, the reward decreased with distance from the PB. There were two penalty conditions 0 and -500. We used BDT to predict the statistically optimal setting points for each condition (2 penalties * 2 sample sizes). Results: *Estimation*: observers' estimates of probability were close to accurate with a tendency for some observers to overestimate probability. Their estimates satisfied density additivity. *Decision*: the settings for the 30 dot condition were close to the optimal settings. However, in the 5 dot condition, they were too close to the PB in both penalty conditions. *Conclusion*: Although their estimates of probability were near accurate, their decision was incorrect, suggesting that observers had a problem with transforming their estimates of probability to their decision when they had limited knowledge of uncertainty.

Title: Predicting memory-based decisions using semantic fluency and preferences

Authors: Z. ZHANG[1], A. NRUSIMHA[2], M. HSU[1], *A. S. KAYSER[3]
[1]Haas Sch. of Business, Univ. of California, Berkeley, Berkeley, CA; [2]UC Berkeley, Berkeley, CA; [3]Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: The past decade has seen substantial progress in our understanding of the neural basis of economic decision making. To date, however, most existing work has focused on "stimulus-based decisions" (SB-D), in which all relevant attribute information is physically present at the time of choice. Such focus is instrumental in identifying how value is encoded and processed in the brain, but may have overlooked important constraints that other cognitive processes, such as memory, impose on decisions. To fill this gap, we examine an important class of so-called "memory-based decisions" (MB-D), such as choosing a dinner restaurant from memory. In contrast with SB-D, in which an externally defined set constrains choices, MB-D require decision makers to recall the set of relevant choice alternatives. We hypothesized that to make MB-D, decision makers must first construct an internal choice set based on semantic memory, after which they make a decision based on valuation of the options in the choice set. We collected independent datasets for brands from two product categories (fast food restaurants and running shoes) in order to define three measures: (1) semantic memory, measured by a classic semantic fluency task (i.e. name as many brands in a category as possible; sample size N = 240); (2) valuation, measured by choices in SB-D with a list of brands in a category; N = 1405); and (3) MB-D, measured by choices of brands in a category without a menu (N = 1405). We then used the semantic fluency and SB-D data as the input to a two-stage model embodying our hypothesis, and used its output to predict MB-D. This model improves substantially over the baseline model that only uses preference (SB-D) information (likelihood ratio test $p < 0.001$ for both categories), implying the critical role of memory in MB-D. It also outperforms models predicting MB-D based on semantic memory only, or on simple additive effects of memory and preference, lending strong support to the proposed mechanism involving the intermediate construction of an internal choice set through recall. These findings reveal an important cognitive mechanism through which semantic memory influences and constrains value-based decision making. They also bear important clinical implications for better characterizing suboptimal decision making in pathological conditions impacting semantic memory, such as Alzheimer's disease and semantic dementia.

Title: Dissecting the decision to respond provides insight into the processes driving successful inhibition between good and bad inhibitors

Authors: *S. ADISE, N. D'ALBERTO, B. CHAARANI, S. HIGGINS, H. GARAVAN
Psychiatry, Univ. of Vermont, Burlington, VT

Abstract: **Introduction:** Deficits in inhibitory control are observed in populations that exhibit maladaptive behavior (e.g., substance abuse, overeating). This suggests that unwanted responses are due to a failure of inhibitory control. The stop signal task (SST) assesses inhibitory control behaviorally by calculating a stop-signal reaction time (SSRT) (i.e., the time needed to stop a response once already initiated). Yet, the ability to stop depends on the decision to respond. Thus, understanding the mechanisms driving go processes in relation to successful inhibition is important.
Objective: The objective of the current study was three-fold: 1) to apply a drift-diffusion model (DDM) to the reaction time of go processes in the SST to parse out different decision-making components, such as response caution (i.e., bias to go/stop), motor execution and stimulus processing time, and speed; 2) to determine if these components relate to the SSRT of good (GI) and poor inhibitors (PI); 3) to examine how these components relate to blood-oxygen-level-

dependent (BOLD) responses in the stopping network.
Methods: Secondary data analysis was conducted on 210 adolescents (n = 95 male; 17-21-years-old) who underwent functional magnetic resonance imaging (fMRI) while performing the SST. SSRT was used to classify subjects as GI and PI; these groups showed differences in BOLD response in the bilateral inferior gyrus (regions associated with stopping behavior). Multiple ANCOVAs were run to assess differences between groups in components of the DDM and BOLD responses to stop trials. Regions of interest were defined based on the stop contrast for all subjects. Covariates were age, sex, handedness, and data collection site.
Results: Preliminary results show that when controlling for covariates, GIs were more cautious (m = 0.69; SD = 0.13) than BIs (m = 0.62; SD = 0.10; $F(1,198) = 7.5$, $p = 0.007$). In addition, motor execution and stimulus processing time was shorter in GIs (m=0.31, SD=0.4) than PIs (m = 0.33, SD = 0.04, $F(1,198) = 14.9$, $p < 0.001$). No significant differences were observed between groups in the speed of the go process. BOLD responses for stop trials between groups did not relate to these decision-making components.
Conclusion: These preliminary results suggest that drift diffusion modeling may provide insight into the decision-making processes contributing to successful inhibition in good and poor inhibitors. However, how these components relate to BOLD activity needs further exploration. Understanding the mechanisms of both go and stop processes in relation to successful inhibitory control may have implications for interventions that target decreasing maladaptive behaviors.

Title: How do analogies happen in the brain?

Authors: *S. R. DEISS
Inst. for Neural Computation, UC San Diego, La Jolla, CA

Abstract: This theoretical research seeks to identify the brain mechanisms of analogical reasoning which produce and then use concepts arrived at through perceptual and higher order induction using similarity comparison. Long thought by many to be the "foundational substrate" of "higher" intelligence, analogical reasoning remains an "opaque" subject the "insight" into which should likely "stem" from deep cortical "folds" and be represented by yet unknown encodings of "spiking" activity. All our concepts, just a few of which were highlighted in quotes in that last sentence, derive from analogical similarities just as our conscious perceptions require

recognition of objects, actions, and processes in terms of their similarities to past experiences. From these acts of recognition, relevant decisions and predictions can be made. For general artificial intelligence (GAI), and especially for neuromorphic engineering (NME), lack of understanding of the underlying brain processes is a serious stumbling block. Is there anything yet that can usefully be said about how this happens in the brain? At the very least we can start listing the features such a model of brain activity must have to suggest where we might look among the spikes and waves to provide some guidance for GAI and NME engineers as well as neuroscience experimentalists.

Title: Dopamine-related changes in striatal pathway competition modify specific decision parameters

Authors: *J. E. RUBIN[1], K. DUNOVAN[2], C. VICH[3], M. CLAPP[4], T. VERSTYNEN[2]
[1]Mathematics, Univ. of Pittsburgh, Pittsburgh, PA; [2]Psychology, Carnegie Mellon Univ., Pittsburgh, PA; [3]Mathematics, Univ. de les Illes Balears, Palma de Mallorca, Spain; [4]Biomed. Engin., Univ. of South Carolina, Columbia, SC

Abstract: Introduction: Mammals selecting actions in noisy contexts quickly adapt to unexpected outcomes to better resolve uncertainty in future decisions. Such feedback-based changes in behavior rely on plasticity within cortico-basal-ganglia-thalamic (CBGT) networks, driven by dopaminergic (DA) modulation of cortical inputs to the direct (D) and indirect (I) pathways of the striatum. DA error signals favor the D pathway over the I pathway for rewarding actions with the opposite tendency for aversive ones, effectively encoding the values of alternative actions. It remains unclear how changes in action value influence the mechanisms of the action selection process itself.
Results: (1) Our simulations of a biologically plausible spiking model of CBGT networks illustrate that feedback-driven DA signals lead to asymmetrical weights in the D and I pathways within a given action channel and the ratio of these weights effectively encodes the action's expected value. (2) Simulations of the full CBGT network in the context of a simple 2-choice value-based decision task under different weighting schemes for cortical inputs to the D and I

pathways (high, medium, and low weight ratio) for one of the action channels yield simulated response times that were fit with variants of a drift-diffusion model (DDM), leaving parameters such as the drift-rate or the boundary height free to vary with the weight ratio. As the ratio increases, the speed of information accumulation in the decision process also increases, providing a direct mapping between network level properties of CBGT systems and cognitive decision processes. (3) Finally, we have incorporated the corticostriatal plasticity module into the CBGT network model to form an integrated learning and decision-making network. Fits of the DDM to integrated network outputs provide novel predictions about the mapping between CBGT and DDM parameters -- drift-rate, boundary height, accumulation onset time, bias, and others -- that best captures RTs associated with variable reward schedules in human experiments performed in our lab. This framework also allows us to explore how particular basal ganglia network features, such as tonic dopamine levels and changes in synaptic connection strengths, relate to changes in decision-making strategies, including those driven by behavioral parameters such as expectation and motivation.

Title: Partially observable Markov decision processes explain probabilistic reasoning in social decision making

Authors: *K. KHALVATI[1], S. A. PARK[3], J.-C. DREHER[4], R. P. RAO[1,2]
[1]Paul G. Allen Sch. for Computer Sci. and Engin., [2]Ctr. for Sensorimotor Neural Engin., Univ. of Washington, Seattle, WA; [3]Ctr. for Mind and Brain, Univ. of California, Davis, CA; [4]Reward and Decision Making Group, Inst. des Sci. Cognitives Marc Jeannerod, Lyon, France

Abstract: When decisions are made in a social context, humans often rely on a model of others to infer their intentions and predict their future actions. This ability can also take into account the fact that others have the same ability for inference and prediction. This human capability, known as Theory of Mind (ToM), involves reasoning about others' mental states and decision making under uncertainty. Here we model this ability using the normative computational framework of Partially Observable Markov Decision Processes (POMDPs). POMDPs provide a formal

framework for combining Bayesian reasoning with long-term utility maximization for optimal decision making under uncertainty.
We show that POMDPs can predict human behaviour in a complex social decision making task that requires accurate predictions about the intentions of others. Specifically, we explore an instance of the Volunteer's Dilemma. In a volunteering situation, a few individuals must bear a cost in order to deliver a greater benefit to all members of the group they belong to. The complexity of the task arises from the fact that while the lack of a sufficient number of volunteers results in a failure to achieve the group's goal, ending up with too many volunteers results in a waste of resources. In such a scenario, a precise estimation of others' intentions can be extremely beneficial for each group member. In our experiment, 30 human subjects played a binary version of a multi-round Public Goods Game (PGG) in a group of 5 players. The number of required volunteers to produce the "public goods" in each PGG was fixed to be either 2 or 4. We compared the predictions of the POMDP model in the PGG task to Q-learning, a reinforcement learning approach that computes actions based on the history of rewards without using a model of others. We found that the POMDP model explained the actions of subjects significantly better than Q-learning: while the POMDP fitted human choices in the PGG task with an accuracy above 80%, Q-learning gave a poor fit (less than 60% accuracy). Additionally, the POMDP model outperformed state-of-the-art descriptive models for predicting actions in the PGG task.
The POMDP framework selects actions by combining probabilistic reasoning about hidden state based on a model of the environment with utility maximization. Q-learning on the other hand is model-free and selects the action having the highest expected reward based on past rewards. Our results demonstrate a greater similarity in behavior between the POMDP model and humans compared to Q-learning, and suggest a mechanism for human social decision making that incorporates probabilistic reasoning about others' intentions when selecting actions.

Title: Cardiac sympathetic dynamics of optimal choice in context

Authors: *N. M. DUNDON[1], V. BABENKO[1], M. CIESLAK[1], N. GARRETT[2], N. D. DAW[2], S. T. GRAFTON[1]

[1]Psychological & Brain Sci., UCSB, Santa Barbara, CA; [2]Princeton Neurosci. Inst., Princeton, Princeton, NJ

Abstract: Many choice tasks, such as foraging, require organisms to accept or reject options without directly observing the alternatives. In such situations, optimal choice (given by the marginal value theorem) requires appraising options relative to the average reward rate of the environment. We hypothesized that such context-appropriate evaluations are supported by autonomic mechanisms. Our task emulated a formal sequential foraging task under a time constraint; participants performed a simple video game in which they were travelers on a space ship that needed refueling to persist in play. Fuel was acquired by capturing serially approaching invaders, whose identities mapped onto a profitability rank (1 to 4) depending on whether they provided a hi or low fuel reward, and a hi or low capture time cost. Participants performed two 12-minute blocks, one with a disproportionately high concentration of rank 1 invaders (hi reward environment) and one with a disproportionately high concentration of rank 4 (low reward environment). Impedance cardiography and electrocardiography were used to measure beat to beat changes of sympathetic tone as measured by the duration of the pre-ejection (PEP) and left ventricular ejection time (LVET). We hypothesized that more demanding environment (low reward) with greater foraging demands would require increased sympathetic drive. Behavioural results demonstrate that in the high reward environment, participants quickly learned the optimal strategy: to only take rank 1 invaders and to pass ranks 2 to 4. In the low reward environment, participants selected more rank 2 and 3 invaders - again the optimal strategy predicted by the marginal value theorem. We further observed shorter PEP and longer LVET in the low reward environment, pointing to greater sympathetic drive when participants foraged in a scarce context. These findings are the first to demonstrate the sensitivity of sympathetic measures acquired over a short time period to the influence of a context defined by reward scarcity and support a contributory role of cardiac sympathetic drive in optimal decision making.

Title: Evidence for hierarchically-structured reinforcement learning in humans

Authors: *M. ECKSTEIN[1], A. G. COLLINS[2]
[1]UC Berkeley, Berkeley, CA; [2]Univ. of California Berkeley, Berkeley, CA

Abstract: Flexibly adapting behavior to different contexts is a critical component of human intelligence. It requires knowledge to be structured as coherent, context-dependent action rules, or task-sets (TS). For example, a computer user might possess different TS that specify the rules for using Windows, Mac, and Linux. This person needs to select the appropriate TS based on the current context, such as selecting the Mac TS in the presence of an Apple symbol. Inferring which TS is optimal in a given context is computationally complex, but can be approximated by a model that employs hierarchically-structured reinforcement learning (RL) (Collins & Frank, 2013). The model is based on classical RL algorithms (Sutton & Barto, 2017), but encompasses two levels. A higher-level RL process learns values for each TS in different contexts. These TS values guide the selection of appropriate TS based on context clues. A second, lower-level RL process learns values for each action in response to different stimuli, within TS. These action values guide the selection of appropriate actions based on stimuli, conditional on the currently selected TS. The model is inspired by the hierarchical organization of cortico-basal-ganglia loops, which underlie RL in the brain. Here, we test specific predictions of this model, specifically that learning TS involves RL values across two levels of abstraction. We tested 51 participants in a novel task and found strong evidence for this model. Participants' behavior showed sensitivity to both TS values and action values, such that higher-valued TS and actions were selected preferentially. Specifically, participants showed a preference for contexts that had been associated with higher-valued TS compared to contexts associated with lower-valued TS. Participants also preferred higher-valued TS in a generalization test, such that higher-valued TS were more often applied to novel contexts. In addition, TS values influenced participants' error patterns, such that more errors were intrusions from higher-valued TS. Furthermore, TS values were associated with learning speed, such that higher-valued TS were acquired faster than lower-valued ones. All of these results were obtained in regression models that also controlled for action values, and were replicated in a second, independent dataset (n=31).Taken together, these results support the claim that human action selection is guided by hierarchical RL mechanisms that involve the acquisition of abstract, context-dependent TS. This work has implications for research on learning and decision making, as well as for clinical conditions that are associated with problems of abstract reasoning.

Title: Where the really hard decisions are - A general framework to quantify decision difficulty

Authors: P. FRANCO, N. YADAV, P. BOSSAERTS, *C. MURAWSKI
The Univ. of Melbourne, Parkville, Australia

Abstract: Current models of decision-making more often than not ignore the level of difficulty of decisions. They assume that the decision-maker is always able to identify the best option - whether it is a choice between two flavours of ice cream or a choice of investment option for a retirement portfolio from thousands of available options. Where decision difficulty has been taken into account, it has been done either informally or in a highly domain-specific way. We propose instance complexity (IC) as a generalisable mathematical framework to quantify difficulty of a decision based on a small number of properties of the decision.
The aim of IC is the characterisation of the computational complexity of individual instances of a computational problem, based on an instance's properties. The main advantage of IC compared to other measures of difficulty is fourfold. Firstly, it is based on the theory of computation (computational complexity theory), a rigorous mathematical framework. Secondly, our measure captures complexity that is intrinsic to a decision task, that is, it does not depend on a particular solution strategy or algorithm. Thirdly, it allows computation of difficulty of a decision task ex-ante, that is, without knowing the solution of the decision task. And finally, it does not require any knowledge of the decision-maker's attitudes or preferences.
We tested the relation between IC and (i) decision quality and (ii) effort exerted in a decision using two canonical variants of the 0-1 knapsack problem, a canonical and ubiquitous computational problem. We show that participants exerted more effort on instances with higher IC but that decision quality was lower in those instances.
We also acquired 7-Tesla functional magnetic resonance imaging data to characterise the neural circuits that code IC and are involved in the allocating of neural resources in response to varying levels of IC.
Together, our results suggest that IC can be used as a general framework to measure inherent complexity of decision tasks and to quantify computational resource requirements of decisions. The latter is particularly relevant for models of resource allocation in the brain (meta-decision-making/cognitive control).

Title: Stability of EEG dynamics in transient cortical networks during decision making

Authors: H. COURELLIS[1], J. R. IVERSEN[3], D. A. PETERSON[4], T. MULLEN[5], *G. CAUWENBERGHS[2]
[1]Bioengineering, UCSD, La Jolla, CA; [2]Dept. of Bioengineering, UCSD, LA Jolla, CA; [3]Inst. for Neural Computation, UC San Diego, La Jolla, CA; [4]Salk Inst. CNL-S, La Jolla, CA; [5]Intheon, San Diego, CA

Abstract: Computation in the brain is driven by the transient dynamical interactions of distal brain regions fulfilling various different functions. During network-level computation, active brain regions exhibit oscillatory activity which, when projected into a phase space, allows for the quantification of attractor states that individual neurons or the region as a whole might tend towards or away from depending on the nature of the computation being conducted. Such descriptions of the brain's dynamics are often conducted on the scale of individual neurons or neuronal ensembles using firing rate information, and are less frequently considered based on population measures of activity such as neural oscillations. We sought to interrogate the transient connectivity and associated non-linear dynamics exhibited by regions of the human cortex in electroencephalographic (EEG) recordings in the context of a reward-based decision making task. Participants were administered a standard multi-arm bandit task with an added probabilistic reward rate reversal during each participant's recording session. Through application of convex-optimization and dynamical systems characterization techniques, we find that the transient connectivity exhibited a number of cortical regions relevant to decision making strongly correlates with dynamical system instability quantified by the largest Lyapunov exponent. Additionally, when transient connectivity information is used to inform the construction of phase spaces during decision making, we find that there are cases in which the relationship between a region's transient connectivity and instability reverses polarity depending on task demands. The results reveal different cortical regions that exhibit either transient-network stabilizing or destabilizing behavior as a function of their participation in transient network dynamics.

Title: Decoding changes of mind in voluntary decisions - Dynamics of choice representations in a fronto-parietal network

Authors: *A. LOFFLER[1,2], P. HAGGARD[1], S. BODE[2]
[1]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom; [2]The Univ. of Melbourne, Melbourne, Australia

Abstract: Many previous studies have investigated the neurocognitive mechanisms underlying the generation of voluntary decisions. However, little is known about how these decisions change over time. In particular, changes in the external environment can cause a Change of Mind regarding ongoing actions. In the current fMRI study, we investigated how the neural patterns associated with initial voluntary choices change as new information can trigger decision reversals. In a novel task, participants made free choices between images of faces and houses, and then had to navigate a manikin to the chosen image on the screen. On some trials, the images changed their location after action onset. Participants could then decide to either pursue their initial choice to earn a higher reward, or switch to the alternative image to save time – depending on the remaining travel distance. Using multivariate pattern analysis, we decoded participants' initial face/house choices from visual areas (inferior occipital lobe and fusiform gyrus), precuneus, angular gyrus and medial prefrontal cortex (mPFC). In visual areas, the decoder trained on initial choices could also classify final face/house choices after image relocation, suggesting that the neural representations of choice options in these areas did not substantially change throughout the decision process. Conversely, cross-classification was not above chance in fronto-parietal areas, indicating changes in neural patterns over time. Further analyses suggested that representations in precuneus and angular gyrus might have been updated to incorporate image distance, which informed participants' Change of Mind decisions. By contrast, mPFC encoded Changes of Mind in participants who did not base their final decisions exclusively on external information about image distance. This suggests an endogenous component of Changes of Mind decision, for which information is present in this area. In conclusion, we found that the fronto-parietal network not only generates initial voluntary

decisions, but continuously integrates new decision-relevant external and internal information over time, allowing agents to dynamically reverse their own choices.

Title: Functional changes in perceptual, memory and value-related regions underlie non-reinforced behavioral change in the short and long term

Authors: *R. BOTVINIK-NEZER[1], T. SALOMON[2], T. SCHONBERG[3]
[1]Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv-Yafo, Israel; [2]Neurobio., Tel Aviv Univ., Tel Aviv, Israel; [3]Sagol Sch. of Neurosci. and the Dept. of Neurobio., Tel Aviv Univ., Tel Aviv-Yafo, Israel

Abstract: Understanding how preferences are constructed and modified is a major challenge in the research of human behavior with broad implications, from basic science to interventions for long-lasting behavioral change. Cue-approach training (CAT) is a novel and unique paradigm for non-reinforced behavioral change. During CAT, some items are presented one by one on the screen and participants are instructed to press a button as fast as they can whenever they hear a neutral cue, consistently paired with some of the items (Go items) but not with others (NoGo items). Results over multiple samples show that participants significantly choose Go over NoGo items immediately as well as months after CAT. The neural underpinnings of this behavioral change are still unclear. Here, we introduce a novel passive viewing task, whereby participants were scanned with fMRI while snack food items were presented individually before, after and one-month following CAT. We hypothesized and pre-registered (https://osf.io/yu3tw/) that the underlying mechanism will involve attentional, memory and value-related processes. Thirty-six healthy participants completed the experiment. A subset of 27 participants returned to a one-month follow-up session. We compared fMRI activity in response to Go vs. NoGo items in three time points: before, immediately after and one-month following CAT, using a multi-stage GLM approach with whole-brain GRTF cluster correction (z&gt2.3, p&lt0.05). We also performed small volume correction (SVC) on preregistered regions: ventromedial prefrontal cortex (vmPFC), hippocampus and superior parietal lobule.We revealed enhanced fMRI response to Go items following CAT in bilateral high level visual regions and in the vmPFC. In the one-month

follow-up, fMRI response to Go items in the left orbitofrontal cortex and right hippocampus was modulated by the choice effect across items. Our results suggest that preferences can be changed for the long term through perceptual processing enhancement without external rewards, context change or self-control. Neural findings demonstrating modification in brain response during passive viewing, indicate a multi-level change in the representation of the items from visual to memory-related and prefrontal regions.

Title: Distinct neural patterns of effort-cost valuation: Evidence from prospective choices

Authors: *N. ARIDAN, N. J. MALECEK[1], R. A. POLDRACK[2], T. SCHONBERG[3]
[1]Dept. of Neurosci., The Univ. of Texas at Austin, Austin, TX; [2]Dept. of Psychology, Stanford Univ., Stanford, CA; [3]Dept. of Neurobio., Tel Aviv Unviersity, Tel Aviv - Yafo, Israel

Abstract: We often consider a compromise between effort and reward in pursuit of our goals. Intuitively, effort requirements impose a cost upon associated rewards, as it makes them more difficult to obtain. Compared to other costs present in common choices, such as risk and delay, the neural basis of effort-based valuation remains poorly understood. Animal models and human neuroimaging studies have primarily linked the anterior cingulate cortex (ACC) and ventral striatum (VS) to the integration of effort and reward. However, studies have also demonstrated their role in salience detection and invigoration to effort demands. This suggest that neural activity observed during anticipation or performance of effort might be separate from cost value. To examine the interaction of value and effort separated from these processes, we asked 40 participants to accept or reject monetary gambles that could be resolved by the future performance of a familiar dynamometer grip-force effort or a fixed risk prospect during fMRI. Participants' willingness to accept prospective gambles reflected discounting of value by effort and risk. Choice-locked neural activation in vmPFC and contralateral primary-sensory cortex tracked the magnitude of prospective effort-cost participants faced, independent of choice time, monetary stakes and risk. Estimates of subjective value discounted by effort were tracked by the activation of a network of regions common to valuation under other costs such as risk and delay, including vmPFC, ventral striatum and sensorimotor areas. Together, our findings support differentiation between neural activity of effort-cost valuation and invigoration within effort-based decisions.

Title: Episodic memory contributions to value-based decisions: Evidence from amnesic patients

Authors: *A. BAKKOUR[1], D. J. PALOMBO[3], A. ZYLBERBERG[2], M. N. SHADLEN[4], M. H. VERFAELLIE[3], D. SHOHAMY[1]
[1]Dept. of Psychology, [2]Dept. of Neurosci., Columbia Univ., New York, NY; [3]Dept. of Psychiatry, VA Boston Healthcare Syst. and BU Sch. of Med., Boston, MA; [4]Dept. of Neurosci., Howard Hughes Med. Inst. - Columbia Univ., New York, NY

Abstract: Memory is central to adaptive behavior, allowing past experience to guide decisions and actions. However, the neurobiological mechanisms by which memory guides decisions and the consequences for behavior remain poorly understood. Here we test the idea that episodic memory contributes to value-based decisions by providing samples of evidence relevant to choice options. This idea may explain why it takes more time to decide between options of similar value: such decisions require more memory-guided evidence and therefore take more time. To examine the role of episodic memory in value-based decisions patients with anterograde amnesia due to medial temporal lobe damage (n=6) and age-matched healthy controls (n=15) participated in a value-based decision task. The task involved choosing between pairs of familiar foods. On each trial, two foods were paired such that the difference in their values (ΔRating; based on participant-specific ratings) differed from trial to trial. We predicted that amnesic patients, compared to controls, would show a different relationship between ΔRating and reaction time (RT). As a control condition, both groups performed a perceptual decision task that involved decisions based on external rather than internal samples of evidence. The perceptual task required choosing the predominant color of a mixture of yellow and blue random dots. On each trial, the stimulus was assigned a color coherence that determined the color category and its

ambiguity. For the food task, controls chose the higher-rated food more often and their RT decreased as |ΔRating| increased. Choices and RTs were well characterized by a drift diffusion model (DDM), which relies on principles of sequential sampling and optional stopping to reconcile choice and RT. The patients, by contrast, showed a different pattern: their choices and RTs were governed more weakly by ΔRating and the DDM was worse at explaining their behavior. The findings from the perceptual task instead revealed similar performance among patients and controls; both groups showed the typical effect of difficulty on RT and accuracy and their DDM fits were similar. The findings point to a critical role for the medial temporal lobe memory system in supporting value-based decisions about highly familiar items. We suggest that deliberation during certain value-based decisions involves episodic memory processes, which contribute to assembling or accumulating evidence bearing on preference, a process that is disrupted in amnesic patients.

Title: Comprehension as Bayesian decision-making: Neural computations of inferring what is meant from what is said in language games

Authors: *Q. MI[1], C. WANG[1,2], X. FU[3], J. GAO[2,4], L. ZHU[1,2,5]
[1]Peking-Tsinghua Ctr. for Life Sci., [2]IDG/McGovern Inst. for Brain Res., [3]Dept. of Biomed. Engineering, Col. of Engin., [4]Ctr. for MRI Res., [5]Sch. of Psychological and Cognitive Sci., Peking Univ., Beijing, China

Abstract: Communication is a ubiquitous feature of social interactions across multiple species. A cornerstone of effective communication is the ability to recognize the intended message of a speaker for a listener (a.k.a., speaker meaning) even though that message is often not coded in the utterance directly. A number of theoretical and behavioral models of pragmatic reasoning have been proposed, in particular the rational speech act, which connects pragmatic inferences with probabilistic inferences by drawing on formal decision models such as Bayesian theory. Here, we investigate the cognitive and neural substrates of pragmatic reasoning by exploring

brain regions that encode model-derived inference signals used to decipher speaker meaning in a stylized communicative setting. Specifically, we examined the fMRI data of a language game where a listener needs to infer a target object in a given context based on a message received from an anonymous speaker. Behavioral analyses show that the process of inferring a speaker's intended referent can be characterized as a Bayesian decision process, which integrates the prior information with a mentally simulated likelihood for speaker's actions. Consistent with the behavioral model, imaging data reveal that the latent likelihood signal derived from the model is expressed in the ventromedial prefrontal cortex (vmPFC), even when Bayesian reasoning is unnecessary for discerning speaker meaning (e.g., when speaking meaning is explicitly coded in the utterance). Interestingly, this region also demonstrates model-dependent connectivity with a number of brain regions, including the dorsomedial prefrontal cortex and temporoparietal junction, which are known to be involved in theory-of-mind, and the left inferior frontal gyrus, which has been repeatedly implicated in language processing. The robustness and specificity of the observed behavioral and vmPFC response patterns are further demonstrated in two additional experiments. Together, these results provide a neuromechanistic account of pragmatic reasoning where effective language interpretation arises from a Bayesian decision process, and vmPFC plays a central role in inferential computations critical for Bayesian reasoning. The data point to a new avenue that bridges the literature of model-based decision neuroscience and that of language and social communication.

Title: Representation of subjective value for self and other agents in the dorsal anterior cingulate cortex is consistent across tasks and predicts social attitudes

Authors: *M. R. PIVA[1], K. R. VELNOSKEY[2], R. JIA[3], A. NAIR[2], I. LEVY[4], S. W. CHANG[2]
[1]Interdepartmental Neurosci. Program, [2]Psychology, Yale Univ., New Haven, CT; [3]Dept. of Comparative Med., Yale Univ. Sch. of Med., New Haven, CT; [4]Section of Comparative Med., Yale Sch. of Med., New Haven, CT

Abstract: While making decisions on behalf of others is ubiquitous in daily life, few studies have addressed the underlying neural processes. One key aspect in decision-making is the

similarity in subjective value between options. We investigated the neural correlates of subjective value disparity and proximity during choice for self and other in two independent behavioral tasks using fMRI. Behavioral paradigms included intertemporal choice (n = 20), in which participants chose between options of smaller amounts of money sooner or larger amounts of money later, and risk (n = 21), in which participants chose between options of smaller amounts of money with larger probabilities or larger amounts of money with smaller probabilities. Behavioral modeling indicated that participants distinguished between themselves and other individuals with dissimilar preferences. We then quantified the subjective value of each option in each trial. Trials in which the value of the two options were similar constituted high-proximity trials, while trials in which the value of the two options were dissimilar constituted high-disparity trials. Univariate neural analyses indicated that while the dorsal anterior cingulate cortex (dACC) responded to high-proximity trials, the ventromedial prefrontal cortex (vmPFC) responded to high-disparity trials, and these results were consistent for both self and other trials and across both behavioral tasks ($P < 0.05$, corrected). However, multivoxel pattern analysis indicated that the dACC, but not the vmPFC, selectively decoded high-proximity versus high-disparity trials, and these results were again consistent across self and other and were replicated in both tasks ($P < 0.01$, permutation). The code for high-proximity versus high-disparity trials in the dACC was generalizable across self and other, as classifiers trained on data from self trials were able to categorize subjective value in other trials and vice versa ($P < 0.01$, permutation). Notably, this neural code in the dACC was generalizable across tasks, as classifiers trained on data taken from the dACC during intertemporal choice were able to predict subjective value in trials from the risk paradigm ($P < 0.01$, permutation). Finally, the level of classification accuracy in other relative to self trials correlated with self-reported social attitudes ($P = 0.03$, Spearman). Together, these results indicate the importance of subjective value disparity and proximity signals in the human dACC, arising during decision-making across different perspectives and contexts.

Title: Architecture of representations in pre-frontal cortex during credit assignment

Authors: *P. WITKOWSKI[1], S. A. PARK[2], E. D. BOORMAN[3]
[1]Univ. of California, Daivs, Davis, CA; [3]Ctr. for Mind and Brain, [2]Univ. of California, Davis, Davis, CA

Abstract: Representations of the causal relationships between behavior and outcome are essential to implementing adaptive goal-directed behavior. The structure of causal relationships in the environment are not always apparent, yet they often must be used to infer relationships from experienced outcomes. In this study we show how the brain represents latent causal relationships when assigning credit for an outcome to its causes and how the brain flexibly updates these representations to maximize reward. Subjects (N=22, 14 Female, Median age = 21) participated in a reward-learning task where they tracked two systems of stimulus-outcome associations. Each system comprised two interrelated stimuli that always led to opposite outcomes, allowing subjects to make inferences about one stimulus from observing the other. In this way subjects learned about directly experienced and inferred associations through knowledge of these interrelations. Behaviorally, we found evidence subjects learned from both directly experienced and inferred past outcomes (experienced: $t(21)>6.95, p<0.001$; inferred: $t(21)>3.73$, $p<0.001$). We analyzed the fMRI data using a combination of univariate and multivariate approaches. Specifically, we used a support vector machine to decode representations of the recently chosen stimulus and the interrelated but unchosen stimulus at the time subjects received feedback for their choices. Our results show that areas in the lateral orbitofrontal cortex and ventrolateral prefrontal cortex, lateral occipital cortex, and hippocampus code for the specific chosen stimulus at outcome time (**fig.1A**). Updates to these representations recruited a network including lOFC, lateral prefrontal cortex, and pre-SMA **(fig.1B**). Finally, medial prefrontal cortex simultaneously coded for a representation of the latent cause – the abstract knowledge about the interrelations between sets of stimuli and outcomes**(fig.1C**). These findings suggest a representational architecture of prefrontal representations for credit assignment.

Title: The role of uncertainty in curiosity about wins versus losses

Authors: *L. L. VAN LIESHOUT[1,2], F. P. DE LANGE[1], R. COOLS[1,2]
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands;
[2]Dept. of Psychiatry, Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Curiosity is a basic biological drive, but little is known about its behavioral and neural mechanisms. In a previous study, we have demonstrated that curiosity is a function of information uncertainty, indicating that we are particularly curious when information provides us with a substantial update of what we know. This is the case even though receiving information is not instrumental, meaning that it will not help us to improve performance or to maximize rewards. It is unclear, however, whether and if so, how this effect interacts with our automatic bias to approach information about positive events. To assess this, we designed a lottery task in which we independently manipulated outcome uncertainty as well as the (reward/punishment) valence of trial outcomes. In contrast to our previous study, participants could either win or lose an uncertain amount of money in different blocks of the task. This allowed us to disentangle the desire for information about positive (win) and negative (loss) events. Results showed that curiosity robustly increased with increasing outcome uncertainty, in both the win as well as in the loss context. In addition, curiosity was overall higher for the win context compared with the loss context. However, there was no interaction between outcome uncertainty and outcome valence, indicating that these two factors have distinct effects on curiosity. These results suggest that curiosity is monotonically related to the uncertainty about one's current world model and that people are driven to improve this model, regardless of outcome valence. Independent of this uncertainty effect, participants exhibit a (Pavlovian approach) bias towards information gain about positive compared with negative events. These findings provide novel insights into the behavioral mechanisms of curiosity and suggest that curiosity is a function of multiple

independent factors, one of which is related to information updating and the other to reward maximization.

Title: Sum before difference: Differential temporal contributions of overall set value and value difference in value based decisions as revealed by ERPs

Authors: *R. FRÖMER, A. SHENHAV
Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: Previous research has characterized the neural dynamics underlying perceptual decisions (e.g., whether some dots are moving leftward or rightward), yet major gaps remain in our understanding of the dynamics underlying value-based decisions (e.g. which of a set of options we want most). Research on perceptual and value-based decision-making alike has demonstrated that a centro-parietally distributed positive event-related potential (CPP) tracks the amount of evidence in support of a given choice option, until that evidence reaches a putative decision threshold and a response is made. However, the limited research into the dynamics of value-based choice has focused on relatively short decisions and often specifically on the dynamics associated with the relative subjective value of one option over another (value difference [VD]), which typically serves as a proxy for the decision evidence. Less is known about the neural dynamics associated with the overall value (OV) of a choice set, despite recent findings that OV and VD contribute in different ways to decision time and to the emotional experiences associated with decision-making. To better characterize these dynamics in more realistic value-based choices, we measured EEG while participants (N=39) made a series of choices between pairs of consumer goods that they had the opportunity to receive. Choices were individually tailored to vary in OV and VD (based on prior ratings of each item), and participants were given up to 4s to make each choice. Using a MASS-univariate approach with cluster-based permutation tests, we found that OV and VD modulated event-related potentials (ERPs) with differential topographies and timing: whereas OV was associated with a CPP locked to stimulus onset (peaking 700ms post-onset, much earlier than most decisions were made, median RT=1.7s), VD was associated with a pronounced frontocentral negativity and posterior positivity

locked to the response (peaking ~ 500 ms pre-response). The timing of the stimulus-locked CPP effect and the lack of a response-locked CPP - including when using RT as a proxy for evidence accumulation - challenge the claims that CPP reflects a signature of a supramodal decision variable. Our results are in line with certain biophysically-inspired computational models of decision-making that predict sequential encoding of OV and VD while suggesting that different patterns of brain activity might underlie the accumulation of additive value (OV) and relative value (VD).

Title: The neural signature of risk in gains and losses underlying bundle valuations

Authors: *P. W. GLIMCHER[1], H.-K. CHUNG[2], J. ZIMMERMANN[3], A. TYMULA[4]
[1]Ctr. Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY; [2]Psychology, [3]New York Univ., New York, NY; [4]Sch. of Econ., Univ. of Sydney, Sydney, Australia

Abstract: The neuroscientific study of decision making has revealed insights about human cognition leading to advanced theories of human behavior. Here, we focus on the neural underpinnings of choice behavior in both the gain and loss domain. Standard theories of rational decision making assume context-independent valuations. However, a stark context-dependency on gain versus loss contexts have been widely observed. To account for this, Kahneman and Tversky (1979) proposed prospect theory; a utility/value function with an inflection point separating concave utility for gains from convex utility for losses (diminishing sensitivity). Paradoxically, prospect theory predicts even more anomalous behavior when subjects choose over riskless losses; bundles of goods encountered in the loss domain. Specifically, prospect theory's value function shape predicts that in the loss domain people prefer losing all of one type of good to losing some of each of the goods in a bundle. To test this prediction, we designed risky and riskless choice tasks in both gain and loss domains using real consumption goods - food bundles - while imaging subjects to investigate neural mechanisms. In both tasks, goods varied from trial to trial, visual stimuli were identical and participants were instructed similarly in all tasks to make a series of choices between two options based on their own preferences in an incentive compatible manner. Behavioral data confirms our previous finding that prospect theory

appears to make inaccurate predictions about the nature of valuation when subjects choose over what are called “riskless bundles” in the loss domain. They showed consistent preferences across gain and loss domain in riskless choices. This was true even while they showed gain-loss-dependent changes of risk attitudes when choosing over simple lotteries of these same goods. Ongoing imaging of 30 subjects should allow us to rapidly test neural representation similarity (discrepancy) in the valuation of food bundle in different contexts. Taken together, these findings point toward the importance of interdisciplinary approaches to better understand the neural circuits and human behavior.

Title: Efficient coding and the adaptation of human choice behavior to the statistics of recent rewards

Authors: *C. K. STEVERSON[1], H.-K. CHUNG[2], J. ZIMMERMANN[3], P. W. GLIMCHER[5], K. LOUIE[4]
[1]Ctr. for Neural Sci., NYU, New York, NY; [2]Psychology, [4]Ctr. Neural Sci., [3]New York Univ., New York, NY; [5]Ctr. Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: It is widely assumed that economic decision making is driven by value encoding in the brain. Efficient coding theory suggests that the representation of value, and hence choice behavior, should adapt to features of the anticipated distribution of values. For example, adaptation to the anticipated range of values is necessary to make use of the full set of possible neuronal firing rates in encoding value. Without adaptation to the range, encoding values for highly valuable items (e.g., houses, cars etc.) unnecessarily degrade coding performance when making choices in a much lower value context (e.g., choosing which coffee to order). It has been hypothesized that the distribution of recently encountered values, which we refer to as the temporal context, drives what is anticipated (encoded) in the next decision. In studies of non-human primates, adaptation to the value range of the temporal context has been previously observed in both neural encodings of value as well as in choice behavior. In this study, we tested

whether human choice behavior also adapts to the distribution of recently encountered values. Subjects performed a two-alternative forced-choice task over monetary lotteries. Choices were divided into two blocks: in one block subjects encountered a larger range of values and in one block they encountered a smaller range of values. About half the choices were "test choices" that appeared in both blocks. We measured how behavior adapts to the range of values by testing how measures, such as choice stochasticity, differ on the test choices across the two blocks. We also designed our experiment to distinguish whether behavior is sensitive only to the shape of the cumulative distribution function of value, as has been proposed in certain classic efficient coding theories, or depends on the cardinality of the values as would be suggested by a model such as normalization. How human choice behavior adapts to the statistics of recently encountered values is a growing but still understudied area. Our works seeks to add this literature in a way that advances our understanding of the influence of the temporal context and the role of efficient coding in human choice behavior.

Title: The parietal cortex dynamically integrates the cost and benefit of time to inform decision timing

Authors: *M.-C. WANG[1], S.-W. WU[2]
[1]Inst. of Neuroscience, Yang Ming Univ., Taipei, Taiwan; [2]Inst. of Neurosci., Yang Ming Univ., Taipei, Taiwan

Abstract: When making a decision, gathering more information about the options under consideration in principle can never hurt. However, collecting information takes time that can be allocated to other potentially rewarding events. Knowing that information is helpful but time is costly, the decision maker not only has to decide which option to choose but when to choose it. Regarding the latter decision problem, little is known about how and how well the brain dynamically evaluates the cost and benefit of time in order to solve the "when" problem. Methods. In a perceptual decision task, subjects were instructed that a box consisted of a total of 100 red and green balls. Unbeknownst to the subjects, on each trial, either there were more green

balls or more red balls. The subjects' task was to guess which ball - red or green - had more in number in the box. In order to provide information about the box, we sampled from the box and *sequentially* presented the samples as red or green dots on the screen. Here, we introduced time cost by implementing a decreasing reward function. That is, on each trial, the gain associated with a correct decision decreased over time. The subjects can freely choose when to make a response. The question is, can he or she balance the benefit of time - accumulating more dots over time leads to better performance - against the cost of time? Results. In order to maximize reward earned, an ideal decision maker in the decision task would choose a time to make a decision that would lead to the maximization of expected gain. Compared with an ideal decision maker, subjects' decision time were typically slower. To explain the suboptimal pattern, we tested 3 models: risk aversion (RA), loss aversion (LA), and probability weighting (PW). Both RA and LA models failed to consistently describe the data. In contrast, a probability weighting function that was convex in moderate to large probabilities successfully described suboptimal patterns across subjects. This indicates that subjects underweight moderate to large probabilities and that the marginal gain in probability of success increased as a function of time. This made waiting become extremely attractive, even though the benefit of waiting was rather limited. With fMRI, we found that activity in the precuneus represents the probability of making a correct decision over time within a trial. By contrast, the inferior parietal lobule dynamically represent the expected gain - the integration of cost and benefit associated with time - of making a decision. Together, these results suggest distinct regions in the parietal cortex involved in information accumulation over time and in the dynamic integration of cost and benefit of time.

Title: Flexible concept representation for value-based decisions

Authors: *G. CASTEGNETTI, M. ZURITA, B. DE MARTINO
Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: A distinctive characteristic of human cognition is the ability to interact flexibly with the environment by using objects as tools to achieve goals. The usefulness of any particular

object depends on the nature of the current goal; in other words, objects acquire value in a context-dependent manner. In the brain, this process is likely to involve construction of conceptual representations of the objects at hand, which are then carved into value representations. This process is likely to be hippocampal dependent (i.e. involving the retrieval of episodic information about previous experiences with similar objects). The medial prefrontal cortex (mPFC) has been shown to play a key role in extracting regularities present in the retrieved information (i.e. schema formation), and has recently been proposed to perform dimensionality reduction to extract goal relevant features. In this study, we sought to investigate how conceptual representations morph into value representations, with particular focus on the interaction between hippocampus (HPC) and mPFC. To do this, we developed a novel task in which volunteers interacted with set of objects in the context of different goals. We first acquired a number of behavioural measures including goal dependent value estimates, confidence estimates and familiarity measures. Pilot data show that our manipulation resulted in markedly different scores when the same object was evaluated in relation to different goals. From these scores we built conceptual similarity matrices, which were then used to detect changes in the fMRI signal when participants imagined how to use objects to achieve a particular goal. Our preliminary data suggest that HPC appears to be preferentially implicated in context representation, whereas mPFC builds value representations in a goal-dependent fashion. In summary, this study provides mechanistic insights into the interplay between HPC and mPFC during the construction of conceptual knowledge, and shows how identical stimuli elicit different neural representations when evaluated in the context of different goals.

Title: Painstaking choices: Distinguishing neural representations of subjective value, conflict,magnitudes,andcontextualbiasesin deterministic decision making with mixed outcomes

Authors: *A. D. SHAPIRO[1], N. M. DUNDON[1], G. N. OKAFOR[1], S. T. GRAFTON[2]
[1]Univ. of California, Santa Barbara, CA; [2]Psychological & Brain Sci., UCSB, Santa Barbara, CA

Abstract: In a world with few free lunches, most choices entail mixed outcomes of both costs and benefits. Decision making requires careful accounting of the positive and negative attributes

of each option to determine its overall value and whether it's worth pursuing. Behavioral economists and psychologists have typically modeled valuation of mixed outcomes using rewards paired with probabilistic risks of loss. However, the subjective value of a probabilistic outcome often diverges substantially from its measurable objective value, making it difficult to parse preference from errors in statistical reasoning. Relatively less work has surveyed models of deterministic decisions. Moreover, the neural representations of subjective value, conflict, magnitudes, and contextual biases in such choices have been left largely unexplored. We were particularly interested in how subjects establish preference between offers of equivalent subjective value and whether normalization models commonly applied to risks in probabilistic decisions would generalize to outcome magnitudes in deterministic decisions. We measured BOLD responses in 24 human participants who made choices about monetary rewards paired with pain stimuli. Experiment 1 was a single-offer approach-avoid task in which participants accepted or rejected individual offers of monetary rewards ranging from $0.01-$1.50 contingent on receiving a cutaneous shock that ranged from minimally to maximally painful. We independently fit each individual's choice outcomes with logistic regression to estimate their cost/reward preference structure and perceived subjective value throughout the decision space. Choice outcomes predicted activity in the caudate, vmPFC, and OFC. Subjective value predicted activity in the anterior insula and dACC. Choice conflict predicted activity in posterior insula, posterior cingulate, cingulate motor area, and sgACC. Value models from Experiment 1 were used to identify subject-specific trial parameters for Experiment 2, a two-offer free choice task in which participants chose between two cost/reward offers with equivalent subjective value (P(Accept)=.5) but different magnitudes (distance along the decision boundary, ranging from min. reward /min. cost to max. reward / max. cost). Rather than normalizing magnitudes to determine choice, subjects formed individualized preferences for a unique magnitude and their choice behavior was largely determined by this preference. Preferred magnitudes selectively predicted activity in vmPFC, OFC, posterior cingulate, and the basal ganglia.

Title: The effort of choosing: Neural correlates of deliberation during value-based decision-making

Authors: *N. CLAIRIS, M. PESSIGLIONE
MBB, Inst. Du Cerveau Et De La Moelle Epinière, Paris, France

Abstract: When deciding about which action to take, people must weigh the costs against the benefits associated with alternative options. FMRI studies have identified a brain network whose activity correlates positively with the appetitive value of potential outcomes. This network, coined Brain Valuation System (BVS), mainly includes the ventromedial prefrontal cortex (vmPFC), the ventral striatum and the posterior cingulate cortex. Less is known about the existence of an opponent brain system that would correlate positively with the aversive value of effort costs, although some brain regions, such as the dorsomedial prefrontal cortex (dmPFC) have been repeatedly implicated. One critical issue is to disentangle between brain activity linked to effort associated with the envisaged options and to effort invested in the decision-making process. To tease apart these neural representations, we recorded the brain activity from healthy participants (n=38) with fMRI and from epileptic patients (n=12) implanted with intra-EEG electrodes while they both performed tasks involving valuation of virtual reward and effort items. More precisely, they performed 3 tasks that required 1) rating of reward appetitive value and effort aversive value on an analog scale, 2) choosing the most appetitive of two rewards, or the least aversive of two efforts, 3) deciding whether or not to make a given effort for a given reward. Reward appetitive values and effort aversive values were simply the ratings assigned by participants to the different items. Response time was taken as a proxy for the amount of effort invested in every task trial. We verified that response time was correlated to the amplitude of pupil dilation, which is considered a valid marker of mental effort. As expected, the appetitive value of reward items were signaled in all tasks by increased activity in the BVS, including the vmPFC. Activity in this brain region was also sensitive to the aversive value of effort items, but with a negative correlation, consistent with the idea of a net value representation. Activity in the putative opponent regions, notably the dmPFC, did not correlate with aversive value but with response time, whatever the task. Thus, we established dissociation between effort costs attached to choice options, which are (negatively) integrated in the vmPFC, and the effort cost entailed by the very process of decision-making, which is (positively) reflected in the dmPFC. Further research is needed to precise whether this activity participates to the decision-making process or simply signals the amount of resource that is consumed by the process.

Title: Neural coding in macaque monkeys of the facial features underlying human social perception of faces

Authors: *J. HUANG[1], J. LIU[2], D. GUO[1], C. K. RYALI[2], J. GUAN[3], A. J. YU[3]
[1]Cognitive Science, Mathematics, [2]Electrical and Computer Engin., [3]Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: Humans readily infer social traits (e.g. attractiveness, trustworthiness, and intelligence) from a stranger's face. Little is known about the neural encoding of the facial features underlying such social judgments. Indeed, up until now it has not been clear whether facial features contributing to human perception of social traits are encoded by face processing neurons of other primates such as monkeys, since it is difficult to elicit social judgments (especially about human faces) from non-human primates. In this work, we overcome this difficulty by using a sophisticated computational modeling and analysis framework, which allows us to accurately predict human rating of different social traits for any novel human face image presented to an experimental subject. Combining these predictions with recordings of neural activities of face-sensitive neurons in the macaque monkey while viewing human face images (Freiwald & Tsao, 2010), we can therefore quantify whether an individual neuron encodes facial features contributing to the (human) perception of a social trait, or a combination of social traits. Specifically, we represent the space of all faces using the Active Appearance Model, which has recently been shown to have latent features encoded by face patch neurons in the macaque monkey, and use linear regression to finding linear combinations of facial features that maximally account for human perception of 20 social traits (e.g. attractiveness, trustworthiness, typicality), 3 demographic traits (race, age, gender), and 7 emotional expressions (e.g. disgust, anger, fear, happiness). We first train AAM on two publicly available datasets of face images, then linearly regress neural responses against human ratings of those images, to predict social and emotional judgments as a function of the AAM latent features. We find a significant number of neurons in the macaque face patches significantly encode the facial features that drive the human perception of all three categories of facial traits that we

investigated, including some that specialize in encoding facial features specific to each of the three categories of traits, and others that encode facial features common to all three categories. Despite these findings, our results do not suggest that the monkey brain encodes social judgment percept analogous to human percept, or that monkeys care about the social dimensions of humans faces. However, they do suggest that the facial featural information necessary for "high-level" human social judgments are already encoded in the macaque monkey brain, in the sense that it is readily decodable using a linear decoder.

Title: A neurally-informed approach to modelling learning in human perceptual decision making

Authors: C. A. DEVINE[1], D. P. MCGOVERN[2], C. GAFFNEY[3], S. P. KELLY[3], R. G. O'CONNELL[3]
[1]Templeogue, Dublin, Ireland; [2]Trinity Col. Inst. of Neurosci., [3]The Univ. of Dublin, Trinity Col., Dublin, Ireland

Abstract: Despite the well-established benefits of training for perceptual decision-making, there is still considerable uncertainty regarding the precise stages of information processing that are altered by learning. The present study seeks to develop a neurally-informed model of how learning affects perceptual decision making. To this end, we isolated distinct electrophysiological signatures of the three key stages of information processing necessary for simple sensorimotor transformations - sensory evidence encoding, evidence accumulation and motor preparation - while subjects (N=22) were trained to perform a two-alternative contrast discrimination task over five days. The stimulus consisted of two overlaid left- and right-tilted gratings each of which underwent subtle antithetical changes in contrast. Separate steady-state visual evoked potentials (SSVEPs) provided a direct read-out of the neural representation of each stimulus while the centroparietal positivity (CPP) and beta-band activity respectively indexed motor independent and effector-selective decision formation. Significant improvements in accuracy and response time were observed throughout training. The neural data suggest that training-related improvements in behaviour arise principally from a progressive boosting of

sensory evidence representation, which had a knock-on effect on the build-up rate of the CPP and beta band activity. Consistent with this, preliminary modelling using the standard drift diffusion model (DDM) attributed the learning effects to increases in the rate of evidence accumulation (drift rate). However, our neural data also suggest that training leads to changes in the amount of accumulated evidence required to trigger a response - a finding that was not predicted by our initial modelling attempts. This neural data will be used to further inform the development of a model that fully characterises the effects of learning on both behavioural and neural signatures of perceptual decision making.

Title: Law enforcement officers' neural processing of intentions of suspects during virtual high threat scenarios

Authors: *R. COOK[1], R. A. HOUSER[2], D. FONSECA[3], W. B. WEBBER[1], I. HEIM[3], D. DOLLIVER[4]
[2]Educational Studies, [3]Col. of Engin., [4]Dept. of Criminology and Criminal Justice, [1]The Univ. of Alabama, Tuscaloosa, AL

Abstract: This project was designed to identify neural correlates of law enforcement officers' assessment of the intentions of others in virtual high threat situations. Specifically, we focused on law enforcement officers (LEOs) decision to *correctly* utilize deadly force. We collected EEG data to understand the active neural correlates in the moments leading up to the decision to utilize lethal force. Participants were five local-level LEOs from a small sized city in the Southern who, on average, had 5.75 years of experience (*SD* = 6.75). The results are a part of a larger data collection project. We used five simulation scenarios that all four participants completed that necessitated the participants to fire their weapon. All scenarios were of situations that LEOs might experience (e.g., DUI traffic stop, hostage situation, etc.). In the scenarios, the virtual suspect directed a weapon at the officer or a bystander, thereby justifying the legal use of deadly force by the officer (Broomé, 2011). We initially collected baseline data of brain activity (a two minute EEG recording) followed by presentation of the six scenarios). We collected EEG

data using a 64-channel mobile EEG amplifier, EEGO Sports (Advanced Neuro Technology; Zanow & Knösche, 2004). Data was collected at a sampling rate of 500 Hz in an ambient temperature room. To examine the neural correlate activity for each EEG epoch, we used sLORETA (standardized low-resolution electromagnetic tomography). sLORETA is a method of creating 3D images depicting the neurological activity and is a useful approach to reduce localization errors and eliminate erroneous sources (Pascual-Marqui, 2002). Source data were based on the heads models from the Montreal Neurological Institute (Oostendorp & van Oosterom, 1989). We created 2s epochs from data up to 10 seconds prior to the participants discharging their weapon, signaling the decision to utilize deadly force. Using sLORETA, we found activation in the frontal lobe (BA 8, 9, 10, 47), the occipital lobe (BA 19), and the temporal (BA 21, 39). We found that emotional recognition and cognitive empathy may be important in LEO decision-making during high threat situations. Our findings provide an opportunity for future research in understanding the neural processing in high threat situations as well as implications to inform LEO training.

Title: A neuroeconomic study of impaired interpersonal decision making in anorexia nervosa

Authors: *Y. ONUMA[1], M. ISOBE[2], T. MIKI[2], M. HAYASE[2], T. NODA[2], M. (NISHIDA) KAWABATA[2], E. MURAO[2], R. MISHIMA[2], K. TOSE[2], H. TAKAHASHI[2], T. MURAI[2], S. NOMA[2]

Abstract: Anorexia nervosa(AN) is a severe eating disorder that characterized by a high mortality rate, restricted eating, and disturbed body image. One of neurocognitive phenotypes of eating disorder is impaired decision making. Previous decision making studies of AN focus on the intrapersonal side. However, interpersonal factors play significant roles in many pathological aspects of the disorder, for example the onset, maintenance, and remission. Considering interpersonal hypersensitivity observed in eating disorder, impaired decision making would manifest in the presence of social peers. However, there are few studies that focus on social interaction, and the neural mechanisms remain unclear. The aim of this study is to investigate the

neural correlates of impaired interpersonal decision making in AN combining structural MRI and economic games, which can quantify interpersonal processes. Ten patients with AN and 18 age and gender-matched healthy controls were studied. As behavioral task, we used two economic games, the Ultimatum Game(UG) and Third Party Punishment(TPP). In MRI scans, participants underwent T1-weighted three dimensional magnetization-prepared rapid gradient-echo(3D-MPRAGE). 3D-MPRAGE data were processed by the Statistical Parametric Mapping 12 software package. Using voxel-based morphometry, we investigated the relationship between regional gray matter volume and the economic game scores. In behavioral results, patients with AN rejected unfair offers in UG more frequently than healthy controls. No significant difference was found between patients and healthy controls in TPP. In brain imaging results, acceptance rate of unfair offers in UG had a positive correlation with the volumes of left medial orbitofrontal cortex and left anterior insula in AN. The typical behavior tendency in AN was observed in the situation where patients with AN were treated unfairly by others. Our findings suggest that two particular brain regions might be important for the impaired social decision making in AN.

Title: Associative learning of self and other ownership

Authors: *P. L. LOCKWOOD[1], M. WITTMANN[1], M. APPS[1], M. KLEIN-FLUGGE[1], M. J. CROCKETT[2], G. W. HUMPHREYS[1], M. F. S. RUSHWORTH[1]
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Univ. of Yale, New Haven, CT

Abstract: Sense of ownership is such a fundamental aspect of human cognition that it influences the grammar of many human languages. For example, words are changed and used in special ways such as the genitive case or the construct state to indicate the ubiquitous association that constitutes the ownership relationship. More specifically, social environments often require that we distinguish what in the world is “ours” and what belongs to other people. However, the

mechanisms that underpin how we acquire a sense of ownership over objects that are ours and others is unknown. Here we used an associative learning task, model-based functional magnetic resonance imaging and a minimal ownership paradigm to probe the behavioural and neural mechanisms underpinning ownership acquisition for ourselves, friends and strangers.
We find a self-ownership bias at multiple levels of behaviour from initial preferences to reaction times and computationally defined learning rates. Several areas within medial prefrontal cortex tracked ownership associative strength between objects and agents. Ventromedial prefrontal cortex and anterior cingulate (ACC) sulcus responded more to self vs. stranger associations but despite a pervasive neural bias to track self-ownership, no brain area tracked self-ownership exclusively. However, ownership prediction errors for strangers were specifically coded in ACC gyrus and value representations in this area were tracked only for friends and strangers but not oneself. Core neural mechanisms for associative learning are biased to learn in reference to self but also engaged when learning in reference to others. In contrast, ACC gyrus exhibits relative specialization for learning about others.

Title: Neural dynamics of performance during virtual battlespace cooperative teaming

Authors: J. SNIDER[1], M. ALAM[2], *J. R. LUKOS[2]
[1]Inst. for Neural Computation, UCSD, La Jolla, CA; [2]Space and Naval Warfare Systems Center, Pacific, San Diego, CA

Abstract: This study investigated the behavioral relationships and physiological correlates of partner interactions as participants performed cooperative missions while walking in a virtual battlespace. Subjects (N=18) navigated through a simulated cargo ship searching for enemies in an immersive VR motion-enabled environment while measuring brain activity (EEG). The goal of the study was to determine if differences in cortical activation patterns during cooperative teaming could be detected based on partner behaviors and if the extent of these differences would correlate with team performance. Our initial findings suggest that we can measure neurophysiological correlates of performance that cannot be understood from behavioral measures alone. Specifically, we observed a wide range of success at the task, with little to no correlation with traditional behavioral measures such as movement speed, reaction time and partner coordination. However, we found that performance was correlated with suppression of cortical alpha power (8-13 Hz) in favor of theta power (4-7 Hz) (see attached Fig). This result is particularly intriguing given that frontal theta power is thought to be related to cognitive workload and motor control, while alpha power is implicated in controlling the balance between sensory input and internal cognitive models of the world. This work is critical to understanding and predicting our Warfighters' ability to interact and make decisions in complex, stressful scenarios.
Figure caption: Cortical results for two representative participants. Data are time-locked to the go cue at t = 0. The poor performer in the left plot shows a wide α synchronization that persists up to the go cue. While the good performer in the middle plot has prominent θ band power that increases as the go cue is anticipated. The right plot shows the difference between θ and α over the last second of the planning interval. The good performer is the top-right points and the poor performer the left-bottom points.

Title: The casual role of dorsolateral prefrontal cortex in multiple option decision making

Authors: *T. WOO[1], C.-K. LAW[1], K. TING[2], C. C. CHAN[3], N. KOLLING[4], K. WATANABE[5], B. K. CHAU[1]

Inst. of Information and Communications Technol., Osaka, Japan

Abstract: Activity in dorsolateral prefrontal cortex (dlPFC) is sometimes reported in decision making experiments. However, the reason why dlPFC is only involved in a subset of decision

making experiments is largely unclear. DlPFC is also implicated in cognitive control and working memory, which are important cognitive processes especially in decisions where there is a large number of alternatives. It is possible that when decisions involve a large set of choices, dlPFC is particularly important to store and manipulate decision information for guiding decision making. The current study examined the roles of dlPFC in information sampling and decision making in choices with multiple options. We recruited healthy human participants to perform a multiple option decision making task in which they chose between choice sets of two, four or sixteen food options. To test the causal role of dlPFC in multiple option decision making, we applied transcranial direct current stimulation (tDCS) over the right dlPFC. In a double-blinded crossover design, participants performed the same task in two separate sessions in which they received either an anodal tDCS to enhance dlPFC or sham tDCS as a control. To test the process of information sampling, we recorded the duration of gaze fixation on each option using an eye tracker. To estimate the decision accuracy of choosing a good food option, participants performed an additional Becker-DeGroot-Marschak (BDM) auction task and indicated their subjective preference to each food option. Our results showed that, in the control sham tDCS session, participants' decisions were accurate when there were longer fixation durations with the better options and shorter fixation durations with the poorer options. These effects were comparable in the anodal tDCS session when dlPFC was enhanced and were also comparable across two-, four- and sixteen-option trials. This suggested that dlPFC was unrelated to how information was sampled. Next, we investigated how the sampled information was used to guide decision making. In the sham session, less accurate decisions were made when there were longer fixations at the poorer options. Interestingly, after anodal tDCS was applied over dlPFC, such effect was attenuated, especially on trials with sixteen options. Furthermore, better decisions were made when there were longer fixations at the better options and this was comparable in the sham and anodal session. Overall, these results suggested that dlPFC did not have a particular role in how decision information was sampled. However, when there was a large number of options dlPFC was important to filter out the decision information of the poorer options.

Title: Constructing single-neuronal representations of another's beliefs in the human prefrontal cortex

Authors: *M. JAMALI, B. L. GRANNAN, R. BAEZ-MENDOZA, Z. WILLIAMS
Neurosurg., Massachusetts Gen. Hospital/Harvard Med. Sch., Boston, MA

Abstract: Humans have the remarkable ability to build a detailed understanding of the world and, based on this, reason about the hidden beliefs and states-of-mind of others. While this capacity to form a complex model of reality and to infer the beliefs of others is a major cognitive milestone in human ontogeny, the process by which these computations are formulated by individual neurons in the human brain is unknown. The human prefrontal cortex has been implicated in inferential processing and the ability to reason about others, and is broadly connected with limbic and temporal-parietal areas thought to be involved in social behavior. Here, we acutely followed the activity dynamic of single prefrontal cells (n = 212), as 11 participants were given detailed story narratives and then required to formulate ideas about them. Using this approach, we show how individual neurons (1) respond to distinct features describing social agents and (2) encode the relation between those agents and specific objects or events in their worlds. When later reasoning about these events, largely distinct neurons become predictive of the other's beliefs and also distinguish another's false beliefs from the participant's own understanding of reality. Taken together, these cellular representations reflect the other agent's own awareness of events and are predictive of variations in their content, further providing detail about the other's beliefs and their relation to experiences in their worlds. Collectively, these findings suggest a detailed cellular process in the human prefrontal cortex that may allow us to construct complex mental representations of others and make inferences about their beliefs. From this perspective, these neurons may be good candidates within the frontal-parietal network for supporting human theory-of-mind.

Title: Striatal prediction errors in a decision-making task are modulated by action execution failures

Authors: *S. D. MCDOUGLE[1], D. E. PARVIN[2], P. A. BUTCHER[1], F. MUSHTAQ[3], Y. NIV[1], R. IVRY[2], J. A. TAYLOR[1]

[1]Princeton Univ., Princeton, NJ; [2]UC Berkeley, Berkeley, CA; [3]Univ. of Leeds, Leeds, United Kingdom

Abstract: Decisions must be implemented through actions, and actions are often prone to error. As such, when an expected outcome is not obtained, an individual should not only be sensitive to whether the choice itself was suboptimal, but also whether she successfully performed the action required to indicate that choice. To explore this scenario, we used a modified version of a classic reinforcement learning task, manipulating the feedback to indicate if negative prediction errors were or were not associated with execution errors. Using fMRI, we asked if prediction error computations in the human ventral striatum, a key substrate in reinforcement learning and decision making, are sensitive to this manipulation. Behaviorally, participants were more tolerant of negative outcomes when they were the result of an execution error compared to when execution was successful, but reward was withheld. A model-driven analysis of the fMRI data revealed an attenuation of negative reward prediction error signals in the striatum following execution errors. These results converge with other lines of evidence suggesting that prediction errors in the mesostriatal dopamine system integrate high-level information with instantaneous reward outcomes. In the present case, cues concerning action execution inform striatal computations.

Title: Neural correlates of subjective and objective freedom of choice

Authors: *L. CHARLES, P. HAGGARD
Univ. Col. London, London, United Kingdom

Abstract: What do we know about the factors that influence our decisions? Are we aware of the true reasons of our ‘free’ choices? The ability to introspect the origin of our choices constitutes a key metacognitive function but little is known of the cognitive process and neural substrate that underlie our sense of freedom of choice.

It has been proposed that when faced with a free choice in the absence of external evidence, the brain might use endogenous noise to break the symmetry between different options, and decide how and when to act. However, the specific mechanisms that underlie such free decisions remain unclear. Which cognitive processes determine the influence of endogenous and exogenous signal used to form free decisions? And can we actually introspect how much our decision are based on each of these two sources, evaluating our true freedom of choice?
In this study, we investigated the brain mechanisms underlying objective and subjective freedom of choice in decision making. In particular, our aim was to determine what are the neural substrates enabling us to detach from sensory affordances and rely on internal signal to make free choices. To do so, we used a novel paradigm that estimated how human decisions were influenced by minor fluctuations in a visual signal that either cued a decision, or left participants free to decide for themselves. By varying the clarity of these cues, we were able to investigate both how fluctuating sensory information could influence action selection processes, and also participants' awareness of such influence.
Confirming previous findings, we observed that when participants were instructed to act freely, they were nevertheless biased in their choice of action by current sensory input. However, they nevertheless experienced their decisions as free. Brain activity recorded with fMRI seemed to confirm this dissociation. While subjective freedom of choice was associated with brain activity in a broad network of brain regions involving pre-motor areas and prefrontal cortex, neural correlate of objective freedom of choice, defined as the ability to detach from sensory affordances, only partially overlapped with these regions. In particular, greater influence by sensory fluctuations seemed to correlate with activity in parietal cortex and posterior cingulate region.
Taken together, these results provide evidence that brain regions involved in actual sensory detachment and the sense of freedom of choice partially dissociate, providing neural evidence consistent with limited ability to introspect the origin of our actions.

Title: Insight into the before and after of problem solving using event related potentials

Authors: T. BURNHAM, 67213, S. OESER, A. LAMP, *J. D. HALONEN
Psychology, Friends Univ., Wichita, KS

Abstract: Individuals regularly make a myriad of choices based on information presented to them. We aim to identify if the underlying neural processes for different modalities of conscious decision-making are temporally similar. The readiness Potential (RP) is an indicator of conscious decision-making processes (Fifel, 2018; Harim, 2018). Here we use the RP to investigate if fundamental differences between language- and visual-based information decision processing exist. Investigations into neural correlates of problem solving have used Chinese characters, riddles, or other puzzles in conjunction with various forms of neural imaging or recording techniques (for review see Sprugnoli et al, 2017). To gain insight about how the brain processes different information, we performed this experiment using riddles in English and Object Rotation Tasks (ORT). Electroencephalographic data was collected using iWorx (Dover, NH) IX-EEG hardware using a 10/20 Electro-Cap (Eaton, OH). After obtaining informed consent and calibrating procedures were performed, participants were exposed to a series of seven ORTs alternating with six written riddles. A total of 20 participants were instructed to press a button held in their right hand when they believed they had the answer. We hypothesized that RP and Event-Related Potentials (ERP) measures would be different between the tasks. Data for RP from electrodes FP1, F3 and F7 is currently under analysis. Repeated measures general linear model analysis of the ERP data indicates significant voltage differences at Fz, Pz, & Cz electrodes.

Title: Perceptual decision-making depends on feature-based attention

Authors: *D. RANGELOV, R. WEST, J. B. MATTINGLEY
The Univ. of Queensland, St Lucia, Australia

Abstract: Researchers have had great success in understanding the neural processes responsible for simple, perceptual decisions such as discriminating the direction of motion of a single patch of moving dots. Most such studies of visual decision-making have employed a single stimulus (e.g., a dot patch) which is, by implication, always relevant to the task at hand. In everyday life, however, decision-making typically involves prioritizing goal-relevant stimulus properties and ignoring irrelevant ones. To date, it remains unclear whether task-irrelevant stimulus properties influence decision-making. To investigate this issue, we used electroencephalography (EEG) to measure neural activity as participants monitored two spatially overlapping patches of moving dots, each in a unique colour and each moving in a different direction. Participants (N = 25) were instructed to monitor the motion direction of one patch of dots (target coloured) and to ignore the other patch (distractor coloured). The overlapping motion patches were presented twice per trial, and participants were required to reproduce the average motion direction of the two target signals. This averaging task enabled us to dissociate decision-related processes associated with the motion stimuli from response selection processes which, by design, could occur only after both signals had been processed. To compute the relative contributions of target and distractor motion to the final decision, we used linear regression modelling with complex-valued data. The regression weights for target signals were several times higher than those for distractors, suggesting that only task-relevant stimulus properties contribute to decision-making. Next, we used forward-encoding modelling of the EEG data to characterise feature-specific brain activity evoked by different motion signals. These analyses revealed strong, direction-specific responses to target signals, starting from 200 ms after motion onset. Remarkably, there was no motion-direction-specific neural response to distractor motion. Thus, even though target and distractor stimuli were physically matched and overlapped completely in space and time, there was virtually no evoked neural activity associated with the distractor dots. Taken together the findings suggest that task-relevance plays a critical role in complex perceptual decision making.

Title: Neural and hormonal basis of sleep deprivation-induced impairments in reward-based decision making

Authors: *J. RIHM[1], L. SCHILBACH[2], S. SCHMID[3], J. PETERS[1]
[1]Dept. of Psychology, Biol. Psychology, Univ. of Cologne, Cologne, Germany; [2]Max Planck Inst. for Psychiatry, Munich, Germany; [3]Univ. Hosp. Schleswig-Holstein, Luebeck, Germany

Abstract: Dysbalanced energy levels, e.g. due to sleep deprivation or fasting, alter valuation and reward representations in the midbrain (Menz et al., 2012, Gujar et al., 2011). Previous literature found that sleep deprivation prior to a risky monetary choice task resulted in more inconsistent choices and attenuated brain valuation signals compared to habitual sleep (Menz et al., 2012). However, an open question is if different homeostatic interventions (e.g. fasting) similarly affect risky monetary decision making and if hormones involved in hunger and satiety signaling, such as ghrelin, modulate possible effects. To answer this question, we tested homeostatic modulations of reward processing in risky monetary decision making in two studies using high-resolution fMRI, a classic probability discounting task, blood concentrations of ghrelin, leptin, insulin, glucose, and cortisol, and short-term fasting (study 1) or sleep deprivation (study 2) as homeostatic manipulations. The studies comprised thirty (study 1) or thirty-six (study 2) lean, healthy men and used randomized, within-subject designs. In both studies, a non-linear probability weighting model (Lattimore et al., 1992) fitted the choice behavior best. In addition, model comparison revealed a superior fit of models allowing decision noise levels (i.e. softmax slope parameter) to change according to a power function over trials. Following sleep deprivation, noise levels increased more over trials (study 2), whereas fasting increased the intercept of the noise power function (study 1). Neither effect was correlated with hormonal changes from the control to intervention sessions. Consistent with previous studies (Menz et al., 2012, Peters & Büchel 2009), parametric modulation of risky choices by subjective values of the probability weighting model revealed a main effect of subjective value in the ACC, lateral PFC, PCC, precuneus, striatum and SN/VTA after both interventions. These effects were not correlated with hormonal changes. Our results indicate that different homeostatic interventions can impact risky decision making via a modulation of decision noise levels, but do not suggest a prominent role for hormonal changes in these effects.

Title: An ERP study of the determinants and dynamics of reactive cognitive control

Authors: *K. L. MANSFIELD[1,2], M. W. VAN DER MOLEN[3], G. J. M. VAN BOXTEL[2]
[1]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [2]Tilburg Univ., Tilburg, Netherlands; [3]Univ. van Amsterdam, Amsterdam, Netherlands

Abstract: The current study used laplacian transformed ERPs to investigate how the dynamic interplay between proactive and reactive control (c.f. Braver et al., 2007) varies with task predictability during mixed stimulus-response (SR) mapping tasks. Seventeen participants (1 male) took part in a mixed SR-mapping task, in which they were required to give a spatially *compatible* or *incompatible* response to left/right gaze direction stimuli, such that the SR mapping rule depended on the blue/green color of the eyes (counter-balanced between participants). We manipulated the predictability of the SR-mapping by varying the probability of *compatible* vs. *incompatible* SR-mappings (80/20, 50/50, 20/80). We assessed reactive control mechanisms using response-locked midline N-120 (c.f. Mansfield et al., 2012) and lateralized motor activity (c.f. Vidal et al., 2003). We anticipated that participants prepare (proactively) for the *expected* SR-mapping, predicting that on *unexpected* trials reactive control corrects the mapping, appointing inhibition of the incorrect response, indexed by ipsilateral positivity, and activation of the correct response, indexed by contralateral negativity. In line with previous behavioral studies that manipulated the probability of SR-mappings, SR-mapping effects were robust with 80%, eliminated with 50%, and reversed with 20% compatible trials. Midline N-120 was most enhanced with *unexpected compatible* trials, suggesting that reactive control was needed most in correcting SR-bindings after participants had proactively prepared for an *incompatible* SR-mapping. However, ipsilateral positivity between N-120 and execution of the response was enhanced for all *unexpected* trials, and mostly for *unexpected incompatible* trials, suggesting that inhibition of the incorrect response tendency might be recruited by reactive control reflected at N-120 or earlier. Differences in activity over motor areas contralateral to the response hand were unreliable. The demand for and mechanisms of reactive control reflect both the predictability and the difficulty (SR-mapping) of the prepared tasks, which we assume to be mediated by strategic performance adjustments associated with proactive control.

Title: Evidence accumulation in abstract decisions cued by varying perceptual information

Authors: *M. NEWTON[1,2], A. KAYSER[2]
[1]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA; [2]Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: Perceptual decision making is thought to depend on the accumulation of sensory evidence in the intraparietal sulcus (IPS), independent of specific motor effector. However, whether similarly general mechanisms apply to evidence supporting abstract decisions is unknown. Under this framework, evidence used to drive both concrete (1st order) and abstract (2nd order) stimulus-response (S-R) relationships should accumulate in the same area of IPS. In contrast, progressively higher-order policy requires progressively more anterior regions of the lateral frontal cortex, each of which is most strongly connected to different parietal regions. Under a network-based hypothesis, evidence used to drive concrete (1st order) and abstract (2nd order) S-R relationships should thus accumulate within different areas of IPS. To evaluate these competing hypotheses, we designed a task in which the coherence of a perceptually graded stimulus (motion, color, or shape) and the level of policy abstraction (1st or 2nd order) were independently varied. Behavioral and fMRI data have so far been collected from 8 human subjects (3 male, ages 18-46). Following training to ensure stable performance, subjects each completed 5 fMRI sessions, for 660 total trials. Within a trial, subjects viewed 3 separate, sequentially presented stimuli - dot motion (up/down), dot color (blue/white), and shape (circle/triangle) - before making a button press. Prior to each run, subjects were informed that one stimulus (e.g. color) would represent the 2nd order cue. Based on the 2nd order percept for each trial (e.g. blue/white color), subjects then made a button press response based upon one of the other features (the relevant feature - e.g. motion) while ignoring the third (the irrelevant feature - e.g. shape). Accuracy was significantly greater on high vs low coherence trials for both the 2nd order and relevant 1st order stimuli, but no such difference was seen for irrelevant stimuli. When both 1st order relevant and irrelevant stimuli cued the same button response, accuracy was significantly greater than when different button responses were cued. This result reflected a strategy shift supported by a significant interaction between 2nd order coherence (high/low) and 1st order response (same/different): subjects were significantly more accurate in the low*same vs low*different conditions, but not in the high coherence comparison. These behavioral results demonstrate not only that coherence and abstraction are processed independently, but also that we can systematically manipulate strategy within a trial subtype. Ongoing imaging analyses will evaluate the neural correlates of these findings.

Title: Neural affective predictors of engagement with online videos

Authors: *L. TONG, M. Y. ACIKALIN, B. KNUTSON
Stanford Univ., Stanford, CA

Abstract: Neural circuits implicated in affect, including the nucleus accumbens (NAcc), anterior insula (AIns), and medial prefrontal cortex (MPFC) have been robustly implicated in guiding decisions involving how to spend money. Less is known, however, about the role that these circuits play in decisions about spending time. We conducted two fMRI studies to test whether neural and affective responses predicted (1) choices to engage with watching YouTube videos, and (2) how much time subjects subsequently spend watching the videos before deciding to disengage. In both studies, subjects viewed 64 YouTube splash screens and were asked whether they wanted to watch the depicted video. In study 2, subjects were then asked to watch 32 of these videos, with the option of skipping any video at any time. Consistent with previous research in the financial decision-making domain, NAcc and MPFC activity in response to its splash screen predicted whether a subjects accepted to watch a video (NAcc: b=0.60, $p<0.05$; mPFC: b=0.54, $p<0.001$; AIns: b=0.324, *ns*). Furthermore, Nacc activity was a significant predictor of video choice controlling for self-reports of positive arousal (b=0.88, $p<0.05$). This pattern of results was replicated using a different set of stimuli in study 2 (NAcc: b=0.58, $p<0.05$; mPFC: b=0.45, $p<0.01$; AIns: b=0.55, $p=0.09$). Moreover, mPFC activation was associated with increased time spent watching the videos, controlling for video length (b=0.046, $p<0.05$). Interestingly, anterior insula responses were most (negatively) strongly associated with time that other subjects spent watching the videos (b=-0.047, $p<0.05$). Our results converge with prior research, indicating that anticipatory NAcc and MPFC signals guide subsequent choice not only in monetary domains, but also in choices about how to spend time. Interestingly, while MPFC signal was the strongest factor associated with subjects' own subsequent engagement with the videos, AIns signal was most strongly related to other subjects' engagement. These results are consistent with the view that different neural circuits carry signal about distinct affective components of a decision, which can vary in the extent to which they generalize across people (Knutson & Genevsky, 2018).

Title: The time course of endogenous brain signals reflect different cognitive processes during human decision making

Authors: *M. D. NUNEZ, K. A. SCAMBRAY, K. K. LUI, J. VANDEKERCKHOVE, R. SRINIVASAN
Dept. of Cognitive Sci., Univ. of California, Irvine, Irvine, CA

Abstract: Electrophysiological research has shown that electrical signals recorded from the human brain track evidence accumulation during perceptual decision making. We have previously found evidence that figure-ground segregation of a visual stimulus before evidence accumulation, dubbed Visual Encoding Time (VET), can be tracked by the latency of a visual evoked potential (a negative peak occurring between 150 and 275 milliseconds after stimulus presentation). In this study we sought to elucidate the contribution of different neural networks as recorded by EEG oscillations (in particular the theta, alpha, and beta bands) on the cognitive components of decision-making that occur after VET (i.e. after the N200 peak-latency). In a preregistered study, we confirm previously found 1-to-1 relationships between N200 peak-latency and non-decision time as estimated by cognitive models. We also found evidence that beta desynchronization reflects a neural network involved in motor execution. In an exploratory analysis we found evidence that posterior theta band power increases during evidence accumulation, in support of published research. We also explore evidence that alpha band power desynchronization reflects internal noise suppression during evidence accumulation. These hypotheses were tested directly by estimating parameters of novel neuro-cognitive models of decision making, fitting both human behavior (reaction time and accuracy distributions) and scalp-recorded EEG simultaneously. A hierarchical Bayesian fitting procedure was used to ensure variance between subjects and conditions was accounted for by cognitive models. A cohesive neuro-cognitive theory of quick human decision making is proposed based on these results.

Title: Modeling behavior of rhesus macaques and humans in an iterative chicken game

Authors: *S. MADLON-KAY[1], W. S. ONG[2], M. L. PLATT[3]
[2]Dept. of Neurobio., [3]CCN, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Competitive opponents today might be cooperative allies tomorrow. Navigating social environments requires understanding strategies of others, and how their actions may change across different situations. To study how the brain generates predictions about others' strategies, and updates those predictions across changing environments, we devised a variant of the "chicken" game that alternates between competitive and cooperative scenarios that is played iteratively, over multiple sessions, by pairs of rhesus macaques or pairs of humans. Two individuals (M1&M2) face each other across screen(s) showing 2 colored annuli and 4 response targets. On some trials, the larger reward (denoted by visual tokens) lies opposite M1 behind the opponent (M2)'s annulus; smaller rewards lie to the left (see figure). To obtain the larger reward, M1 goes straight, but if M2 also goes straight the annuli collide and neither monkey gets reward. On some trials, a "cooperation bar" allows both monkeys to obtain larger rewards if and only if both choose to go left; if only one yields he receives a smaller reward. 4 trained monkeys maximized juice intake by attending to the reward tokens as well as the choices of their opponent, while 55 human pairs played cooperative strategies with far less regard to the reward amounts. To describe choice behavior, we constructed a learning model where the agent, M1 uses his beliefs about the strategy of his opponent, M2, to predict M2's action on each trial. M1's beliefs about M2's strategy are represented as a logistic regression relating the potential payoffs of a trial to the probability of M2 swerving versus going straight. M1 learns M2's strategy by updating his beliefs using a strategic prediction error, the mismatch between his expectation about M2's actions and what M2 did. We find that the belief updating model fits choice behavior best, over the reinforcement-learning model, while the intermediate model with static beliefs regarding M2's strategy also improved but to a lesser extent in both human and non-human primate plays. We also collected eye-tracking data on one or both of the players. Surprisingly,

the monkeys spent more time looking at their opponents, while humans rarely did.
Our results indicate that while rhesus macaques played strictly in accordance to the payoffs, humans cooperate more than is conventionally considered rational, and as a whole, have similar gaze and joystick movements. Both are able to learn about the strategies of others, and are able to perform predictions based on at least one level of reasoning.

Title: Integration of social information and value by superior temporal sulcus (STS) neurons in monkeys trading in a simulated stock market

Authors: *A. W. HUTTUNEN[1], M. L. PLATT[2,3]
[1]Wharton Sch., [2]CCN, Univ. of Pennsylvania, Philadelphia, PA; [3]Wharton Sch., University of Pennsylvania, PA

Abstract: People have a keen ability to act on the basis of inferences made about others' intentions, an ability referred to as theory of mind (ToM). However, individuals in stochastic and complex environments, especially financial markets, often maladaptively employ ToM when forecasting others' value estimations, leading to herding and bubble markets. Prior research supports the hypothesis that connections between brain areas associated with value judgements (e.g. ventromedial prefrontal cortex; vmPFC) and those associated with theory of mind (e.g. temporal parietal junction; TPJ) underlie suboptimal decision making due to artificial inflation of stock values in 'bubble markets.' Current work in our lab demonstrates that macaque middle superior temporal sulcus (mSTS), the putative homolog of human TP, is engaged during strategic social decision making, highlighting a potential role for STS in social biasing of decisions in financial markets. In order to further explore the evolutionary roots and neural circuit mechanisms underlying these behaviors, we developed a rudimentary 'stock market' task for rhesus macaques (*Macaca mulatta*), which was also validated in humans. Multichannel electrodes recorded electrophysiological activity from mSTS while monkeys made investment decisions on a touchscreen computer for juice reward in 4 conditions: 1) computer opponent, 2) replay opponent, 3) dummy opponent, and 4) live opponent. Preliminary results indicate that macaque mSTS neurons differentially signal the value of actions in social and non-social

contexts, and that firing rates are modulated by the outcome value of others' choices. Furthermore, we observed an overall increase in engagement of mSTS neurons during the formation of bubble markets compared to non-bubble markets. This research suggests that mSTS neurons encode a social information signal that is likely integrated into downstream valuation computations (e.g. in vmPFC). Ultimately, the spontaneous inclusion of social information signals, which is helpful in most social situations, leads to suboptimal decisions in bubble markets.

Title: Tonic pupil dynamics predict individual differences in the complexity of mental models used for adaptive decision-making

Authors: *A. L. FILIPOWICZ[1], C. M. GLAZE[2], J. W. KABLE[3], J. I. GOLD[2]
[2]Dept. of Neurosci., [3]Dept. of Psychology, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: To make good decisions in uncertain environments, humans build mental models of relevant environmental statistics and adapt these models when environments change. Despite the importance of adaptive behavior in our everyday lives, there are substantial gaps in our understanding of how this model-building process differs between individuals and the brain networks underlying these differences. We have recently demonstrated that the complexity of a mental model, measured as the size of the space over latent variables to which it is sensitive, is an important source of individual differences in adaptive decision-making. Here we present evidence that individual differences in adaptive behavior linked to mental model complexity are reflected in pupil-linked physiological arousal, a proxy for system-wide levels of norepinephrine. Concepts such as 'mental effort' and 'cognitive abilities' have been identified as a key, albeit loosely defined, factors related to pupil dynamics. We propose that this effort is more precisely defined in terms of the complexity of the mental model used to solve a given task. We measured the pupil diameters of human subjects performing an auditory adaptive decision-making task. The task required them to predict which of two sources would generate a tone on each trial. The source generating the tone sometimes switched, with the probability of a source switch, or

'hazard rate', also changing at unannounced points throughout the task. Mental model complexity was measured using a novel information-bottleneck method that calculates the extent to which participant responses encode past information about both the source generating tones and the environment's hazard rate. According to this metric, more encoded information corresponds to more complex models. Consistent with our previous results, participants with more complex mental models adapted better to changes in the task environment but produced noisier responses than participants with simpler models. Pupil analyses revealed that low frequency tonic pupil dynamics were modulated by different task hazard rates, behaving differently on trials where switches occurred rarely (low hazard rate) compared to environments in which switches occurred more frequently (high hazard rate). Moreover, the strength of this modulation was related to mental model complexity, such that subjects with more complex models showed stronger hazard rate-dependent modulation of tonic pupil dynamics. These results suggest that the neurobiological mechanisms that govern tonic pupil dynamics contribute to individual differences in the complexity of mental models used for adaptive decision-making.

Title: Integrating abstract structures and constructing cognitive maps about social hierarchies

Authors: *S. A. PARK[1], D. S. MILLER[2], E. D. BOORMAN[1]
[1]Ctr. for Mind and Brain, Univ. of California, Davis, Davis, CA; [2]UC Davis, DAVIS, CA

Abstract: During navigation, animals' hippocampal-entorhinal circuit integrates path information including location, distance and direction. Recent findings suggest that this circuit may serve a more general mechanism for constructing the cognitive maps of task environments beyond spatial navigation. Here we test whether human brains follow the same principles underlying path integration while integrating social hierarchical structures and building a cognitive map of social networks. Participants first learnt the social hierarchies of two groups on two independent social dimensions separately. Second, under each dimension, participants learnt the relative hierarchy of one individual in a group against another in the other group, which created a unique associative path across groups per individual in the social network. Last, in the fMRI, participants inferred the relative hierarchy between pairs who had not been compared in the given dimension. We examined whether participants recalled specific individuals whose hierarchy had been compared between groups and used these relevant representations as "hubs"

between the two networks to enable the transitive inferences. Behaviorally, we found that the reaction time for inferences not only depends on the different levels of hierarchy between the pairs, but also the within-group Euclidean distance from the hub in the two-dimensional social space. Neurally, both the Euclidean distance and the within-dimension difference between individuals in hierarchies were encoded in the entorhinal cortex (EC). During inference decisions, the medial prefrontal cortex (mPFC) encoded the Euclidean distance from the hub. To test for neural representations of the hub, we adopted trial-by-trial fMRI suppression. While subjects performed a cover task to detect the gender of suppression images, we found suppression in hippocampus and retrosplenial cortex (RSC) for the specific trials where the pair was followed by their hub compared to other matched hubs that were not theirs. Our findings provide preliminary evidence that the human EC integrates the relationship between abstract and discrete entities into a cognitive map. They further suggest the mPFC retrieves relevant representations from prior experiences to meet current demands and infers social relationships across groups based on the spatial map. These results shed light on how abstract and discrete structures are combined and represented in the human brain, suggesting that general mechanisms in the human EC can be extended to map abstract social networks and used by the mPFC to guide goal-directed inferences, supporting their roles in higher social-cognitive functions.

Title: vmPFC activity during decision making under uncertainty predicts trauma-related symptoms in combat veterans

Authors: *R. JIA[1,2], L. RUDERMAN[1], C. GORDON[3,4], M. HORVATH[3,4], C. DEFONTES[3,4], S. MIRCHANDANI[3,4], I. HARPAZ-ROTEM[3,4], I. LEVY[1,2,4]

Abstract: Combat soldiers face high levels of uncertainty in the battlefield, yet the role of individual uncertainty attitudes in the development of trauma-related psychopathology has hardly been examined. We have recently used a paradigm inspired by behavioral economics, and

identified variations in decision making under uncertainty that were associated with posttraumatic stress disorder (PTSD) (Ruderman et al., 2016). Here, we use the same task to explore neural markers of trauma-related symptoms.
We used a monetary task to assess risk and ambiguity attitudes of 78 combat veterans. Subjects chose between a certain win (or loss), and playing a lottery which offered a larger gain (or loss) but also chance of zero outcome. Outcome probabilities for half of the lotteries were precisely known, and were ambiguous for the other half. fMRI was used to track neural activation while subjects completed 240 decisions. One choice was randomly picked for payment to ensure task engagement. We evaluated PTSD symptoms by CAPS (Clinician-Administered PTSD Scale), and used additional measures to assess trauma exposure and other psychiatric symptoms including depression, anxiety and addiction.
Behaviorally, we replicated our recent result using a dimensional approach, and found that veterans with more severe PTSD symptoms (higher CAPS) were more averse to ambiguous losses (Pearson's correlation $r=0.25$, $p<0.05$), but not gains. Veterans with higher CAPS were also more averse to risk under gains ($r=0.3$, $p<0.05$), but not losses. A whole-brain analysis revealed that overall activation in vmPFC, an area involved in both value-based decision making and fear learning, was negatively correlated with CAPS ($p<0.05$). Interestingly, when controlling for correlations between symptom clusters, emotional numbing remained the only significant cluster. Severity of this symptom cluster predicted activation under gains, but not losses ($p<0.05$), emphasizing the significance of studying reward processing in PTSD.
Our results demonstrate the potential of neuroeconomics techniques for studying psychopathology, and for devising objective diagnostic tools that compensate the insufficiency of DSM based categorical diagnoses.

Title: Model-based inference involves interactions between orbitofrontal cortex and hippocampus in humans

Authors: *F. WANG[1], G. SCHOENBAUM[3], T. KAHNT[1,2]
[1]Dept. of Neurol., Northwestern Univ., Chicago, IL; [2]Dept. of Psychology, Northwestern Univ., Evanston, IL; [3]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: Model-based inference requires using prior knowledge about the associative structure of the task to infer outcomes. Such model-based reasoning has been associated with neural processing in the orbitofrontal cortex (OFC) and hippocampus. However, the specific contributions of these two regions to model-based behavior, and how they interact during inference, has remained unclear. To address these questions, we used functional magnetic resonance imaging (fMRI) and multivoxel pattern analysis in the context of a sensory preconditioning task. Participants (N=23) first encoded pairs of visual cues (A->B, C->D; preconditioning). Subsequently, they learned associations between the second cue of each pair and monetary outcomes (B->$1, D->$0; conditioning). Finally, participants were probed to predict the outcome associated with all cues (A, B, C, D; probe test). Of note, because cues A and C were never directly paired with the outcome, successful outcome prediction required participants to retrieve and combine cue-cue (A->B, C->D) and cue-outcome associations (B->$1, D->$0). Behavioral responses during the probe test showed that participants were able to predict the correct outcomes in response to cues A and C. To test for neural representations of value-neutral cue-cue associations during preconditioning, we used a searchlight-based fMRI pattern-similarity analysis. We found that activity patterns in the OFC and hippocampus elicited by the two cues of each pair became increasingly similar over multiple presentations, suggesting that these regions encode the associative task structure in the absence of value. Furthermore, we conducted a pattern-based classification analysis and tested whether inference in response to A and C in the probe test involved the reactivation of cues B and D. Specifically, we trained a support vector classifier on activity patterns evoked by cues B vs D during conditioning, and tested it on activity patterns evoked by cues A vs C in the probe test. This analysis revealed significant reactivation of B vs D in response to cues A vs C in the OFC, but not the hippocampus. However, functional connectivity between the OFC and hippocampus increased during inference trials, suggesting that reinstatement of learned associations in the OFC could be mediated by enhanced OFC-hippocampus connectivity. Collectively, these findings show that the OFC, and its functional interactions with the hippocampus, play an important role in representing the associative structure of the task environment to support model-based inference.

Abstract: Light/fluorescence microscopy allows to visualize cells and tissue and can provide information about the location of specific molecules by tagging them with genetically encoded markers or other molecular probes or by labeling with fluorescent antibodies. However, this information is constrained by the limited resolution of the fluorescence microscope as well as by the absence of cellular context on the nano-scale. The Golgi staining method is based upon the deposition of silver or mercury particles within a seemingly random small set of isolated neurons. These particles can be easily visualized by both light and electron microscopy. We developed a method based on the old Golgi staining technique that allows merging electron and light-microscopy based images from the same object, and adapted electron microscopy visualization protocols. This novel approach allows to trace neurons over the entire length of their projections throughout the brain, while still revealing to see ultrastructural details, which is in stark contrast to the currently used Golgi protocols. We optimized Golgi staining for use in block face scanning electron microscopy and developed an algorithm for automated neuronal tracing. Successful implementation of our novel approach will significantly contribute to the study of functional connections in the brain.

Abstract: Focused Ion Beam Scanning Electron Microscopy (FIB-SEM), developed for materials science and the semiconductor industry, has been applied to biological imaging for over a decade. Conventional FIB-SEM systems offer superior isotropic resolution, yielding data that needs minimal image registration and post processing. However, deficiencies in its imaging speed and long-term system stability limit the maximum imaging volume. I will present advancements that accelerate image acquisition and markedly improve reliability of conventional FIB-SEM, expanding the imageable volume by more than four orders of magnitude to beyond 10^7 μm^3 at 8 x 8 x 8 nm^3 voxel resolution. These large volumes are ideal for connectomics, where the excellent z resolution can help in tracing of small neuronal processes of small insects and minimize the time-consuming human proofreading effort. Even higher resolution is achievable on smaller volumes, generating ground truth for connectomics and providing important insights into cell biology. In our largest connectomic study to date, we have acquired a *Drosophila* hemi-brain dataset spanning the entire central complex, a complete unilateral mushroom body, and partial optic lobe. The next grand project, a complete *Drosophila* central nerve system (CNS) acquisition, is currently in progress.

Title: Gas cluster ion milling of serial thick sections for connectomics

Authors: *K. J. HAYWORTH, D. PEALE, Z. LU, C. XU, H. F. HESS
Howard Hughes Med. Inst., Ashburn, VA

Abstract: Focused Ion Beam Scanning Electron Microscopy (FIB-SEM) has a demonstrated ability to generate high contrast, high-resolution (<10nm) isotropic datasets for connectomics, however samples must typically be restricted to <50 microns in the direction of the FIB beam as glancing-angle milling results in artifacts over longer distances. Removal rate is also limited due to a current/spot size tradeoff. These are not serious limitations when using standard SEMs, but they are major obstacles to integrating FIB with multibeam SEMs. Wide area samples such as serial sections collected flat and side-by-side on a common substrate are better suited. We have begun exploring Gas Cluster Ion Beam (GCIB) milling of serial thick sections as an alternative to glancing-angle FIB milling. GCIB is a technique that has been used in the semiconductor industry to polish surfaces at the nanometer scale and to produce nanometer scale depth profiling

of polymer films for mass spectroscopy. We attached a GCIB-10s gun from Ionoptika to a Zeiss Ultra SEM creating the first combined GCIB-SEM system. We verified that smooth, <10nm sequential surface removal and SEM imaging could be achieved for large area 100nm thick brain sections. To do so we used a 10kV beam of Ar2000 (clusters of 2000 argon atoms) directed such that the beam made an angle of 30 degrees to the rotating tissue's surface. To apply this technique to larger sections we developed a high voltage electron irradiation technique that pre-cooks thick sections making them conductive prior to GCIB-SEM imaging. As a demonstration we collected three sequential 1 micron sections of Drosophila brain on silicon and performed ~250 mill/image cycles completely imaging through the depth of all three sections. We found that under these conditions there is ~10% variance in milling rate that had to be computationally 'flattened' prior to stitching the volume images of the sequential sections together. The resulting dataset appears suitable for connectomic tracing and is similar in quality to FIB-SEM but produces somewhat rougher surface images under secondary electron detection. Since GCIB can achieve high removal rates and is not limited in area we think it represents a promising path for integration with multibeam SEMs.

Title: Mitochondrial size gradients in cortical neurons revealed by 3D electron microscopy

Authors: *A. FORYCIARZ[1], N. TURNER[1], K. LEE[1,2], W. SILVERSMITH[1], W. WONG[1], J. WU[1], S. DORKENWALD[1], T. LEWIS, JR[3], Y. HIRABAYASHI[4], F. POLLEUX[5], N. M. DA COSTA[6], R. REID[7], H. SEUNG[1]
[1]Princeton Univ., Princeton, NJ; [2]MIT, Cambridge, MA; [3]Dept. of Neurosci., Columbia Univ. Med. Ctr., New York, NY; [4]Neurosci., [5]Dept Neurosci., Columbia Univ., New York, NY; [7]Neural Coding, [6]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Neurons are among the most highly polarized cells in our body and this includes compartmentalized organelle structure and function. Mitochondria play a crucial role in the functioning of neurons by synthesizing ATP and buffering intracellular Ca^{2+}, both necessary for synaptic function. They are highly dynamic organelles, are constantly changing through fusion and fission events to adapt to changing environment in the cell (Youle et al. 2012), moving across cells (Narayanareddy et al. 2014) and often forming long filaments (Popov et al. 2005,

Amchenkova et al. 1988). The morphology and location of mitochondria can provide insights into specialized function they perform in different parts of the neuron. Observations of neuronal mitochondria thus far have mainly been in dissociated neurons in vitro, single neurons in vivo with light microscopy, or small volumes (< 1000 um^3) with 3D electron microscopy (EM). Recently Dorkenwald et al. (2017) demonstrated automated reconstruction of mitochondria from 3D EM of millions of um^3 of avian brain. Such large-scale reconstructions open up the possibility of obtaining more detailed and quantitative information about either cell-type specific and/or compartment-specific mitochondrial morphology and distribution. We acquired 3D EM images of mouse primary visual cortex (V1). All neurons with somas in the imaged volume were reconstructed using a semiautomated pipeline described elsewhere. We applied a 3D convolutional network to classify voxels as either mitochondrion or background. The mitochondrial voxels were grouped into over 900,000 mitochondria using connected components. For subsequent analyses, we focused on the mitochondria that were contained in neurons with somas in the volume. Each mitochondrion was assigned to either axon, dendrite, or soma. We calculated the distance from soma centroid to each mitochondrion centroid. It is well-known that axonal mitochondria are typically shorter and smaller than dendritic mitochondria. Our data show that somatic mitochondria are intermediate in size between axonal and dendritic mitochondria. This comparison may be simplistic, as mitochondria vary in size systematically with distance from the soma. We found that the size (length and volume) of axonal mitochondria decreases with distance from the soma. In contrast, the size of dendritic mitochondria increases with distance from the soma up to almost 100 microns. Our data so far strongly suggest that the balance between mitochondrial fission and fusion must be compartment-specific with fusion dominating over fission in dendrites and vice versa in axons.

Abstract: Communication between neurons relies on the release of chemical neurotransmitters, which represent a key-defining feature of a neuron's chemical and functional identity. These are packaged into vesicles for release at the synapse by specialized vesicular transporters. However, imaging tools designed to determine the neurochemical identity of synapses and synaptic vesicles *in vivo* are quite limited. We developed a genetically-encoded probe to identify glutamatergic synapses at both the levels of light and electron microscopy (EM). More specifically, we generated a fusion of VGLUT2 and miniSOG (mini singlet oxygen generator), a fluorescent protein that generates singlet oxygen when activated by blue light to locally catalyze the polymerization of diaminobenzidine (DAB) into an osmiophilic reaction product, easily detected by EM. We designed the new glutamatergic synapse EM probe to concentrate and accumulate DAB signal inside synaptic vesicles, so they can be easily distinguished from the unlabeled vesicles. To extend this to animals, we generated and injected an adeno-associated virus into Cre-driver mouse lines to allow Cre-conditional expression of VGLUT2-miniSOG in specific cell types. Importantly, VGLUT2-miniSOG is functional, because it can rescue Channelrhodopsin-2 (ChR2)-assisted glutamate co-release from dopamine neurons from which VGLUT2 had been knocked out. Immunostaining for miniSOG indicates that VGLUT2-miniSOG can be efficiently detected in synaptic terminals where it localizes with other synaptic markers. Furthermore, following photooxidation and EM processing, DAB staining confirmed synaptic vesicle labeling consistent with VGLUT2-miniSOG successfully trafficking to these organelles, with pristine preservation of the ultrastructure. Using a 3D imaging method, serial block-face scanning EM (SBEM), we assessed the subcellular distribution of transporter-defined vesicles at nanometer scale. To confirm the specificity of the VGLUT2-miniSOG labeling within the lumen of the vesicles, we used DAB conjugated with a lanthanide (cerium) chelate and implemented a method called multicolor-EM. This allowed us to uniquely differentiate the spectral signal of the cerium in the DAB deposits by imaging electron energy-loss spectroscopy (EELS) in an energy-filtered transmission EM. Finally, we developed a novel deep learning approach to perform automatic segmentation of the labeled vesicles. These tools should be very useful to the neuroscience community for work ranging from the subcellular structural/molecular biology of neurotransmission to long-distance tracing of neural network connectivity.

Title: A novel method for the quantitative analysis of ultrastructure in astrocyte monolayers after an ischemic stroke-like insult

Authors: *G. E. SANCHEZ IRIZARRY[1], A. H. MARTINS[5], N. SABEVA[2], N. MARTINEZ-RIVERA[6], I. I. TORRES-VAZQUEZ[7], P. A. FERCHMIN[3], V. A. ETEROVIC[4], Y. FERRER ACOSTA[3], E. ROSA-MOLINAR[8]

Abstract: Astrocytes the most abundant glial cell type in the brain, are key participants in the complex cellular response following injury to the central nervous system, and an important component of their intermediate filament system is glial fibrillary acidic protein (GFAP). In prior fluorescent microscopy studies of astrocytes, we show that following ischemic-like insults, nicotinic acetylcholine receptor blockage decreases astrocyte reactivity. Now, we extend those studies using fluorescence and immuno-electron microscopy to quantitatively characterize structural changes of reactive astrocytes and to study changes in GFAP filament immunoreactivity, respectively. After stroke, astrocytes around the affected area undergo astrogliosis that results in increased reactivity, proliferation, and the formation of a glial scar. Following neurotoxic insults, the 4R-cembranoid molecule (4R) has been shown to decrease astrocyte reactivity in vivo and to have neuroprotective effects against ischemic stroke. Previous studies have shown that 4R neuroprotective signaling is mediated via nicotinic acetylcholine receptors (Ferchmin et al; J Neurosci. Res. 2013;91:416-425; Ferchmin et al; Neurotoxicology 2014; 44: 80-90) and data suggest that this compound decreases astrocyte reactivity after ischemic-like insults such as oxygen-glucose deprivation (OGD). Building on those prior studies and using light and immuno-electron microscopy of cultured astrocytes, we characterize 4R-neuroprotection occurring via astrocyte-specific signaling, and we quantitatively characterize astrocyte reactivity and morphological changes. Following an ischemic-like insult, we analyze changes in anti-GFAP intermediate filament immunoreactivity using fluorescence and immuno-electron microscopy. Isolated murine cortical primary astrocytes (Lonza, M-ASM- 330) were

grown to confluency and underwent OGD for 3 or 6 hours. Afterwards, astrocytes were treated for 24 hours with 4R or vehicle. Astrocyte monolayers were fixed and processed for correlative light and immuno-electron microscopy to identify and quantify GFAP immunoreactive astrocytes. Analyses suggest anti-GFAP intermediate filament immunoreactivity decreased in OGD astrocyte cultures treated with 4R, in contrast to those treated with vehicle. These results not only increase understanding of nicotinic modulation following ischemia, but also demonstrate how correlative light and immuno-electron microscopy studies may advance quantitative characterization of proteins.

Title: Regulation of calcium dynamics due to intracellular ultrastructure: Insights from high resolution reconstruction and computational modeling

Authors: *M. HABERL[1,2], J. LAUGHLIN[3], E. P. CAMPBELL[4], M. BELL[3], T. DEERINCK[1,2], P. RANGAMANI[3], M. H. ELLISMAN[1,2], B. L. BLOODGOOD[4]
[1]Neurosciences, [2]Natl. Biomed. Computation Resource / Natl. Ctr. for Microscopy, [3]Dept. of Mechanical and Aerospace Engin., [4]Divsion of Biol. Science, Neurobio., UCSD, La Jolla, CA

Abstract: The endoplasmic reticulum (ER) of neurons extends from its' origin at the nuclear envelope throughout the cell body continuing into the axonal and dendritic arbors, including small branches within dendritic spines. It is well known that the ER is critical for the regulation of intracellular calcium, and that its limiting membrane is enriched in Ca channels (IP3-activated and Ca-activated (aka., ryanodine receptors), which in concert with Ca pumps, binding proteins and plasma membrane channels, modulate the spatiotemporal dynamics of calcium signaling. What remains unknown is how the precise intracellular positioning and 3D fine structure of the ER, in concert with these channels, regulates calcium dynamics and its signaling. We have employed a combination of large-scale automated methods for high resolution reconstruction and segmentation to build accurate models of the entire ER within whole neurons; and are now using simulation strategies to explore how intracellular ultrastructure regulates calcium dynamics in the context of these accurate geometries. Reconstructing the ER is a multiscale problem spanning from the few nm-scale of ER diameter to the mm-scale of neuronal projections. Tracking the ER

into dendrites and axons requires wide-field data acquisition but must retain nanometer scale for accurate 3D EM-based models. We have used serial block-face-scanning electron microscopy (SBEM) to generate high-resolution 3D EM volumes of the rodent cerebellum and applied deep learning-based computational algorithms for automated reconstructions of these intracellular details together with many other intracellular structures (eg., mitochondria and Golgi apparatus). These reconstructions then serve as geometric domains for computational modeling of the spatio-temporal dynamics of calcium to study the influence of ER shape and proximity from the plasma membrane on neuronal Ca signaling. Predictions from simulations are expected to help address how the neuronal fine structure, across large somatic areas and in local domains such as dendritic spines, branch points as well as at axon initial segments and at nodes of Ranvier may contribute to local and long-distance signaling. This work not only forms the basis for next generation simulation studies but also points to very specific localization experiments that remain to be carried out to determine the identities of molecular specializations at numerous sites where the ER is found to make close associations with the neuronal plasma membrane.

Title: A harmonious image analysis workflow for large format electron microscopy: Web-based collaboration and local processing enabling rigorous GABA-post-embedding immunogold quantification

Authors: C. CLARKSON-PAREDES[1], C. A. BRANTNER[1], C. ZUGATES[3], M. RUST[4], *A. S. POPRATILOFF[2]
[1]Nanofabrication and Imaging Ctr., [2]George Washington Univ., Washington, DC; [3]arivis AG, Washington, DC; [4]arivis AG, Rostock, Germany

Abstract: Electron microscopy (EM) image segmentation and analysis are difficult due to the complexity of shapes and intensities presented in single data sets. Thus, many of the classical image analysis approaches relying on thresholding, spatial filtering and object separation cannot

be reliably employed. The most critical step in structuring an EM data set is the segmentation and sampling of analogous objects of interest. This is routinely done by hand-navigated outlining on a single machine by one individual at time, which imposes time constrains for segmenting larger data sets. Our interests are in the hypoglossal nucleus and the surrounding areas intimately connected with the XII motoneurons (i.e., reticular formation and nucleus of the solitary tract). We employ large ultrathin sections containing the entire brainstem of a mouse, offering a robust map to navigate and focus for sampling at very specific areas of interest. The sections were mounted on silicon and processed for post-embedding immunogold with antibodies against GABA. Secondary antibodies conjugated to 10 nm gold particles were used for immuno-detection. We utilized Helios NanoLab 660 SEM (Thermo Fisher, FEI) with concentric backscattering detector in immersion mode to detect elastically backscattered electrons by landing low voltage (2kV) electrons. This approach allowed for the generation of high-quality, large area data sets by fusing large number of adjacent fields (MAPS, FEI). Individual image HFV measured 6.38µm (3072x2048px). These sets contain the structural information of similar quality as transmission electron microscope data, but allowed us to sample from a much larger sample in a cyto-architecturally justified way. Gold particles encoding GABA are readily distinguishable from the uranium stain. To increase the number of sampled GABA positive and negative synapses, a data set representing large area of hypoglossal nucleus was uploaded to arivis WebView. Synaptic terminal segmentation was crowd sourced using this platform, representing a flexible and modular commercial solution with collaborative Web tools, allowing multiple investigators to segment synaptic terminals at the same time. We built a workflow to convert image data into a pyramidal redundancy-free format and transfer it to a Web server, perform collaborative segmentations, and used our Web-derived results directly in optimized particle-counting and distribution analysis. Data transfer, processing, results analysis are all completely self-contained on the platform. Using this approach, we quantified GABA differences in concentration and localization in presynaptic terminals.

Abstract: Melatonin (MT) (N-acetyl-5-methoxytryptamine) regulates the biological, neuroimmunological, antioxidant, gastroprotective, anti-inflammatory, anxiolytic-antidepressant, antiproliferative and reproduction rhythms. Currently, there is a therapeutic use with administration of exogenous MT as a sleep inducer, without knowing the toxicity and side effects that may occur. Debeliuk et al., showed that 300 μg of MT (30 days), decreased the weight of the testicles and affected the production of testosterone in rats. Redins et al., reported that 100 μg of MT (22 days), injured the ultrastructure of Leydig cells in mice and Tuncer et al., found a tubular degeneration, edema and obstruction of seminiferous tubules with the administration of 3 mg / kg of MT (30 days) in rats. With the intraperitoneal administration of 300 μg of both MT and M3C substances (30 days), macroscopic and immunohistochemical studies were carried out to determine if the testicular cell structure of the rat seminiferous tubule (TS) presents any change with chronic administration of them. Post-treatment, were anesthetized the rats and with intracardiac perfusion of SSI (0.9%) and buffered formaldehyde, the testes were extracted for histopathological study (haematoxylin-eosin) and immunolocalization of MT with the anti-melatonin specific antibody. The MT and the M3C were located in ERA.

Title: Golgi stereology: A novel and efficient method for quantification of neurons, dendritic fibers and spines on Golgi-stained sections using unbiased stereology

Authors: *P. R. MOUTON[1], F. DU[2], J. SEBAT[3], Y. KOLINKO[4], B. SCHWER[5]
[1]Stereology Resource Ctr., Tampa, FL; [2]FD Neurotechnologies, Ellicott City, MD; [3]Inst. for Genomic Med., UCSD, San Diego, CA; [4]Histology and Embryology, Charles Univ., Pilsen, Czech Republic; [5]Dept. of Neurolog. Surgery, Univ. of California, San Francisco, San Francisco, CA

Abstract: For more than a century, Golgi staining has been an effective histology method for understanding the microscopic morphology of individual brain cells, dendritic spines, and patterns of fiber branching and interconnectivity. Previous attempts to quantify these microstructures using camera lucida-type drawings have relied on semi-quantitative approaches using public-domain (free) software such as Fiji (Fiji Is Just Image J) or costly neuron tracing programs from commercial vendors. Well-known problems include projection bias, e.g., fiber measurements from projected images (2-D Sholl analysis); and low precision and high labor and opportunity costs from excessive time and effort spent tracing a negligible fraction of neurons in each region of interest (reference space). Here we propose the use of unbiased methods to quantify global stereology parameters for neurons through entire reference spaces of standard Golgi-Cox stained sections. The required equipment is a computerized stereology system with an ordinary light microscope equipped with a motorized XYZ stage and a high-resolution digital camera interfaced to a PC and monitor. Neocortex and CA1 molecular layers from eight mice were outlined at low power (4x) on a systematic-random sample of 6-10 sections per reference space to estimate total volume (Cavalieri point counting). Second, thin focal-plane Z-axis scanning at high magnification (60x, n.a 1.4) was done at a minimum of 200 systematic-random locations to estimate total length and length density of fibers (space balls probe) and total numbers, volume densities of neurons and dendritic spines (optical disector probe). Among the findings are a mean total length of 25.3E+3 mm and length density of 3562 mm/mm3 for Golgi-stained fibers in neocortex. About 2 hours or less was required to achieve a high level of sampling stringency as evidenced by a low mean coefficient of error (CE) of about 0.10. Benefits of Golgi Stereology include high accuracy and precision due to unbiased probe sampling through entire reference spaces; and more than 10x efficiency compared to the fastest tracing methods. Though the present studies were done using the Stereologer system (SRC Biosciences, Tampa, FL), the same approach is theoretically possible using any comparable-equipped stereology system. Golgi Stereology may provide the most user-friendly and versatile method to date for quantifying the structural basis of neurological diseases. Also, the approach could be useful for preclinical safety and efficacy testing of drug strategies for the therapeutic management of afflicted patients.

Title: PharmacoSTORM: A powerful approach for antibody- or fluorescent protein-free super-resolution imaging

Authors: *S. C. PROKOP[1], P. ABRANYI-BALOGH[2], L. BARNA[3], G. M. KESERU[2], I. KATONA[3]
[1]Inst. of Exptl. Med., Hungarian Acad. of Sci., Budapest, Hungary; [2]Res. Ctr. for Natural Sciences, HAS, Budapest, Hungary; [3]IEM HAS, Budapest, Hungary

Abstract: A major challenge for contemporary neuroscience is to uncover the nanoscale molecular changes underlying neuropsychiatric diseases. Super-resolution imaging techniques, such as Stochastic Optical Reconstruction Microscopy (STORM) or Photo-Activated Localization Microscopy (PALM) are the methods of choice for visualization of nanoscale protein distribution, but these approaches suffer from the lack of selective antibodies against important molecular targets or from the various pitfalls associated with overexpression of tagged proteins, respectively. Here we introduce PharmacoSTORM, which uses specific ligands labeled with proper fluorescent dyes to measure the nanoscale distribution of signaling molecules. We first overexpressed hemagglutinin (HA)-tagged α7-nicotinic acetylcholine receptor in HEK293 cells and simultaneously performed immuno- and ligand stainings using antibodies and Alexa647-labeled α-bungarotoxin, respectively. Notably, the signals acquired by different labeling procedures showed high degree of correlation. In agreement with the basic pharmacological principles, the signal intensities originating from fluorescent ligand binding were saturable. The superior sensitivity of super-resolution imaging was reflected by the fact that low concentration of Alexa647-α-bungarotoxin was not visible with confocal microscopy, but was detectable with STORM imaging with unprecedented localization precision. Since ligand-based staining lacks amplification steps, this approach can more precisely determine molecular quantity. PharmacoSTORM could also be applied to tissue preparations, and visualized the nanoscale density of nicotinic receptors at neuromuscular synapses. Finally, to demonstrate the general applicability of the PharmacoSTORM approach, we have also developed novel compounds, which enabled the nanoscale visualization of the CB_1 cannabinoid and the D_3

dopamine receptors, two G protein-coupled receptors widely implicated in many neuropsychiatric disorders. PharmacoSTORM by these compounds allowed the qualitative anatomical and the quantitative pharmacological profiling of nanoscale receptor distribution. In summary, we propose that PharmacoSTORM is an efficient new tool for super-resolution imaging of difficult and low-copy number molecular targets.

Title: Enhancing structural contrast in t1 mri protocols using multimodal targeted tissue probes

Authors: *J. SHELESTAK[1], N. BEALS[2], N. PENMAN[2], S. BASU[2], S. HUANG[2], R. CLEMENTS[1]

Abstract: The imaging of soft tissue is important in both the research and clinical diagnosis of damage and disease. Magnetic resonance imaging (MRI) utilizes the electromagnetic energy released from altering the proton spins of hydrogen under changing magnetic fields to image these soft tissues. Contrast agents are often necessary to improve the resolving capability of MRI to detect subtle changes in tissues that occur. However, most of the common contrast agents provide only non-specific contrast enhancement and are generally toxic in low concentrations. New nanoparticles have recently been developed, one gadolinium based (GdNP) and one gold based (AuNP) that can function as contrast agents with the ability to target specific tissues. The GdNP has been previously shown to provide ten times the signal as typical contrast agents at equal concentrations. This allows for a much lower concentration of contrast agent to be needed to create similar contrast enhancement. These nanoparticles are capable of targeted contrast enhancement by conjugating them to dyes or antibodies that can bind to specific tissues. This also serves to further reduce the necessary concentration needed to visualize changes to specific tissues under MRI. Both nanoparticles have been conjugated to bind to serum albumin (SA) in the neurovasculature of the brain. This conjugation provides a multimodal approach to imaging by binding the nanoparticles to these fluorescent dyes allowing for contrast enhancement under in vivo MRI and fluorescent staining under microscopy. Utilizing a known model for Blood Brain barrier permeability, cuprizone, we can image the vasculature under healthy conditions as well as look for signs of BBB hyper-permeability using these nanoparticles. These probes allow

for enhanced detail of soft tissue alterations in disease states or damage for both diagnosis and research.

Title: In silico electromagnetic and electrophysiological modelling of neuronal current imaging using ultra-low field nuclear magnetic resonance

Authors: E. NEUFELD[1], *A. M. CASSARA[1], J. H. STORM[2], N. HOEFNER[2], R. KOERBER[2], N. KUSTER[1]
[1]IT'IS Fndn., Zurich, Switzerland; [2]Physikalisch Technische Bundesanstalt (PTB), Berlin, Germany

Abstract: The feasibility of non-invasive imaging of neuronal currents (NCI) in the brain by means of Nuclear Magnetic Resonance (NMR) techniques has been debated for more than a decade. NCI cannot be easily applied at high Larmor fields (>1T) due to (i) the relative weakness of the magnetic fields generated by neurons in the brain (NMFs), and (ii) the concomitant and dominant NMR signal contribution by the metabolic blood oxygen level dependent (BOLD) effect. The implementation of NCI techniques using low field (LF) NMR (<50uT, corresponding to Larmor frequencies <5kHz), has recently been explored in experimental and computational studies using simplified phantoms mimicking the brain to assess the theoretical sensitivity of NCI, with promising results. Current research combines experimental and computational approaches to allow realistic *in-silico* NCI simulations in order to (i) optimize LF-NMR hardware, (ii) optimize NCI sequences, (iii) estimate sensitivities of the techniques, and (iv) design experimental strategies in preparation of *in vivo* human trials. The identification, separation and quantification of the different deteriorating (e.g. field inhomogeneities, partial volume effects, etc.) or interesting (weak, transient and distributed NMFs) physical contributions to the NMR signals is the primary purpose of *in silico* modelling. The approach required the development of a flexible NMR solver within the Sim4Life platform (ZurichMedTech,Zurich,CH) for life sciences investigations to be used in combination with i) validated electromagnetic models of magnetic resonance imaging (MRI) hardware and of

experimental phantoms; ii) validated and iii) realistic computational models of extended neuro-electric sources (e.g. computed from electrophysiological models of neural microcircuits) positioned within high-resolution anatomical human head models to provide realistic estimations of *in vivo* NMFs. Experimental work included i) inverse source reconstruction (e.g. equivalent current dipole position and orientation) of magnetoencephalographic (MEG) signals of long-lasting human neuronal activities subsequent to median nerve stimulation to calibrate experimental and numerical head phantoms and sources; ii) the construction of test phantoms; iii) NMR-modeling validation experiments; and iv) LF-MRI experiments with novel NCI sequences. The computational modeling is capable of reproducing different physical and physiological factors involved in the generation/alteration of the NCI signal. Uncertainty assessment is currently being performed to quantify the reliability of the modeling predictions against measurements.

Title: Targeted noninvasive delivery of novel clathrin-based superparamagnetic iron oxide nanoparticles for magnetic resonance imaging of dopamine transporters in mouse brain

Authors: *J. K. KIM[1], D. MINTZOPOULOS[1], C. W. ADAM[1], S. E. LUKAS[1], M. J. KAUFMAN[1], F. VITALIANO[2], G. VITALIANO[1]
[1]McLean Hosp., Belmont, MA; [2]ExQor Technologies, Boston, MA

Abstract: Objective: Magnetic Resonance Imaging (MRI) offers high spatial resolution but has poor sensitivity for visualization of molecular targets. Superparamagnetic iron oxide (SPIO) contrast agents along with antibodies are used to improve MRI sensitivity and molecular targeting, but they cannot cross an intact blood-brain-barrier (BBB) limiting their use. Our goal was to enable MRI molecular imaging using novel clathrin-based nanoprobes carrying SPIO and

antibodies, which noninvasively pass an intact BBB, to target dopamine transporters (DATs). **Methods**: Clathrin triskelia (CT)-nanoprobes were synthesized by conjugating anti-DAT antibody and SPIO to CT using polyethylene glycols (PEGs) at 1:1:1 molar ratio. Adult male mice or rats were given saline or CT-nanoprobes intranasally (68 pmol, 50 µL). Four hours later, their brains were collected for iron staining or *ex-vivo* MRI. Voxel-wise R_2* relaxation rates were obtained using a series of gradient-echo images (TR=1.5 s, TE=3.2, 4, 5, 6, 7, 8, 9, 10 ms; 128x128 in -plane matrix; 0.2 mm resolution; 64 slices at 0.5 mm thickness; 7 averages). R_2* values in the striatum (STR), substantia nigra (SN) and visual cortex (vCTX), a control region with low DAT expression, were calculated. **Results**: The iron stained brain slices showed an accumulation of CT-nanoprobes in brain regions rich in DAT (e.g., STR). MRI studies revealed that R_2* values were significantly higher in the STR ($p=0.0010$) and SN ($p=0.0007$) compared to vCTX in animals that received CT-nanoprobes, but not in saline treated animals. CT-nanoprobes significantly increased R_2* in the STR ($p<0.0001$) and SN ($p=0.0002$) compared to saline without significantly altering R_2* in the vCTX. **Conclusions:** CT-nanoprobes noninvasively delivered SPIO contrast agents along with anti-DAT antibody to the mouse brain, enabling detection of DAT using MRI. These preliminary results merit further investigation into the use of clathrin as a new theranostic for noninvasive molecular brain imaging and targeted drug delivery.

Title: Transparent nanoporous gan for optoelectronic neural interface to the brain networks

Authors: *J. LEE[1,2]
[1]West Virginia Univ., Morgantown, WV; [2]WVU Rockefeller Neurosci. Inst., Morgantown, WV

Abstract: Over the past decade, advances in optogenetic techniques have opened new possibilities for studying a wide range of neuroscientific problems and brain functions. While recently, a number of devices have appeared for advancing optogenetic methods, researchers are

still unable to simultaneously apply spatio-temporally controlled multispectral optical stimulation with electrophysiology. The major challenge is finding a material with the appropriate electrical conductivity and optical transparency (or active light source).Here, we report the optical and electrical characteristics of a nanoporous GaN layer as a new class of optoelectronic neural probe. A fully transparent and electrically conductive n-GaN layer was epitaxially grown by MOCVD and various nanoporous structures were prepared by an electrochemical etching process in acid (e.g., oxalic or nitric acid). While the optical refractive index is precisely controlled by changing the pore size and ratio with doping concentration and applied voltage, the electrical property remains conductive. Compared to the unmodified n-GaN process, NP-GaN shows improved electrical properties in electrical impedance spectroscopy and cyclic voltammetry measurements. We demonstrated its multiple optical and electrical functionality for compact multisite optical/electrical stimulation and simultaneous electrical recording of neural activity in in-vivo mouse model.

Title: Transparent microelectrode arrays for simultaneous high-density electrophysiology, electrical stimulation and two-photon imaging

Authors: *P. ARTONI[1], Y. QIANG[2], K. SEO[2], S. CULACLII[3], V. HOGAN[1], W. LIU[3], H. FANG[2], M. FAGIOLINI[1]
[1]F. M. Kirby Neurobio. Ctr., Boston Children's Hospital, Harvard Med. Sch., Boston, MA; [2]Dept. of Electrical and Computer Engin., Northeastern Univ., Boston, MA; [3]Dept. of Bioengineering, Univ. of California, Los Angeles, CA

Abstract: Electrophysiology and Calcium (Ca^{++}) imaging are two complementary physiology techniques heavily adopted *in vivo* to study brain activity. While the first has great temporal precision, the latter has excellent spatial and cellular resolution. Significant attention has been given to the study of LFP/EEG oscillations in the time domain as different frequency bands of

the LFP/EEG reflect the interaction between different neuronal populations. Two-photon imaging, on the other hand, allows the study of Ca^{++} transients of large networks with cell resolution capabilities. Combining these two powerful techniques would represent a significant advance in our ability to dissect how network activity is generated and propagates across brain region in health and disorders. To achieve such goal transparent microelectrodes arrays (transparent MEAs) would be ideal. However, scaling down the size of the electrodes in a microelectrode array to allow dense spatial recordings is very challenging when the electrodes and the interconnections have also to be transparent for imaging. Here we developed a nanomesh composite structure with bilayers of Au/PEDOT:PSS to allow high transparency for imaging while with low impedance for high-performance LFP/single-unit recordings, by leveraging the existing from multi-decade-long development and in *vivo* application of commercial MEAs. We were able to generate microelectrodes with 130 kΩ at 1 kHz for 20-μm-diameter microelectrodes, which are comparable to the performance of microelectrodes in non-transparent, Michigan-style arrays. This approach also allowed high transparency of the film and high conductance on the wiring itself between each electrode and the recording system. The electrodes were tested for stimulation and for online artifacts rejection, together with a state-of-the-art wireless recording. The newly generated transparent MEA were implanted in adult mice and LFP, multi-unit, and single-unit recordings were acquired simultaneously with epifluorescence or 2-photon imaging in the awake animals. We measured visual evoked responses using a 32-channel flexible and transparent device, along with the concurrent 2-photon imaging of single neurons in the layer 2-3 in the mouse visual cortex. We then evaluated the biocompatibility of the MEAs by ex vivo staining of both the implanted and control cortex for the marker for microglia activation IBA. We did not detect any significant inflammation up to 3 weeks after the surgery. Together our results indicate that these electrodes are scalable to high density, are reliable and can be coupled with the Ca^{++} imaging across different neuronal populations.

Abstract: The last decades have witnessed substantial progress in optical technologies revolutionizing our ability to record and manipulate neural activity in genetically modified animal models. Meanwhile, human studies mostly rely on electrophysiological recordings of cortical potentials, which cannot be inferred from optical recordings, leading to a gap between our understanding of dynamics of microscale populations and brain-scale neural activity. By enabling concurrent integration of electrical and optical modalities, transparent graphene microelectrodes can close this gap. However, the high impedance of graphene constitutes a big challenge towards the widespread use of this technology. Here, we experimentally demonstrate that this high impedance of graphene microelectrodes is fundamentally limited by quantum capacitance. We overcome this quantum capacitance limit by creating a parallel conduction path using platinum nanoparticles. We achieve a 100 times reduction in graphene electrode impedance, while maintaining the high optical transparency crucial for deep 2-photon microscopy. Using a transgenic mouse model, we demonstrate simultaneous electrical recording of cortical activity with high fidelity while imaging calcium signals at various cortical depths right beneath the transparent microelectrodes. Multimodal analysis of Ca^{2+} spikes and cortical surface potentials offers unique opportunities to bridge our understanding of cellular dynamics and brain-scale neural activity.

Title: Different strategies for designing ECoG electrode arrays for functional mapping and brain decoding

Authors: *T. KAIJU[1], M. HIRATA[2], T. SUZUKI[1]
[1]Ctr. for Information and Neural Networks(CiNet), Natl. Inst. of Information and Communications Tech., Suita-Shi, Japan; [2]MEI Center, Osaka Univ., Endowed Res. Dept. of Clin. Neuroengineering, Suita, Japan

Abstract: Recently, electrocorticography (ECoG) is being used to map cortical functions in clinical situations as well as for decoding brain signals to build brain-machine interface (BMI) systems. An ECoG electrode array contains multiple channels on its surface; however, consensus regarding their ideal designs, such as the optimal diameter and spacing of these channels, has not been reached yet. To use ECoG for functional mapping, it is important to delineate potential distribution over the electrode surface; however, to use ECoG for decoding brain signals, it is more important to accurately estimate variables of interest (e.g. specific joint angle). These two purposes are qualitatively different; thus, the optimal design of an ECoG array might not be the same for both. In this study, we investigate optimal electrode design for both purposes. Somatosensory evoked potentials (SEP) elicited by electrical stimulation of different body parts were simulated in an area of 10 × 10 mm^2 by an evoked potential model and additive noise. We compared decoding accuracy of stimulated body parts under the assumption that the SEP signal was recorded by the electrodes which had different sizes of channels (500 × 500 μm^2 to 10 × 10 mm^2). We also recorded SEPs from monkeys, elicited by electrical and vibrational stimulation of the fingers by using a high-density ECoG array (96 channels, channel size: 350 μm × 350 μm; inter-electrode distance: 700 μm). The simulation results show that if the number of channels and the surface area of an array are fixed, smaller channel sizes will allow for more accurate decoding of brain signals. On the other hand, this improvement in accuracy depends on the amplitudes of the simulated evoked responses. It was also found that the recorded amplitude of the evoked responses become larger when using electrodes with smaller channel sizes. The actual data derived from monkeys support these results.The results suggest that a smaller channel size may result in an increased signal-to-noise ratio of cortical responses and an improvement in prediction accuracy. However, in an electrode array with small channels, the channels are normally placed further apart, and this makes it difficult to delineate global responses over the array. We conclude that in our research setting, a relatively large channel size (e.g. 2 × 2 mm^2, if there are 25 channels in 10 × 10 mm^2) is optimal for mapping cortical topography, but a smaller channel size (e.g. 500 × 500 μm^2) is optimal for brain-signal decoding if an electrode is optimally placed.

Abstract: Microelectrodes provide a direct access to study brain activities electrically from the external world, which has advanced our fundamental understanding of brain functions. However, they, typically based on micro-wires or silicon, inevitably trigger tissue response and fail to perform during the long-term implantation, due to huge mechanical mismatch with delicate brain tissues and biocompatibility issues. Therefore there is a pressing need to transform the materials from traditional inorganic materials toward biocompatible and functional organic ones. In the previous studies, we have pioneered to leverage thermal drawing process to fabricate flexible and biocompatible polymer fibers, which can be utilized as neural interfaces. These fibers are entirely based on polymers, integrated with multi-functionalities and have demonstrated stable chronic performance over the extended period of implantation. However, due to the low electrical conductivity of polymer materials we chose as electrode, i.e., carbon loaded polyethylene (CPE), the recording site had to be sufficiently large to maintain the moderate impedance for capturing single-neuron activities. Therefore, there has been ongoing push for developing new polymer composite materials with improved electrical performances. In the meantime, they should be much reduced in size, more flexible and also reasonably robust. Here we report the development of a new composite electrode with carbon nano fibers(CNF) doping into CPE. We demonstrated that in situ CNF unidirectional alignment can be achieved during the thermal drawing, which contributes to a drastic improvement of electrical conductivity by 2 orders of magnitude compared to a conventional polymer electrode, while still maintaining the mechanical compliance with brain tissues. The resulting fiber has a miniature

footprint, including a recording site with a reduced size comparable to a single neuron and maintained impedance that was able to capture neural activities. Its stable functionality as a chronic implant has been demonstrated with the long-term reliable electrophysiological recording with single-spike resolution and the minimal tissue response over the extended period of implantation in wild-type mice. We can further integrate these new organic microelectrodes with optical waveguides and microfluidic channels within a single fiber to realize multimodal study of brain activities. In addition, this organic electrode could also be further developed for biomolecule sensing. Technology developed here can be applied to basic brain studies as well as clinical implementation for neuro-rehabilitative applications.

Title: More precise and complex braided microelectrodes for neural interfaces

Authors: *T. KIM[1], S. F. GISZTER[2]
[1]Neurobio. & Anat., [2]Dept Neurobiol & Anat, Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Since SFN 2008, we have tested the concept of highly flexible braided microelectrodes which comprise interwoven ultra-fine microwires (9.6μm diameter wire) in a tubular braid. These form a microelectrode array for electrophysiological applications such as neural interfaces. Due to highly flexible mechanical properties and the open diamond shaped windows on the braid wall, braided microelectrodes allowed us to record neural signals from the spinal cord in freely moving animals and showed less chronic immune responses and more neural survival in the vicinity of implant. To build more precise and complex micro-braid structures, we have now developed an advanced micro-braiding machine which is a second generation version based on our awarded patent for a micro-braiding apparatus. We rebuilt the 2nd machine in order to produce more precise tubular braids, in a robust and fully automated manufacture and provide more advanced complex braiding options. We redesigned mechanical components for safer wire handling, and smoother, but faster processing and developed our own electronic devices and a PC control program to control the 28 stepper motors used in braid plate actuation independently and automatically. This new machine can handle 12 single or bundle

groups of strands (Vs. 6 single strands by the 1st prototype machine) independently so that it can produce both complex tubular microbraid structures with 12 single strands, and also complex varying tubular braid structures. By controlling braiding directions the machine supports combinatorics applications, which can increase yields of neural recording via combinations of multiple recording sites on a single wire and precise juxtapositions of multiple recording sites on multiple wires. The automation of Z axis with 0.4µm resolution for the max 400mm travel stroke along the braid axis allows a realized braid pitch that is specific and consistent along the length of a braid and the maximum length of braid structures can now be up to 40cm for larger animal applications. With the 2nd micro-braiding machine, we not only manufacture more precise and complex braided microelectrodes in easier, more reliable and faster ways, but also potentially extend the use of braided microelectrodes to various different electrophysiological applications including combinatorics, peripheral nerve interface as intrafascicular electrodes, deep brain research in a larger animal, spinal implants, etc. We plan for the braided microelectrodes distribution for test applications in cooperation with other neuroscientists and neural engineers in various fields, and with potential for future clinical application.

Abstract: Despite decades of research into the function of neuronal oscillations, we still lack an understanding of their mechanistic functions. One possible explanation is that most studies aimed at uncovering the function of a given oscillation still use arbitrarily defined and sometimes

overlapping frequency bands. To remedy this, we set out to revise the taxonomy of brain oscillations based on their thalamocortical circuit mechanisms. We examined rhythmic neuronal activity patterns in multi-scale neuroelectric activity of several cortical regions (auditory and motor), thalamic structures (relay nuclei, thalamic reticular nucleus and pulvinar), and the dorsal striatum of non-human primates. We analyzed frequency specific effects on cell type specific neuronal activity as well as functional and effective connectivity in the dataset without any prior assumptions to classify neuronal oscillations solely based on their spatiotemporal fingerprints, and to infer the underlying circuitry generating each distinct oscillatory class. We then incorporated a computational modeling approach to refine the rudimentary circuits defined by electrophysiological recordings. The analyses of concurrent electrocorticographic (ECoG) or electroencephalographic (EEG) recordings of neuronal activity enabled us to identify macroscale markers of the distinct thalamocortical oscillatory patterns and compare these to motifs of human ECoG and EEG recordings.

Abstract: Understanding the information processing achieved by neural microcircuits will require recordings from large numbers of interconnected neurons. Although neural devices with large numbers of electrodes have become an important neuroscience tool, they are typically not suitable for this goal. To achieve the stiffness needed to penetrate into the brain, each element

typically has a width of at least 25-100µm (with cross-section in the thousands of μm^2). This large foreign body causes substantial direct mechanical damage and is also detected and rejected by the brain's immune system. The immune reaction leads to loss of neurons in the vicinity of the electrodes, one factor that frequently curtails the duration of chronic neural recordings. Furthermore the spacing between elements must be large to avoid total destruction of the tissue (for example, in a standard Blackrock array contacts are separated by 400µm). Finally, large devices must generally be removed from the brain before processing the tissue for histological analysis, impeding the ability to visualize recording sites within intact circuits. Here we report next-generation silicon-based neural probes at cellular-scale (5x10µm cross-section), with ultra-high-density packing (as little as 66µm between shanks) and 64 or 256 closely-spaced recording sites per probe, distributed across 32 shanks. The relatively short (500µm) distal portion with cellular-scale cross-section is coupled to a more robust upper portion (far from the recording sites). The fabrication process is based on the Michigan probes process with extensions to integrate stiffeners and e-beam lithography, allowing for high density interconnects. We show that these probes can achieve stable, chronic, *in vivo* single-unit recordings from superficial or deep brain structures in freely-moving rats. Gliosis and neuronal loss were greatly reduced compared to prior silicon probes. In a preliminary recording from primary motor cortex, 149 units were simultaneously detected and large single-units were still observed after 143 days of implantation. For each unit, an average of 37 other units were recorded within a 300µm radius, close enough to be directly interacting partners. Furthermore, we demonstrate a slice-in-place approach for the precise registration of the recording sites relative to adjacent neurons and to anatomical features. This scalable technology provides a valuable tool for the examination of information processing within neural circuits, and potentially for human brain-machine interfaces.

Title: Design and development of ultrathin microelectrode arrays

Authors: *J. O. USORO, F. DEKU, J. J. PANCRAZIO, S. F. COGAN
Bioengineering, The Univ. of Texas at Dallas, Richardson, TX

Abstract: Current state-of-the-art intracortical electrode arrays can record useful signals for cortical mapping as well as for control of brain-machine interfaces (BMI). However, reported mechanical failure modes suggest that these devices lack the mechanical/electrical stability needed for chronic applications. Amorphous silicon carbide (a-SiC) intracortical microelectrode arrays (MEA) have shown promise in being used as chronically implantable devices for recording extracellular neural activity. A-SiC is well tolerated in the cortex, resistant to corrosion, and exhibits flexibility as a thin film, which may help mitigate insertion and micromotion-induced foreign body response. Here, we report the design and fabrication of ultrathin microelectrode arrays tailored for long-term neurobehavioral studies in rats. The a-SiC MEAs were fabricated using standard thin-film fabrication techniques. Films of a-SiC were deposited by plasma enhanced chemical vapor deposition and metal traces were formed through sputter deposition and patterned through lift-off photolithography. Electrodes are 200 μm^2 and coated with a sputtered iridium oxide film to reduce impedance. Electrical connection to the MEAs was achieved by mounting an Omnetics connector directly on the array. The shanks are 2 mm in length with 8 electrodes per shank. Shank pitch is 200 µm in an effort to enable recordings from individual cortical columns. The shanks are 6 µm thick and 53 µm wide so that at least one dimension falls within the ultra-thin range for probes, which have been shown to reduce glial scar formation. Initial experiments to test the utility of this novel technology in a behaving rat model are underway. MEAs will be assessed by recording single unit activity (SUA) and performing electrochemical impedance spectroscopy over 16 weeks from 4 devices implanted in the motor cortex of rats which have been previously trained to perform a knob supination task. From previous studies, we expect to resolve SUA on the order of 50-200 µV with an array yield of active channels similar to, or greater than the 60% seen in our acute experiments. A decoding algorithm correlating the neural activity and supination task will consist of linear filters and is expected to perform with accuracy similar to that seen in literature. Preliminary data from the pilot study will be presented at the conference. The results from this pilot study will demonstrate the feasibility of a-SiC MEAs for chronic recording and decoding applications in a behaving animal model. Moreover, they will inform future studies of neural decoding using a-Sic MEAs in terms of device geometry, performance, and single unit stability.

Title: Long-term evaluation of a parylene-based multi-electrode array for recordings from the hippocampus of behaving rats

Authors: *H. XU, W. JIANG, A. HIRSCHBERG, K. SCHOLTEN, E. MENG, D. SONG
USC, Los Angeles, CA

Abstract: Obtaining single-unit activities from multiple neurons in neural networks from behaving animals is crucial for the understanding of cognitive functions of brain circuits and is also the foundation to develop effective cortical prosthetic devices. However, severe immune response caused by micromotion between stiff implants, such as microwire electrode array, and surrounding brain tissue often limits the signal quality and lifetime of penetrating devices. To reduce the stiffness mismatch between recording devices and brain tissue, we developed a flexible, polymer based multi-electrode array for recording single neuron activities from multiple sub-regions of the rat hippocampus, a major subcortical structure that closely associates to the formation of new long-term memory. Parylene C, a biocompatible polymer, was used as the structural and insulation material of the multi-electrode array. 64 Platinum (Pt) recording electrodes were placed in groups along eight individual shanks to conform to the distribution of hippocampal neurons. By supporting the top half of the probe array with dissolvable polyethylene glycol (PEG), the effective length of the Parylene array was temporarily reduced and bucking threshold of the array was increased and enabled the straight insertion of the flexible array into the desired hippocampal region without introducing extra shuttle devices into the brain tissue. Over forty units were recorded with Parylene arrays from acute implantations. Signal to noise ratio (SNR) of spike activities recorded with the Parylene array was comparable to that of the commonly used microwire electrode array. Next step, we will evaluate the performance of the Parylene array over long term. The Parylene array will be chronically implanted and neural recordings will be collected from free moving rats. Signal qualities, including units yield, SNR and signal stability over time will be examined and compared with recordings collected with microwire electrode arrays. Long-term tissue respond to the implants will also be tested through immunohistochemistry stains.

Abstract: Long-term recordings of extracellular spikes by chronically implanted electrodes in vertebrate brain remain an unsolved challenge. To extend the recording time and improve the quality of the recorded signals we prepared scalable single shank polyimide (PI) platforms (280 µm wide and 16 µm thick). The platform is subdivided into a distal perforated part and a solid proximal part. The perforated part (opening area = 45 - 65 µm by 8 µm) of the PI platform tapers to form a sharp tip. The PI platforms were composed of 2 or 16 planar electrodes (Ø = 25 µm) located along the edges of the platforms tip. Electrodes were implanted into the rat primary somatosensory cortex (S1) or to frontal associative area (FrA). Immunohistological cryosections of the PI platform together with the surrounding tissue revealed that 2 weeks after implantation, microglia, astrocytes and neurites extended into the perforated platform, leading to apparent local "anchoring" of the brain tissue to the platform. To test the durability and recording quality of the system we conducted weekly telemetric recordings from freely moving rats. The longest recording that we have obtained lasted 8 months (the recordings were terminated because of skin infection). Recordings of the electrophysiological signals for weeks revealed large extracellular action potentials. The recorded amplitudes varied over time without a dominant trend of amplitude decline. This suggests that either the current source was not stable or that the impedance between the current source and the sensing pads was not constant. The immunohistological cryosections of the PI platform together with the surrounding tissue revealed minimal foreign body response. These observations are consistent with the view that the use of perforated PI platform functionalized by polyethylenimine and laminin facilitates mechanical integration of the platform with cortical tissue and thereby supports long-term stable recordings from freely moving rats.

Abstract: For short and long term neural applications, it is desirable to reduce or ideally eliminate the foreign body response to the implanted devices. One way to do so is to minimize the size of the device and thus the bending stiffness of the implant affecting the soft brain tissue. Recent findings in the field of neural engineering have led to the development of ultra-thin and ultra-flexible intracortical electrode arrays, presumably “invisible” for the host tissue and unable to trigger a noticeable immune response in long-term applications. However, reduced probe size comes at the cost of fewer individual electrodes, more challenging handling and fabrication, as well as mechanical properties less suited for chronic in vivo experiments. It is therefore important to better understand which design parameters offer the best trade-off.
In this study, we compare two kinds of polyimide-based electrode arrays which differ only in their width: one kind is only 30 µm wide while the other has a width of 100 µm. Both device types are 12 µm thick and display electrodes 20 µm in diameter, spaced so that they target each one of the six cortical layers. The devices were chronically implanted into the brain of adult rat models and different time points were selected for perfusion and subsequent evaluation and quantification of the differences in the elicited immune response of the brain (via immunohistochemistry). Some of the probes were also used for long term recording of electrophysiological activity. Control devices (i.e. identical but without connector) were used to study the influence of the connector and cement on the short and long term tissue reaction to the implants.
The wider probes (100 µm width) featured a pair of identical electrodes per cortical layer (instead of a single one) with the aim to achieve a better reconstruction of the neuronal configuration and status around the probe. The study’s goal is to systematically investigate the influence of selected geometrical parameters on the performance of thin-film polyimide based neural prostheses in vivo.
Key concept: This study is part of a bigger project which aims to find a clear answer to the question “how small does a neural probe have to be to become invisible for the host tissue and yet to record long term high quality signals?”

Title: jULIEs: Microwire based neural probes for localized extracellular recordings and stimulation in the mouse brain

Authors: *R. R. RÁCZ[1], M. KÖLLő[2], T. ACKELS[1], G. RACZ[1], C. BULZ[1], T. WARNER[1], A. SCHAEFER[1]
[1]Neurophysiol., The Francis Crick Inst., London, United Kingdom; [2]UCL, London, United Kingdom

Abstract: Research into brain dynamics at biophysical, circuit and systems level is of fundamental importance for the advancement of our understanding on how the central nervous systems works and drives individual behaviour. Micro-fabricated charge sensing extracellular probes are considered one of the most powerful techniques capable of addressing cell populations in different brain regions at relevant read-out frequencies and resolution. Although promising, microfabricated devices have limitations in terms of shank size and overall geometry, recording fidelity and available modalities or lateral site density and channel count. To overcome these challenges, here we introduce a nanomaterials modified microwire platform with superior flexibility capable of extracellular recordings and stimulation of neural activity. These modalities are enabled by functionalization of the inert high specific surface recording site with a high charge storage capacity material packaged to fit industry standard read-out and stimulation electronics. At the core of the jULIEs probes are atomically-flat-shank microwires with diameters <25µm and sites ranging between 1 and 10 µm ± 0.2µm, resulting in minimal stray capacitances (<0.1pF/mm length) and superior coupling with the extracellular space. Microwire tips are angle-polished to <30° to facilitate insertion and bi-directional movement in tissue

during unit localization. Charge capacity and interfacial impedances are controlled and adjusted by modifying recording sites with nanosized IrO_x to achieve coupling capacitances above 1pF/μm^2 at ~1kHz. Cyclic voltammetry and electrochemical impedance spectroscopy between 1Hz and 200kHz around the open circuit potential in 150mM saline has been used to characterize the electrode-tissue interface. jULIEs neural probes containing 16, 32, 64, 128 channels have been packaged with connectors compatible with Intan RHD2000 amplifiers and tested in the olfactory bulb (OB) of anaesthetized mice (4-6 weeks old, Ketamine/Xylazine anesthesia). Under 2p imaging guidance we performed localized stimulation in the OB of Tbet-GCaMP transgenic mice using a NLA8000A stimulation isolator. Action potentials were reliably recorded with amplitudes up to 1.6mV and activity has been reproducibly evoked by electrical stimulation at current levels between 20 and 50µA. Thus, the combination of nanostructured high specific surface material with high charge storage capacity IrOx provides a versatile platform for minimally invasive, highly localized neural recordings and stimulation.

Abstract: Long-term recording of neuronal activity from freely behaving rodents over extended periods is critical for basic and applied brain research. The recording and stimulating qualities of the majority of the currently used in vivo multielectrode array (MEA) platforms deteriorate over time due to chronic immune response of the brain to foreign implants, the so called brain foreign body response (FBR). Earlier studies suggested that the use of perforated MEA platforms may help improve the duration and recording quality of implanted devices. Nevertheless, the impact

of MEA-platform perforation on the duration of recording in freely behaving rat and the underlying structural relationships formed between the brain tissue and the perforated platform were not studied. To study these parameters we prepared perforated polyimide (PI) platforms (280 µm wide, 16 µm thick and pore sizes of 8x45-65µm) with 2 to 16 planar microelectrodes (Ø 25 µm) located along the edges of the platforms tip. Weekly telemetric recordings from freely moving rats revealed large field potentials for months (currently the longest recording period is 8 months) without deterioration. Immunohistochemical confocal imaging of cross sections through the brain tissue together with the PI-MEA platform (two weeks and 8 months after the platform implantation) revealed that the overall density of microglia and astrocytes was only slightly elevated adjacent to the PI-MEA perimeters. No large-diameter neuronal "kill zone" was observed. Occasionally neuronal somata and neurites appeared to form direct contact with the MEA surface. Importantly, neurons branches along with astrocytes and few microglia extended into the platforms perforations leading to local “anchoring” of the brain tissue to the MEA. The long-term electrophysiological recordings using the perforated PI-MEA platforms together with the observed ingrowth of neurites, astrocytes and microglia into the perforated platform suggest that beside for the reduced FBR the ingrowth of brain tissue into the perforation significantly improve the long-term recording stability.

Title: Simultaneous intra- and linear extracellular recordings with corresponding morphology: Towards a ground-truth data for multichannel electrodes

Authors: *D. MESZENA[1,2], I. PAL[2], B. P. KEREKES[1], G. MARTON[2], K. TOTH[2], L. WITTNER[2], Z. SOMOGYVARI[3], I. ULBERT[2,1]

Abstract: An integrative experimental method is presented for simultaneous recording of extra- and intracellular activity. In spite of the widespread use of multi-channel extracellular electrodes, very limited knowledge is available about the intracellular validation of these signals. Whole-cell patch clamp recordings were used to detect intracellular single cell activity, in rat hippocampal slices, *in vitro*. Simultaneous extracellular signal was detected from the vicinity of the same neuron with a novel, 32-channel laminar edge-probe. Electrophysiological measurements were completed with subsequent histological analysis. Dendritic and axonal morphology of the intracellularly recorded and filled cell was revealed by three dimensional reconstruction performed with the aid of the Neurolucida system. The presented method allows the investigation of single cell contribution on the extracellularly recorded signals. Furthermore, our experimental system let us determine the exact Euclidean cell-electrode distances. The knowledge about the spatial location of the cell compartments and the electrode contacts can help to determine the impact of single cell activity on extracellular recordings. The simultaneous, multimodal signals recorded with our system can yield additional information for various model-based calculations of neuronal dynamics.

Title: A scalable active pixel electrode array CMOS-probe for large-scale intracortical recordings

Authors: *F. BOI[1], G. ANGOTZI[1], A. LECOMTE[1], E. MIELE[3], G. MANDELBAUM[4], S. ZUCCA[2], T. FELLIN[2], J. ASSAD[4], B. SABATINI[4], L. BERDONDINI[2]
[1]Neurosci. and Brain Technologies, [2]Inst. Italiano Di Tecnologia, Genova, Italy; [3]Univ. of Cambridge, Cambridge, Italy; [4]Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Monitoring neural signals at cellular scale, within and among brain circuits is of the utmost importance to understand how the brain processes information. However, this goal remains challenging and requires the development of neurotechnologies capable of high spatial and temporal recording resolutions over large brain areas. Over the last decade significant advancements in CMOS electrode array devices permit large-scale electrophysiological recordings (in vitro and ex vivo) at sub-millisecond temporal resolution from large

microelectrode arrays (*doi: 10.1039/b907394a*), and this technology has recently started to be transferred to high-density CMOS neural probes. For instance, a CMOS probe with 384 recording channels that can address 960 recording sites was successfully developed (*doi: 10.1038/nature24636*). However, this choice of architecture implies that only a configurable sub-set of electrodes is accessible for recording thus effectively decreasing the density of available channels. In this work, we propose an 'active pixel' solution to achieve true high-density (>1000 electrodes/mm^2) full-frame recordings. A first generation of our probes was designed in a standard 180nm CMOS technology to provide low-power (< 3 mW, well below the limit of 40 mW reported in the literature) circuits for 512 active sensing electrodes (size of 15 µm × 15 µm, centre-to-centre pitch of 29 µm). The design includes in-pixel circuits for amplification underneath each electrode site and on-chip circuits for reading out the whole-array at 30 kHz/electrode using time division multiplexing. For implantation, silicon micromachining techniques were used to shape the CMOS devices (110 µm W × 9 mm L) and to reduce the thickness down to 40-50 µm. Electrodes sites were finally modified by electrodepositing platinum and PEDOT, resulting in pixel impedance below 1 MΩ at 1 kHz. Experimental performances of a first generation of these CMOS probes demonstrate the capability of recording both LFPs and spiking signals in head-fixed anesthetized or behaving mice and the capability to avoid light-stimulation artefacts due to the continuous recalibration of the in-pixel amplifiers. Low-noise performances down to 12 µV rms (full bandwidth up to 10 kHz) can be achieved with optimized in-pixel circuit designs. Furthermore, this technology is eligible for a recently-developed real-time closed-loop setup that is able to manage recording/stimulating procedures. In perspective, our approach allows to investigate modular probe geometry and the integration of these CMOS-probes with ultra-low power wireless circuits that we have recently reported (*doi: 10.1109/TCSI.2017.2762159*).

Title: Simplifying stereotaxic insertion of cannula and electrodes using 3D printing of surgical guides designed with freely available software

Authors: *R. W. SIKES[1], A. F. PAQUETTE[2]
[1]Dept Physical Therapy, Movement and Rehab Sci., [2]Physical Therapy, Movement and Rehab Sci., Northeastern Univ., Boston, MA

Abstract: Stereotaxic guided procedures are regularly used in preclinical neuroscience to make injections and record neuronal activity in the cortex and deep nuclei. This involves anesthetizing and mounting animals stereotaxic frame using ear bars and a nose clamp and positioned carefully. After exposing the skull, precise micromanipulators are used to mark the skull at locations relative to the skull sutures, providing access to the target structure. Small hole(s) are carefully drilled through the skull without damaging underlying tissues. Then manipulators are used to insert a guide cannula through the hole to the depth of the target structure, and the cannula(e) are affixed to the skull using dental acrylic secure the cannula(e) to small screws inserted nearby. In skilled hands, stereotaxic insertion of a single cannula can be made with good precision in a short time. But as the number of target structures increase, it becomes increasingly difficult and time consuming to precisely position and anchor the cannula to the skull manually. Many excellent commercial devices have been created to simplify precise insertion of multiple cannulae and electrodes using standard production methods. With the emergence of 3D printing, methods have been published showing how to produce remarkably complex implants and surgical guides that can be customized and printed economically. Customization of these 3D printed models, however, requires skill in manipulating and editing 3D surfaces.
Here, we present a method that simplifies the creation and customization of 3D printed surgical implants designed for insertion of guide cannula. Some 3D printed implants are custom fitted to the contours of the skull with MRI or other image and sophisticated 3D printing design software, requiring a depth of skill and knowledge to design and edit the implants. For the relatively flat skulls of rodents, we simplify the design process by modeling the stereotaxic atlas coordinate system for a standard weight animal into the dimensions of a single flat implant that is stereotaxically attached to the skull. This simulates the process of stereotaxic placement but removes the need to microposition each cannula independently. Furthermore, 3D design requires only XYZ plane movement and scaling. Our inexpensive, autoclavable design can be easily edited using free or inexpensive 3D design software and has a wide range of applications in preclinical research.

Abstract: A challenge of using minimally invasive surface electrode arrays is that mapping of neuronal circuit activity onto electrophysiological signals detectable from the cortical surface is poorly understood. To address this challenge, we combined surface and laminar electrophysiological recordings to achieve sufficient spatiotemporal information for reconstruction of regional variations in 3D current flow between the intra- and extracellular compartments. This information can then be used for prediction of the most plausible circuit activity. In addition, we combined these electrophysiological recordings with calcium imaging in layer 5 pyramidal cells to evaluate the contribution of active dendritic calcium conductances in these cells to the extracellular potential. All experiments were done in the mouse Barrel cortex in vivo under general anesthesia. Our surface electrode array was composed of 32 channel microelectrodes (pitch=200 υμ, diameter=20 um) and made of a semiconducting polymer, PEDOT:PSS. The substrate consisted of a biocompatible and transparent parylene C layer with a total thickness of 5-10 um. These PEDOT:PSS/Parylene surface electrode arrays provided outstanding optical transparency allowing 2-photon imaging throughout the cortical thickness (using excitation wavelengths longer than 1100 nm). The laminar electrode array, consisting of 23 channels spaced by 100 um, was inserted along the cortical depth axis, immediately adjacent to the surface array. To generate well controlled localized neuronal activity, we stimulated single whiskers on the mouse snout using a piezoelectric stimulator. Laminar (depth) profiles of extracellular potentials at different distances from the principle barrel column were estimated by keeping the laminar electrode in place, and stimulating single whiskers 1-4 columns away. In this way, we obtained an average 3D volume estimate of the extracellular potential induced by a single-whisker stimulus. In addition, single trial analysis in response to repeated single-whisker stimuli revealed variability not only in the amplitude but also in the spatial location of spiking and local field potentials. Our study illustrates the power of novel neuroscience tools allowing 3D electrophysiological data acquisition and integration with optical imaging modalities, opening the door for mechanistic studies of neuronal circuit dynamics during stimulus-induced and ongoing (spontaneous) neuronal activity that until now have been out of reach.

Title: Extracellular matrix enhances neural network formation and activity on multi-electrode array

Authors: *D. LAM[1], H. A. ENRIGHT[1], S. K. G. PETERS[1], J. OSBURN[1], A. P. DE OLIVEIRA SALES[2], J. E. CADENA PICO[2], D. SOSCIA[2], K. KULP[1], E. K. WHEELER[2], N. O. FISCHER[1]
[1]Physical and Life Sci. Directorate, [2]Engin. Directorate, Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: The brain's extracellular matrix (ECM) is a highly organized structure that has a heterogenous molecular composition (e.g. collagen, proteoglycans, glycoproteins and glycosaminoglycans) and accounts for approximately 20% of the total volume in the adult brain. ECM acts as a physical barrier to reduce the diffusion of soluble and membrane-associated molecules and cell migration. Additionally, it has important functions during development, in synaptic plasticity, and following injury. While studies have investigated the effects of individual ECM molecules in 2D and 3D in pure neuronal cultures or co-cultured with glia, it is important to recognize the complexity of ECM in the brain. In this study, we examined the effects of decellularized rat brain ECM and a commercial human ECM cocktail, MaxGel, on a co-culture of primary neuron and astrocytes *in vitro*. We compared electrical activity of the neuronal networks grown with or without ECM interfaced to a PDL-coated Multi-Electrode Array (MEA) device. The MEA devices present a noninvasive experimental approach for long-term interrogation of neuronal networks. We have recently developed a complex culture system on a MEA device using primary rat neurons and glial cells (i.e. astrocytes, oligodendrocyte precursor cells). Increasing the cellular complexity in culture has shown firing responses (e.g. firing rate, burst events) and synchronized activity at earlier stages in culture compared to neuronal cultures alone. Here, we also observed a similar response (i.e. early firing responses, increased active electrodes) by increasing the molecular complexity of the extracellular matrix. Flow cytometry and immunocytochemistry were used to identify the cell-type specific populations, cell morphology, and the phenotypic state of astrocytes. We report that the 2D construct represents a

reproducible and reliable method to study the complex neuronal-astrocyte network and can be further enhanced to recreate a 3D tissue model relevant to the brain.

Abstract: Microelectrode arrays on flexible substrates are promising for mechanically compliant neural interfaces and for large-scale electrophysiological recording from intact brains. Recently, there has been a great interest in devising flexible microelectrode arrays that can achieve cellular resolution. Here, we introduce a new biocompatible microelectrode array composed of platinum nanorods (PtNRs) on micrometer thin parylene C layers fabricated using scalable microfabrication processes. We show by extensive electrochemical testing that PtNRs exhibit 16 times larger charge injection capacities (CIC) and 10 times lower impedances compared to planar Pt. The devices are compatible with standard in-hospital sterilization techniques with minimal degradation in their performance. We carried out in-vivo characterization in starling birds and measured action potentials from the cortical surface with electrode diameters of 20, 40, and 100μm. Overall, we believe that the new PtNR microelectrodes with facile integration with standard microfabrication can advance neural probe technology by offering outstanding features with regard to next generation chronic neural stimulation and recording from the central and peripheral nervous systems.

Title: A modular high-density 294 channels μECoG system on macaque vlPFC for auditory cognitive decoding

Authors: *C. CHIANG[1], J. LEE[2], C. WANG[1], A. J. WILLIAMS[1], Y. E. COHEN[2,3], J. VIVENTI[1]
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Otorhinolaryngology, Univ. of Pennsylvania, Philadelphia, PA; [3]Bioengineering, Univ. of Pennsylvania, Pennsylvania, PA

Abstract: Background: Discerning sound is a complex neurocomputational problem because the stimuli of interest in the real world change simultaneously along multiple dimensions and are often mixed together with other environmental sounds. It is not well understood how the brain transforms a mixture of acoustic stimuli into distinct perceptual representations. There is broad consensus that auditory perceptual decisions are mediated by the ventral auditory pathway. At the later stages of this pathway, including the ventrolateral prefrontal cortex (vlPFC), neurons can encode decision outcomes. However, the spatiotemporal resolution of the neural code that underlies perception and cognition over this region is still unclear; and until recently, it was not possible to record from large numbers of brain sites simultaneously. We, therefore, developed a modular high-resolution electrode array system with long-term viability and used it to study the information that could be decoded from vlPFC micro-electrocorticographic (μECoG) signals during an auditory detection task.
Method: We molded three separate μECoG arrays into one with silicone and implanted this high-density modular system in one adult male rhesus macaque. A custom 3D-printed titanium chamber was mounted on left hemisphere using MRI-based targeting (BrainSight software, Rogue Research). The molded 294-contact polyimide μECoG array (30 μm total thickness; 229 μm diameter gold contacts; 610 μm contact spacing; 10.4 by 11 mm^2 sensing area) was implanted subdurally over vlPFC. Intan headstages and an OpenEphys recording system were used to record μECoG activity while the monkey participated in a “hearing-in-noise” task in which they reported hearing a “target” vocalization from a background “chorus” of

vocalizations. We titrated task difficulty by varying sound level of the target vocalization, relative to the chorus.
Result: We present a decoding analysis of the μECoG signal relationship to behavior with respect to spatial resolution, neural frequency bands, time, and cognitive/behavioral state. We found that individual channels varied significantly in their ability to decode various behavioral parameters (e.g., hits versus misses): some channels were at chance, whereas others performed significantly better than chance. When we considered those channels that performed better than chance, we found that, as we increased the number of channels, decoding performance improved. This improvement was seen across a variety of neural frequency bands.

Title: A high-density carbon fiber intracortical electrophysiological recording array technology

Authors: *T. L. MASSEY[1,2], S. R. SANTACRUZ[3], J. F. HOU[2], K. S. J. PISTER[2], J. M. CARMENA[4], M. M. MAHARBIZ[5]

Abstract: The ideal intracortical electrophysiological recording array would have a breadth of characteristics, including minimal adverse biological response, full-volume sampling of single-unit activity, and scalability to a large number (>thousands) of recording electrodes. No device yet meets all of these criteria. This work presents significant steps toward such a device, demonstrating a high-density 32-channel carbon fiber microwire neural recording array capable of acute in-vivo recording of single-unit extracellular potential. Departing from the in-plane architectural paradigm of conventional microwire-style neural recording arrays, a two dimensional array substrate is microfabricated in silicon and 5 μm diameter carbon fiber monofilaments are threaded through holes in that silicon substrate to create an array of carbon

fiber extracellular recording electrodes; the method can be scaled to an arbitrary number of recording electrodes. In addition to scalability, this device architecture enables electrode pitch four times finer than the state of the art among microwire arrays for extracellular electrophysiology. The fine diameter of the carbon fibers affords both minimal cross-section and nearly three orders of magnitude greater lateral compliance compared to traditional 25 μm tungsten microwires, with these features serving to minimize the adverse biological response of the implanted electrodes.
The substrate microfabrication and array assembly processes are robust and repeatable, and with the introduction of a robotic system to automate the insertion of carbon fibers into the through-silicon vias with submicron precision, the processes are fundamentally scalable to an array with a large number of electrodes. A specially formulated isotropically conductive adhesive mechanically and electrically bonds the carbon fiber recording electrodes to the silicon substrate, and post-processing of both the adhesive and the recording sites serves to further lower the impedance for superior electrophysiological characteristics. Acute extracellular electrophysiological recording is demonstrated in M1 in a rat, with single-unit action potentials being recorded on many channels. This carbon fiber microwire intracortical electrophysiological recording array is a promising technology for increasing information density while minimizing the adverse biological response, particularly in applications where microwire arrays are already commonplace.

Title: Open ephys++: High performance open-source firmware, apis, and hardware for closed-loop neuroscience experiments

Authors: *J. P. NEWMAN[1], J. ZHANG[1], J. VOIGTS[2], M. T. HARNETT[3], M. A. WILSON[4]

Abstract: Testing certain hypotheses about neural coding requires experiments that can execute complex closed-loop algorithms on fast timescales. Existing acquisition systems can cope with high data rates or low latencies. However, recording form many channels while maintaining low closed-loop latencies usually requires highly specialized hardware. We present open-source hardware designs, protocols, and programming interfaces that enable sub-millisecond bidirectional communication with arbitrary arrangements of head borne sensors and actuators. This interface allows scientists to implement closed-loop control algorithms entirely in software on a commodity PC. Our architecture is generic and can be used to serialize and control any mixture of sensors over a tiny, easily commutated 2-conductor microcoxial cable. We provide concrete examples of this architecture in the form of next generation multifunction headstages used for rodent tetrode electrophysiology. First are 256 or 64-channel headstage (using neural amplifier chips from Intan Technologies) for use with behaving rats or mice, with integrated FPGA, high-bandwidth data serializer, 9-axis IMU, and 2 or 32-channel LED drivers. Second is an galvanically-isolated PC-housed acquisition board containing headstage deserialization circuitry, digital I/O, and FMC interfacing circuitry. Additionally, we demonstrate seamless integration with the popular UCLA microendoscope. Due to the simplicity, modular nature, and performance of these designs they may prove an appealing generic acquisition backend to support the development of next-generation head-borne sensors.

Title: The effect of contact size on the µECoG signal acquired from the surface of the rat auditory cortex

Authors: *A. J. WILLIAMS, M. TRUMPIS, B. BENT, C. CHIANG, J. VIVENTI
Biomed. Engin., Duke Univ., Durham, NC

Abstract: Micro-electrocorticography (µECoG) is a method of reliably recording brain activity at high-resolution from the surface of the cortex without damaging brain tissue (Viventi et al.,

2011). Currently, µECoG electrodes are designed using a wide range of contact sizes to measure brain activity; however, the influence of size of the recording contact on the signal acquired *in vivo* is still undetermined (Chang, 2015; Khodagholy et al., 2015; Slutzky et al., 2010). This work will show a thorough analysis of the effect of contact size within a µECoG array on signal metrics from acute recordings taken from rat auditory cortex.

A 60-channel gold µECoG electrode array was designed with four different contact sizes of 20, 50, 100, and 150 µm diameter arranged in a grid pattern as shown in Figure 1. The array was fabricated on a polyimide substrate with standard micro-fabrication methods. Subdural *in vivo* recordings were taken from the surgically exposed auditory cortex of anesthetized female Sprague Dawley rats aged 4-6 months. Recordings were carried out in a sound-attenuated chamber with responses to tone pips of 13 frequencies at eight sound pressure levels recorded to reconstruct frequency intensity response areas. Responses to brief broadband click stimuli and *in vivo* impedance for each electrode were also recorded. Acquired neural signals were analyzed using previously established methods evaluating evoked-signal-to-noise ratio (ESNR), spatial resolution, auditory response tuning and decoding accuracy (Insanally et al., 2016; Trumpis et al., 2017).

Preliminary data from epidural recordings has shown no difference between signals acquired using contact sizes, most likely due to the presence of the dura attenuating signals from the brain. In future work, we will repeat the experiment using a subdural preparation and investigate action potentials recorded from the µECoG devices. We anticipate that the ability for the array to record action potentials from the surface of the brain will more strongly depend on the size of the electrode contacts.

Title: Quick and consistent method for stability assessment of microelectrodes

Authors: M. MA[1], T. P. ZANOS[3], M. R. KRAUSE[1], C. C. PACK[2], *T. E. KENNEDY[4]
[1]Neurol. and Neurosurg., [2]Neurol & Neurosurg, McGill Univ., Montreal, QC, Canada; [3]Ctr. for Bioelectronic Med., Feinstein Inst. for Med. Res., Manhasset, NY; [4]Neurol. & Neurosurg., Montreal Neurolog. Instittute, Montreal, QC, Canada

Abstract: Cortical multielectrode arrays (MEA) offer some of the highest resolution technology for detecting clinical user intent for controlling prostheses, such as robotics and functional electrical stimulation. The long term performance of these neuron-machine interfaces (NMI) depends on signal recording stability. This project analyses over seven months of Utah Array recordings from inferotemporal and prefrontal cortices of adult macaque monkeys, to quantify both the gradual decline of individual channels and implant level failures. Stability assessment was first performed by counting stable units, via regular spike sorting; and subsequently by counting stable channels, via a novel rule-based method applied to the firing rate distribution. The latter relies only on the timing of above-threshold events - befitting newer NMI decoding techniques, and hence is both quick (fully automated) and consistent (not requiring subjective steps involved in spike sorting and matching between single-units). The method is implemented in Matlab and enables efficient and objective evaluation of future microelectrode technologies.

Title: Electrode array platform for transcutaneous neural recording and stimulation

Authors: *I. P. CLEMENTS, A. B. HARRISON, A. C. WILLSIE, A. J. PREYER, E. A. BROWN, J. D. ROSS
Axion Biosystems, Atlanta, GA

Abstract: Improved capabilities for non-invasive sensing and manipulation of neuromuscular activity would advance areas of clinical diagnostics, therapeutic stimulation, and neural prosthetics. Here we describe a non-invasive, automated platform for targeted monitoring and manipulation of human nerves and muscles. Flexible arrays of transcutaneous electrodes were coupled to a custom-designed IC offering up to 64 channels of simultaneous stimulation and recording. Signals were further conditioned with custom electronics and array-based processing techniques. Neural signals were manipulated and recorded with high precision and sensitivity through conformable, transcutaneous electrode arrays. Array-based stimulation enabled stimulation selectivity without requiring precise anatomical placement. Array-based recordings enabled 2D mapping of neural propagation and longitudinal tracking of nerve signals between sessions. EMG signals were also mapped, with H-reflex and M-wave recruitment curves automatically generated. The developed platform increases efficiency of typical diagnostics, in which bipolar electrodes are repeatedly repositioned by a highly skilled operator. Novel capabilities are enabled, such as automatic anatomical registration, longitudinal monitoring, and 2D spatial mapping of nerve signals to reveal branching or focal slowing. The system is designed for scalable and cost-effective manufacturing. Ultimately, this platform will enable rapid advancements in both neuromuscular research and medical device development, with applications in neuropathological diagnostics, advanced therapeutics, and neural prosthetics.

Title: On the shape and extent of extracellular action potential waveforms across the rodent brain

Authors: *S. CHEN[1,2], J. P. NETO[3], M. PACHITARIU[1], A. R. KAMPFF[3], N. A. STEINMETZ[2]
[1]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [2]Univ. Col. London, London, United Kingdom; [3]Sainsbury Wellcome Ctr., London, United Kingdom

Abstract: Extracellular recording of action potentials is a gold-standard technique widely used to measure neuronal activity with high temporal and spatial precision. However, little is known about the detailed shapes of the extracellular fields associated with the action potentials of various types of neurons, and how these characteristics influence the experimenter's ability to successfully record neurons in diverse brain regions.
Here we used a custom "ultra-dense" electrode array with 255 small (5x5 μm), densely packed (6 μm center-to-center spacing) TiN recording sites, spanning 89x101 μm, to measure these shapes at higher resolution than previously possible. We performed recordings with this probe in urethane-anesthetized rats from five brain regions: isocortex, hippocampus, striatum, thalamus, and cerebellum. We analyzed the data using Kilosort (Pachitariu et al. 2016), a spike sorting algorithm designed to optimally incorporate information from many recording sites that each observe the same neuron, as is the case with these probes.
We observed in all regions that some neurons had broad field extents, detectable at high amplitude across all or most of the recording sites, as expected from recordings with less dense arrays. However, we furthermore observed that in all regions some neurons had extracellular potentials confined to extremely small areas, such that only one or a few sites had detectable action potential amplitudes (>50 μV), implying a total detectable extracellular field extent of ~5-10 μm radius.
We suggest that such small-field neurons may be typically un-detectable by other electrophysiological tools. Arrays with larger sites will not resolve these small fields with detectable amplitude, and the classic technique of isolating neurons by moving a sharp-tipped electrode to stay near the neuron will have difficulty because of the adjustment precision required to keep within a few microns of these neurons. Moreover, these neurons will be particularly susceptible to any movement of the brain relative to the probe (as in electrode "drift"), as small-field neurons will effectively disappear into the gaps between sites and become un-trackable. The existence of neurons with such small fields across the brain may provide a partial answer to the classic "dark matter" problem in neuroscience - i.e. that fewer neurons are observed than expected with extracellular techniques (Shoham et al. 2006).

Title: Translation of PEDOT/Parylene C ECoG microelectrode arrays for recording stimulus driven action potentials in songbirds

Authors: *L. A. HOSSAIN[1], J. HERMIZ[2], Z. ARNEODO[3], M. GANJI[2], N. ROGERS[4], T. GENTNER[3], V. GILJA[2], S. A. DAYEH[1]
[1]Materials Sci. and Engin. Program, [2]Dept. of Electrical and Computer Engin., [3]Biocircuits Inst., [4]Dept. of Physics, UCSD, La Jolla, CA

Abstract: Understanding cognitive processing in intact brains is the subject of intense research efforts to resolve stimulus-evoked activity of individual and networks of neurons across different cortical layers. Traditionally, single unit activity is conveniently recorded with penetrating depth electrodes. But these electrodes cause damage to natural structure and connection in the brain tissue. Recording single unit activity from the cortical surface has been demonstrated recently with low impedance PEDOT:PSS microelectrodes built on thin flexible substrates. Here, we build similar devices with 'through' vias in between the microelectrode contacts and insert depth electrodes to validate and correlate surface recorded activity with activity at underlying cortical layers and demonstrate stimulus-evoked single unit activity at the cortical surface in songbird experiments.
The PEDOT devices were fabricated using a conventional surface micromachining procedure in arrays of 5x6 microelectrodes with 20μm diameter and 200μm center-to-center spacing. The metal lines were embedded in ~2.9μm parylene C on both sides, and the PEDOT:PSS was spun-cast from solution and cured in ambient at 140°C for 1 hour. Electrochemical impedance spectroscopy was used to evaluate the properties of the electrochemical junction and yield of our process. The microelectrode impedance magnitudes were 67.6kΩ±17kΩ at 1kHz, with a 96% yield on the best devices. We implanted the microarrays acutely into the HVC region of the cortex on starlings (n=6) and optimized the procedure for conformal contact to the brain surface. Recordings were on both male and female starlings with Testosterone administered 2-5 weeks before recording. Upon playing a pre-recording of the bird's own song, stimulus-evoked high gamma activity was observed from the HVC. By altering the auditory stimuli, distinct activity

was recorded that is highly correlated to the stimuli when the song was known to the bird and less correlated for the unknown stimuli. The enhanced electrochemical properties of our microelectrodes also enabled the detection of single units from the surface. Like the LFP, these surface spikes were evoked by the auditory stimuli of the bird's own song. These characteristics match the spiking patterns previously recorded from depth electrodes in the same birds. Therefore, we believe that validation of these microelectrode arrays in decoding stimulus-evoked activity from the surface may pave the way for better understanding of information processing in superficial layers in intact brains and without penetrating the brain to record from deeper layers.

Title: Exploring pathogenesis-based biomarkers for Parkinson's disease using various components of peripheral blood

Authors: *J. KANG[1], H. HEO[1], Y. KIM[1], J. CHANG[1,2]
[1]Dept. of Biomed. Sci., Ajou Univ. Grad. Sch. of Med., Suwon, Korea, Republic of; [2]Dept. of Brain Sci., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disorder which appears motor symptoms including shaking, rigidity and bradykinesia. Despite its rapid increase in prevalence, there is currently no effective treatment for PD. In addition, since symptoms of PD begins to appear only after a loss of significant numbers of nerve cells at the affected brain region, it is critical to start the appropriate medical intervention at the early stage of the disease progression. To diagnose the early stage of PD before the development of Lewy bodies inside nerve cells, which is a major pathologic feature of PD progression, it is necessary to find biomarkers that are specific for early PD patients. Though efforts to find biomarkers for PD have been done in many ways, no clinically-applicable biomarkers have yet been identified. Here, we aimed to investigate whether groups of selected proteins based on previous studies on the pathogenesis of PD could be candidates of

useful biomarkers for PD. Considering the clinical use of biomarkers, peripheral blood is a good resource because it can be obtained through relatively non-invasive ways as well as the advantage of containing components that are distinct from cerebrospinal fluid. For this study, a total of 20 patients with idiopathic PD and age-matched 20 patients with essential tremor (ET) which were diagnosed according to the UK Brain Bank Criteria were enrolled consecutively at Ajou University Hospital. There were no significant differences in age, sex, general cognition or medical history between the PD and the ET groups. We first screened which selected pathogenesis based-proteins in the peripheral blood of patients could be quantitatively analyzed by western blotting. As a result, it was found that 4 proteins in the whole blood, 14 proteins in the plasma, and 37 proteins in peripheral blood mononuclear cells can be analyzed. Through additional quantitative analysis of these targets, we finally have found multiple biomarker candidates that significantly increased or decreased in the blood of PD patients.

Title: Discovering Miro inhibitors as a novel approach to treat Parkinson’s disease

Authors: *R. VANHAUWAERT, X. WANG
Neurosurg., Stanford Univ., Palo Alto, CA

Abstract: Cells balance their energy homeostasis and minimize oxidative stress by regulating mitochondrial function and transport and by eliminating dysfunctional mitochondria. It is not surprising that defects in this regulation will be detrimental to all cells; this is especially true for neurons because of their remarkable length and complexity of axons as well as the variable and specialized energetic demands of these highly-polarized cells.
Our lab recently implicated misregulated mitochondrial transport and clearance in the pathogenesis of Parkinson’s disease (PD). Interestingly, we found that PD-causing genes PINK1, Parkin and LRRK2 target Miro for removal from damaged mitochondria and their pathogenic mutations impair Miro removal and delay mitophagy. This defect renders vulnerable neurons to accumulate damaged mitochondria, causing energy shortage and oxidative stress, and consequently leading to neurodegeneration (Hsieh et al., 2016). Miro is a motor/adaptor on the mitochondrial surface that mediates mitochondrial motility and is removed from damaged

mitochondria to enable mitochondrial clearance via mitophagy. Remarkably, partial reduction of Miro arrests damaged mitochondria and restores mitophagy, both in LRRK2 mutant iPCS-derived neurons from PD patients and flies (Hsieh et al., 2016).
Since partial reduction of Miro rescues functional neuronal defects in both *in vitro*and *in vivo*models for PD (Hsieh et al., 2016), a small molecule that partially inhibits Miro could lead to new therapeutic treatments for this devastating disease. In order to adapt our cell-based and animal models to a high throughput drug screen, we have developed three Miro detection methods. Besides the traditional Western blot detection, we established a Miro ELISA and an immunohistochemistry approach using fibroblasts from PD patients and healthy controls. In collaboration with industrial partners we are conducting a targeted Miro inhibitor screen. Preliminary results reveal an initial 72 compounds that specifically target Miro. Now, we are testing their efficiency to reduce Miro levels in PD-patient fibroblasts using our assays. Our approaches could facilitate the discovery of powerful Miro-inhibitors with the hope to translate those to more effective treatments for Parkinson's patients.

Title: Structural and functional biomarkers of Parkinson's disease: Using structural and functional neuroimaging to identify the presence and severity of Parkinson's disease

Authors: *P. MACDONALD[1], N. M. HIEBERT[2], A. R. KHAN[3], L. NACI[6], A. VO[4], B. T. WANG[3], A. M. OWEN[4], K. N. SEERGOBIN[5]

Abstract: Parkinson's disease (PD) is a progressive disorder for which there are no reliable biomarkers. The aim of this study was to explore the potential of structural and functional

analyses to assess the presence and track the progression of PD patients. Parkinson's disease (PD) is a common, complex, heterogeneous neurodegenerative illness with a broad range of possible motor and non-motor symptoms. The neural changes underlying most PD symptoms and signaling disease progression, however, remain poorly understood. Using a 3T MRI scanner, patients with PD and healthy controls were tested on two separate occasions, with one completed on and the other off dopaminergic medication. On both days, functional data were acquired while participants watched a short film, as well as diffusion tensor (DTI) and T1-weighted scans. While watching these films, distinct neural networks are activated in a specific and reproducible manner among healthy controls. Deviations in the synchronicity within each of these neural networks provides and innovative means to capture deficits in sensory and cognitive processing which may be used as functional biomarkers for disease. Frontal-parietal control network (FCPN), default mode network (DMN), dorsal attentional network (DAN), and primary visual sensory networks were investigated. DTI data were used to first parcellate the striatum into seven distinct sub-regions, guided by cortical regions to which they are reciprocally connected. The segmentation resulted in caudal-motor, rostral-motor, executive, limbic, parietal, occipital, and temporal striatal sub-regions. Volume of each sub-region was calculated for each striatal sub-region. Functional data revealed that synchronicity within FCPN was significantly greater in healthy controls, compared to PD patients when both were tested in the OFF state. Additionally, synchronicity within the DMN network was reduced in patients in the early compared to late-stages of PD. Structurally, the caudal-motor striatum was significantly atrophied in PD patients compared to controls. Finally, volume of limbic striatum, the only striatal sub-region innervated by the later-degenerating ventral tegmental area, was sensitive to disease progression using both motor and cognitive indices. Structural measures of striatal sub-regions, as well as cortex-wide functional connectivity measures, provided a sensitive means for distinguishing PD patients from controls and for tracking disease progression.

Abstract: In Alzheimer's Disease (AD), pathophysiological processes affecting the structure of the brain are estimated to begin up to 20 years before clinically significant cognitive symptoms become evident. Thus, structural neuroimaging markers, such as hippocampal volume, may facilitate detection of AD-related pathology in the pre-clinical stage. Challenges in the processing of structural MRI scans, as well as a lack of normative data, have so far prevented this method from being used in a quantitative manner in clinical practice. However, with the imaging data from UK Biobank, and recently developed automated MRI processing tools, the utilisation of this method in a clinical setting becomes more feasible.
Here we report detailed normative information on the hippocampus in relation to age, sex, whole brain volume, and symmetry in 12,245 healthy participants of the UK Biobank. Brain images were processed, with imaging-derived phenotypes made available for general access. Hippocampal volume was estimated with FIRST. Information on hippocampal volume was then further analysed to provide normative volume percentiles across age.
We present percentiles, or nomograms, for hippocampal volume to serve as comparison values in both research and clinical settings in the largest cohort of healthy participants currently available. Examination of hippocampal volume across age also revealed an acceleration of hippocampal atrophy around ages 62-68 years. In addition, the analysis revealed larger mean hippocampal volumes in males than in females, but larger hippocampal volume in relation to total brain size in females. Finally, the data indicate asymmetry of the hippocampus, as the right hippocampus was slightly, but significantly, larger than the left hippocampus.
The reported nomograms will allow the clinician to assess a patient's hippocampal volume in relation to their age-group and thereby provide a potential indication of their risk for dementia. Openly available standardised and automated MRI processing pipelines will simplify the process of obtaining a measure of hippocampal volume from standard MRI scans in clinical practice. The results also suggest that the hippocampus may be more vulnerable to pathological processes than other brain tissue in later life, possibly linked to an increasing risk of dementia. While the current findings are based on cross-sectional data, the longitudinal health outcomes that will become available in UK Biobank over the next years will add invaluable information on the significance of hippocampal atrophy in healthy and pathological ageing.

Title: Oligomerization can convert a cyclic peptide antagonist into a potent and selective activator of the EphA4 receptor

Authors: *M. GÓMEZ-SOLER, S. LOMBARDI, C. ZHAO, B. C. LECHTENBERG, S. J. RIEDL, E. B. PASQUALE
Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: Eph receptor tyrosine kinases and their ephrin ligands are key players in many processes occurring during neural development and in the adult nervous system. For example, aberrant EphA4 activity has been associated with inhibition of nerve regeneration after injury and exacerbation of neurodegenerative diseases. We previously identified peptide antagonists selectively targeting the extracellular ligand-binding domain of EphA4. These peptides have been useful not only as research tools but also for demonstrating the potential therapeutic value of pharmacologically inhibiting EphA4 in *in vivo* animal models of spinal cord injury, amyotrophic lateral sclerosis (ALS) and Alzheimer's disease. Modifications of one of these peptides have yielded a potent and stable cyclic peptide antagonist (designated APY-d3) that selectively inhibits ephrin-induced EphA4 activation. In contrast, selective activation of EphA4 remains a challenge. Soluble forms of the ephrin ligands have been used to activate EphA4 in *in vitro* and *in vivo* studies. However, the promiscuous nature of the ephrin ligands prohibits their use for selective activation of individual Eph receptors. Because ephrin binding leads to Eph receptor oligomerization and subsequent activation, we hypothesized that oligomerization of the APY-d3 peptide antagonist might transform it into a potent and selective EphA4 agonist. Thus, we designed an APY-d3 peptide linked to biotin (APY-d3-bio), which can be oligomerized by complexation with the tetrameric avidin. By measuring inhibition of ephrin-A5 binding to EphA4 in ELISAs, we determined that APY-d3 biotinylation does not affect peptide potency, while oligomerization through avidin binding increases potency without compromising selectivity. In addition, treatment of HEK293 cells stably expressing EphA4 with oligomeric APY-d3-bio increased phosphorylation of Y779 in the EphA4 activation loop, which is indicative of receptor activation. We used BT549 breast cancer cells as a model for cells with

endogenous co-expression of EphA4 and other EphA receptors that can be activated by the same ephrins. Treatment of these cells with oligomeric APY-d3-bio allowed us to identify cellular signaling networks specifically activated by EphA4. To ensure scientific rigor, ELISAs were performed at least 3 times, with each experiment including triplicate measurements and controls. Experiments with cells were repeated at least 3 times with similar results. This work illustrates the value of APY-d3 oligomerization as a strategy to selectively activate EphA4 in cells expressing multiple Eph receptors and to elucidate EphA4-specific downstream signaling pathways.

Title: Functional ultrasound - Novel in-vivo imaging technique for pre-clinical CNS drug discovery

Authors: *A. SHATILLO, T. MIETTINEN, J. KOPONEN, A.-M. KÄRKKÄINEN, D. MISZCZUK, A. J. NURMI
Charles River Discovery, Kuopio, Finland

Abstract: Functional ultrasound (fUS) is a novel imaging technique that was recently introduced to the field of preclinical CNS research. Method utilizes latest technological advancements for ultrafast plane-wave acquisition of doppler ultrasound signal with real-time data processing. Applied to neuroimaging in laboratory animals, this approach enables high sensitivity imaging of relative cerebral blood volume (rCBV) with unrivaled temporal and spatial resolution. High penetration depth allows whole brain coverage in both rats and mice. Moreover, non-invasive signal recording and small footprint of the fUS sensor creates a perfect opportunity for awake imaging in non-anesthetized animals with minimal stress and habituation period. Physiologically, fUS readout is based on the same neurovascular coupling mechanisms as commonly used functional MRI (MRI). Taken together, fUS imaging will likely soon become an invaluable method for basic research and pre-clinical drug discovery tool, allowing fast screening of the novel compounds for modulating neuronal metabolism and hemodynamic response in the brain. Similarly to fMRI, fUS can be used to study sensory processing, mapping of pharmacological response and resting-state functional connectivity analyses. Multiple experimental paradigms

(e.g. acute dosing vs. pretreatment-challenge) combined with different approaches to data analysis gives flexibility to look into specific aspects of the test compound-induced brain effects. Deliverables include multiple quantitative temporal (time to peak, full width at half-maximum, area under the curve, amplitude etc.) and spatial (statistical maps of activity) characteristics.
As early adopters of the technology, Charles River Discovery presents here our wide validation of fUS imaging for pre-clinical drug testing. This work is focusing on brain responses to commonly used psychoactive compounds as well as fUS applications in several CNS disease models.
Provided data and methodology established within this study, demonstrates extensive research and drug testing capabilities of functional ultrasound platform in pre-clinical setting.

Title: Reproducibility of free water imaging in Parkinson's disease

Authors: *W. T. CHU[1,2], D. B. ARCHER[2], R. G. BURCIU[2], S. LAI[3], S. WU[4], M. S. OKUN[5,6], N. R. MCFARLAND[5,6], D. E. VAILLANCOURT[2,1,5]
[1]Biomed. Engin., [2]Applied Physiol. & Kinesiology, [3]Radiation Oncology, [4]Biostatistics, [5]Neurol., [6]Neurosurg., Univ. of Florida, Gainesville, FL

Abstract: Quantitative and reproducible Parkinson’s disease (PD) progression markers are essential for the development of therapeutics. However, reproducible imaging biomarkers have been elusive. Free water is a measure that can be calculated from a diffusion tensor imaging scan of the brain and has recently been shown to predict the progression of motor symptoms in PD patients. The objective of this study was to evaluate the reproducibility of free water measurements in the substantia nigra, putamen, caudate, globus pallidus, subthalamic nucleus, thalamus, cerebellar peduncles, cerebellar vermis and lobules V and VI, and corpus callosum of the brain in PD patients. The study examined 19 PD patients who individually received two identical diffusion scans (test and retest). After the test scan, subjects were pulled out of the scanner and briefly repositioned before being placed back in the scanner for the retest scan. Two methods for analyzing regions of interest (ROIs) were evaluated: (i) a hand-drawn ROI method

and (ii) a standard ROI method using the same ROIs for all subjects. Paired t-tests were used to assess test-retest differences in free water. Test-retest variability was defined as the absolute difference of test minus retest divided by the mean of test and retest and expressed as a percent. The results demonstrated that there was no significant difference ($p > 0.05$) between test and retest free water using either ROI method. Test-retest variability of free water in the posterior substantia nigra using hand-drawn ROIs = 9.1 ± 8.7% and using standard ROIs = 8.0 ± 6.4%. Other ROIs had test-retest variability ranging from 3.6 ± 2.2% to 11.1 ± 9.2%. These data suggest that free water is a highly reproducible measure in PD patients and supports the feasibility of using free water as a PD progression biomarker.

Abstract: Due to constant increase in life expectancy, dementias such as Alzheimer's Disease (AD) are becoming one of the leading health issues of our time. One of the major challenges in dementia research is the ability to provide accurate diagnosis in the premortem setting, especially before clinical symptoms are evident. Indeed, one often cited reason for repeated failures in AD clinical trials is that treatment is begun too late in the disease course. While highly desirable, non-invasive, early diagnostic tools are not yet available. "Liquid biopsies" utilizing the exosomal content of patient-derived plasma have been proposed as a promising approach to the identification of dementia-related biomarkers. Indeed, recent studies have demonstrated that neurally-derived exosomes from AD patients carry AD biomarkers such as amyloid-β and

phospho-Tau, as well as pre- and post-synaptic markers, which can potentially be used to differentiate between preclinical and clinical disease progression. Neurally-derived exosomes can be enriched via immunoprecipitation utilizing antibodies targeting the neuronal cell adhesion molecule, L1CAM. As AD pathology does not only involve the degeneration of neurons but also encompasses neuroinflammation and gliosis, new biomarkers are likely to be found in other neural cell types, such as glia and microglia. In order to isolate exosomes from different neural cell types from patient plasma, we sought to identify cell-type specific exosomal surface markers that can be used for immunoaffinity enrichment. As a proof of principle, we isolated exosomes by ultra-centrifugation methodology from the human glioblastoma cell line U251 and performed mass-spectrometric analysis, which identified 1053 unique proteins. Gene ontology analysis indicated that 65% of these proteins are associated with extracellular exosomes (string-database) and the NCI-60 cancer cell line database indicated a high probability that proteins are derived from the U251 cancer cell line and are of astrocytic origin (Enrichr-database), thus validating our approach. Additional multiplex proteomic characterization of exosomes is currently underway analyzing human cells of astrocytic, oligodendrocytic, neuronal, microglial and neuro-endothelial origin. We will further evaluate if cell specific surface proteins can be utilized to successfully enrich exosomes originating from distinct cell types of the human brain, which may lead to the development of biomarkers for diverse disorders of the brain including dementia, stroke and aging.

Title: Cell-specific mitochondrial proteomic analysis in a mouse model of mitochondrial disease

Authors: *A. GELLA, P. PRADA, I. BOLEA, E. SANZ, A. QUINTANA
Inst. de Neurociències, Univ. Autònoma de Barcelona, Barcelona, Spain

Abstract: Leigh Syndrome (OMIM: #256000) is the most common pediatric presentation of a defined mitochondrial disease (MD). This progressive neurodegenerative disorder is

characterized by a rapid deterioration of cognitive and motor functions, in most cases resulting in death due to respiratory failure. To date, no general curative treatment is available for this devastating disorder. Strikingly, MD neuropathology presents a remarkable selectivity for certain neuronal populations, which may likely be driven by differential mitochondrial protein content in neurons. Using a mouse model of MD that is a correlate of the human Leigh Syndrome, we isolated cell-type specific intact mitochondria and protein alterations were estimated by using protein- and peptide-based approaches and LC-MS/MS methods. These results widen the spectrum of candidate proteins driving susceptibility to MD and open new targets to develop effective treatments for MD.

Title: SUVN-I6107: A novel true muscarinic M1 receptor positive allosteric modulator (M1-PAM) devoid of cholinergic side effects

Authors: J. TADIPARTHI, G. RAMALINGAYYA, N. GANUGA, S. YATHAVAKILLA, R. MEDAPATI, A. VUYYURU, R. KALLEPALLI, N. MUDDANNA, R. PALACHARLA, G. BHYRAPUNENI, T. THATIPARTHI, T. NARASIMHULA, S. JARUGUMALLI, *K. MUDIGONDA, R. NIROGI
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Targeting the cholinergic system is a viable option for developing new treatments for Alzheimer's disease (AD). Compounds that target the muscarinic (M1) receptor such as M1 agonist and M1-PAM though demonstrated efficacy in animal models, also cause cholinergic side effects restricting their clinical use. SUVN-I6107, a M1-PAM was evaluated for its binding potential at the orthosteric and allosteric site of muscarinic receptors, its ability to potentiate the effect of acetylcholine in the reporter gene assay was evaluated. The pharmacokinetics and brain penetration was evaluated in rodents. The efficacy of SUVN-I6107 was evaluated in animal models of cognition. The effect on the modulation of soluble amyloid precursor protein-α (sAPP-α) was studied in rat cortex. Effect on neuronal oscillations was evaluated in combination with donepezil. Cardiovascular safety was assessed using the patch clamp technique. Cholinergic side effects were evaluated in mice, rat and dog. SUVN-I6107 is a M1-PAM with no agonistic activity. It has good selectivity over closely related muscarinic receptor subtypes. SUVN-I6107

modulated acetylcholine potency when tested in in-vitro IP1 assay and produced about 3-4 fold increase in striatal levels of IP1 at doses several fold higher than therapeutically active dose. It has adequate water solubility and found to be orally bioavailable (67%) with good brain penetration and free fraction. SUVN-I6107 demonstrated efficacy in the object recognition task and enhanced cerebral blood flow in rats. At therapeutically effective doses, SUVN-I6107 potentiated the effects of donepezil on elicited hippocampal theta levels and promoted non-amyloidogenic APP processing in rats. SUVN-I6107 did not show cholinergic side effects in rat and dogs up to dose several fold higher than the pharmacological active dose in animal models. SUVN-I6107 was found to be safe when tested in hERG patch clamp assay and in early stage animal toxicity studies. SUVN-I6107 did not induce convulsion (mice and rat) and found to non-mutagenic in Ames assay. SUVN-I6107 demonstrated robust efficacy in animal models without inducing cholinergic side effects. SUVN-I6107 is a true M1-PAM demonstrating robust efficacy in animal models and is devoid of side effects associated with M1-PAM.

Abstract: Parkinson's disease (PD), multiple system atrophy (MSA), and progressive supranuclear palsy (PSP) are neurodegenerative disorders that are difficult to distinguish clinically as they share similar motor and non-motor features. Whereas dopamine transporter imaging can help identify Parkinsonism, it cannot distinguish between different forms of Parkinsonism. Diffusion MRI is a promising technique that allows for the *in vivo* quantification of brain microstructure, and recent small sample studies at one site have shown it can distinguish between different forms of Parkinsonism. A large scale diffusion MRI study using automated methods that is effective across sites with different pulse sequences would be advantageous given the heterogeneity in scanners across the world. The purpose of this study was two-fold: (1) determine which of several possible normalization pipelines provides the best inter-subject alignment in 17 Parkinson's-related regions of interest by comparing free-water within hand-drawn regions to template-derived regions in 104 subjects (31 controls, 40 PD, 17 MSA, 16 PSP) from one site, and (2) evaluate the clinical diagnostic capability of free-water using 5-fold cross validation artificial neural network modelling in the largest PD/MSA/PSP cohort to date, collated across 14 different MRI scanners and including 746 subjects (240 controls, 399 PD, 52 MSA, 55 PSP). We found that normalizing the fractional anisotropy image to a high-resolution fractional anisotropy template using symmetric diffeomorphic mapping in the Advanced Registration Tools software provided the best alignment of Parkinson's-related regions. Our neural network modelling displayed high test accuracy for all models (Control vs. PD/MSA/PSP: 94.3 ± 1.5%, PD vs. MSA/PSP: 86.1 ± 2.5%; MSA vs. PD/PSP: 86.3 ± 2.1%; PSP vs. PD/MSA: 88.7 ± 2.3%). This study provides an automated normalization pipeline and region of interest template that accurately distinguishes between different forms of Parkinsonism using clinically-relevant regions and variable pulse sequences.

Title: Multi-plex digital spatial profiling validation of neurodegenerative and neuroinflammation protein targets in human ffpe brain sections

Authors: A. ROSENBLOOM[1], L. BOGATZKI[1], H. METZ[1], W. CARTER[2], *J. R. KUHAR[3], Y. LIANG[4], G. GEISS[4], J. BEECHEM[4]
[1]NanoString, Seattle, WA; [3]Marketing, [4]R&D, [2]Nanostring Technologies, Seattle, WA

Abstract: Neurodegenerative diseases, including Alzheimer's, Parkinson's, and amytrophic lateral sclerosis (ALS), affect millions of people worldwide and represent an increasing burden in terms of healthcare economics and societal impact. The investigation and characterization of the abundance, distribution and co-localization of neurodegenerative and neuroinflammatory targets within the human brain are critical for the advancement of our understanding of progressive degenerative disease. Nanostring's Digital Spatial Profiling (DSP) technology allows for simultaneous analysis of >40 proteins from discrete regions of interest (ROI) in FFPE tissue sections, providing morphological context to high plex molecular analysis. The assay relies upon antibody probes coupled to photocleavable oligonucleotide tags. After hybridization of probes to slide-mounted formalin fixed paraffin-embedded (FFPE) tissue sections, the oligonucleotide tags are released from discrete regions of the tissue via UV exposure. Released tags are quantitated in a standard nCounter® assay, and counts are mapped back to tissue location, yielding a spatially-resolved digital profile of analyte abundance. In this study, we validate an antibody-based panel designed to characterize key proteins of interest on the DSP platform. To validate antibodies for this technology, the specificity and sensitivity of each antibody was assesses for predicted immunohistochemistry (IHC) staining pattern on appropriate tissues as well as signal-to-noise ratios of positive counts above background. Each target was also evaluated in single versus multiplex to ensure there are no effects of multiplexing antibodies. Immunohistochemical analysis of antibodies chosen for this panel display indistinguishable staining patterns on control tissues for unconjugated primary antibodies and oligo-conjugated primary antibodies. Key targets validated include Tau, Map-2, NeuN, Tdp-43, GFAP, MBP, CD11b, CD68, HLA-DR, Vimentin, Iba1, S100B, VCAM1, Olig2, APP, CNPase, Park5, Park7, Synaptophysin, β3-tubulin etc. Ongoing efforts will expand the antibodies validated for with DSP specific for brain tissue.

Abstract: Human motor activity possesses fractal structures as characterized by similar fluctuation patterns across multiple time scales from seconds to hours. Such fractal regulation (FR) is robust in healthy young subjects and is degraded with aging. Our recent study further showed that FR degradation is predictive of increased risk of developing incident Alzheimer's dementia. However, the underlying brain correlates of FR are still unclear. Here we tested whether FR degradation is associated with specific changes in brain structure. We studied 338 older non-demented adults (age: 81.5±7.1 [SD]) in the Rush Memory and Aging Project who had motor activity continuously recorded for up to 10 days and underwent antemortem magnetic resonance imaging (MRI) scan. The temporal correlations in activity fluctuations at time scales ~0.1-1.5h were examined to assess FR. Based on the structural MRI scans, gray matter volumes of 34 cortical and 10 subcortical regions were obtained. FR in activity were positively associated with gray matter volumes of 14 cortical regions and 2 subcortical regions (Bonferroni corrected $p<0.05$). After adjustment for age, sex, and education, the associations remained in 13 cortical and 1 subcortical regions, including 7 regions that are known to be linked to Alzheimer's disease (AD) pathology (as highlighted in red in Figure): lateral orbitofrontal, supra marginal, isthmus cingulate, superior temporal, fusiform, and accumbens area. To conclude, degradation of FR in motor activity is associated with lower cortical gray matter volumes in various brain regions/sub-

regions which possibly are the brain correlates responsible for the maintenance of FR. The overlap with AD-related regions suggests that FR degradation may share or contribute to the etiology of AD pathology.

Title: How early can fractal regulation predict the risk for Alzheimer’s dementia?

Authors: C. HU[1], L. YU[2], J. YANG[2], D. A. BENNETT[2], *K. HU[1], P. LI[1]
[1]Div. of Sleep and Circadian Disorders, Brigham & Women's Hospital/Harvard Med. Sch., Boston, MA; [2]Rush Alzheimer's Dis. Ctr., Rush Univ. Med. Ctr., Chicago, IL

Abstract: Many neurophysiological systems exhibit fractal regulation (FR) as indicated by similar fluctuation patterns in their outputs at different time scales. Our recent study of 1,097 subjects in the Rush Memory and Aging Project showed that degraded FR in motor activity is associated with increased future risk of developing Alzheimer's dementia (AD) in older individuals. Here we tested whether the association depends on time lag between the assessment of FR and diagnosis of AD. To this end, we re-examined the same datasets in the previous study, in which 220 (out of 1,097) non-demented subjects at baseline developed AD later (AD subjects) and the other 877 subjects did not (non-AD subjects). The time lag from baseline to AD onset ranges between 1-11 years with an average of 4.7 years (Figure 1A). Actigraphy was monitored continuously for up to 10 days at baseline and was used to assess FR at time scales of ~1-90 minutes. Using a Cox proportional hazards model, we examined the association of baseline FR with incident AD repeatedly in multiple subsets of these 1,097 subjects. Two types of subsets were considered for each selected threshold of time lag (i.e., 1, 2, ⋯ , 11 years): (Type 1) AD subjects who developed AD before the threshold (green line in Figure 1B); and (Type 2) AD subjects who developed AD after the threshold (red line in Figure 1B). All non-AD subjects were included in each subset. For Type 1 subsets, we found that degraded FR, as indicated by smaller FR metric, was associated with increased risk for incident AD for all time lag threshold values with the smallest p value at time lag ≤4 years (green line in Figure 1C) and the largest hazard ratio at time lag of ≤1 year (green line in Figure 1D). For Type 2 subsets, the association was only significant when the threshold value of time lag was not greater than 4 years (red lines in Figure 1C and D). Our results indicate that FR can better predict the risk of incident AD when the assessment of FR is within or equal to 4 years before the clinical diagnosis of AD.

Title: Brain delivery and central effects of peptide drug by intranasal administration in mice

Authors: *J.-I. OKA[1], S. SASAKI-HAMADA[1,2], R. NAKAMURA[1], T. FUNANE[1], Y. NAKAO[3], C. YAMASHITA[3]
[1]Tokyo Univ. of Science, Fac Pharm Sci, Lab. Pharmacol, Noda, Chiba, Japan; [2]Physiol., Kitasato Univ., Sagamihara, Kanagawa, Japan; [3]Lab. of Pharmaceutics and Drug Delivery, Tokyo Univ. of Sci., Chiba, Japan

Abstract: We previously reported that the intracerebroventricular (i.c.v.) administration of glucagon-like peptide-2 (GLP-2) exerted antidepressant-like effects both in naïve mice and adrenocorticotropic hormone (ACTH)-treated mice, and that the i.c.v. administration of neuromedin U (NMU) inhibited lipopolysaccharide (LPS)-induced memory impairment and neuronal cell-death. However, the i.c.v. administration is invasive, costly, and impractical for the delivery of drugs into human brains, and thus we need to develop a non-invasive and effective way to deliver GLP-2 or NMU into the brain. In order to utilize GLP-2 or NMU as a clinical treatment tool for depression or amnesia, we prepared three peptide derivatives containing cell-penetrating peptides (CPPs) and a penetration-accelerating sequence (PAS) for the intranasal (i.n.) administration. CPPs including arginine-rich peptides have been shown to deliver various bioactive molecules with low membrane permeability into cells, and led to the regulation of cell functions. Macropinocytosis is transient, actin-driven fluid-phase endocytosis that involves membrane ruffling and the formation of large vacuoles called macropinosomes, which plays an important role in the cellular uptake of arginine-rich CPPs, resulting in highly efficient intracellular delivery. The addition of a PAS to CPPs has been reported to enhance the efficiency of the intracellular delivery of bioactive peptides by promoting endosomal escape *in vitro*, but no *in vivo* study was done to demonstrate brain delivery of peptides with a PAS and CPPs. In the present study, we examined i.n. delivery to the brain and central effects of peptide derivatives containing a PAS and CPPs. PAS-CPPs-GLP-2 (i.n.) was effectively delivered into the brain, and exerted antidepressant-like effects on naïve and ACTH-treated mice. Moreover, we prepared two NMU derivatives containing CPPs, octaarginine (R8), and each penetration-accelerating sequence, namely FFLIPKG (PASR8-NMU) and FFFFG (F4R8-NMU), for the i.n. administration. In the Y-maze test in mice, the i.c.v. administration of LPS significantly decreased spontaneous alternation behavior, which was prevented by the prior i.n. administration of PASR8-NMU or F4R8-NMU. The i.n. administration of PASR8-NMU or F4R8-NMU just

before the Y-maze test improved LPS-induced memory impairment in mice. We herein provided for the first time the efficiency of the addition of a PAS to CPPs *in vivo*. These results suggest that these peptide derivatives are useful in the clinical treatment of psychiatric and neurological disorders by the intranasal administration.

Title: Intracranial pressure monitoring for the safety optimization of intrathecal drug delivery to the CNS

Authors: *V. BELOV[1,2,3], J. APPLETON[1], P. GIFFENIG[1], M. PAPISOV[1,2,3]
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]Shriners Hosp. for Children, Boston, MA

Abstract: Objectives. High volume intrathecal (IT) administration is a promising method for barrier-free delivery of macromolecular therapeutics to the CNS. Estimates of its safety thresholds are currently based on limited empirical data thus demanding more comprehensive mechanistic investigation. The goal of this exploratory study is to characterize the dynamics of pressure disbalances in the cerebrospinal fluid (CSF) caused by various modes of IT administration. **Methods**. A 1F piezoresistive diffused semiconductor pressure sensor mounted at the tip of a 20 cm long 0.8 F polyimide catheter (Millar, Inc) was used in all intracranial pressure (ICP) measurements. In rats, the sensor was inserted through a cannula into the cisterna magna. In monkeys, the configuration of the subcutaneous injection ports prevented the sensor placement in the subarachnoid compartment; therefore, ICP was measured within a catheter connected to the port. The recorded values were corrected for the hydrodynamic resistance in the catheter line, based on in vitro measurements. Signal processing was carried out using a FE221 Bridge Amplifier coupled with a PowerLab 4/35 (ADInstruments). Control of both modules and waveform analysis was performed using LabChart 8 software (ADInstruments). **Results.** In rats, a safely tolerable linear elevation of the steady state ICP values at 0.4 mmHg•μl^{-1}•min was

characteristic for the slow infusion rates in the range of a good compensatory reserve (<37 µl/min, ICP stabilization under 18±3 mm Hg) and for the higher rates in the range of a poor compensatory reserve (37-62 µl/min, ICP stabilization between 18±3 and 28±4 mm Hg). Physiological compensation was impaired above 62 µl/min, leading to the exponential ICP elevation found intolerable for > 10 min. However, the acute ICP elevations followed by rapid relaxations, characteristic for bolus injections, were not lethal up to 200 mm Hg (1.5 ml at 4.4 ml/min) and were sigmoidally related to injected volumes. In monkeys, ICP elevation was a linear function of the infusion rate and appeared to be impacted by the pressure resistance in the external catheter line. **Conclusions.** Accelerated CSF drainage and factors of IT compliance enable safe physiological accommodation of the added volume in the subarachnoid space in a rate- and ICP-dependent manner. Monitoring of ICP during the IT injection/infusion procedure can enable safe IT delivery of even large volumes.

Title: Effects of silver- and gold nanoparticles on the nervous system- *In vitro* and *in vivo*

Authors: *F. JOHANSSON[1], N. ABDULLA[2], E. SÖDERSTJERNA[1], U. ENGLUND JOHANSSON[3]
[2]Clin. Sci., [3]Div. of Ophthalmology, [1]Lund Univ., Lund, Sweden

Abstract: Much attention is given to nanoparticles (NPs) as carriers in drug delivery of therapeutical agents to central nervous system, including the retina. Nanomaterials are increasingly used in diagnostics, imaging and targeted drug delivery. AuNPs are employed as *e.g.* anti-cancer agents and AgNPs are commonly used due to their antibacterial effects. Despite widespread use, the documentation is limited on the direct effect of Ag- and AuNPs on eukaryotic cells, including neural cells and tissue. Hence, we investigate the uptake and distribution of especially Ag- and AuNPs, as well as their possible toxic effect in a battery of assays ranging from human neural stem cells (HNSC) to the mouse eye *in vivo*. Low concentrations of Ag- and AuNPs (0.022- 0.4 µg/ml) are studied at a cellular-, tissue and organ level, using a HNSC lines and administration to the mouse eye *in vivo*. Uptake and distribution of the NPs are analyzed using TEM. HNSC viability, (MTT and TUNEL assays), cell proliferation (Ki67 marker) and cell cycle analysis and phenotypic differentiation (GFAP (glial/neural) and DCX (neuronal) markers) were studied, including function using

electrophysiology. Adverse effects after intravitreal inj. eere studied using the parameters: gross morphology, glial- and microglial response, cytotoxic effects (apoptosis (TUNEL assay) and oxidative stress (AvidinD staining)). $AgNO_3$ is used as a positive control for the reported toxic effect of Ag ions. Ag- and AuNPs of two different sizes are included, 20 and 80 nm, respectively. Initial data show that in the HNSC assay 20 and 80 nm Ag- and AuNPs are taken up into the cytoplasm, nucleus and mitochondria. Moreover, NP exposure may facilitate HNSC differentiation and neurite outgrowth, and affect the electrophysiological characteristics of human neurons. In *in vivo* studies using the eye as a model, neuronal toxicity (apoptosis and oxidative stress) was primarily seen in the outer nuclear layer, harboring the photoreceptors. Our results strongly suggest careful investigation of the eventual adverse effects of Ag- and AuNPs if these are considered for usage in both daily consumer products and medicine, since models of our nervous systems are clearly affected.

Title: Targeted delivery to brain endothelial cells and transport across the blod-brain barrier of shark antibodies (vNAR) following intravenous administration

Authors: *C. L. JACOBSEN[1], K. B. WICHER[2], L. RUTKOWSKI[2], F. S. WALSH[2], T. MOOS[1]
[1]Aalborg Univ., Aalborg Ost, Denmark; [2]Ossianix, Inc, Philadelphia, PA

Abstract: Large molecules in the circulation do not pass through the BBB in sufficient amount to elicit a pharmacological response in the central nervous system (CNS), which is a huge challenge for the treatment of neurological diseases. However, a novel class of small single chain antibodies adapted from the shark immune system (a.k.a. vNAR antibodies) may overcome the obstacle of the BBB when targeted to brain capillary endothelial cells (BCECs). The present study aimed to exploit the cerebral distribution after intravenous injection in female BALB/c mice (n=16) of two vNAR antibodies targeting either the transferrin receptor (TfR) (K4_B2-hFc) expressed by BCECs or both the TfR and CD20 (DUV-B2(HC2N). Using immunohistochemistry, vNAR immunoreactivity was observed in BCECs throughout the entire

CNS. Brain slides of non-immune vNAR-injected animals were devoid of immunoreactivity, except for choroid plexus epithelial cells. The latter were however also labeled irrespective of the injected compound suggesting non-specific uptake at the blood-CSF barrier. K4_B2-hFc and DUV-B2(HC2N) immunoreactivity were observed intraneuronally in several brain regions of the CNS, including forebrain and midbrain regions, but immunoreactivity was mainly in the lower brain stem where the pontine, trigeminal motor, facial motor, and vestibular nuclei, as well as the Purkinje cells of the cerebellum exhibited prominent labeling. Our results show that systemically administered vNAR antibodies accumulate in BCECs in the entire brain as well as neurons primarily in the lower brain stem. These findings indicate that the vNAR antibodies targeting the TfR carry the potential of delivery of therapeutics across the BBB.

Title: Noninvasive neuromodulation with ultrasonic drug uncaging: Electrophysiological assessment

Authors: *M. ARYAL, J. B. WANG, Q. ZHONG, R. D. AIRAN
Radiology, Stanford Univ., Palo Alto, CA

Abstract: Current neuromodulation techniques suffer from invasiveness or limited tissue penetration or spatiotemporal resolution. We have proposed that polymeric perfluorocarbon nanoemulsions can be used to uncage neuromodulatory drugs with focused ultrasound (FUS), enabling noninvasive pharmacological neuromodulation. Here, we accomplish noninvasive neuromodulation with ultrasonic uncaging of the anesthetic propofol. We use visual evoked potentials (VEPs) to determine the temporal kinetics and dose-response relationship of the neuromodulatory effect. Visual evoked potentials were recorded from subdural electrodes implanted on male Long-Evans rats (~200gm). FUS (650 kHz, 1 Hz burst frequency) was used

while varying in-situ pressure, burst length, and brain target. Percentage change of the N1P1 VEP amplitude was measured before, during, and after ultrasonic drug uncaging after administration of propofol (1 mg/kg) versus blank nanoparticles. With visual cortex (V1) sonication, VEPs were attenuated by 15±5%, 34±10% with 1.2, 1.8 MPa sonication pressure, respectively (Fig.1). VEPs were attenuated by 13±8%, 15±5%, 27±8%, with 10, 50, 100ms ultrasound bursts, respectively (Fig.B). While sonicating lateral geniculate nucleus (LGN), VEPs were attenuation by 9±3%, but were not attenuated at motor cortex (M1, Fig.B). The temporal kinetics of these effects had half-lives of 8.8-14.8 s. This work establishes that noninvasive pharmacological neuromodulation with ultrasonic drug uncaging is temporally precise with respect to sonication, with dose-response relationships with sonication pressure and burst length, and with spatial specificity to the sonication site. Presented as mean +/- S.E.M., N=5-10. ns: not significant; *:p<0.05, **:p<0.01, ***:p<0.001; ****:p<0.0001 by two-tailed t-tests.
Fig.1 (A) Schematic of recording electrode placement (*left*) and sonication sites (*right*), represented by the expected full-width half-maximum of the ultrasound field in each location. (B-C) Dose-response relationship, spatial specificity of ultrasonic propofol uncaging.

Abstract: The development of therapeutics for CNS disorders has been impeded by the inability of many potentially therapeutic molecules to cross the blood brain barrier (BBB) and engage their targets. Antisense oligonucleotides (ASOs) are promising therapeutics for treating CNS disorders due to their specific targeting and extended pharmacological effect, however their size and charge impedes their ability to cross the BBB. The intrathecal (IT) dosing route offers a solution for bypassing the BBB and delivering drugs directly to the CNS. Determining the pharmacokinetics (PK) and pharmacodynamics (PD) of ASOs presents unique challenges imposed by anatomical and functional properties of the IT space and reliance upon ex vivo histological molecular techniques. We developed an imaging approach using radio and fluorophore-labeled ASOs tracking PK and employed neuroreceptor targeting ASOs to enable tracking of PD using receptor-targeting radiotracers.
We demonstrate these PK/PD principles using two ASOs which target the MALAT1 non-coding RNA and the GABA-A receptor subunit GABRA1 mRNA. Dynamic SPECT/CT imaging with the ^{125}I-MALAT1 ASO showed widespread time and dose dependent exposure of the neuroaxis tissues following lumbar IT injections, with exposure in cortical structures. A dosing study using either unlabeled GABRA1 or MALAT1 ASO (n=4 per cohort) demonstrated progressive decline in ^{18}F-flumazenil uptake specific to the GABRA1 ASO, with the effect in cortical structures. We confirmed with ex vivo studies that the reduction of ^{18}F-flumazenil uptake corresponded to GABRA1 mRNA and protein reduction produced by the ASO.
We also imaged a Cy7-labeled GABRA1 ASO using 3D cryofluorescence imaging to demonstrate the correlation between the distributions of the IT administered ASO with the regional receptor knockdown demonstrated by the ^{18}F-flumazenil. This 3D cryofluorescence imaging technique offers a bridge between in vivo molecular imaging and ex vivo histology enabling the 3D visualization of the distribution of the fluorescently labeled ASO.

Abstract: Antisense oligonucleotides (ASOs) are a versatile drug platform for the treatment of many neurological diseases. Currently ASO therapies must be administered directly into the cerebral spinal fluid to gain access to the central nervous system. Drug delivery approaches to achieve blood to brain transfer of systemically administered ASO therapies represent a promising future avenue with many clinical benefits. We have demonstrated that a cholesterol conjugated RNase H gapmer ASO achieves blood to brain delivery after intravenous administration. Through a series of imaging studies using fluorescently modified ASOs, we determine the mechanisms leading to blood-to-brain transfer. Chemical structure-activity relationship studies uncover important principles in the design of cholesterol conjugated ASOs for achieving blood to brain transfer. The results from our studies document the feasibility of achieving blood to brain delivery of ASOs.

Title: Development and characterization of an *in vitro* human iPSC-derived blood-brain barrier model

Authors: *P. HAYDEN, M. KLAUSNER, J. MOHN
Mattek Corp., Ashland, MA

Abstract: Objective and Rationale: Solute distribution between blood and brain is strictly regulated by the blood-brain barrier (BBB). The BBB poses a challenge for delivering therapeutics, including anticancer, antibiotic or antipsychotic drugs into the brain. Preventing potentially damaging molecules from overcoming the BBB is also an increasing problem, especially when combinations of therapeutics are encountered. Medical and pharmaceutical scientists therefore have a growing need for rapid, reliable in vitro models of the BBB for preclinical screening of pharmaceutical BBB transport properties. Differentiation of human iPSC into blood-brain barrier endothelial cells was recently reported. The goal of the current exploratory work is to build upon this breakthrough to produce scalable and reproducible human

iPSC-derived BBB models for use in toxicology and drug development applications.
Methods: iPSCs (male, 68 years old) were differentiated to endothelial progenitors by activating canonical Wnt signaling. Subsequent treatment with retinoic acid led to further endothelial differentiation and acquisition of a BBB-phenotype. The differentiated cells were seeded onto microporous membrane inserts and development of BBB specific properties were assessed at various times and culture conditions. Development of barrier function was assessed by measurement of transendothelial electrical resistance (TEER). Immunocytochemical (ICC) staining was performed to evaluate the expression of tight junction protein ZO-1, and BBB-specific markers including glucose transporter GLUT1 and various drug transporter proteins.
Results: Optimization of seeding density and culture conditions resulted in uniform endothelial cell monolayers with evidence of robust tight junction and barrier formation. TEER > 1000 ohms X cm^2 was maintained for up to 6 days. ICC staining demonstrated uniform expression of the tight junction protein ZO-1 localized along the endothelial cell borders. Permeation of Lucifer yellow across the BBB culture was low, further demonstrating development of barrier function. GLUT1 showed diffuse staining.
Conclusions: These results show significant progress in development of a reliable human BBB model that will be useful for preclincal screening of candidate pharmaceutical compounds. The model is easily scalable and can be adapted to 96-well microporous membrane plate formats, allowing use in high-throughput applications. Further efforts will continue to characterize expression and activity of BBB drug transporters, and the inventory of iPSC-derived BBB cells will be expanded to include an array of ages, gender and disease conditions.

Title: Focused ultrasound blood brain barrier opening mediated delivery of MRI-visible nanoclusters for noninvasive neuromodulation with spatiotemporal precision

Authors: *M. C. RICH[1], J. SHERWOOD[3], Y. BAO[3], F. LUBIN[1], M. BOLDING[2]
[1]Neurobio., [2]Radiology, Univ. of Alabama Birmingham, Birmingham, AL; [3]Dept. of Chem. and Biol. Engin., Univ. of Alabama at Tuscaloosa, Tuscaloosa, AL

Abstract: Systemic drug delivery produces off target effects which limits the ability to pharmacologically treat or investigate region specific brain function. Furthermore, side effects can often outweigh clinical treatment potential and confound preclinical results. Additionally, many potentially useful drugs cannot penetrate the blood brain barrier (BBB) requiring drug modifications that jeopardize or completely abolish its therapeutic action. Local drug delivery currently requires invasive methods such as injections, cannulae, and pumps that damage tissues confounding results and limiting translational efficacy. Agents that are not BBB permeable can now be delivered to specific brain regions via focused ultrasound (FUS) mediated BBB opening. FUS can be targeted anywhere in the brain with high spatial resolution to open the BBB, allowing location specific passage of systemic agents into target brain regions. However, FUS BBB opening by itself requires the use of BBB impermeable agents, lacks temporal control and circulating drugs can still cause systemic effects. Here we employ an MRI visible albumin based nanoclusters to encapsulate neuromodulators for delivery to target brain regions noninvasively via FUS facilitated BBB opening. We show that nanoclusters can encapsulate neuromodulators such as glutamate and NBQX with a very low baseline release rate. In addition, we show that IV injected nanoclusters can locally diffuse into the brain with FUS facilitated BBB opening (BBBO) and provide enhanced MRI contrast at the site of delivery. Drug release into brain tissue is triggered by a second FUS treatment (FUS-release) using different parameters from the FUS used to open the BBB. Furthermore, FUS-release causes a change in MRI contrast providing in-vivo confirmation of drug release. Importantly, we show that the drug loading capacity of the nanoclusters is sufficient for inducing localized changes in neural activity in response to glutamate release from nanoclusters in vivo. This new platform will provide noninvasive activation and silencing of spatially precise brain locations to test for effects on behavior while providing independent validation of the site of neuromodulation. This avoids the circularity of using the neuromodulatory effect to verify location of delivery.
