Abstract: While some actions are triggered directly by instantaneous incoming sensory information, most take into account internal information streams that represent information accumulated over longer time periods. Despite decades of study, much is still unknown at the level of neural circuits about how the brain integrates sensory information in between actions, stores this information, and transmits it to inform future actions. We made use of modern whole-brain microscopy methods and the advantages of genetically modified zebrafish to search the entire brain, cell-by-cell, during behavior, for neural integrators involved in motor preparation. Larval zebrafish respond to visual motion, but swim in discrete swim bouts. Accordingly, visual motion must be integrated in between swim bouts to influence future motor output. Our whole-brain activity screen identified a single brain region in the hindbrain that responds to visual flow, integrates and stores it in ongoing activity, and modulates future behavior. These neurons respond to stimuli that encourage the fish to swim, and integrate them so that temporally separated stimuli have an additive effect. Moreover, their activity levels are positively correlated with preceding levels of motor output. However, surprisingly, stimulating the neurons suppressed instantaneous swimming, yet advanced the onset time of future swims. Network models based on these results suggests a brainstem integrator network that, in between actions, stores visual information while actively suppressing motor output, and during actions transmits the stored information to premotor circuits through post-inhibitory rebound. Voltage imaging using novel voltage indicators revealed precise temporal dynamics of this population of neurons in relation to behavior consistent with this model. These findings suggest inhibitory integrators as a complementary alternative to integrate-to-bound models for sensory integration and motor decisions.

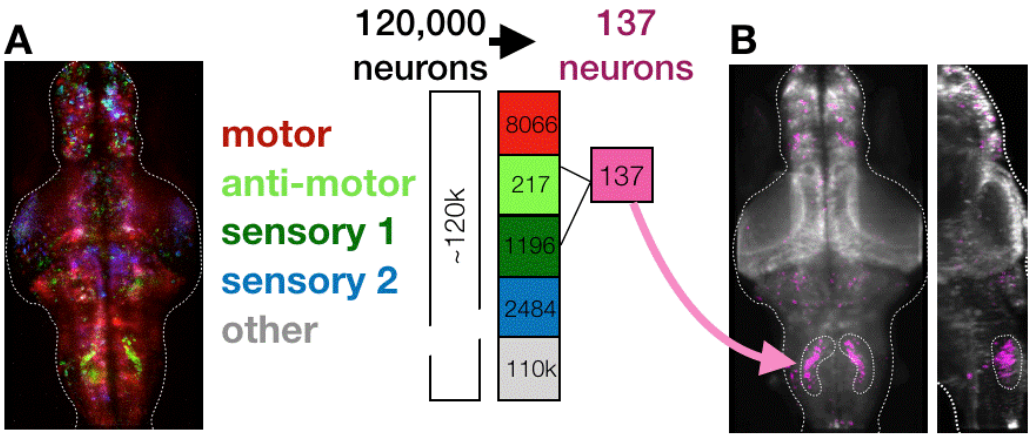

Fig.1. From whole brain activity to ~137 sensory integrator neurons through intersectional analysis.

Title: Sensory organization in the primordial lamprey cortex

Authors: *S. MYSORE SURYANARAYANA, J. PÉREZ FERNÁNDEZ, P. WALLÉN, B. ROBERTSON, S. GRILLNER
Karolinska Institutet, Stockholm, Sweden

Abstract: The lamprey lateral pallium, is conserved in relation to the mammalian cortex with the same efferent connectivity, having projections to the basal ganglia and the different brainstem nuclei (Ocaña et al., 2015). Furthermore, it has a three-layered microcircuit *bauplan* that includes many features of the three-layered reptilian cortex, the mammalian piriform cortex and the neocortex and can be regarded as a primordial vertebrate cortex (Suryanarayana et al., 2017). We examine here, the organization of different sensory inputs to the lateral pallium. The lamprey pallium had been regarded as being entirely olfactory. However, we show that visual input is relayed to pallium via thalamus, along with processed visual information from pretectum/tectum. Extracellular multi-unit recordings showed that neurons in the dorsomedial pallium are activated in a retinotopic fashion by extracellular stimulation of the retina - the "visual" cortex. This visual region is distinct from motor regions. Stimulations of specific retinal quadrants elicited responses in separate visual pallial areas. Local injections of gabazine in the visual pallium resulted in the loss of this retinotopic organization indicating that GABAergic neurons may be responsible for maintaining specificity. Optic nerve stimulations during whole-cell recordings of pallial neurons elicited EPSP's and recruited inhibition. In ongoing experiments, we are investigating responses in visual pallium for visual stimuli delivered on a computer screen placed in front of the contralateral eye. Furthermore, local injections of gabazine in thalamus also resulted in the loss of retinotopy in pallium. We are investigating whether there is also a retinotopic organization maintained in thalamus, by whole cell recordings of prelabelled thalamo-pallial neurons and quadrant-specific extracellular stimulation. Somatosensory information is also relayed via thalamus, which receives inputs from the dorsal column nuclei, activated by sensory input. Extracellular stimulation of the dorsal column in the spinal cord, elicited responses in the ventromedial parts of the lateral pallium, distinct from the visual areas - a "somatosensory" cortex. Stimulation of the trigeminal nerve also elicited responses in rostrolateral areas, distinct from the visual area. Taken together, these findings represent the first report of the remarkable organization of sensory input in the cortex of the phylogenetically oldest vertebrate.

Title: Humans use their prior knowledge to compensate for noisy mental transformations

Authors: *E. D. REMINGTON[1], T. V. PARKS[1], M. JAZAYERI[2]
[1]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [2]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: Many skills rely on performing noisy computations on noisy sensory measurements. Bayesian models suggest that humans compensate for measurement noise and reduce behavioral variability by biasing perception toward prior sensory expectations. Whether the same holds for noise in mental transformations that observers apply to sensory measurement is not known. To determine whether humans rely on their prior knowledge to compensate for additional noise during mental transformations, we tested human subjects on four tasks, including 1) a time interval measurement and production task, 2) a length measurement and production task, 3) a center-out reaching task, and 4) a multiple-choice length discrimination task. In each task, we compared performance across two contexts. In one context, which we termed the “identity context”, responses had to match the stimulus veridically. This was compared to a "remapped context" in which subjects had to apply a non-unity transformation to the sensory measurements to produce accurate responses.
In all tasks, we observed an increased regression to the mean in the remapped context compared with the identity context. This behavior was consistent with a Bayesian model which mitigates the effects of mental transformation noise associated with mental transformations. These results suggest that humans not only optimize behavior to minimize the effect of measurement noise, but also adjust their behavioral responses to account for the additional noise associated with mental transformations.

Title: Neural mechanisms for memory-dependent flexible decision making in mice

Authors: *S. KIRA[1], G. PICA[2], S. PANZERI[2], C. D. HARVEY[1]
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]`Istituto Italiano Di Tecnologia, Rovereto, Italy

Abstract: A hallmark of decision-making is the ability to flexibly combine a new sensory stimulus and past experiences, such as those stored in working memory, to generate an action for positive outcomes. In flexible decision-making, the same sensory information can lead to different decisions or actions depending on the content of working memory. We have developed approaches to study flexible decision-making in the mouse. Specifically, we have used optogenetic and calcium imaging tools to evaluate and compare the importance of neural activity in different cortical areas. We designed a novel delayed match-to-sample task for mice based on navigation in a virtual reality T-maze. In the task, at the start of the maze, a sample cue is presented, and its identity must be stored in the mouse's working memory during a delay segment. At the T-intersection, a mouse is presented with a test cue that the mouse must combine with working memory of the sample cue in order to make a turn in the appropriate direction. To identify cortical regions that are necessary for performance of the task, we bilaterally inhibited different cortical areas in a grid-wise manner across all of dorsal cortex with optogenetics. We evaluated the necessity of regions during distinct epochs of the task. Inactivation of posterior parietal cortex, primary visual area, and secondary visual areas reduced behavioral choice accuracy. The effect was most prominent when the inhibition was applied during the test cue presentation, suggesting a causal involvement of these regions in the integration of sensory and memory information to make a decision. We have also collected two-photon calcium imaging datasets from a wide range of cortical regions during the task. We are analyzing these data to understand population codes for various components of the task, including visual perception, working memory, and sensorimotor transformation. Also, we are using new information theory approaches to identify neural activity patterns that carry stimulus information that is used to inform the choice, and thus might be important for key sensorimotor transformations. By comparing many cortical regions in the same task, we aim to understand the flow of decision-related information across cortex during flexible decision-making.

Title: Brain networks, dimensionality, and global signal averaging in resting-state fMRI: Hierarchical network structure results in low-dimensional spatiotemporal dynamics

Authors: *S. J. GOTTS[1], A. W. GILMORE[1], A. MARTIN[2]
[1]Lab. of Brain and Cognition, NIMH/NIH, Bethesda, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: One of the most controversial practices in resting-state fMRI functional connectivity studies is whether or not to regress out the global average brain signal (GS) during artifact removal. Some groups have argued that it is absolutely essential to regress out the GS in order to fully remove head motion, respiration, and other global imaging artifacts. Others have argued that removing the GS distorts the resulting correlation matrices, qualitatively alters the results of group comparisons, and impairs relationships to behavior. At the core of this argument is the assessment of dimensionality in terms of the number of brain networks with uncorrelated time series. If the dimensionality is high, then the distortions due to GS removal could be effectively negligible. In the current study, we examine the dimensionality of resting-state fMRI data using principal component analyses (PCA) and network clustering analyses. In two independent datasets (Set 1: N=62, Set 2: N=32), scree plots of the eigenvalues level off at or prior to 10 principal components, with prominent elbows at 3 and 7 components. While network clustering analyses have previously demonstrated that numerous networks can be distinguished with high thresholding of the voxel-wise correlation matrices, lower thresholding reveals a lower-dimensional hierarchical structure, with the first prominent branch at 2 networks (corresponding to the previously described "task-positive"/"task-negative" distinction) and further stable subdivisions at 4, 7 and 17. Since inter-correlated time series within these larger branches do not cancel to zero when averaged, the hierarchical nature of the correlation structure results in low effective dimensionality. Consistent with this, partial correlation analyses revealed that network-specific variance remains present in the GS at each level of the hierarchy, accounting for at least 18-20% of the overall GS variance in each dataset. These results demonstrate that GS regression is expected to remove substantial portions of network-specific brain signals along with artifacts, not simply whole-brain signals corresponding to arousal levels. We highlight alternative means of controlling for residual global artifacts when not removing the GS.

Title: Do task-negative responses reflect cortico-cortical competition from task-positive brain regions?

Authors: *K. D. CSUMITTA[1], A. OSSOWSKI[2], A. W. GILMORE[1], S. J. GOTTS[1], A. MARTIN[1]
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Dept. of Psychology, Georgia State Univ., Atlanta, GA

Abstract: Previous work has identified functional brain networks showing task-induced increases in activity and networks showing task-induced decreases in activity, known respectively as "task-positive" and "task-negative", or "Default Mode" (Raichle et al., 2001), networks. These systems are proposed to be intrinsically competitive, such that activity in one suppresses activity in the other (e.g., Fox et al., 2005; 2009). In the current study, we examine the relationship between task-positive and task-negative networks in the brain using a slow-event related fMRI task design in which 40 participants were asked to name pictures of common objects aloud. If these functional networks are intrinsically competitive, then: 1) trial-level BOLD responses across task-positive and task-negative voxels should be anti-correlated, and 2) the correlation between the BOLD response and behavior (Response Time, RT) in task-positive and task-negative regions should have opposite valence. To test these predictions, we extracted the peak BOLD response and naming RT for 100 naming trials. As expected, task-positive responses were found in occipitotemporal and lateral frontal brain regions and task-negative responses were observed in regions of the Default Mode Network (posterior cingulate, inferior parietal, ventromedial prefrontal, superior frontal gyrus, anterior STS, frontal pole, right middle frontal gyrus). Greater connectivity was also observed within- than across-networks. These results were thresholded to obtain 8 task-negative regions of interest (ROIs), and ROI trial-level BOLD responses for each participant were correlated with responses in the rest of the brain. In contrast to the competitive dynamics proposal, we found predominantly positive correlations between task-negative ROIs and the rest of the brain. This positive coupling was not obviously due to residual artifacts, and was supported by complementary analyses of run-level beta weights. Although a few areas showed RT-BOLD slope reversals between task-positive and task-negative regions, the portion of variance related to behavior was small and did not detract much from the overall positive coupling. Taken together, these results argue against the simple proposal that cortico-cortical competition explains the presence of task-negative responses. We conclude by highlighting alternate possible mechanisms, such as centralized gating through the thalamus.

Title: Perception-action patterns revealed by event-related potentials

Authors: *M. KILINTARI[1], R. J. BUFACCHI[1], G. NOVEMBRE[1], Y. GUO[1], P. HAGGARD[2], G. IANNETTI[1]
[1]Dept. of Neuroscience,Physiology and Pharmacol., Univ. Col. London, London, United Kingdom; [2]Inst. of Cognitive Neuroscience, Univ. Col. London, London, United Kingdom

Abstract: The way we interact with our environment is often guided by the perception of salient events happening in it. Reconceptualising an example given by Pylyshyn (1986), a pedestrian who approaches a crossing will alter his action, i.e. will stop, instead of continuing his route, when the traffic light suddenly becomes red. What defines the relationship between such everyday actions and common sensory stimuli? In a series of nine experiments, we used (i) an isometric force paradigm and (ii) a voluntary movement task entailing complex visuomotor transformations, to examine whether the presence of an evoked response (ERP) affects motor output. In the isometric force experiments (n=4), we used a highly sensitive transducer to record fine-scale variations of isometric force exerted by the fingers, and measured EEG and EMG activity, while sudden and temporally unexpected stimuli of different sensory modalities were delivered. In the visuomotor task experiments (n=5), the same stimuli were delivered concomitantly to the beginning of the movement, which participants had to perform as fast and accurate as possible. EEG activity was recorded, and the temporal and spatial features of the voluntary movement were quantified using the movement parameters Movement Onset Time, Total Time Movement, Path, Accuracy and Speed. We obtained the following main results. First, salient sensory stimuli modulated motor output regardless of the sensory modality of the eliciting stimulus. Second, this modulation had distinct patterns depending on the specific task: (i) in the visuomotor task, the presence of sensory stimuli resulted in a reduction of Movement Onset Time and an increase in Accuracy, while (ii) force modulation followed a complex triphasic pattern consisting of alternating decreases and increases, time-locked to stimulus onset. Third, (i) the magnitude of force modulation was predicted by the amplitude of the cortical activity elicited by the same stimuli, whereas (ii) the modulation of motor parameters was independent of the presence of an evoked response. In summary, we observed a tight coupling between stimulus

induced cortical activity and motor output in the isometric force task, which was not present in the visuomotor task. There, goal-related but stimulus-independent neural activities correlated with behavioural performance. These results suggest that saliency detection is not merely a perceptive but a reactive process, which however has differential effects on motor output, depending on the time proximity between stimulus and action and on action's complexity.

Title: Human egomotion visual areas respond to long-range leg movements

Authors: S. DI MARCO[1,2], C. SERRA[1,2], *C. GALLETTI[3], P. FATTORI[3], G. GALATI[2,4], V. SULPIZIO[2,5], S. PITZALIS[1]

Biomed. and Neuromotor Sci., Univ. Bologna, Bologna, Italy; [4]Dept. of Psychology, Sapienza Univ., Roma, Italy; [5]Biomed. and Visuomotor Sci., Univ. of Bologna, Bologna, Italy

Abstract: Optic flow constitutes a rich source of essential visual cues for guiding egomotion while moving in the environment. Egomotion perception involves the integration of multiple sensory signals arising from visual as well as vestibular, somatosensory and motor systems (Greenlee et al., 2016). Monkey neurophysiology and human neuroimaging studies have demonstrated that passive viewing of optic flow stimuli activates a large cortical network of temporal, parietal, insular and cingulate visual motion regions (including the well-known areas MST, VIP, V6 and CSv). Although all these regions respond to egomotion-compatible visual stimuli, they are well different in terms of anatomical position and functional properties. Indeed, some of them have a clearly retinotopic organization whereas others show also somatosensory or vestibular responses. Recently it has been also shown that area V6+ is connected with posterior visual regions (Tosoni et al., 2015), while area CSv has strong connections with the medial somatosensory cortex and motor areas (Smith et al., 2017). One possible hypothesis is that posterior egomotion visual regions (as V6+) contribute only to the visual analysis of egomotion signals while anterior egomotion visual regions (as CSv) provide sensory information to the motor system with the aim of guiding locomotion. To test this hypothesis, we used a combined approach of brain mapping methods, task-evoked activity and resting-state functional connectivity by fMRI. We localized with high consistency across 18 subjects a set of six

egomotion visual areas (V6+, V3A, VIP, CSv, pCi, PIC) by using a Flowfields stimulus (Pitzalis et al., 2010). Then, we tested their response to a motor task implying active long-range leg movements. Finally, we examined their pattern of functional connectivity. We found that, among these visually defined areas, only CSv, pCi and PIC responded to leg movements. Functional connectivity analysis showed that the visuomotor areas CSv, pCI and PIC are connected with the cingulate motor areas, the supplementary motor area and notably, with the medial primary somatosensory and motor cortex, which represent the leg and foot. In conclusion, results revealed a gradient of functional specialization and cortical connections, with the most posterior regions dedicated to the analysis of visual attributes of egomotion and the most anterior regions additionally committed to the analysis of motor components of egomotion, likely integrating visual information with locomotion-relevant proprioceptive and vestibular signals. We propose that CSv, pCi and PIC provide a pivotal link between perception and action aimed at locomotion control.

Title: Large-scale EM reconstruction of microcircuits supporting sequential activity in parietal cortex

Authors: A. T. KUAN[1], L. N. DRISCOLL[1], C. D. HARVEY[1], *W.-C. A. LEE[2]
[1]Harvard Med. Sch., Boston, MA; [2]BCH / Harvard Med. Sch., Boston, MA

Abstract: Recent work has demonstrated that neurons in posterior parietal cortex (PPC) are activated in temporal sequences corresponding to navigational decisions during a two-alternative forced-choice task. However, it remains unknown how these sequences of activation arise. One approach to understanding the circuit basis of decision-making is to analyze the connectivity of choice-selective neurons. In this project, we combine large-scale serial-section electron microscopy (EM), *in vivo* calcium imaging, and navigational behavior in virtual reality to create

a unified structural and functional map of mouse PPC. We will investigate how connectivity supports task-relevant functional activity, such as whether choice-selective neurons form distinct subnetworks and exhibit synaptic connections consistent with feedforward signal propagation. Here, we present a preliminary EM connectomic dataset centered on functionally characterized PPC. We show correspondence of cell bodies in the EM volume with cells chronically imaged during 30 days of behavior and present preliminary analysis from reconstructions of choice-selective cells. By leveraging methodological innovations, including automated sectioning onto tape substrates and automated reel-to-reel imaging with transmission electron microscopes, we demonstrate the ability to rapidly and comprehensively image the structure of functionally characterized neuronal populations. This technology will enable investigations into the circuit mechanisms underlying complex behaviors.

Title: Synchronizing movements to a visual rhythm shifts the neural frequencies of entrainment to lower frequency bands compared to passive perception of visual rhythms

Authors: *D. COMSTOCK, R. BALASUBRAMANIAM
Cognitive and Information Sci., Univ. of California - Merced, Merced, CA

Abstract: There has been growing evidence that multiple timing systems exist within the brain. Given the evidence linking the motor system to rhythm perception, it is likely that engaging the motor system during a rhythm task will alter the timing mechanisms involved in rhythm perception. While the role of the motor system in auditory rhythm perception has been well studied, the role of the motor system in visual rhythm perception remains relatively unknown. To investigate the role of the motor system in visual rhythm perception we recorded scalp EEG while participants were tasked to passively entrain to a visual flashing rhythm and then to tap in synchrony while entraining with a visual flashing rhythm. Analysis of the neural time-frequency activity at the channel level showed entrainment in alpha and beta bands over motor regions, peaking at flash onset in the passive synchronization condition. During the synchronization condition, that activity shifted so that alpha and beta peaked prior to onset. Additionally, a shift from beta band entrainment in the passive condition to delta band entrainment in the synchronization condition was seen over central and parietal regions. Using ICA and dipole

source localization, we found indication of mu rhythm entrainment in the motor cortex during passive entrainment that, during synchronization, was reduced while entrainment shifted to the beta band. Additional sources in the posterior parietal cortex, temporal parietal junction, and in the pre-motor area showed a shift from beta band entrainment during the passive condition to delta band entrainment in the synchronization condition. The frequency band switching shown in these findings indicate the networks switching to adjust to changing tasks demands, while the presence and modulation of mu rhythms can be seen as an indirect measure of increased coupling between the visual and motor systems. The switching to lower frequency bands may be a result of increased need to share timing information across networks.

Title: Effective connectivity during the processing of self-generated movements and their consequences

Authors: *B. ARIKAN, B. VAN KEMENADE, B. STRAUBE, A. JANSEN, T. KIRCHER
Philipps Univ. Marburg, Marburg, Germany

Abstract: Sensory consequences of self-generated movements are often perceived as less intense and generate less neural activity compared to externally-generated stimuli. Such attenuation has been explained as resulting from predictions made regarding the consequences of self-generated movements, which are then compared with actual sensory consequences. Brain areas that have been suggested to be involved in this process include regions of the sensorimotor network as well as cerebellar and parietal areas. However, exact underlying mechanisms are still unclear. Here we used dynamic causal modelling (DCM) for fMRI to assess effective connectivity in the left primary motor cortex (M1), left secondary visual cortex (V5), posterior part of the right cerebellum and left posterior parietal cortex (PPC). 20 participants underwent fMRI as they executed self- vs. externally-generated movements of the wrist while seeing an online recording of their movements in real-time or with a delay. We investigated which area (PPC, M1, cerebellum) was mainly responsible for the observed attenuation in visual cortex. More specifically, we tested on the one hand whether the PPC or M1 plays a central role in the hierarchy of sensorimotor processing during self-generated movements, and on the other hand

the contribution of the cerebellum in attenuating activity in sensory areas during self-generated movements. Bayesian model selection and Bayesian model averaging suggest that the PPC up-regulated activity in M1 while attenuating activity in V5 during self-generated movements. Cerebellar contribution was negligible within this model, possibly because time modulations were not considered. Results provide support for current accounts of PPC as a top-down prediction area in sensorimotor processing.

Title: The role of thalamus in the flexible control of timed behavior

Authors: *T. V. PARKS[1], E. D. REMINGTON[1], M. JAZAYERI[2]
[1]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [2]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: Adopting a dynamical systems framework, previous results in our lab have provided evidence that flexible control of covert motor timing might be accomplished by the modulation of initial conditions and inputs associated with the dorsomedial frontal cortex (DMFC) including supplementary eye field and supplementary motor area (Wang et al. 2018; Remington et al. 2018). Currently, the neural circuits that provide the necessary input to DMFC for the control of behavior are not known. Recent studies of sensorimotor function have highlighted the importance of thalamocortical interactions in sensorimotor computations. We thus set out to explore whether thalamus could be the source of this input.
We recorded spiking activity from thalamocortical neurons, putatively in the ventral lateral area and area X, of two macaque monkeys (one female and one male) trained to measure time intervals and subsequently produce timed motor responses according to context-specific stimulus-response rules. In one context, monkeys had to reproduce a measured interval veridically, whereas in the other, the target interval was 1.5 times the measured interval. We

analyzed neural trajectories across the population of thalamic neurons as a function of the context and interval. Within each context, trajectories were structured with respect to the produced interval, similar to that observed previously in DMFC. This corroborated previous results that thalamus through its interactions with DMFC may play a role in the control of motor timing. Next, we asked whether thalamus has an explicit representation of the context information needed to control the behavior. We found that indeed the population activity had a representation of context consistent with thalamus providing a context-dependent input to DMFC. However, this signal was relatively weak suggesting that putative context-dependent signals to DMFC may originate from other, possibly cortical, brain areas.

Title: Neural mechanisms underlying training-based negative compatibility effect

Authors: *M. DI[1,2], Y. LI[1,2], Y. WANG[1,2]
[1]Sch. of Psychology, Shaanxi Normal Univ., Shaanxi, China; [2]Shaanxi Provincial Key Lab. of Behavior & Cognitive Neurosci., Xi'an, China

Abstract: The negative compatibility effects (NCE) is a surprising phenomenon that performance to the targets are faster in incompatible trials (i.e. prime and target indicate opposite responses) than compatible trials (i.e. prime and target indicate the same response) in masked priming paradigm. Previous studies used relevant (composites of perceptual features to target and alternative) and irrelevant (composites of target-irrelevant features) masks to examine the contribution of perceptual updating and motor inhibition to NCE. However, the prime/target used in these studies (e.g. arrow) could induce strong stimuli and response (S-R) link due to long-term experimce during development, which results in the debate about the relative role of perceptual updating and motor inhibition in NCE remains unresolved.
To address this issue, we used short-term training paradigm to establish new S-R link between prime/target and response in the present study. Moreover, BOLD changes with fMRI to investigate the neural mechanism underlying the training-based NCE. Specifically, we examined

the neural substrates that are involved in the generation of NCE with relevant and irrelevant masks before and after S-R link established. Each subject participated in 3 sessions within 8 days: 1-day pre-test fMRI session, 4-day S-R link training session and a 1-day post-test fMRI session. The NCE responses with BOLD index were calculated by contrast each compatible condition against the corresponding incompatible condition.
For relevant mask condition, behavior results showed that NCE was occurred at both pre- and post- training session. We also found brain areas which showed
increased NCE responses in post-test than in pre-test session, including both lower and higher visual areas, SMA, thalamus, posterior cingulate cortex. These results indicated that both perceptual updating and motor inhibition contributed to NCE with relevant mask. In addition, OFC revealed decreased NCE responses in post-test than in pre-test session, which implied that cognitive control demand might decreased after training. For irrelevant mask condition, NCE was only significant at post-test session and only SMA activation showed increased NCE responses at post-test session than in pre-test session. These results suggested that only motor inhibition contribute to NCE triggered by irrelevant mask.
Our findings provide evidence to the neural mechanism underling short training-based NCE. Both perceptual updating and motor inhibition contributes to short training-based NCE triggered by relevant mask, whereas only motor inhibition contributes to short training-based NCE triggered by irrelevant mask.

Title: Relationship between cortical and striatal activity during visually guided behavior

Authors: *A. J. PETERS, N. A. STEINMETZ, K. D. HARRIS, M. CARANDINI
Univ. Col. London, London, United Kingdom

Abstract: Corticostriatal interactions are believed to play an essential role in learning and executing stimulus-action transformations. We investigated this relationship by recording the propagation of activity across the cortex and striatum during a visually guided behavior, in which mice reported the position of a visual stimulus by turning a wheel in the correct direction with their forelimbs. Stimulus contrast varied across trials, allowing for easier or harder detection conditions.
To directly relate cortical and striatal activity during behavior, we recorded from both structures simultaneously. We used widefield calcium imaging to record from the dorsal surface of the cortex and a 384-channel electrode array (Neuropixels probe, Jun et al. Nature 2017) to record from a one-dimensional section of the striatum, stretching diagonally from dorsomedial to dorsolateral at 0.2 mm anterior to bregma.
Firing rates in the striatum could be predicted from linear regression of cortical calcium signals, establishing a functional relationship that largely matched anatomical connectivity. Progressing from dorsomedial to dorsolateral striatum, activity was best predicted from visual cortex, then from frontal cortex, and finally from orofacial somatomotor cortex. The boundaries of these representations along the electrode appeared to show sudden transitions rather than a graded shift in predictor location.
During each trial, task-related activity within each striatal domain largely matched that of activity within its corresponding cortical area. Between stimulus onset and movement execution, striatal activity progressed from medial to lateral sites on the electrode. Simultaneously, cortical activity progressed from visual areas to frontal areas and finally to somatomotor areas.
Different cortical and striatal domains exhibited different activity profiles. Activity in visual cortex and dorsomedial striatum aligned best to stimulus onset but included sustained activity during movement. Activity in frontal cortex and dorsocentral striatum aligned best to movement with a peak at movement onset. Finally, activity in somatomotor cortex and dorsolateral striatum aligned best to movement and including sustained activity after movement onset.
By recording activity simultaneously across large areas of the cortex and striatum, we have found that corticostriatal domains can be functionally determined and that task-related activity within each corticostriatal domain is generally consistent. We have also observed that activity profiles across each corticostriatal domain are unique, suggesting a progression of processes that underlie behavior in this task.

Abstract: Cortical plasticity is a fundamental process in recovery from motor dysfunction. However, it is not clear how the plasticity is induced at a circuit level. In this study, we investigated motor recovery and underlying neural plasticity upon optogenetic suppression of a cortical area for eye movement. Using visually guided eye movement task in mice, we suppressed a small portion of the secondary motor cortex (MOs) which encodes the contraversive eye movement, i.e., movement toward the contralateral side. We found that optogenetic unilateral suppression severely impaired the contraversive eye movement on the first day. However, repetitive suppression on the following days turned out to be ineffective and the mice restored capability for the contraversive eye movement. Moreover, longitudinal *in vivo* two photon calcium imaging revealed that the regained capability was accompanied by an increased number of neurons encoding for the ipsiversive eye movement in the unsuppressed contralateral MOs. Additional suppression of the contralateral MOs impaired the recovered eye movement again, indicating that the newly-acquired ipsiversive preference was compensatory plasticity responsible for the recovery. Our study directly demonstrates an indispensable contribution of the contralateral hemisphere for the motor recovery and that the directional encoding of eye movement can be dynamic across hemispheres.

Title: Effect of viewing distance on object responses in macaque areas 45B and F5

Authors: *I. CAPRARA, C. STOCKEM, P. JANSSEN
Dept. of Neurosci., Ku Leuven, Leuven, Belgium

Abstract: In order to perform real-world tasks like grasping efficiently, the primate brain has to process visual object information so that the grip aperture can be adjusted before contact with the object is made. For this reason, extensive research has been conducted to assess the way in which different brain areas contribute to 3D shape perception and how this is conveyed to the motor cortex. Previous single-cell and monkey fMRI studies have shown that disparity-defined 3D shape is processed in both the ventral (inferior temporal cortex, IT) and the dorsal visual stream. In area AIP and in the anterior subsector of F5 (F5a), 3D shape -selective neurons are also active during object grasping. Moreover, electrical microstimulation of 3D shape-selective clusters in AIP during fMRI activates F5 and area 45B (Premereur E et al., 2015, PLoS Biology *13: e1002072*), indicating that these two frontal areas represent important downstream areas for object processing during grasping. Here, we investigated whether and how F5 and 45B neurons encode object shape and viewing distance during visual fixation of real-world objects. We recorded in two macaque areas, 45B (N = 48) and F5 (N = 32), during a passive fixation and visually- guided grasping task. Using a commercial robot, we presented four real-world objects, two spheres (large - 6cm – small - 3cm), and two plates (large - 6cm – small - 3cm) at two viewing distances, one within reaching distance (28cm) and one outside reaching distance (56cm). Many neurons in area 45B were object-selective (main effect of object in 56% of the neurons, ANOVA $p < 0.05$) and selective for viewing distance (main effect of distance in 50% of the neurons, significant interaction between object and distance in 29% of the neurons, ANOVA, $p < 0.05$). At the population level, the selectivity for viewing distance only emerged in the later epoch of the response (between 200 and 600 ms), with a clear preference for the near viewing distance, whereas in the initial part of the response (0-200 ms), no differences between near and far were observed. In contrast, F5 neurons were less frequently affected by shape (main effect of object in 22% of the neurons) or distance (main effect of distance in 41% of the neurons; significant interaction between object and distance in 16% of the neurons, $p = 0.0086$, z-test). At the population level, F5 neurons did not exhibit any preference for near or far viewing distances, neither in the early epoch nor in the late epoch of the response. In conclusion, contrary to our expectations, neurons in area 45B – but not F5 neurons – prefer objects presented in peripersonal space.

Title: Connections between functional domains in posterior parietal cortex and motor cortex for running or climbing in galagos revealed by microstimulation

Authors: *Q. WANG, C.-C. LIAO, I. STEPNIEWSKA, H. X. QI, M. GABI, J. H. KAAS
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Previous studies have demonstrated that posterior parietal cortex (PPC) in prosimian galagos and other primates can be subdivided into up to eight functional domains from which specific types of complex movements (e.g. reach, grasp or hand to mouth) can be evoked by 500 ms long trains of electrical pulses. Studies of some of these domains, mostly within the forelimb representation, have shown their specific connections with premotor and primary motor areas of the frontal cortex and with other areas of parietal and occipital cortex. However, connection patterns of the most medial PPC domain from which combined forelimb and hindlimb movements suggestive of running or climbing behavior can be evoked remain unclear. Here, we investigated the functional organization of this domain and its cortical connections with other brain areas in two adult male galagos (*Otolemur garnetti*). First, we employed 500 ms trains of intracortical microstimulation to map the PPC region above the intraparietal sulcus and identified the climbing/running domain which is located dorsally close to the medial wall. Then we made two injections of different retrograde tracers, cholera toxin B subunit (CTB) and fluoro-ruby (FR), in this domain. Flattened cortices were cut parallel to the surface and divided into series processed for cytochrome oxidase and myelin staining for cortical architecture, and CTB and FR for labeled neurons. Injections in the climbing/running domain revealed that the densest patches of labeled neurons were in the cortex adjacent to injection site and through out most of rostral PPC (PPCr), other dense connections were with primary motor (M1) and premotor cortex (PMC), mostly in dorsal locations from which hindlimb and forelimb movements can be evoked. Other labeled neurons were densely distributed in arm and leg regions of the parietal somatosensory areas (area 3a, 3b, 1/2). Numerous neurons were also labeled in cingulate motor areas
of the medial surface of the hemisphere dorsal to the cingulate sulcus. Less dense connections were with the secondary somatosensory area (S2) and parietal ventral area (PV) in cortex of the upper bank of the lateral sulcus. Occasionally, we observed labeled neurons anterior to the ventral premotor areas (PMV). These preliminary results indicate that the climbing/running movement domain exists in the rostromedial portion of PPC receives dense motor and somatosensory inputs from the hindlimb and forelimb cortical representations. In addition, our microstimulation results provide further evidence for the climbing/running domain in PPC and functionally matched domains in M1 and PMC.

Title: Modulation of cell-type-specific spike-field coherence in posterior parietal cortex during coordinated visual behavior

Authors: *M. F. KHAZALI, Y. WONG, B. PESARAN
Ctr. for Neural science, New York Univ., New York, NY

Abstract: Neurons in the intraparietal sulcus (IPS) of the posterior parietal cortex (PPC) are involved in coordinated eye-arm movements to visually-defined targets. Before coordinated visual behaviors, many PPC neurons display elevated activity in spatial response fields. Previous work demonstrates that spike-field coherence (SFC) within and between the lateral and medial banks of the IPS also predicts the properties of upcoming coordinated visual movements and movement choices. Neuronal coherence may reflect cell-specific neuronal morphology and biophysical properties as well as task-dependent functional interactions between populations of neurons. Here, we analyze extracellular recordings of 778 PPC neurons in four macaque monkeys performing coordinated look-reach movements to remembered visual targets to test whether SFC in PPC depends on putative neuronal cell-type (M1:211 neurons, M2:463, M3:68, M4:34). We identified four different populations of neurons based on their spike width (Hartigan's dip test, $p<0.05$; narrowest NS1:133 neurons, second narrowest NS2:141, widest WS1:225; second widest WS2:229). SFC in the beta band (13-30 Hz) was more prominent than SFC at other frequencies. SFC magnitude across the population during both baseline period before the movement target was flashed (Kruskal-Wallis test; $p = 0.027$) and the planning period after the target was flashed ($p=0.007$). NS1 neurons exhibited the greatest magnitude SFC (pairwise rank-sum $p<0.05$) during both epochs. Moreover, WS1 showed higher spike-field coherence during baseline and planning than NS2 (pairwise rank-sum $p<0.05$), but was not different from WS2. Whereas WS2 SFC was higher than NS2 SFC during planning alone (pairwise rank-sum $p<0.05$), as it did not differ from NS2 one during baseline. The spatial extent of SFC also varied with putative cell-type. NS1 cells showed the highest SFC with locally-recorded LFP activity (pairwise rank-sum $p<0.05$) and other putative cell-types expressed similar SFC (pairwise rank-sum $p>0.05$). WS1 and NS1 spikes showed the greatest SFC with LFP activity recorded from different area nearby PPC (same coherence level pairwise rank-sum $p>0.05$) as compared to each of the other neuron-cell-types NS2 and WS2 (pairwise rank-sum $p<0.05$). These results demonstrate that SFC reflects cell-type-specific mechanisms.

Title: Semi-chronic subdural electrocorticography, local field potentials, and spike recordings over posterior parietal cortex during coordinated visual behavior

Authors: *B. PESARAN[1], A. L. ORSBORN[2], V. SANCHEZ[3], M. F. KHAZALI, 10003[2]
[1]New York Univ. Ctr. for Neural Sci., New York, NY; [2]Ctr. for Neural Sci., [3]New York Univ., New York, NY

Abstract: Neurons are the basic information encoding units in the brain. However, interpreting individual unit activity alone provides insufficient information about neural processing because the brain operates at multiple scales, from single neurons to interacting brain regions. Monitoring brain activity at different scales can therefore enable better understanding of brain function. Posterior parietal cortex (PPC) activity during coordinated hand and eye movements illustrates the need for multiscale recordings sampled simultaneously across extended cortical areas. Many behavioral aspects of coordinated movements are explained by coherent activity across the lateral and medial banks of PPC. Thus, we performed electrophysiology recordings at different spatial scales over the lateral and medial banks of PPC using a previously developed semi-chronic recording system (Orsborn 2015). The system allows both subdural micro-electrocorticography (μECoG), local field potential (LFP) and single-unit recordings in the same tissue volume. We apply tuning analysis of single unit, multi-unit, and LFP responses recorded by microdrive at different cortical depths and μECoG arrays from a rhesus macaque (Monkey M) performing a variety of coordinated reach and saccade tasks. Each trial began with a baseline period in which M was required to maintain touch and fixation on a central cue. A peripheral target appeared then for 0.3s (memory trials) or for the whole period (delay trials). The central cue then switched from yellow to gray, signaling a “go” cue, after which M made coordinated hand and eye movements to a peripheral target. M was trained on task variations to fully dissociate reaches and saccade. He performed variations with coordinated reach and saccades to the same location, reach and saccade to different locations, reaching while holding fixation, and saccading while holding center touch. He performed delay and memory trials for each task variation. Preliminary results show that all forms of signals (spikes, multiunit and LFPs) indicate visual response after presenting visual target over the receptive field of the recording sites. We similarly observed sustained activity after the visual response in all signal types. Sustained

activity was spatially localized to different anatomical areas depending on task, with responses in the lateral bank during saccade trials and in the medial bank during reach trials. LFPs recorded from different depths with microdrive or from the surface activities of μECoG showed similar sustained activity in Beta band. This sustained activity was observed on the lateral and medial banks during memory saccades and reaches, respectively.

Title: Clarifying the anatomical organization and cortical projections of multiple major white matter tracts associating the human temporal and parietal lobes

Authors: *D. BULLOCK[1], H. TAKEMURA[4], C. F. CAIAFA[5,6], L. KITCHELL[2], B. MCPHERSON[2], B. CARON[3], F. PESTILLI[1]
[1]Psychological & Brain Sciences; Neurosci., [2]Psychological & Brain Sciences; Cognitive Sci., [3]Neuroscience; Optometry, Indiana Univ. - Bloomington, Bloomington, IN; [4]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communicatio, Suita-shi, Japan; [5]Indiana Univ., Bloomington, IN; [6]CONICET, Buenos Aires, Argentina

Abstract: Traditionally, norms of neuroscientific attention have caused researchers to primarily study larger white matter tracts that are aligned to the rostral-caudal axis. These tracts include the superior longitudinal fasciculus, the arcuate fasciculus, the inferior fronto-occipital fasciculus, and the inferior longitudinal fasciculus. More recently, modern in-vivo imaging studies have begun elucidating several tracts in the posterior of the human brain that are instead aligned perpendicular to the rostral-caudal axis. These tracts transfer information directly between the dorsal and ventral aspects of the posterior human cortex. Here we examine several of these tracts, namely, the temporal-parietal connection, the posterior arcuate, and the two components of the middle longitudinal fasciculus.In this work, we compare the anatomical features, volumes,

and connectivity patterns of the rostro-caudal aligned and rostro-caudal perpendicular tracts using diffusion-weighted magnetic resonance data from the Human Connectome Project (1.25 mm, b=2000 mm^2/s), modern tractography methods (ensemble tractography), and statistical validation techniques (LiFE). Furthermore, we developed an automated segmentation method to identify these four tracts along with the more studied rostro-caudal tracts. Our results indicate a significant degree of interconnectivity between the ventral and dorsal streams of the human brain. We find that the rostro-caudal perpendicular tracts can be reliably segmented across subjects. Their statistical evidence, volume, and fiber length are generally smaller than those of the more well established rostro-caudal aligned tracts. We also report that the collective architecture of these four vertical tracts instantiate a dual set of parallel white matter structures, conducting information directly between the parietal and temporal lobes. These tracts constitute an important but understudied set of connections in the human brain, which are fundamental in linking cortical areas involved in face recognition, object and word perception, and controlling or planning eye and limb movements. As such, this pattern of connectivity suggests that theories of visual perception and action may need to expand their accounts to incorporate models of cortical function with direct information flow between the posterior dorsal and ventral cortex.

Title: Mapping response properties in lateral intraparietal area (LIP) of the rhesus macaque

Authors: H.-K. KO, *K. KRUG
Oxford Univ., Oxford OX1 3PT, United Kingdom

Abstract: Primate sensorimotor area LIP is thought to have a central role in visual attention, saccade guidance and decision-making. Anatomically, it is divided in dorsal and ventral LIP. LIP neurons may exhibit a visual receptive field or a saccade target response field or both. The nature of the visual receptive field, the distribution of these properties and the relationship between maps are not fully understood.
Using a guidance grid and maps from structural MRI, we carried out multiple penetrations orthogonal to the cortical surface to map systematically neuronal response properties across LIP in one Rhesus macaque. We screened cells for activity during a delayed saccade task to targets

across the visual screen. If cells showed delay-period activity, we tried to establish a visual receptive field with a patch of moving dots. We collected complete data sets from 24 single cells that both responded significantly to a visual stimulus such as moving dots and also responded in a delayed saccade task in comparison with fixation task on a blank screen. LIP neurons usually had both a clear response field and a receptive field, but sometimes the visual receptive field was ill-defined. As previously reported, visual receptive fields were found generally in the contralateral visual hemifield; response fields could be either contra- or ipsilateral. Cells recorded more posteriorly and ventrally tended to have lower visual receptive fields, progressing upwards with penetrations moving anteriorly.
The visual receptive fields of these neurons were tested for direction and disparity tuning with patches of coherently moving random dots positioned over the receptive field. 29% (7/24) of cells showed significant direction tuning and 38% (9/24) significant disparity selectivity (ANOVA, $p < 0.05$). At sites with significant visual tuning for the isolated single unit (SU), multi-unit activity was usually also tuned. We then studied the combination of stereo and motion information to investigate how LIP cells process this cue combination during a relevant perceptual decision. We presented a structure-from-motion cylinder over the receptive field of the cell and one of two response targets on the response field. The other target was presented symmetrically in the opposite hemifield. The monkey was trained to discriminate the rotation direction of the cylinder by making a saccade to the appropriate target in a reaction time task. 38% (9/24) of cells were tuned to cylinder disparities (ANOVA, $p<0.05$) and many responded to choices about the cylinder.
In sum, LIP contains at least one crude map of the contralateral visual field and many cells show tuning for direction of motion and binocular disparity.

Title: Mapping functional connectivity between layers of the superior colliculus

Authors: A. L. SMOULDER, *U. K. JAGADISAN, N. J. GANDHI
Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The superior colliculus (SC) is a laminar structure involved in visual stimulus detection and eye movement generation. Superficial layer neurons respond most strongly to visual stimulus onset, whereas intermediate/deep layer neurons are active both after target onset and immediately before a saccade. While anatomical connectivity between layers has been extensively studied, functional connectivity across the layers has not been thoroughly characterized. Mapping the functional connectivity of SC in vivo will contribute to our understanding of sensorimotor transformations and related phenomena such as visual input suppression during saccades. Additionally, spectral decomposition of effective information transfer can elucidate the frequency content of interactions between layers.
We sought to determine this circuit of information flow by using a laminar multi-contact electrode to record from all layers of a macaque SC during a delayed saccade task. This paradigm dissociates the neural activity into two epochs: target onset (visual response) and saccade onset (motor response), with a delay period in between. We used conditional Granger Causality to compute the temporal dynamics and spectral content of functional connectivity within SC. This quantifies the directed (asymmetric) correlation between SC layers while conditioning on the signals from other layers to exclude redundant connections.
Preliminary results indicate bidirectional information flow across layers. During the visual epoch, superficial layer activity Granger causes intermediate layer response, most prominently in beta band frequencies. Beta band activity has been shown to decrease during movements, so it is feasible that the increase in activity observed is reflective of eye movement suppression. Also, during this epoch, intermediate layers show ascending information transfer to superficial layers at sub-alpha frequencies, and to a lesser extent, in the beta band. In contrast, little Granger Causality was observed during the delay, pre-, and peri-movement periods, indicating a lack of inter-layer communication while hinting at intra-layer processing and/or influences from outside SC. Immediately following saccade onset, two patterns emerge. First, superficial-to-intermediate Granger Causality is observed similar to target onset, indicative of target reafference. Second, intermediate layer activity Granger causes both superficial and deep SC layer responses in alpha band frequencies. These interactions, along with further analysis of data, help illustrate the effective information transfer within SC during an oculomotor task.

Title: Functional circuits for goal-directed behavior in the superior colliculus

Authors: *J. ESSIG[1], G. FELSEN[2]
[2]Dept. of Physiol. and Biophysics, [1]U. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: The midbrain superior colliculus (SC) is a conserved sensorimotor structure essential for spatial attention and orienting behaviors. Experiments in mice, cats and primates demonstrate a topographical representation of contralateral space along the horizontal axis of the SC whereby increased neural activity at specific sites in the collicular network predictably elicit behaviors to distinct spatial targets. In natural environments with many stimuli available for attention, it is hypothesized that behaviorally salient targets are selected in the SC via competitive interactions, however the functional circuitry underlying competition in the SC, and the mode of competition, is unknown. Here, we measure how intrinsic inhibition in the SC shapes neural activity during target selection and acquisition by recording and manipulating optogenetically-identified inhibitory SC neurons in mice performing an odor-guided spatial choice task. Trained GAD2-Cre mice expressing channelrhodopsin-2 (ChR2) in GABAergic neurons via a Cre-dependent viral strategy were implanted with an "optetrode" drive, an optic fiber surrounded by four tetrodes, in the rostral or caudal SC to enable light delivery to and extracellular recordings from the same population of neurons. GABAergic neurons were identified based on short-latency light responses (i.e., "optotagging") before and after each behavioral session. We hypothesized that caudal GABAergic neurons locally influence SC activity by inhibiting outputs representing contralateral choices, and therefore predicted that activity in these neurons would promote ipsilateral choices. However, we instead found that the activity of these neurons was higher during the selection of and movement towards the contralateral reward port, and that optogenetically activating these cells during target selection biased choices contralaterally. Notably, we obtained similar results in the rostral SC. These results suggest that GABAergic SC neurons mediate target selection through functionally long-range, as opposed to local, connections to shape intercollicular dynamics and suppress output representing competing targets. We are currently incorporating these findings into biologically relevant attractor network models to examine inter- and intra-SC circuit motifs underlying the neural dynamics for goal-directed behavior.

Title: Population dynamics of delay period activity during a saccade task

Authors: *M. R. HEUSSER[1,2], U. K. JAGADISAN[1,2], B. R. COWLEY[3,2], N. J. GANDHI[1,2]

Abstract: The superior colliculus (SC) is a midbrain structure crucial for the generation of fast eye movements, or saccades. SC neurons are known to encode multiple types of signals. For instance, aptly named visuomotor SC neurons increase their firing rates following stimulus onset and when generating a motor command. This multiplexing of visual and motor information is most apparent in the activity of SC neurons during a delayed saccade task. The paradigm temporally dissociates the visual and motor epochs and consequently reveals two distinct bursts of activity that are widely thought to be visual- and movement-related, respectively. However, the structure of population activity during the delay period, i.e., between visual target onset and eye movement onset, is not as well characterized. SC activity during the delay period likely reflects cognitive processes, transformations of signals from a sensory to motor reference frame, and movement preparation. To investigate the structure of neural activity during the delay period, we recorded SC activity from two male rhesus macaques (Macaca mulatta) with a multi-contact laminar probe while they performed a standard delayed saccade task to a target placed either in the population's response field or in the diametrically opposite direction. We sought to characterize the evolution of SC activity throughout the trial with clustering and decoding techniques. We first performed a clustering analysis of population activity, seeking any systematic trends across the delay period, and used this clustering approach to inform our decoding analyses. Population spike counts in sliding windows during the delay period were fed into a logistic regression classifier trained on predefined activity windows (baseline, visual, delay, motor, or other), and the decoder returned the most likely category to which the neural activity belonged. A general trend emerged: activity early in the delay period was often classified as visual, but late in the delay period as motor, with a smooth transition between the two categories. Overall, this preliminary analysis shows that SC population activity during the delay period is not static, but rather reflects a dynamic transition between two multiplexed signals.

Title: Decoding the sound of hand-object interactions in primary somatosensory cortex

Authors: *K. M. BAILEY[1], B. L. GIORDANO[2], A. KAAS[3], F. W. SMITH[1]
[1]Sch. of Psychology, Univ. of East Anglia, Norwich, United Kingdom; [2]Inst. de Neurosciences de la Timone, CNRS and Aix Marseille Univ., 13007 Marseille, France; [3]Dept. of Cognitive Neuroscience, Fac. of Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands

Abstract: Neurons, even in earliest sensory regions of cortex, are subject to a great deal of contextual influences from both within and across modality connections. Such connections provide one way for prior experience and the current context to shape the responses of early sensory brain areas. Recently we have shown that cross-modal connections from vision to primary somatosensory cortex (S1) transmit content-specific information about familiar but not unfamiliar visual object categories. In the present work, we investigated whether hearing sounds depicting familiar hand-object interactions would also trigger such activity in S1. In a rapid event-related functional magnetic resonance imaging (fMRI) experiment, right handed participants (*N*=10) listened to five exemplars from each of three categories of auditory stimuli: hand-object interactions (e.g. bouncing a ball), animal calls (e.g. dog barking), and pure tones (unfamiliar control). Participants listened attentively, and performed a one-back repetition counting task, which eliminated any need for a motor response during scanning. An independent finger-mapping localizer was completed afterwards, and used to define finger-sensitive voxels within anatomically drawn masks of the right and left post-central gyrus (PCG). Multivariate pattern analysis revealed significant decoding of different hand-object interactions within bilateral PCG, whilst no significant decoding was found for either control category. Crucially, in the finger-selective voxels, decoding accuracies were significantly higher for decoding hand-object interactions compared to both control categories in left PCG. Further analyses also revealed significant decoding in pre-motor cortex (PMC) for familiar hand-object interactions. Our findings indicate that hearing sounds depicting familiar hand-object interactions elicit different patterns of activity in PCG, despite the complete absence of tactile stimulation. Thus cross-modal connections from audition to early somatosensory cortex transmit content specific information about familiar hand-object sounds. This finding is consistent with Predictive Coding models, which suggest that the key goal of even the earliest sensory brain areas is to use the current context, together with prior knowledge, to predict forthcoming stimulation.

Title: Visual and proprioceptive inputs affect the location of evoked somatosensory percepts in amputees

Authors: *B. CHRISTIE[1,2], H. CHARKHKAR[2], D. J. TYLER[1], R. TRIOLO[2]
[1]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [2]Louis Stokes Cleveland VA Med. Ctr., Cleveland, OH

Abstract: Cross-modal links between vision, somatosensation, and proprioception play an important role in fine motor control, balance, and locomotion. For instance, orientation of the eyes to a body site enhances tactile acuity [Pierson 1991], and visuo-proprioceptive conflicts can modify reaction time to tactile stimuli [Folegatti 2009]. However, the impact of visual and proprioceptive inputs on the spatial location of tactile perception is not well established.
By utilizing cuff electrodes to apply electrical stimulation to the residual peripheral nerves of two trans-tibial amputees, we have elicited tactile sensations referred to their missing limbs. This unique opportunity enabled us to evoke somatosensation without physical contact, decoupling somatosensation from vision and proprioception.
Participants were asked to draw the location of stimulation-evoked percepts on a diagram of an intact foot. Experimental conditions included baseline, seated, and upright standing. While seated, an experimenter touched plantar regions of the participant's prosthetic foot while he observed. During upright standing, the participants were instructed to put pressure on plantar areas of their prostheses. Standing conditions were repeated while participants looked at their prostheses or closed their eyes.
Preliminary results suggest that both proprioception and vision can change the spatial location of a somatosensory percept. When the baseline percept was located in the residuum, incongruent proprioceptive inputs affected percept location more strongly than vision. However, incongruent visual inputs had a stronger influence when the baseline sensation was located in the phantom heel. Visual and proprioceptive inputs made approximately equal contributions for baseline sensation in the toes.
In conclusion, proprioception appears to have a stronger influence on somatosensory location than vision in the residuum, which may represent the prioritization done in able-bodied individuals. In the phantom limb, amputees appear to rely more strongly on vision than

proprioception from the residuum. This may be due to the missing proprioceptive ankle information and a disrupted body schema. Continued testing will allow us to examine cross-modal integration in a manner that has never been possible before.

Title: Representational interactions during audiovisual speech entrainment: Redundancy in left posterior superior temporal gyrus and synergy in left motor cortex

Authors: *H. PARK[1], R. I. I. INCE[2], P. G. SCHYNS[2], G. THUT[2], J. GROSS[3]

Abstract: Integration of multimodal sensory information is fundamental to many aspects of human behavior, but the neural mechanism underlying these processes remain mysterious. For example, during face-to-face communication we know that the brain integrates the dynamic auditory and visual inputs but we do not yet understand where and how such integration mechanisms support speech comprehension. Here we quantify representational interactions between dynamic audio and visual speech signals and show that different brain regions exhibit different types of representational interaction. With a novel information theoretic measure, we found that theta (3-7 Hz) oscillations in the posterior superior temporal gyrus/sulcus (pSTG/S) represent auditory and visual inputs redundantly (i.e. represent common features of the two) whereas the same oscillations in left motor and inferior temporal cortex represent the inputs synergistically (i.e. the instantaneous relationship between audio and visual inputs is also represented). Importantly, redundant coding in the left pSTG/S and synergistic coding in the left motor cortex predict behavior - i.e. speech comprehension performance. Our findings therefore demonstrate that processes classically described as integration can have different statistical properties and may reflect distinct mechanisms that occur in different brain regions to support audiovisual speech comprehension.

Title: Examining the size-weight illusion with visuo-haptic conflict in immersive virtual reality

Authors: *G. BUCKINGHAM
Univ. of Exeter, Exeter, United Kingdom

Abstract: When we experience our environment, we do so by combining our sensory inputs with our prior knowledge. This combination of top-down and bottom-up information causes surprising perceptual effects such as the size-weight illusion (SWI), were small objects feel heavier than equally-weighted large objects. This powerful illusion is thought to occur because the experienced heaviness reflects a contrast to the lifter's prior expectation that the large object will outweigh the small object. Interestingly, there is evidence that the strength of the SWI varies depending on the modality the lifter uses to experience the size differences. Ellis and Lederman (1993) showed that the SWI experienced by individuals lifting blindfolded (i.e., experiencing only haptic the size cues was substantially larger than that induced when lifting with a string (i.e., experiencing only visual size cues), and that adding visual size cues added nothing over and above haptic size cues. It is, however, unclear whether these findings are due to the reliability of the sensory modality removal used to experience the size difference, or a consequence of removing one sensory input. To further investigate multisensory contributions to the SWI, I placed vision and touch cues to size in conflict with one another using immersive virtual reality. An Optitrak motion capture system tracked the positions of SWI-inducing stimuli in real time, and images of the objects were displayed to participants in Unity through and Oculus Rift head-mounted display. With this setup, 22 participants lifted and judged the heaviness of identically-weighted cylinders across three within-subject conditions: (1) objects appeared different sizes but were physically the same size, (2) objects were physically different sizes but appeared to be the same size, or (3) objects both looked and actually were different sizes from one another. Consistent with prior work, size differences experienced with the hands induced a larger SWI than that induced with visual size differences. In contrast to prior work, however, congruent vision and haptic size cues yielded a larger-still SWI. These findings not only add to our understanding of how different modalities combine to influence our hedonic perception, but also highlight the value of cue conflict paradigms for studies of multisensory integration and showcase how immersive virtual reality can develop experimental cue-conflict paradigms with high ecological validity.

Title: Influence of age and practice on the discrimination of sequential and simultaneous vibrotactile stimuli

Authors: *L. A. MROTEK[1], V. SHAH[1], M. CASADIO[2], K. A. NIELSON[1], R. A. SCHEIDT[1,3,4]
[1]Marquette Univ., Milwaukee, WI; [2]Univ. of Genova, Genova, Italy; [3]Northwestern Univ., Chiicago, IL; [4]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Sensory augmentation via vibrotactile feedback (VTF) can be used in body-machine interfaces to enhance the precision of movement in healthy individuals and in patients with impaired proprioception (e.g., some survivors of stroke). However, learning to use limb state information encoded within VTF to plan and control goal-directed movements requires considerable cognitive effort. To what extent can interpretation of vibrotactile stimuli improve with practice? We examined the capability of healthy people in two groups, Middle Age (40-55 yr) and Older Age (65-90 yr), to discriminate vibrotactile stimuli applied sequentially or simultaneously within and across dermatomes, as well as the extent to which vibrotactile discrimination changes with practice. Stimuli were applied using vibration motors (ERM tactors) taped to the forearm. We tested locations in dermatome C7 (posterior proximal forearm) and dermatome T1 (anterior middle forearm). Stimuli were applied in one location sequentially (C7 **or** T1), in two locations sequentially (C7/T1 or T1/C7), or two locations simultaneously (C7+T1). We used a two-alternative, forced choice approach and the method of constant stimuli to estimate the just noticeable difference in the magnitude/frequency of vibratory stimuli within each condition. In all cases, a "standard stimulus" was presented at 186 Hz and a "probe stimulus" was presented within a range of 100Hz to 235Hz (5 frequencies above and 5 below the standard). Each probe was presented 10 times in each condition. The presentation order of standard and probe stimuli and testing locations was pseudorandomized and counterbalanced. Probability that the subject would declare the probe stimulus greater than the standard was computed in each condition and fit with a cumulative Gaussian distribution function. The Middle

Age group was better at discriminating vibrotactile stimulation than the Older Age group. Within the Middle Age group, we found sensory discrimination to be better in the C7 and T1 sequential conditions vs. the C7+T1 simultaneous condition. The Middle Age group did not improve appreciably with practice, except for in the C7+T1 simultaneous condition. Discrimination performance in the Older Age group was highly variable: some (but not all) members initially struggled with discriminating the vibration stimuli, especially in the C7+T1 simultaneous condition. However, the performance in the Older Age group improved over 3 days of practice. This evidence of perceptual learning is encouraging, suggesting that interpretation of sequential and simultaneous vibrotactile cues can be improved with extended practice, even in older individuals.

Title: Vibrotactile feedback guided reaching during single and dual-task conditions

Authors: *V. SHAH[1,2], L. A. MROTEK[1], M. CASADIO[2,1], R. SCHEIDT[1,3,4]
[1]Dept. of Biomed. Engin., Marquette Univ., Milwaukee, WI; [2]Dept. Informatics, Bioengineering, Robotics and Systems Engin., Univ. of Genova, Genova, Italy; [3]Feinberg Sch. of Med., Northwestern Univ., Chicago, IL; [4]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Vibrotactile feedback (VTF) is a non-invasive and inexpensive way to augment sensation or display useful information in body-machine interfaces. The initial learning of VTF cues requires significant cognitive resources, but may eventually transition into an autonomous phase requiring less overt attention (c.f., Fitts & Posner, 1973). Our long-term goal is to enhance control of upper limb movements with the real-time use of VTF, thus requiring users to integrate VTF cues into the planning and ongoing control of movements. To advance this goal, we used a dual-task condition to determine the effects of cognitive load on VTF-guided reaching, and the extent to which VTF-guided reaching can improve across 5 days of training. We hypothesized

that VTF training improves reach performance in a way that is impervious to dual-task interference, and that 5 days of training suffice to increase expertise of VTF-guided reaching such that secondary task learning can also occur. Ten young participants with no neurological impairment gave written consent to 5 days of experiments wherein they held the handle of a planar manipulandum with the dominant hand. Four eccentric rotating mass motors were used to create a vibrotactile display that encoded information about the {X, Y} position of the handle. The vibrotactile display was attached to the non-moving arm. Each participant performed two tasks, individually and simultaneously (the dual-task condition). The primary task asked participants to make goal-directed reaches under three different feedback conditions: visually-guided, VTF-guided, and none (i.e., proprioception alone). We analyzed target capture error and target capture time. The secondary task required participants to perform a cued, choice reaction time task. We analyzed choice accuracy and reaction time. Participants received 30 minutes of VTF-guided reach training on each of 5 days; we assessed single and dual-task performance before training (Day 1) and after training (Days 1, 3, & 5). Repeated measures ANOVA and post-hoc t-test found significant ($p < 0.05$) pre-to-post-training improvements in single-task reach performance (~17 % target capture error reduction) that were largely preserved in the dual-task condition (~14% target capture error reduction). These results support the hypothesis that VTF training improves reach performance despite dual-task loading. By contrast, we found no significant improvements in target capture time or in secondary task performance. Lack of improvement in these variables suggests that 5 days of training did not suffice to bring VTF-guided reaching into the autonomous phase of learning.

Title: a new psychophysical paradigm to directly quantify the perception of body ownership during the rubber hand illusion

Authors: *M. CHANCEL, H. H. EHRSSON
Karolinska Inst., Stockholm, Sweden

Abstract: Introduction: The perception of limbs as one's own is referred to as the sense of body ownership (BO). This bodily experience depends on the integration of signals from multiple sensory modalities (Ehrsson, 2012). However, a major shortcoming of the current literature is the

lack of a sensitive psychophysics method to adequately register BO while controlling for cognitive bias. To fill this gap, we developed a new discrimination task for a more precise and direct measurement of BO based on a version of the Rubber Hand (RH) Illusion. **Method**: The participants' right hand lies hidden beneath a table. On this table two identical right RHs are placed in parallel with the same orientation as the real hand (the real hand lays between the RHs). Three robot arms repeatedly apply taps to the two RHs and to the participants' real hand. Each RH is touched repeatedly for 12 sec (1 Hz); either synchronously with the other RH and the participants' hand or with a delay that is systematically varied (50, 100, or 200 ms, the longer the delay the weaker the BO for that RH). The participants then have to decide which of the two RHs that feels more like their own. In experiment 1 (N=24 participants), we manipulated the distance between the real hand and the two RHs in the horizontal plane: both RHs were placed 5 cm away from the real hand or one was 10 cm away from the real hand (projection on the horizontal plan). In experiment 2 (N=22 participants), we manipulated the texture congruency between the visual and tactile stimuli (plastic versus foam tubes). **Results**: The proportion of "the right RH feels more like mine" for each delay was efficiently fitted by cumulative Gaussian curves (fitting performed with the Palamedes toolbox). This fitting did not work under conditions known to abolish the RHI (e.g. rotating the RHs 90º) as demonstrated in separate control experiments. By performing ANOVAs the psychometric curves' means under different distance conditions we found that participants favoured the RH that was closer to their real hand (Exp1: $F(2, 46) = 55.7$, $p < .001$, $\eta^2 = 0.71$), which is in line with the previous literature. The results from the second experiment showed how incongruency between the seen and felt tactile properties of the objects touching the RHs and the real hand led to a significant reduction in BO (Exp2: $F(2, 42) = 26.26$, $p < .001$, $\eta^2 = .56$). This demonstrates the sensitivity of our method and solves a controversy in the previous literature. **Discussion**: Taken together, our results show that BO constitutes a genuine perceptual multisensory phenomenon that can be quantified with psychophysics. This has important bearings on theoretical models of BO and future empirical studies on the rubber hand illusion.

Title: Unconscious body ownership during continuous flash suppression

Authors: *B. VAN DER HOORT[1,2], N. RADZIUN[2], H. H. EHRSSON[2]
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Karolinska Insitute, Stockholm, Sweden

Abstract: Body ownership is traditionally defined as the conscious sensation that our body is our own. However, the implicit assumption that body ownership requires consciousness has never been directly tested. In the rubber hand illusion, body ownership is induced through simultaneous stroking of the rubber hand (in view) and the participant's real hand (out of view). In the current study, we combined the rubber hand illusion with continuous flash suppression, which prevented conscious visual perception of a stranger's hand and an object stimulating it, while participants' real hand was stimulated synchronously.
In Experiment 1a (n = 40), continuous flash suppression successfully rendered the rubber hand invisible. However, despite the absence of visual awareness of the rubber hand, participants displayed a significant increase of ownership for the masked hand after a period of synchronous stimulation. To be more specific, their skin conductance responses to physical threats towards the location of the masked hand were increased (Z = 2.25, n = 30, p = 0.024), and their felt hand position drifted towards the masked hand (Z = 3.07, n = 40, p = 0.002).
In Experiment 1b (n = 40), continuous flash suppression was removed, rendering the hand clearly visible. As expected, when the hand was visible, the ownership measures remained significant (skin conductance response: Z = 2.252, n = 30, p = 0.024; proprioceptive drift: t(39) = 2.21, p = 0.033). In fact, visibility of the hand did not even alter the magnitude of the objective ownership measures (skin conductance response: U = 414, p = 0.75: proprioceptive drift: U = 674, p = 0.22), which suggests that, for the measures used in this study, visual awareness of the rubber hand does not increase ownership.
In a final experiment (Experiment 2, n = 30*)*, we found that the 'unconscious body ownership' as described by Experiment 1a, has a promoting effect on visual awareness. The time needed for the masked hand to break through continuous flash suppression was decreased when unconscious ownership was induced (t(29) = 3.17, p = 0.004).
Taken together, our results show that ownership can be induced for a hand that is not consciously perceived, which is probably driven by unconscious multisensory integration. These results emphasise the importance of subconscious processes in body ownership, and in doing so, might call for a re-evaluation of how body ownership is defined.

Title: The supernumerary hand illusion revisited: Disambiguating ownership of one and two right rubber hands

Authors: *C. FAN[1], H. EHRSSON[2]
[2]Dept. of Neurosci., [1]Karolinska Institutet, Stockholm, Sweden

Abstract: Can we experience that we have three arms? Some previous experiments have successfully adopted a modified version of the rubber hand illusion to elicit a supernumerary hand illusion, in which participants felt two rubber hands as their own hands. However, some other studies have provided conflicting results suggesting only one fake hand can be owned and incorporated into body representation. Thus, it is still unclear if we can truly experience ownership over extra limbs.

To address this issue, we studied the supernumerary hand illusion with a modified experimental design that allowed us to disambiguate ownership of one or two rubber hands. The participant's real right hand was hidden under a platform while two identical right rubber hands were placed adjacently above. The participant's real right hand was placed directly under the right rubber hand. After 2 minutes of stroking of the two rubber hands and real hand, participants answered a questionnaire (Experiment 1; N = 40, 14 males, mean±SD age: 27.9±7.29 years). The questionnaire included separate statements about ownership and referral of touch to each of the two rubber hands and to both hands simultaneously. We used a two-by-two factorial design where we applied synchronous strokes to both rubber hands (SS), synchronous strokes to one and asynchronous to the other (AS and SA) or asynchronous strokes to both fake hands (AA). In Experiment 2 (N = 24, 12 males, mean±SD age: 29.3±9.58 years), we applied a "syringe threat" to the right rubber hand after one-minute of strokes while recording participant's skin conductance response (SCR) as objective physiological evidence of ownership. Here we threatened the right rubber hand in the SS, SA and AA conditions, which allowed us to directly contrast dual versus single hand ownership.

Questionnaire results of Experiment 1 demonstrated that participants felt both referral of touch and ownership over both rubber hands in the critical SS condition when both fake hands were stroked synchronously with the real hand (S5: $\chi 2$ (3) = 43.629, $p < 0.001$; S6: $\chi 2$ (3) = 56.867, $p < 0.001$). SCR results of Experiment 2 confirmed the participants respond more intensely when threatening the right rubber hand in SS condition compared to the SA and AA conditions (SS > SA: t (23) = 3.009, p = 0.006; SS > AA: t (23) = 2.353, p = 0.028).

Taken together, these results demonstrate that the rubber hand illusion can be used to induce the true sense of ownership over supernumerary hands. These findings emphasize the dynamic flexibility of body representation and bring new perspectives into current engineering studies of supernumerary robotic limbs and advanced prostheses for amputees.

Title: Fluidity of gender identity induced by illusory body sex change

Authors: *P. TACIKOWSKI, J. FUST, H. EHRSSON
Karolinska Inst., Stockholm, Sweden

Abstract: Introduction: Gender identity is a subjective sense of being male, female, both, or neither. It remains unknown how stable or fluid gender identity is over time. Here, we induced a perceptual illusion of having the opposite-sex body to test the hypothesis that the perception of one's own masculine or feminine physical characteristics shapes gender identity dynamically.
Methods: In four behavioral studies, 205 healthy adults (102 females; age: 26±5) wore head-mounted displays and observed a stranger's body (male or female) from a first-person perspective. The stranger's body was continuously stroked with a ball attached to a stick and the experimenter applied synchronous touches on the corresponding parts of the participant's body. We expected that this visuotactile synchrony (sync) would induce a perceptual illusion that the stranger's body is one's own, whereas asynchrony (async) would break the illusion and serve as a near-perfect control. Thus our 2-by-2 within-subject design included the "body-sex-change" condition (sync-opposite-sex) and three control conditions (sync-same-sex, async-same-sex, async-opposite-sex). We measured the illusion psychometrically and objectively by recording skin-conductance stress responses when the stranger's body was physically threatened. Gender identity was measured with objective behavioral tests (Implicit Association Task) and self-report questionnaires. These measures were applied during each condition which allowed us to track changes in gender identity across different embodiment contexts.
Results: As expected, psychometric and skin-conductance data showed that the body-sex-change illusion was successfully induced in all our studies. With regard to the main research question, we found that participants who experienced a strong body-sex-change illusion balanced their implicit associations between the self and both genders (Study I: ρ_{64}=0.31; P=0.014) and shifted their subjective sense of masculinity/femininity toward the opposite gender (Study II: r_{33}=0.46; P=0.007). We also found that the illusion led to less stereotypical beliefs about oneself (Study

III: r_{44}=0.35; P=0.022) and reduced implicit gender-stereotypes (Study IV: ρ_{64}=0.46; P=0.008). Importantly, updating of gender identity was enhanced for participants who generally had a strong gender-bias, which suggests that an internal conflict between pre-existing attitudes and ongoing body perception underlies fluidity of gender identity.
Conclusions: These findings show that body perception dynamically shapes gender identity and that the sense of own gender is more fluid than commonly assumed.

Title: Investigating the multisensory mechanisms of full-body ownership using the illusion of owning an entire artificial body

Authors: *S. H. O'KANE[1], H. EHRSSON[2]
[2]Dept. of Neurosci., [1]Karolinska Institutet, Stockholm, Sweden

Abstract: Introduction: The notion we each experience ownership for the single, entire body we call our own resonates fascination across diverse academic fields. In cognitive neuroscience, the use of the full-body ownership illusion has led to significant advancements in knowledge. However, how multisensory information across the body gives rise to a unified percept remains elusive. We investigated whether increasing the number of body parts involved in the illusion promotes enhanced perceived full-body ownership.
Methods: 48 healthy adults (28 males, mean age 26.9 ± 6.2) wore head-mounted displays providing a first-person perspective of a mannequin's body. Whilst observing tactile stimulation applied to the mannequin, temporally synchronous or asynchronous tactile stimulation was applied to their real bodies, involving 1, 2 or 3 body parts simultaneously (trunk; trunk and right arm; trunk, right arm and leg). We collected questionnaire, illusion onset (sec) and threat-evoked skin conductance (SCR) (μS) data and hypothesized that our measures would differentiate the synchronous from asynchronous conditions, but also potentially varying degrees of illusion intensity related to the number of body parts stimulated.
Results: As expected, illusion scores derived from the questionnaire were significantly increased for synchronous versus asynchronous stimulation ($Z = 5.460$, $p < .001$; $Z = 5.349$, $p < .001$; $Z = 5.423$, $p < .001$). However, post-hoc analyses revealed no significant differences depending on the number of sites receiving synchronous stimulation ($Z = 0.993$, $p = .320$; $Z = 2.012$, $p = .044$;

Z = 2.377, p = .017). No significant differences in illusion onset time (sec) were found ($\chi 2(2)$ = 0.424, p = .809), suggesting this aspect also remained stable. Interestingly, only items specific to illusory ownership of the mannequin's right arm and leg revealed significant differences across the synchronous manipulation. Highlighting the essential role of multisensory integration, ownership ratings for these parts were significantly higher during conditions in which they were stimulated than not (Z = -2.850, *p* = .004; Z = -3.500, *p* < .001; Z = -2.930, *p* = .003; Z = -3.283, *p* = .001). Finally, a significant difference in the magnitude of SCRs was identified for 1 body part (synchronous) versus 3 body parts (asynchronous) (Z = 2.322, *p* = .020), whilst there was no significant difference for 1 versus 3 body parts (both synchronous) (Z = -1.218, *p* = .223). **Conclusions**: These findings are consistent with the notion that full-body ownership is mediated by generalization from part-to-whole, a percept that is only subtly enhanced by converging multisensory input across multiple body segments.

Title: Incongruent visuo-tactile-vestibular stimulation leads to body disownership and feelings of depersonalisation and derealisation

Authors: *N. PREUSS, H. H. EHRSSON
Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Introduction: Vestibular sensations are often reported when individuals experience a loss of ownership such as during out-of-body illusions or dissociative experiences. The purpose of the present study was to investigate whether incongruent multisensory information results in a decreased perception of ownership over one's own body and, moreover, if this additionally results in feelings of depersonalization and derealization. A depersonalization experience concerns the feeling of 'the self being detached from the own body' whereas a derealization experience concerns the experiences of the world around us as being 'unreal'. **Methods:** Participants (N=30) saw their own body from a first-person perspective through a head-mounted display showing a live 3D-video stream during six different conditions. In these conditions they were exposed to direct current galvanic vestibular stimulation (DC-GVS), no stimulation or

sham stimulation, where the electrodes were attached to the neck and DC stimulation was applied. At the same time, touches were applied to their abdomen and upper legs using a wooden stick. These touches were either synchronous or temporally delayed for one second, i.e. asynchronous. Each block lasted for three minutes and afterwards they filled out a questionnaire concerning ownership ('I felt as if the body I saw was my body') and depersonalization and derealization experiences (Likert-scale 0-4). **Results:** As predicted, Wilcoxon signed-rank test and Bayesian t-tests showed that asynchronous visuo-tactile stimulation resulted in a decreased ownership rating ($p<0.009$, $BF>6$). Importantly, Bayesian mixed models revealed that both DC-GVS and asynchronous visuo-tactile stimulation increased depersonalization ratings (DC-GVS mean increase=0.2, SD=0.1, CI: 0-0.4; visuo-tactile asynchronous mean increase =0.2, SD =0.1, CI= 0-0.3). Moreover, the derealization ratings were affected by asynchronous visuo-tactile stimulation (visuo-tactile asynchronous mean increase=0.2, SD =0.1, CI= 0.1-0.4). **Discussion**: We conclude that weak sensations of depersonalization and derealization can be elicited in healthy participant through incongruent visual, tactile and vestibular signals in a full-body disownership paradigm. This finding is important because it provides a new mechanistic multisensory framework to investigate depersonalization and derealization in cognitive neuroscience and cognitive psychiatry.

Title: Effect of vestibular information on early visual processing: An EEG study

Authors: *T. UENO[1], K. MATSUSHITA[2], M. OGAWA[2], A. AOYAMA[2]
[1]Grad. Sch. of Media and Governance, [2]Fac. of Envrn. and Information Studies, Keio Univ., Fujisawa-Shi, Japan

Abstract: The vestibular system has a critical role in sensing body tilt, gravity direction, and acceleration input, and receives information from other sensory systems such as the visual system. Because of the technical difficulty in designing a neuroimaging experiment for testing the vestibular system in humans, however, little is known about the interaction between vestibular and visual information. Here, we tested the visual-vestibular interaction using EEG with two apparatuses: a virtual reality head-mounted display and an inversion table. Videos of falling scenes in either upward or downward direction were randomly displayed by the VR

device, while a participant's body tilt was alternately manipulated for every eight video plays in either an upright or inverted manner by the inversion table. Therefore, four combinational conditions were established with regard to the orientation of retinal images and the direction of gravity. Event-related potential analysis revealed that continuous attenuation of visual activity was observed from 100-200 ms after the start timing of falling in the inverted body condition as compared with the upright condition, irrespective of the visual falling direction. Moreover, Granger causality analysis showed feedback connection from the temporoparietal vestibular area to the visual area.These findings indicate that visual activity is suppressed by unusual vestibular information and that visual-vestibular interaction begins at a relatively early stage of visual processing.

Title: The calcium-gated chloride channel anoctamin 2 as a modulator of inhibitory transmission in the cerebellum

Authors: F. AUER, D. FLEISCHHAUER, L. SCHÜSSLER, L. SCHÜLE, F. MÖHRLEN, *S. FRINGS
COS Mol. Animal Physiol., Heidelberg Univ., Heidelberg, Germany

Abstract: Neuronal networks process incoming signals through excitatory and inhibitory synapses. Both methods of passing information can be modulated independently, which is particularly important for learning processes and memory formation. Severe problems may occur when these mechanisms of plasticity are impaired. We observed such a dysfunction in a mouse line lacking Anoctamin 2 (ANO2), a calcium-gated channel that conducts chloride and bicarbonate. These mice show motor coordination deficits as well as impaired motor learning, indicating an important role of ANO2 in the cerebellum. Previous studies have provided initial evidence that spontaneous inhibitory postsynaptic currents (IPSCs) are transiently reduced after climbing fiber activity. This form of short-term synaptic plasticity, which has been named *depolarization-induced depression of inhibition* (DDI), is supposed to be dependent on a diminished chloride gradient at the GABAergic synapses on Purkinje cell dendrites. Our initial data suggested that DDI was decreased in $ANO2^{-/-}$ mice but the precise role of ANO2 could not be established. The present exploratory study aims to further elucidate this mechanism of

synaptic plasticity.
We performed whole-cell patch clamp recordings on Purkinje cells in acute cerebellar slices of adult male mice, both wildtype (C57Bl/6) and ANO2$^{-/-}$. We stimulated inhibitory interneurons to monitor evoked IPSCs in Purkinje cells. Then a train of depolarizing pulses was given via the patch pipette to mimic a climbing-fiber signal. This way, DDI can be induced through opening of dendritic voltage-gated calcium channels without climbing fiber activity. During the recording, the Purkinje cells are loaded with the fluorescent pH-sensitive dye HPTS to measure IPSCs and changes in pH simultaneously. In addition, we investigated the localization of ANO2 by immunohistochemistry and by single-cell PCR. Moreover, we examined density and arrangement of synapses by climbing fibers and interneurons on the dendritic arbor of Purkinje cells.
First results indicate that DDI is indeed reduced in ANO2$^{-/-}$ mice. This supports the assumption that ANO2 is expressed in Purkinje cells and is necessary for this type of synaptic plasticity, which could explain the symptoms of ataxia in ANO2$^{-/-}$ mice. The changes in pH during the measurements seem to be similar for wildtype and ANO2$^{-/-}$ mice, suggesting that ANO2 is not a major player in bicarbonate homeostasis. Furthermore, immunohistochemical stainings of ANO2 also indicate the localization of ANO2 in Purkinje cell dendrites. The data suggest that ANO2 is an important modulator of inhibitory transmission in the cerebellum.

Title: The interaction of Purkinje cell firing rate-dependent phase response curves and cerebellar network oscillations

Authors: *Y. ZANG, E. DE SCHUTTER
Computat. Neurosci. Unit, Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: Phase response curves (PRCs), describing the response of spiking neurons to brief external stimuli, have been widely used to study biological oscillations. The shapes of PRCs are variable between different neurons and even differ for the same cell under different states. In mammalian neurons, Purkinje cells are unique because of their phase-independent PRCs at low firing rates. Positive peaks of Purkinje cell PRCs get larger and broader with increasing firing rates. However, none of the existing models or theories can reproduce this phenomenon, leaving the underlying mechanisms undetermined.

We have developed a new morphologically detailed Purkinje cell model, which is constrained by a plethora of available experimental data (https://doi.org/10.1101/284026). Our new model reproduces the transition from phase-independent integrator to a phase-dependent mode by increasing the simple spike firing rate. This model highlights the critical regulatory role of dendrites in Purkinje cell somatic firing properties and PRC. In our model without dendrites, the PRC peaks get smaller and narrower at higher firing rates.
We further test the role of the firing rate-dependent PRC in the synchronization of Purkinje cells. Purkinje-to-Purkinje inhibitory connections have been well documented in recent years. We have built a sparsely connected network including 200 Purkinje cells with 0.2 connection probability. In the network model, we find that the network can exhibit "spike-to-spike synchrony" under a *in vitro* condition at high cellular firing rates but not at low firing rates. With larger background synaptic input noise, the coefficients of variation (CVs) of interspike intervals increase, and the network is gradually dominated by high-frequency oscillations (~ 160 Hz). In agreement with previous findings (de Solages *et al*. 2008), the oscillation power can be reduced by larger noise, but the oscillation frequency is relatively insensitive to the noise level. At higher cellular firing rates, the network oscillation power increases when the CVs of interspike intervals are the same. This increased oscillation power is due to the larger and broader PRCs at high cellular firing rates. Given the fact that cerebellar nuclear neurons preferentially relay the spike timing of synchronized Purkinje cells, the firing rate-dependent PRC may be a critical property of the cerebellum to organize its output.

Title: The role of local inhibitory circuits in expression of cerebellar-dependent motor memories

Authors: *M. J. ROWAN, J. CHRISTIE, A. BONNAN
Max Planck Florida Inst., Jupiter, FL

Abstract: The cerebellum plays a key role in motor learning using multiple sites of plasticity within its circuitry. A major component of the cerebellar circuit are molecular layer interneurons (MLIs). MLIs provide feedforward inhibition onto Purkinje Cells (PCs) thereby controlling the output of the cerebellar cortex. Thus, plasticity within this inhibitory circuitry could play a major

role in the expression of motor memories. In acute cerebellar slices, we observed potentiation of MLI feedforward inhibition onto PCs following conjunctive stimulation of parallel fibers and climbing fibers. This complemented LTD at parallel fiber-PC synapses. Thus convergent forms of plasticity work in unison to weaken the ability of parallel fibers to excite PCs. To assess the role of MLIs in the expression of learning, we used fiberphotometry to directly measure population-level calcium activity of MLIs *in vivo* during vestibulo-ocular reflex (VOR). The VOR is a compensatory eye movement in response to head rotation that is subject to re-calibration through cerebellar dependent plasticity. MLI activity was measured both before and after VOR learning. In naïve animals, MLIs displayed a phasic response to vestibular stimuli. Interestingly, the phase of the MLI response was shifted following gain increase learning indicating a dramatic change in the organization of their activity following adaptation. In a second set of experiments, we manipulated MLI activity using optogenetics to inhibit MLIs before and after VOR gain-increase training. Although inhibiting MLIs had no effect on baseline VOR performance, we found that optogenetic suppression of MLI activity after learning resulted in near-elimination of the learned increase in VOR gain. Together our results suggest that MLIs are an important site of memory storage necessary for rapid expression of motor learning.

Title: MLI disinhibition relieves gating of climbing fiber-mediated learning in the cerebellum

Authors: *K. ZHANG[1], G. G. GROSS[2], D. B. ARNOLD[2], J. M. CHRISTIE[1]
[1]Max Planck Florida Inst., Jupiter, FL; [2]Biol., USC, Los Angeles, CA

Abstract: The cerebellum has emerged as a key model system to study motor learning**.** However, the mechanisms underlying the regulation and encoding of adaptive movements in its cortex are poorly understood. Our previous work indicates that inhibition from molecular layer interneurons (MLIs) is sufficient to override the ability of climbing fibers (CFs) to instruct learning during adaptation of the vestibular-ocular reflex (VOR). However, to assess for the necessity of MLIs in gating learning, we used a genetically encoded toolkit to manipulate the activity of floccular MLIs during the performance of the VOR. Suppressing MLI activity with halorhodopsin during a normally non-adapting visual-vestibular stimulus produced an increase in the VOR. This adapted response resembled the learned change in the VOR induced by CFs during retinal slip errors. This result suggests that MLI inhibition prevents CFs from instructing learning when adaptation is unnecessary or inappropriate. It also implies that inhibition from

MLIs must be suppressed for CF-mediated learning to occur. In support of this hypothesis, we found that mice with ablated inhibition between MLIs were unable to adapt their VOR during opposite direction visual-vestibular pairing. However, learning could be rescued in these mice by optogenetic suppression of MLI activity during visual-vestibular pairing. Thus, disinhibition of CF-evoked Purkinje cell signaling appears to be accomplished by an MLI-MLI microcircuit. These findings point to a decisive role for MLIs in regulating how and when learning is implemented in the cerebellum.

Title: Development of large-scale artificial cerebellum and its petaflops simulation on PEZY-SC2 processor

Authors: *W. FURUSHO, T. YAMAZAKI
The Univ. of Electro-Communications, Tokyo, Japan

Abstract: The cerebellum is a repeated structure of a corticonuclear microcomplex, which is considered as a functional unit of the cerebellum. Because the structure of the cerebellum is known clearly, many numerical cerebellar models have been built on workstations, accelerators such like graphics processing units (GPUs) and supercomputers. In this study, we built a numerical model of the cerebellum on a supercomputer Gyoukou developed by PEZY Computing K.K. and ExaScaler Inc. Gyoukou is composed of 10,000 PEZY-SC2 processors. A PEZY-SC2 processor contains 2,048 processing elements and hierarchical cache memory We implemented a spiking network model of a corticonuclear microcomplex composed of 1 million neurons on a PEZY-SC2 processor, where neurons were modeled as leaky integrate-and-fire units. Using 7,920 out of 10,000 PEZY-SC2 processors on Gyoukou, we built a network model of the cerebellum composed of 8 billion neurons. As a cerebellar learning mechanism, we implemented synaptic plasticity at parallel fiber-Purkinje cell synapses called long-term depression and long-term potentiation on this model. We optimized our program by using local memories on processing elements and hierarchical cache memory to achieve realtime simulation. As a benchmark test, we carried out a computer simulation of a typical form of cerebellar

learning on eye movement reflex called gain adaptation of optokinetic response (OKR). We confirmed that our model could perform the simulation in realtime. In fact, a 6-sec simulation completed within 2.2 sec of wall clock time. Next, we measured performance of our program. We achieved 1.85 petaflops in single precision floating points in the OKR simulation, indicating 2.9 percent of the effective performance. Finally, we examined a weak scaling property in computational time. We confirmed that the execution time was almost constant while increasing the number of used prosessors and the number of neurons simultaneously. This weak-scaling property allows us to build a human-scale artificial cerebellum with online learning capability if we could use more processors. In summary, our artificial cerebellum will provide a means to gain better understanding of what the cerebellum computes.

Title: Dynamic coordination of climbing fiber input to Purkinje cell populations during goal-directed action

Authors: *D. KOSTADINOV, M. BEAU, M. B. POZO, M. HAUSSER
Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: The activity of cerebellar Purkinje cells (PCs) is important for motor execution and learning. Activation and suppression of PCs can inhibit and drive movements, respectively, and coactivation of climbing fiber and parallel fiber inputs to PCs drives parallel fiber synaptic plasticity that is a major locus of cerebellar learning. In this framework, climbing fibers, which trigger complex spikes (CSs) in PCs, carry error signals and drive trial-by-trial adaptation, but do not modify behavior in real time. However, in some behavioral contexts, complex spiking can precede movement and cannot therefore solely encode errors. These complex spikes may serve as a timing signal for movement initiation. Our goal is to reconcile how predictive and reactive CS signals are represented in PC populations during motor execution, learning, and predictive sensory processing.
To address this question, we used 2-photon microscopy to image CS-evoked dendritic calcium transients across 200-300 PCs expressing GCaMP6f while mice performed a virtual-reality based sensorimotor integration task. Mice were head-fixed and trained to use a steering wheel with

their forepaws to translate a virtual object from eccentric visual positions to the midline to obtain a delayed reward.
PC dendrites in the simplex lobule and adjacent vermis exhibited diverse and spatially clustered CS signals in our task. PCs fired complex spikes just prior to movement onset, during the delay between the end of movement and reward, and in response to the audible click associated with reward. Vermis PCs showed prominent motor-related signals, the amplitude and timing of which were predictive of trial outcome. Many were also activated by the reward click. In contrast, simplex PCs exhibited less prominent motor signals, while responses during the delay period and at reward delivery were more reliably observed. Co-activation of adjacent microzones was dynamic and task-related. In both simplex and vermis, reward click responses were contextually modulated: random rewards evoked large responses, task-related rewards evoked moderate responses, and tone-cued rewards evoked negligible responses. However, omissions of expected reward evoked well-timed error responses in simplex PCs but not vermis PCs.
Our results illustrate regional differences in predictive and reactive CS signals: medial cerebellar regions preferentially signal movement kinematics and more lateral regions preferentially signal learned associations and errors. These findings help resolve two opposing views of the role of climbing fiber input for cerebellar function.

Title: Response to hypoxic preconditioning of glial cells from the roof of the fourth ventricle

Authors: *M. BECERRA GONZÁLEZ[1], E. GUALDA[2], P. LOZA-ALVAREZ[2], A. MARTÍNEZ-TORRES[1]
[1]Neurobiología celular y molecular, Univ. Nacional Autónoma De México, Querétaro, Mexico; [2]Super-resolution Light Microscopy & Nanoscopy, Inst. de Ciencies Fotoniques, Castelldefels, Barcelona, Spain

Abstract: Recent evidence shows that the cerebellar surface that contacts the ventricular cavity possesses a peculiar diversity of cellular populations, which contrasts with the idea that the organization of cerebellum is highly stereotyped. This population includes oligodendrocytes,

glial and neuronal lineages, and probably progenitor cells. On the surface of the lobe I, a novel structure was found and named the Ventromedial cord (VMC). It is composed by GFAP+ and nestin+ glial cells. Cells positive for these markers and in contact with the cerebrospinal fluid are known to respond to hypoxic preconditioning (HPC) through proliferation and differentiation, therefore we explored whether the VMC maintains this ability.
Analysis of the VMC was performed using adult (P25) transgenic mice (n = 3-6), expressing the green fluorescent protein under the GFAP promoter (GFAP-GFP). Clarified brains analyzed by light sheet microscopy revealed a reduction in the number of cells of different lobes of cerebellum. By day 4 after HPC, GFP expression decreased in the VMC. Cryoprotected coronal sections showed displacement of Bergmann glia (BG) somas, and a gradual retraction of their processes; furthermore, Golgi staining disclosed a decrease in the area of the soma of BG and a rise in the length of protrusions. Western blots showed a decrease in expression of glial identity markers and an increase in the markers for mature neurons NeuN, microglia Iba1 and stem cells nestin. Immunofluorescence for Iba1 indicated that HPC induces morphological changes in the soma of microglial cells, which is a feature of these cells in the "activated" state. A slight incorporation of BrdU was found in the roof of the fourth ventricle and a screen of behavioral tests for motor coordination showed a tendency to lower performance.
We conclude the VMC exerts a homeostatic response after HPC that is evidenced by changes in the expression of glial markers and morphology.

Title: Mechanisms of Purkinje cell-dependent instructive signaling in the cerebellum

Authors: *A. BONNAN[1], M. J. M. ROWAN[1], C. A. BAKER[2], M. BOLTON[1], J. M. CHRISTIE[3]
[1]MPFI, Jupiter, FL; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]Synapse Physiol. Group, Max Planck Florida Inst., Jupiter, FL

Abstract: The cerebellum is known to play a crucial role in motor learning. Purkinje cells (PC) give rise to the sole output of the cerebellar cortex and are therefore pivotal in this process. PCs can fire two different types of spikes: simple spikes (SS) in response to parallel fiber (PF)

stimulation and complex spikes (CS) as a result of climbing fiber input. The CS is a multicomponent response that includes a burst of sodium spikes at the soma and a dendrite-wide Ca^{2+} transient. A classic theory of cerebellar function postulates that CFs carry instructive signals to PCs that guide learning. However, recent findings indicate that learning may occur independent of CF activity suggesting the existence of other candidate instructive signals. To study the mechanistic basis of instructive signaling, we used the vestibulo-ocular reflex (VOR), a compensatory eye movement in response to head motion that is subject to re-calibration through cerebellar-dependent plasticity. We used optogenetics to selectively manipulate PC activity during vestibular stimulation and probe for the consequences of this activity by examining the gain of the VOR. Using subcellular targeting motifs to limit expression of channelrhodopsin to the PC soma and different intensities of stimulation, we were able to evoke activity with large, small or no dendritic Ca^{2+} influx during vestibular stimulation. We found that PC activity associated with dendritic Ca^{2+} was sufficient to induce a transient memory in the VOR and that the direction of this memory depended on the amplitude of the evoked Ca^{2+} signal. However learning did not occur when Purkinje cells were activated without a dendritic Ca^{2+} transient. Our results suggest that Ca^{2+} influx in PC dendrites is necessary for learning and determines the direction of learning.

Abstract: A common feature of learning and memory systems is that the neural circuitry required for the expression of long-term memory is distinct from that required for the expression of memory soon after acquisition. Whereas this transformation has been clearly demonstrated at

the level of phenomenology—for example, from hippocampus-dependent to hippocampus-independent storage of declarative memories—the mechanism by which changes supporting consolidation are orchestrated across synaptic sites is not well understood.
We explored this problem in a well-characterized system: the gaze-stabilizing cerebellar and brainstem circuitry underlying the vestibulo-ocular reflex (VOR). When the head rotates in space, the eyes reflexively counter-rotate so that image motion on the retinas is minimized. Experience in a virtual environment where the visual feedback is manipulated to suggest that head movements are eliciting erroneously large or small eye movement responses induces an adaptive adjustment of the amplitude of the VOR. Initially, the expression of learning depends on the cerebellar cortex, but over time becomes cerebellum-independent, presumably reflecting a transfer of the synaptic changes supporting the memory to a site downstream.
We constructed a circuit model of VOR learning that includes empirically motivated plasticity rules at synaptic sites in the cerebellar cortex and brainstem. In the cerebellar cortex, we used an error-driven rule consistent with the Marr-Albus-Ito theory. In the brainstem, the hypothesized target of consolidation, we used two candidate learning rules based on previous studies: a heterosynaptic rule, and a Hebbian rule with a sliding threshold. During simulated VOR training, our model with either brainstem rule was able to consolidate learned increases in eye movement amplitude, *without* replay of training signals in the post-training period. In both cases, the dynamics of the brainstem synapse integrate changes in the cortical synapse, and therefore require fine-tuning for stability. Our results suggest that the storage of an analog connection weight for long-term memory is analogous to the maintenance of persistent analog activity in working memory networks; hence, continuous attractor dynamics may also be important for memory consolidation.

Title: Supralinear Ca^{2+} signals in cerebellar Purkinje neurons associated with concomitant parallel fibre and climbing fibre inputs: mGluR1-dependent and mGluR1-independent distinct components

Authors: *K. AIT OUARES[1], M. CANEPARI[2]
[1]Liphy, Saint Martin D Héres, France; [2]Equipe MOTIV, LIPhy, CNRS UMR 5588, St Martin d'Hères cedex, France

Abstract: In cerebellar Purkinje neurons (PNs), the concomitant activation of parallel fibre (PF) synapses and of the climbing (CF) input produce a Ca^{2+} signal larger than the linear summation of the signals associated with the PFs and the CF (supralinear Ca^{2+} signal). This phenomenon, strictly dependent on the delay between the PF and the CF inputs, is associated with short-term and long-term PF synaptic plasticity. Using ultrafast membrane potential (V_m) and Ca^{2+} imaging techniques, we explored the supralinear Ca^{2+} signals at different delays between a train of five local PF-EPSPs and a CF-EPSP. These techniques included the use of Ca^{2+} indicators of different affinities and the pharmacological inhibition of specific molecular targets. We found that when the CF-EPSP occurs with ~10 ms from the end of the PF train, the supralinear Ca^{2+} signal is independent of type-1 metabotropic glutamate receptors (mGluR1) and is due to two mechanisms: the increased Ca^{2+} influx through P/Q-type Ca^{2+} channels enabled by PF-depolarisation inactivating A-type K^+ channels; and a transient saturation of endogenous Ca^{2+} buffers amplifying free Ca^{2+} concentration. At longer delays (~100 ms), the supralinear Ca^{2+} signal is mGluR1-dependent and correlated with an increase in mGluR1-dependent Ca^{2+} influx via cation channels. In this case, the supralinear Ca^{2+} signal is not associated with larger depolarisation since the additional V_m transient produced by the cation current is compensated by a slow dendritic hyperpolarisation preventing activation of P/Q-type Ca^{2+} channels. These results shed new light on one of the most important phenomenon in cerebellar physiology.

Title: Purkinje cell dendrites encode graded information dependent on the level of climbing fiber activity

Authors: *J. M. CHRISTIE, S. B. AMAT, M. A. GAFFIELD
Synapse Physiol. Group, Max Planck Florida Inst., Jupiter, FL

Abstract: Climbing fibers excite Purkinje cells producing dendritic Ca^{2+} signals useful for instructing plasticity and learning. Experimental evidence indicates that climbing fiber-evoked

responses in Purkinje cells encode a range of behaviorally relevant information. The mechanisms that contribute to graded responses in Purkinje cells aren't currently known. Excitation from parallel fibers and inhibition from molecular layer interneurons have the potential to modulate climbing fiber-mediated Ca^{2+} signaling in Purkinje cells contributing to the dynamics of the integrated, dendritic response. It also remains possible that the level of presynaptic climbing fiber activity itself conveys information pertinent for determining the amplitude of the postsynaptic Ca^{2+} signal. We sought to examine these possibilities by directly monitoring the activity of Purkinje cells, climbing fibers, and molecular layer interneurons in cerebellar Crus I of awake mice to a range of unexpected sensory stimuli. Graded Ca^{2+} signals were produced in Purkinje cell dendrites; the amplitude of the response changing with the type and intensity of the stimulus. Interestingly, the presynaptic activity level of climbing fibers was altered in a likewise manner. In contrast, molecular layer interneurons responded opposite to what would be expected for these neurons if suppressive inhibition was directly responsible for determining Ca^{2+} signal amplitude (i.e., MLI activity increased with the size of the evoked response in Purkinje cells). These results demonstrate that the amplitude of climbing fiber-evoked Ca^{2+} signals in Purkinje cell dendrites is a largely determined by the firing level of climbing fibers.

Title: Optogenetic stimulation of amygdala central nucleus specific to conditioned stimulus is sufficient to modulate cerebellar learning

Authors: *S. J. FARLEY[1,2], J. H. FREEMAN[2,1]
[1]Iowa Neurosci. Inst., Iowa City, IA; [2]Psychological and Brain Sci., The Univ. of Iowa, Iowa City, IA

Abstract: Pharmacological inactivation of the amygdala central nucleus (CeA) in rats impairs delay eyeblink conditioning (dEBC), a well-known cerebellum-dependent task (Farley 2016, 2018). In order to better understand amygdala modulation of cerebellar learning, we used gain-of-function and loss-of-function optogenetic techniques in the CeA with adult rats during dEBC. For gain-of-function, channelrhodopsin (AAV-hSyn-hChR2(H134R)-EYFP) in the CeA was stimulated with 473nm (blue) light. Archaerhodopsin (AAV-hSyn-eArch3.0-EYFP) in the CeA was used as the loss-of-function opsin, stimulated by 561nm (green) light. Control animals

received AAV-hSyn-EYFP to their CeA. After recovering from optical implant surgery, rats commenced training in five, 100-trial sessions of dEBC. Trials consisted of tone (CS) - shock (unconditioned stimulus [US]) pairings. Blue light was illuminated at 20 Hz (5 ms pulses) for the ChR2 animals, and green light was constant for Arch animals. In all cases, laser stimulation was limited to the duration of the conditioned stimulus (CS) period only (400 ms). Animals trained with Arch stimulation showed impaired learning relative to controls, whereas animals trained with ChR2 stimulation showed a slightly enhanced learning curve. The rate of conditioned responses for ChR2 animals was only slightly enhanced compared to controls. However, CR onset latency was significantly lower during acquisition with ChR2 stimulation compared to controls and Arch animals. CR amplitude and CR area were also significantly increased for the ChR2 animals. Similar to our previous findings (Farley 2016, 2018), no metrics pertaining to the unconditioned response (peak, latency, area, etc) revealed group differences or interactions across opsin groups. This finding suggests that amygdala modulation during cerebellar associative learning may not be occurring through the US pathway. Since all of the statistically significant findings were across CR characteristics, it may be that perturbations to the CeA effect the sensory input of the CS to the cerebellum (Farley 2016, 2018; Pochiro 2015; Siegel 2015; Taub 2010). Thus, the CeA may have a modulatory role for gating sensory information in pre-cerebellar areas, e.g. the pontine nucleus.

Title: Cerebellar climbing fibers signal reward expectation in both voluntary and classically conditioned behaviors

Authors: *W. E. HEFFLEY, Z. XU, C. HULL
Duke Univ., Durham, NC

Abstract: Classical models of cerebellar learning posit that climbing fibers operate according to a supervised learning rule to instruct changes in motor output by signaling the occurrence of movement errors. However, recent evidence has challenged this view by demonstrating that climbing fiber-driven complex spiking can signal a different type of error consistent with a temporal difference (TD) reinforcement learning rule after the acquisition of learning in an aversive conditioning paradigm. To test whether sensory prediction error provides a

generalizable model to explain the behavior of climbing fibers in other regimes and across other cerebellar regions, we have measured complex spiking in head-fixed mice during two reward-driven behavioral paradigms. First, we trained mice to associate a visual cue with an upcoming reward and measured complex spiking both at the population level and within individual Purkinje cell dendrites before and after learning. These data suggest that individual climbing fibers can signal distinct task features before and after learning in a manner that is consistent with reward expectation. However, we do not find evidence that climbing fibers can signal negative prediction error in this task, and thus our data are not strictly consistent with a TD learning rule. We also trained mice on a second task that requires a properly timed forelimb movement to receive reward. Population and single dendrite Purkinje cell calcium imaging revealed similar climbing fiber driven responses as observed in the classical conditioning paradigm. Specifically, climbing fiber activity scaled with reward expectation. Again, however, we did not observe activity consistent with negative reward prediction errors as required by TD reinforcement learning models. Instead, we observed elevated complex spiking when reward expectation was high but no reward was delivered, consistent with climbing fibers signaling an unsigned prediction error related to violated expectation. Results from these two behavioral paradigms thus suggest that climbing fibers can both report and evaluate predicted task outcomes, consistent with the hypothesis that the cerebellum operates according to a forward model. However, these results also suggest that such predictive instructional signals are not driven exclusively by motor errors.

Title: Sensory and motor representations in the inferior olive

Authors: *D. MARKOV[1], R. FELIX[2], M. ORGER[2], R. PORTUGUES[1]
[1]Max Planck Inst. of Neurobio., Martinsried, Germany; [2]Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: The olivo-cerebellar system plays a pivotal role in sensory-motor control and coordination in vertebrates. According to the classical theory of cerebellar cortex, the inferior olive (IO) provides Purkinje cells with error information which drives motor learning in the cerebellum. Even though this process has been extensively studied over the last five decades, it remains unclear whether the nature of IO signals is more sensory, motor or both. Therefore, our aim in this study is to characterize sensory and motor representations in the IO and investigate

their potential interactions and spatial organization. In our experiments, we presented a set of different sensory stimuli (monocular and binocular translational and rotational motion) to larval zebrafish, while simultaneously tracking their eye and tail movements and recording calcium activity in genetically identified IO neurons with a 2-photon microscope. We found direction-selective sensory responses that formed a spatially-organized functional map. Interestingly, directional tuning properties of the IO neurons were predictive of their morphological characteristics, obtained with single-cell labeling, with different functional types projecting to distinct regions of the cerebellum. To isolate sensory-related responses from motor-related activity and their interactions we employed a virtual reality behavioral assay. Although we found few purely motor representations, a subpopulation of the IO neurons modulated their response depending on behavioral output and its visual feedback. These data add evidence that IO signals provide Purkinje cells with a combination of sensory and motor related information.

Title: An adaptive control theory for cerebellar mediated tuning of the oculomotor neural integrator

Authors: *A. ALEMI[1], E. R. F. AKSAY[2], M. S. GOLDMAN[3]
[1]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; [2]Weill Cornell Med. College, Cornell Univ., New York, NY; [3]Ctr. for Neurosci., Univ. of California Davis, Davis, CA

Abstract: Neural systems need to adapt and tune their dynamics in the face of changes in the environment. For tuning of the dynamics of motor outputs, the cerebellum is thought to be a key locus of adaptive plasticity. Here, we formulate this idea in the language of adaptive control theory. We focus on a specific cerebellar mediated motor control function: the maintenance of stable eye position by the oculomotor neural integrator brain region. This circuit is responsible for accurately holding the eyes at a given position by temporally integrating transient eye velocity input commands and keeping the resulting eye position commands in short-term memory in the format of persistent activity. Experimental evidence (Major et al 2004) suggests

that the cerebellum is necessary for the tuning of the oculomotor integrator; however, a general theory for how the oculomotor system can use biologically plausible synaptic plasticity rules to stably tune and consolidate this tuning is missing.
We construct a circuit model in which the oculomotor neural integrator is recurrently connected to the cerebellum. Retinal slip error signals are separately conveyed via the climbing fibers to the cerebellar Purkinje cells. We consider two potential sites for synaptic plasticity: one site is at the parallel fiber to Purkinje cell synapses and is guided by the retinal slip error; the other site is at the neural integrator recurrent connections and is guided by the Purkinje cell output. We find a set of local, correlation-based, synaptic plasticity rules such that a cost (Lyapunov) function consisting of squared deviations from optimal tuning is non-increasing. Our results demonstrate that the system gets tuned as long as the plasticity within the cerebellum occurs faster than the plasticity at the neural integrator recurrent connections. This suggests a justification from first principles for the common assumption that the cerebellum performs fast learning that is consolidated more slowly by cerebellar target circuits. This work may provide a general framework for understanding cerebellar mediated adaptation of motor commands.

Title: Short duration voluntary exercise does not alter cerebellar morphology or motor performance in a mouse model of human spinocerebellar ataxia type 1

Authors: *E. DEENEY, R. EMPSON
Physiol., Univ. of Otago, Dunedin, New Zealand

Abstract: Individuals that suffer from spinocerebellar ataxia type 1 (SCA1) exhibit motor coordination deficits that progressively worsen and to date there is no effective treatment for SCA1. The climbing fibre-Purkinje neuron (CF-PN) synapse is a critical cerebellar synapse that shows abnormalities in both human SCA1 patients and in a mouse model of SCA1, and could be a site for therapeutic intervention. Exercise increases longevity in SCA1 (154Q) mice and has mixed benefits in human ataxia patients, but the beneficial effects of exercise for PN morphology and motor performance are not known. Here, we tested the hypothesis that a short period of voluntary exercise rescues PN morphology and motor performance in SCA1 mice.
Twelve-week-old ataxic SCA1 and non-ataxic wild-type (WT) mice were sub-divided into

exercising (E) and non-exercising (NE) groups for three weeks. Mice were individually housed in smooth-walled cages to encourage voluntary wheel running. Thereafter, we examined their fore-limb and hind-limb base-of-support (Catwalk, Noldus). After completion of testing, we prepared sagittal cerebellar sections (30 μm) for fluorescence immunohistochemistry and confocal microscopy using calbindin (Cb) to identify PNs and measure molecular layer height (MLH) within folia III, VI, VIII and X of the cerebellar cortex.
SCA1 NE mice exhibited PN dendritic atrophy throughout all folia compared to WT NE mice and this was not altered in SCA1 or WT E mice (interaction $P<0.05$, column $P<0.001$, two-way ANOVA, n = 6 per group, for both measurements). Gait analysis revealed a significant difference between fore-limb and hind-limb base-of-support between WT and SCA1 mice ($P<0.01$, two-way ANOVA, WT: n = 6 and SCA1: n = 5), similarly this was not influenced by exercise ($P>0.05$, two-way ANOVA, SCA1 NE: n = 7 and SCA1 E: n = 5).
These findings indicate that a short period of voluntary exercise is insufficient to alleviate symptoms in SCA1 mice. Instead, forced exercise, or motor learning activities of a more challenging nature, may be more beneficial for treating SCA1.

Title: Purkinje cells in a cerebellar neural network model acquire climbing fiber driven activity modulation for accurate movements

Authors: *H. YAMAURA, T. YAMAZAKI
The Univ. of Electro-Communications, Chofu, Tokyo, Japan

Abstract: The cerebellum plays an important role in accurate movements. Purkinje cells that are the only output cells of the cerebellar cortex project to deep cerebellar nucleus cells and inhibit them. Burst activity of the deep cerebellar nucleus cells is related to movements. Previous studies demonstrated that suppression of Purkinje cells activity can activate deep cerebellar nucleus cells and cause limb movements. However, plasticity mechanism of Purkinje cells activity modulation and effect on motor control have not been fully elucidated. In order to understand these mechanism, we built a neural network model of the cerebellum. First, we investigated how modulation of Purkinje cells activity is acquired. Purkinje cells receive input from parallel fibers (granule cell axons) and climbing fibers. Long term plasticity of Purkinje cells occurs by

correlated the parallel fibers activity with the climbing fibers activity. By conducting computer simulations, we demonstrated that the cerebellar model can acquire pauses in Purkinje cell activity depending on the climbing fiber inputs. Next, we investigated how do the modulation in Purkinje cell activity contribute to motor control. In experimental study, lever-pull task in mouse is used. In the task, mouse has to pull and hold the lever. We consider that motor commands to pull and hold are needed in order to execute the task accurately. The experimental study demonstrated that Purkinje cells receive climbing fiber inputs at various periods during the task. We conducted computer simulations based on the experimental data. We demonstrated that the Purkinje cells in the neural network model acquire various activity modulation depending on the spike timing in climbing fiber. Further, we simulated as Purkinje cells showing various modulation patterns project to deep cerebellar nucleus cell. Assuming that motor commands correspond to neural activity, we demonstrated that combination of various modulation patterns of Purkinje cells activity can generate desired activity of the deep cerebellar nucleus cell. The results indicate Purkinje cells acquire various modulation patterns depending on the climbing fiber inputs and combination of various modulation patterns of Purkinje cells activity contribute to accurate movements.

Title: Activity of cerebellar climbing fibers represents forelimb movements during voluntary lever-pull task in mice

Authors: *N. HIDAKA[1,2], S. TSUTSUMI[2], K. IKEZOE[1], Y. ISOMURA[3], M. KANO[2], K. KITAMURA[1,2]
[1]Univ. of Yamanashi, Chuo, Yamanashi, Japan; [2]Dept. of Neurophysiol., Univ. of Tokyo, Tokyo, Japan; [3]Tamagawa Univ., Machida, Tokyo, Japan

Abstract: Execution of voluntary movements depends critically on the cerebellum. The Purkinje cell (PC), which provides a sole output from the cerebellar cortex, plays a central role in motor control and learning. Decades of studies suggest that climbing fiber (CF) inputs to PCs represent errors in movements and are considered to function as teaching signals for motor learning. However, it is still unclear what components of signals for voluntary movements CFs convey,

and how they contribute to motor control and learning. Here, we performed *in vivo* two-photon calcium imaging in mice preforming forelimb lever-pull task in order to investigate activity patterns of CFs during execution of a voluntary movement.
Mice were trained to pull and hold a mechanical cantilever voluntarily using their left forelimb. Each successful lever-pulling/holding (> 400 ms) was rewarded by a drop of water (6-8 µl). Since Ca^{2+} transients in PC dendrites *in vivo* report complex spiking, i.e., PC responses to CF inputs, a genetically-encoded calcium indicator GCaMP6f was expressed in PCs located in the forelimb area of lobule V of the cerebellar vermis/paravermis.
We observed GCaMP fluorescence signals from a population of PCs while monitoring the lever trajectory induced by forelimb movements, and analyzed correlation between population CF signals and lever-movements. We found activation or suppression of CF signals to PCs corresponding to lever pull/hold movement, and that average activity patterns could be classified into three distinct categories. (i) Large and transient increase at the onset of lever-pull movement, (ii) high activity that was maintained during lever-holding period, and (iii) suppression of CF signals during lever-pull and -holding period. We also found that PCs that showed similar activity patterns tended to be spatially clustered, which presumably corresponds to the cerebellar microzones.
These results suggest that activity patterns of cerebellar CFs represent the information about forelimb movements and that CFs projecting to PCs in the same cerebellar microzone have similar properties. Therefore, it is possible that the combination of these distinct types of PCs, which converge on deep cerebellar nuclei neurons, could fully represent motor commands or trajectories for forelimb movements.

Title: Impaired reach-to-grasp responses in mice depleted of striatal cholinergic interneurons

Authors: *N. ABUDUKEYOUMU, M. GARCIA-MUNOZ, Y. NAKANO, G. W. ARBUTHNOTT
Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: Cholinergic interneurons (ChIs) are sparsely distributed within the striatum, a nucleus that plays important role in voluntary motor control, associated learning, procedural memory, action selection and planning and execution of movement. Sparsely distributed ChIs are 1-3% of all striatal neurons and the main source of striatal acetylcholine.
Here we report the effect of depletion of ChIs in the dorsolateral striatum in a reach-to-grasp task. To selectively deplete ChIs, we used the saporin ribosome-inactivating-immunotoxin that targets choline acetyltransferase. C57BL/J male mice, 21 days old, received a stereotaxic unilateral infusion of the toxin (0.3µl/3min), and sham control group was injected with saline. Following one week postsurgery recovery, animals were food deprived for 12 h everyday and trained for 12 days at night during their active circadian cycle.
The mean percentage ± SEM of successful performance in the reach-to-grasp task for the last 6 training sessions was 51.11 ± 4.09% (n = 25), 48.79 ± 7.7% (n = 9) and 26.28 ± 5.19% (n = 13) for intact control, sham control and ChIs-depleted mice, respectively. These results indicate that striatal depletion of ChIs impair reaching accuracy, whereas no significant differences were observed in control or sham operated mice. Moreover, a positive correlation between loss of ChIs and performance in the reach-to-grasp task was observed. Our results suggest that the participation of ChIs in striatal mediated motor learning impact on the function of interneurons and projection neurons of the whole striatal microcircuitry (*Abudukeyoumu, N., Hernandez-Flores, T. et al. Eur. J. Neuroscience, in press*).

Title: Distinct roles for cortico- and thalamo-striatal projections in motor skill learning and execution

Authors: *S. B. WOLFF, A. K. DHAWALE, R. KO, B. P. ÖLVECZKY
Harvard Univ., Cambridge, MA

Abstract: The remarkable capacity of the brain to acquire and execute motor skills depends on a distributed motor network. While many individual components have been identified, less is known about their specific roles and how they interact during learning and execution of motor skills.
To address this, we train rats in a lever-pressing task which results in spatiotemporally precise movement patterns. Our previous finding that motor cortex is necessary for learning, but not for

execution of this motor skill, suggests that motor cortex may act as a tutor for subcortical motor circuits during learning. A main candidate to receive this tutoring is the dorsolateral striatum, a major target of motor cortical projection neurons. In line with this hypothesis, we show that the striatum is indeed necessary both for the acquisition and execution of the motor skills we train. Furthermore, chronic and selective silencing of motor cortex's direct projections to the striatum, by viral and molecular strategies, prevented animals from learning the motor skill. In line with our previous lesion experiments, the same silencing did not affect skill execution when it was done after learning. We next tested the contribution to skill execution of striatum's other main input, that from thalamus. We found that chronic silencing of thalamo-striatal projections disrupted both skill execution and learning. These findings identify the striatum as a central player and suggest distinct roles for its cortical and thalamic inputs during motor skill acquisition and execution.

Title: The firing rate of external globus pallidus neurons is modulated by proactive, selective behavioral inhibition

Authors: *B.-M. GU, M. A. FARRIES, J. D. BERKE
Neurol., UCSF, San Francisco, CA

Abstract: The basal ganglia are critically involved in behavioral control, including both the initiation and inhibition of actions. In a reactive "Stop-signal" task - in which an instructed action must be abruptly cancelled - the STN and GPe appear to be involved in rapidly pausing, then cancelling, actions respectively (Schmidt et al., 2013; Mallet et al., 2016; Schmidt & Berke 2017). However, behavioral inhibition can also be proactive - being prepared in advance to stop if needed. We have been testing the hypothesis (Aron 2011) that the indirect pathway (striatum to GPe) mediates the proactive inhibition of specific actions. We first modified our prior rat stop-signal task to assay proactive inhibition. Distinct starting nosepoke locations were associated with either 1) no possibility of needing to stop; 2) a 50% probability of a Stop cue, but only if the Go cue instructed left, or 3) a 50% probability of a Stop cue, but only if the Go cue instructed right. Well-trained rats (n=5) demonstrated proactive inhibition by selectively longer reaction

times for the movement that might be followed by the Stop cue. In ongoing single-unit recordings from GPe during this task we found that a substantial proportion of GPe neurons (68/209 cells) show changes in firing rate that reflect the engagement of proactive inhibition. Especially, GPe cells were modulated when proactive inhibition was engaged to the contralateral direction to the recording site. Furthermore, most of these modulated cells show response selectivity when the animal makes choice. These results support the hypothesis that GPe is selectively involved in being prepared to stop specific actions if needed.

Title: Striatal fast-spiking interneurons help guide learning from disappointments and restrain unrewarded actions

Authors: *J. R. PETTIBONE[1], A. MOHEBI[2], R. HASHIM[2], J. D. BERKE[2]
[1]Neurol., Univ. of California- San Francisco, San Francisco, CA; [2]Neurol., UCSF, San Francisco, CA

Abstract: Successful action selection often involves weighing evidence for and against each alternative. The dorsal striatum is thought to facilitate this process by storing such evidence in the synaptic weights of spiny projection cells (MSNs) and using it to make choices. MSN activity can be strongly shaped by inhibitory input from nearby parvalbumin-positive (PV) fast-spiking interneurons (FSIs). We have previously shown that FSIs preferentially increase their activity during choice execution, and that adjacent MSN-FSI pairs have opposite action preferences. Yet it remains unclear what information FSIs specifically convey to MSNs in the context of adaptive decision making. To better understand this we have been recording from, and precisely manipulating, FSIs and MSNs in a trial-and-error "bandit" task. We report three observations. First, we have employed an optogenetic "tagging" procedure in transgenic knock-in PV-Cre and PV-Flp rats to record from identified PV+ striatal FSIs. We confirm prior suggestions that observing a transition to erratic bursting during slow-wave sleep provides a highly accurate method of identifying PV+ neurons (9/9 tagged cells to date). Second, using silicon probes and drivable tetrodes (n=6 rats, 143 MSN/103 FSI) we observe that FSIs fire more

during choice execution when the previous trial was unrewarded. Comparing activity to model-derived action values, we find that the firing rate of ~25% of the FSI population specifically correlates with evidence against performing an action. Third, we expressed the inhibitory archaerhodopsin in PV-Cre rats (n=7) to transiently suppress FSIs during key task events. Suppressing FSIs before movement onset increased the likelihood of repeating a previously unrewarded contralateral choice, consistent with a diminished ability to utilize negative evidence. In addition to this immediate effect on using values for decision-making, we also found that FSIs are important for updating values. Inhibiting FSIs during reward feedback blocked the normal shift in reaction time that accompanies updated reward expectations. These combined effects on performance and learning suggest an active role for FSIs in learning from unrewarded choices, and restraining them in the future.

Title: Forebrain dopamine value signals arise independently from midbrain dopamine cell firing

Authors: *A. MOHEBI[1], J. R. PETTIBONE[1], A. HAMID[2], J.-M. WONG[3], R. KENNEDY[3], J. D. BERKE[1]

Abstract: The mesolimbic dopamine projection from the ventral tegmental area (VTA) to nucleus accumbens (NAc) is a key pathway for both reward-driven learning and motivation. In head-fixed animals, brief changes in VTA dopamine cell firing can encode reward prediction errors (RPEs), vital learning signals in computational theories of adaptive behavior. However, in unrestrained animals NAc dopamine release more closely resembles reward expectations (values), motivational signals that invigorate approach behaviors. This discrepancy might be due to distinct behavioral contexts, changes in the tonic firing of dopamine cells, or a fundamental dissociation between firing and release. To resolve this, we directly compared dopamine cell firing with dopamine release in the same adaptive decision-making task. With microdialysis

(n=19 rats, 58 probe locations across 7 subregions), we found that dopamine release covaries with reward expectation in two specific forebrain hotspots, NAc core and ventral prelimbic cortex. The dopamine input to NAc core is provided by lateral VTA neurons. Yet the firing rates of optogenetically-identified lateral VTA dopamine cells (n=29, from 4 TH-Cre rats) showed RPE-like responses to reward-predictive cues and did not vary with reward expectation. We conclude that critical motivation-related changes in NAc dopamine release are unlikely to arise from VTA dopamine cell firing but may instead reflect local influences over forebrain dopamine varicosities.

Title: Dopamine neurons targeting dorsomedial striatum are modulated by reward and choice independently

Authors: *R. S. LEE, M. G. MATTAR, N. F. PARKER, I. B. WITTEN, N. D. DAW
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Dopaminergic (DA) neurons in the midbrain are essential both for learning and for generating movements, but most physiological studies have primarily examined a correlate of the former function: reward prediction error signals. In a previous study, Parker et al. (Nature Neuroscience, 2016) found that two projection-defined DA subpopulations have dissociable properties: in rodents performing a “two bandit” reward learning task, calcium activity in DA terminals in the ventral striatum more strongly encoded reward prediction error. Conversely, DA terminals in the dorsomedial striatum (DMS) were activated during contralateral, relative to ipsilateral choices, potentially reflecting a correlate of movement in DA neurons. However, a major question remains unresolved; these putative movement-related responses may also reflect a prediction error signal, the temporal-difference error for the value of the contralateral action. A lateralized prediction error signal arises in some reinforcement learning algorithms that maintain separate state-related versus action-related decision variables, updated with distinct decision variables. Such a signal would be correlated with contralateral choices, since animals will tend to choose the higher-valued action.
Thus, to determine whether choice encoding in DMS is better viewed as a value-related decision

variable rather than a movement signal, we examine the time course of DMS responses over the course of a trial, and as a function of previous events. We find two indications that the contralateral choice selectivity reflects the direction of movement and not a value-related decision variable. First, although modulation of responses by expected value is present (as assessed through the identity and reward status of the immediately preceding choice), its influence on DA responses reflects an orthogonal reference frame - reward modulates the encoding of the chosen action, rather than the contralateral action-which is separable from the simultaneously present movement effects. Second, the average movement-related modulation reverses polarity immediately following the animals' leverpress, likely reflecting a reversal in the animals direction of movement immediately upon pressing the lever and then returning to harvest reward. Together these results demonstrate that choice encoding is separable from reward encoding in the dopamine system.

Title: Movement-related activity in ventral basal ganglia and dopaminergic midbrain is gated by behavioral state

Authors: *R. CHEN, P. A. PUZEREY, V. GADAGKAR, J. H. GOLDBERG
Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: Dopamine (DA) neurons and their inputs from the ventral basal ganglia (vBG) exhibit both reward and movement related firing, but it remains unknown if these signals can be differentially gated by behavioral state. For example, movement-related dopamine signals have been observed in some studies but not others. One possibility is that some neurons are movement related and others are not. Yet another possibility is that a single neuron can be movement related under certain behavioral states but not others. We recorded single DA and vBG neurons in birds transitioning between singing and non-singing states while monitoring body movement with microdrive-mounted accelerometers. The activity of many vBG neurons was locked to body movements with millisecond time-scale precision but only during non-singing states. During

singing, these neurons ‘switched’ their tuning and became precisely time-locked to specific song syllables, and not to body movement. Similarly, many DA neurons exhibited phasic movement related activity but only during non-singing states; during singing these neurons lost their movement related signaling and instead encoded singing-related performance error. Changes in neuronal tuning could occur on 10 millisecond timescales at state boundaries. Our findings demonstrate that movement related activity in single neurons can dramatically change with behavioral context.

Title: Social context-dependent modulation of dopaminergic performance error

Authors: *V. GADAGKAR, P. A. PUZEREY, J. H. GOLDBERG
Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: Dopamine (DA) neurons encode phasic error signals that both modulate striatal plasticity for learning and also control the vigor of ongoing behavior. It remains poorly understood how DA subserves these two functions. Songbirds provide a tractable model for studying the dual roles of dopamine. First, songbird DA neurons encode song performance error signals - necessary and sufficient for learning - characterized by suppression following worse-than-predicted song syllable outcomes and activation by better-than-predicted ones. Curiously, striatal DA signaling is also thought to control the variability of ongoing song. Specifically, songbirds sing in two distinct DA-dependent motor states. (1) Undirected song is produced while alone and is associated with vocal variability and low levels of striatal DA. (2) Female-directed song is associated with a reduction in variability and higher levels of striatal DA. To investigate how DA may implement these dual functions, we recorded from antidromically identified, striatal projecting DA neurons as we controlled perceived error (with distorted auditory feedback) and behavioral state (with female present or absent). Performance error-encoding DA

neurons exhibited no change in tonic firing rate or pattern between undirected and directed singing. Yet singing-related performance error signals observed during undirected singing were significantly reduced or even gated off in the presence of the female. Our findings suggest a spiking-independent mechanism for the previously reported increase in striatal DA during directed song. Further, they demonstrate that dopaminergic error signals can be gated off by social context.

Title: Calcium signals of the striatal pathways during the performance of a chain of sequences

Authors: *I. LINARES-GARCIA, J. RAMÍREZ-JARQUÍN, F. TECUAPETLA
Inst. of Cell. Phisiology, Natl. Autonomus Univ. of Mexico (UNAM), Mexico - CDMX, Mexico

Abstract: The striatal activity have an important role in the generation sequences of actions. Different contributions have been attributed to the two types of striatal projection neurons (SPNs), the striatonigral “direct”, and the “indirect” striatopallidal pathway. An increase in the activity of the striatonigral pathway have been implicated in the increase of movements, while an increase in the activity of the striatopallidal in the reduction of movements, suggesting that the former is required in producing action while the latter is important in ending it. To evaluate this possibility in this study we ask: How the SPNs of the two striatal pathways are recruited throughout the generation of a chain of sequences to achieve a goal?
To address this question, we recorded the activity of striatonigral and striatopallidal neurons through the green calcium indicator GCaMP6f in striatonigral (D1-Cre) and striatopallidal (A2A-Cre mice) in a head-fixed behavioral task where mice learn to do chain of two sequences of lever press in a restricted period of time. We recorded the neuronal activity at the different phases of learning of the chain of sequences.
Our preliminary results show three findings: 1) both pathways are recruited at the onset, the end and the development of the chain of sequences. 2) The striatopallidal cells show a preferential

modulation during the transition between the two sequences in the chain. 3) Calcium signals related to individual sequences in the chain were found in the two pathways.
Our data will be discussed on the light of the current striatal-basal ganglia models.

Title: Encoding of sequential context in a songbird cortical-basal ganglia circuit important for context-specific learning

Authors: *L. TIAN, M. S. BRAINARD
UCSF, San Francisco, CA

Abstract: Motor skills depend on the reordering of individual gestures into a larger set of sequences; skilled performance of sequences requires the ability to appropriately modify gestures depending on sequential context. The neural mechanisms underlying these context-dependent modifications are poorly understood. Bengalese finch song is a motor skill consisting of variable sequences of discrete gestures, or “syllables.” Bengalese finches can modify the spectral structure of a given syllable in a context-specific manner in order to escape disruption of singing-related sensory feedback (Hoffmann & Sober 2014; Tian & Brainard 2017). Localized inactivation studies indicate that this context-specific learning depends on the anterior forebrain pathway (AFP), a cortical-basal ganglia circuit specialized for song. The AFP adaptively biases syllable structure with high specificity for sequential context (Tian & Brainard 2017). This specificity suggests that during learning the AFP undergoes modifications that reflect the conjunction of signals representing sequential context and performance feedback. Here we test whether there are signals in the AFP encoding context by recording from the AFP during production of individual syllables in different sequential contexts. We found that neural activity in LMAN, the cortical output nucleus of the AFP, depends on sequential context, as measured by the ability to decode the sequence in which a given rendition of a syllable is embedded. We

further hypothesized, based on previously reported effects of AFP inactivation on context-specific learning (Tian & Brainard 2017), that while activity in the AFP depends on both sequential context and syllable identity, activity in downstream motor circuitry depends more strongly on syllable identity and relatively weakly on sequential context. To test this possibility, we leveraged the fact that the AFP contributes to syllable structure by biasing activity in the downstream motor nucleus RA (Kao et al. 2005; Olveczky et al. 2005; Andalman & Fee 2009). This predicts that context-dependent variation in AFP activity should contribute to context-dependent variation in syllable structure. Indeed, we found that blocking AFP output decreases context-dependent variation in syllable structure. These results support a hierarchical organization in which context-specificity of syllable modifications may reflect the learned association between contextual signals and motor biasing activity in the AFP, while syllable structure that is similar across contexts reflects syllable-specific activity in downstream motor circuitry.

Abstract: Associative learning is the process in which a new response associates with particular stimulus throughout trial and error. The neural mechanisms underlying associative learning related to the striatum has been studied extensively using sensory discrimination task. Lesion and electrophysiological studies in rats have suggested that different striatal regions, such as the dorsomedial and dorsolateral parts of striatum, associate with the discrimination learning task. However little is known how the pattern of striatal activation changes during acquisition of associative learning. Therefore, we performed a small-animal neuroimaging with 2-deoxy-2-[^{18}F] fluoro-D-glucose (FDG)-PET to assess dynamic changes in patterns of brain activation in an auditory discrimination task with Long Evans rats. Serial FDG-PET scans were performed before and after the start of the learning (2, 6, 10 and 24 days). Under freely-moving condition,

FDG was intravenously injected just before the starting of a 30-min behavioral task. Fifty-five minutes after the FDG injection, a 30-min static PET scan was performed under anesthesia. Voxel-based statistical parametric mapping analysis revealed that the neural activities in the posterior region of the dorsolateral striatum increased at day 6, then turned to decrease at day 10. Meanwhile, the dorsomedial striatum was deactivated at day 24 as compared with either of day 2, 6 or 10. These findings suggest that the associative learning evokes dynamic shifts of neuronal activation pattern in sub-regions in the striatum. Moreover, this study demonstrates that small animal FDG-PET enables us to provide a useful information on the regional neural activity in the entire brain during the acquisition of operant conditioning task.

Title: Night-time sleep does not play a major role in consolidation of basal ganglia-dependent vocal learning in adult songbirds

Authors: *S. KOJIMA[1], D. LEE[1], K. KAI[1], R. O. TACHIBANA[2]
[1]Korea Brain Res. Inst., Daegu, Korea, Republic of; [2]Inst. of Neuroinformatics, Univ. of Zurich / ETH Zurich, Zurich, Switzerland

Abstract: Birdsong is a complex motor skill that songbirds develop by learning from other individuals. This song learning critically depends on a basal ganglia-thalamo-cortical circuit called the anterior forebrain pathway (AFP), which is discrete and specialized for song learning. Although in many songbird species song learning depends on age and does not naturally occur in adult birds, small changes in a specific feature of song, such as pitch of a song syllable, can be experimentally induced by training adult birds to avoid aversive noise playback (Tumer & Brainard 2007). Recent studies have demonstrated that the initial expression of this pitch-shift learning is driven by an instructive signal from the AFP that biases song structure to avoid noise playback (Andalman & Fee 2009; Warran et al. 2011). It is still unclear and controversial, however, how this "AFP-bias" of song structure is consolidated in the song motor pathway during song learning. Here, we investigated this issue by examining AFP-bias at different times of a day. AFP-bias was estimated by pharmacologically blocking the synaptic transmission from

the AFP output nucleus LMAN to the song motor nucleus RA and by measuring magnitudes of reversions of learned changes in the pitch of a target syllable as reported in previous studies. We found that birds learning to change the pitch have substantial AFP-bias in the morning and that its magnitude is comparable with that in the previous evening. These results do not support the hypothesis that AFP-bias is consolidated in the motor pathway during night-time sleep and thus disappears by the next morning, and instead suggest that consolidation of AFP-bias occurs predominantly during daytime. In support of this conclusion, pharmacological inactivation of RA during a night-time period did not significantly affect learning (pitch changes) on the following day. Our results contrast sharply with previous studies demonstrating the importance of sleep for consolidation of learned motor behavior, and thus provide new insight into the mechanisms of motor learning and memory.

Title: Basal ganglia modulation of motor thalamus

Authors: *A. D. LIEN[1], A. C. KREITZER[2]
[1]GIND, [2]Gladstone Inst. of Neurolog. Dis., San Francisco, CA

Abstract: The ability to accurately plan and execute movement is fundamental. In the mammalian brain, the basal ganglia-thalamo-cortical circuit is believed to be important for initiating and suppressing movement. Anatomically, the output nuclei of the basal ganglia form inhibitory synapses on neurons in the motor thalamus which sends excitatory projections to motor cortex. Motor cortex in turn projects to brainstem and spinal cord circuits that control the musculoskeletal system. It has long been hypothesized that increases and decreases in basal ganglia inhibition of motor thalamus can suppress and enhance thalamic activity and in turn reduce or promote movement however direct evidence is lacking. Here we tested these hypotheses by recording the spiking of motor thalamus neurons in awake mice during optogenetic manipulation of basal ganglia circuitry or during performance of a forelimb movement task. We demonstrate that spiking in a distinct region of motor thalamus is suppressed during optogenetic activation of striatal indirect pathway medium spiny neurons (iMSNs). Spiking of these same thalamic neurons was modulated around the time of lever movement in a

task where mice used their forelimb to pull a lever for reward. The cortical projection targets of these thalamic neurons are currently being identified.

Abstract: Controlling action involves hierarchical steps, decision-making, planning and execution. Cortico-basal ganglia circuits are critical for appropriately enacting these processes. Across cerebral cortex and basal ganglia, limbic, associative and sensorimotor information are thought to be processed in parallel, segregated closed loops. Indeed, cortico-striatal projections show a clear topography; dorsolateral striatum (DLS) receives input from sensorimotor cortex, whereas dorsomedial (DMS) and ventral striatum (VS) have input from prefrontal and limbic areas. However, structure of striatal output through substantia nigra pars reticulata (SNr), thalamus, and ultimately to cortex remains obscure. Furthermore, whether they form parallel closed loops or interlace open loops has yet to be determined in rodents. To address this question, we first performed retrograde transsynaptic wildtype rabies tracing (RABV) combined with anterograde tracing by cholera-toxin b subunit (CTb) from three cortical areas of rats, by which cortico-striatal input and striatal output neurons tri-synaptically connecting to each cortical area were identified. RABV/CTb injections in primary or secondary motor cortex

yielded RABV+ neurons and CTb+ terminals in DLS, indicating a closed loop between them. Surprisingly, we also found RABV+ neurons in VS, DMS and tail of striatum (TS) without CTb+ terminals, suggesting that VS, DMS and TS can target motor cortex despite the absence of its direct input. Conversely, RABV/CTb injections in medial prefrontal cortex showed an essentially closed loop since RABV+ and CTb+ labeling were only found in VS and DMS but not in DLS or TS. To determine whether and how such striatal connections to motor cortex were mediated by thalamus/SNr, we performed Cre-dependent monosynaptic modified RABV tracing from nigro-thalamic neurons specifically projecting to motor thalamus, and analyzed RABV+ striatal neurons. This revealed an identical distribution of RABV+ neurons to our transsynaptic RABV tracing from motor cortex; VS, DMS, DLS, and TS have output to motor thalamus and in turn to motor cortex. These results unveiled a previously unidentified hierarchy of cortico-basal ganglia output, whereby limbic/associative VS and DMS can access motor cortex through thalamus, but sensorimotor DLS cannot do so to prefrontal cortex. Further experiments are conducted to map the topography of striato-nigral, nigro-thalamic, and thalamo-cortical projections. We propose a revised framework for the organization of cortico-basal ganglia circuits, which are not segregated closed loops, but interact in a one-way hierarchical manner for controlling action.

Title: Mapping the Basal Ganglia output projection

Authors: *J. LEE[1], W. WANG[2], B. SABATINI[2]
[1]Dept. of Neurobio., [2]Harvard Med. Sch. Dept. of Neurobio., Boston, MA

Abstract: Basal ganglia is a phylogenetically old and evolutionary conserved set of structures important for reinforcement learning and movement control. Although a lot of work have focused on the corticostriatal pathway, very little is known about the substantia nigra reticulata(SNr) output to different target regions. Using a combination of dual anterograde tracing, retrograde tracing and optogenetics with slice physiology, we show that SNr target different thalamic, collicular and brain stem regions in a topographical manner. Different regions of SNr, which receive inputs from different striatal sectors, targeted different sectors of VM and

Pf, consistent with the segregated closed loop model for thalamostriatal and thalamocortical loops. Our data provides a framework to investigate the function of different BG pathways as well as different SNr projections to distinct target areas.

Title: Processing of competing cortical inputs in the basal ganglia

Authors: *M. ISRAELASHVILI[1], I. BAR-GAD[2]
[1]Bar Ilan Univ., Ramat Gan, Israel; [2]Bar-Ilan Univ., Ramat-Gan, Israel

Abstract: The basal ganglia are a group of interconnected sub-cortical nuclei that are involved in motor, associative and limbic functions. They receive information from most areas of the cerebral cortex and the thalamus, and project back to frontal cortical areas through the thalamus, thus forming the cortico-basal ganglia-cortico loop. Currently, the main network level model of the basal ganglia is the action selection model. This model emphasizes the role of the basal ganglia, within the cortico-basal ganglia-cortical loop, in choosing one or more actions out of a multitude of such actions presented by the cortex. According to this model, projections from the cortex to the striatum, the main input nucleus of the basal ganglia, excite a subset of striatal neurons that leads to a release of the selected action. The selection process of the action within the striatum involves both feedback and feedforward inhibition that inhibits all other potential actions. Currently, there is limited physiological support for the functional role of the striatal inhibitory network and for the validation of action selection hypothesis. In this study we examine the processing of competing cortical input in the basal ganglia of freely behaving rats. We use optical stimulation of cortical areas in conjunction with somatosensory input while performing extracellular recordings from the striatum and globus pallidus. Characterization of the neuronal activity that occurs during separate as well as simultaneous stimulation of different cortical areas was performed. We observed both synergistic and antagonistic interactions between cortical inputs, supporting a complex representation of the cortical activity by the basal ganglia in general and the striatum in particular. This remapping of cortical information suggests that the study of cortico-basal ganglia information processing requires the progression to a study of the interaction between multiple sources of input to this pathway.

Title: Identifying a learning role for the songbird basal ganglia

Authors: *J. SINGH ALVARADO[1], M. BEN-TOV[2], M. G. KEARNEY[2], R. D. MOONEY[3]
[1]Neurobio., [2]Duke Univ., Durham, NC; [3]Duke Univ. Dept. of Neurobio., Durham, NC

Abstract: The basal ganglia (BG) plays a key role in the acquisition and execution of complex behaviors. Reinforcement learning (RL) models have been extensively proposed as an appealing framework for understanding BG function, yet demonstrating RL implementations in neural circuits has remained challenging. Two factors contribute to this difficulty: the diversity of behaviors the mammalian BG contributes to, and the limited understanding of how the BG contributes to a specified behavior. The songbird is an experimentally tractable platform where these issues can be addressed; an anatomically and functionally segregated network of specialized brain nuclei selectively control the acquisition and execution of song, enabling the direct linkage of neural circuits and a single behavior. Furthermore, the RL framework has been extended to songbird learning, where it posits the BG striatal spiny neuron (SN) as a critical locus of plasticity. Despite their influence, little experimental evidence exists to test these hypotheses. To bridge this gap, we combined genetic ablation, optogenetic inactivation, and single-photon deep brain imaging of SNs in the songbird BG homologue Area X. Genetic ablation of SNs in adult zebra finches leads to progressive loss of spectral features, stuttering, and failure to initiate song. In contrast, rapid optogenetic inactivation of SNs had no outstanding acute effects, but prevented adaptive plasticity when precisely triggered during an experimental RL paradigm. Imaging from populations of Area X neurons over multiple months revealed heterogeneous and spatiotemporally biased activity, with the majority of neurons firing during one part of a motif. While we observed highly stereotyped and reliable SNs, the majority were recruited during the minority of song trials. Current analysis is focusing on SN dynamics during RL, as well as the context dependence of SN activity. These results begin to test implementations of RL in a specialized circuit during an innately learned behavior, as well as provide evidence for a highly temporally precise role of SNs in learning.

Title: Enhanced neuromodulation with paired brain and spinal cord stimulation in a large animal of cervical contusion injury

Authors: *P. T. WILLIAMS[1], J. R. BRANDENBURG[2], D. Q. TRUONG[3], A. DE PAOLIS[3], H. BORGES-DESOUZA[3], D. RYAN[2], J. WONG[2], S. AMBIA[2], H. ALEXANDER[2], L. CARDOSO[3], M. BIKSON[3], J. H. MARTIN[1,4]

Abstract: Regaining hand function is the highest priority for people with cervical SCI. Our lab is developing therapeutic neuromodulation using brain and spinal cord stimulation to promote recovery of hand function in a large-animal model of SCI that can be scaled to patients. We use patterned cortical electrical stimulation (intermittent theta burst stimulation; iTBS), shown in the rat to strongly activate the corticospinal tract (CST), the principal pathway for hand control, to promote recovery of skill and dexterity. We combine this with transcutaneous spinal direct current stimulation (tsDCS) to further strengthen connections and improve function after SCI.
Our goal was to produce a moderate C4 contusion using the IH Spinal Impactor. Simulations using the finite element method (FEM) were run on a segmented model of the spinal column based on MR and microCT scans in order to compare probe shapes and force magnitudes on the distribution of stress and strain during contusion. Predictions of lesion extent were corroborated in pilot studies to induce a mild, moderate, or severe lesion.
We determined if the paired therapy augments the efficacy of motor cortex activation of muscle. In separate sessions we compared MEPs before, during, and after iTBS or tsDCS alone, and in combination. In line with the findings in the rat studies, iTBS alone, c-tsDCS alone, and the combination, augmented the period of post-stimulation MEP facilitation.
Our next goal was to evaluate the effect of stimulation therapy after SCI. We induced a moderate lesion revealed by MR-scans (3.5 mm spherical probe hit at 800 kDyn force with a 1 s dwell) in one animal. Assessments of upper-limb control showed more severe motor impairments on the left side, so iTBS was delivered with an epidural electrode to the contralateral motor cortex. We paired this with tsDCS (4 mA cathodal), as in the rat studies, using montages guided by FEM

models of current density, to target the cervical enlargement. We delivered the paired therapy for 30 min/day on 10 consecutive days in the chronic phase, after spontaneous recovery had plateaued.
We tested the neuromodulation of MEP amplitudes with iTBS or tsDCS alone, and in combination, and found greater MEP enhancement after therapy compared to before. Importantly, we also found improvements in reaching accuracy with the limb receiving the iTBS component of the therapy.
These encouraging results show a strengthening of motor cortex-to-muscle activation, facilitation of motor cortex-mediated MEP potentiation, and an improvement in motor skill. These preliminary findings point to a neuromodulatory strengthening of the corticospinal system for improved motor control after cervical injury.

Title: Can changes in manual dexterity and white matter integrity identify mild cognitive impairment from normal aging?

Authors: *C. RODRIGUEZ-ARANDA[1], S. A. CASTRO-CHAVIRA[2], V. K. BYRE[2], A. EVJEN[2], O. VASYLENKO[2], M. M. GORECKA[1], K. WATERLOO[1], E. KAMYCHEVA[3], S. H. JOHNSEN[3], T. R. VANGBERG[3]

Abstract: Epidemiological research has demonstrated that manual dexterity deteriorates early in degenerative diseases and that changes in hand function may be a useful, non-invasive indicator of dementia. However, no experimental data corroborating this assumption exist. In healthy elderly, hand dexterity declines have been associated with deterioration in the microstructure of cerebral white matter. Thus, the present study aims to examine whether specific dexterity declines exist in individuals with mild cognitive impairment (MCI) as compared with healthy age-matched controls and whether these differences are associated with cerebral white matter degeneration. Two specific tracts were explored: corticospinal (CST) and uncinate fasciculus

(UF). The former underlies motor dexterity and the latter has been found to differentiate MCI from normal aging. **Material:** 26 right-handed MCI patients (*M* age = 71.2 y) and 29 right-handed healthy elderly (*M* = age 70.9 y) were tested with the Purdue Pegboard test and video recorded with Vicon Motus to calculate movement times (MT) and kinematic parameters during task performance. Reaching, grasping, transport and inserting were analyzed separately with each hand. Movement times and kinematics including path length, angle and linear and angular velocities were calculated. Significant group differences on dexterity were selected and correlated with white matter indices. MRI data were acquired on a 3T MR scanner. Tract-based analysis using FreeSurfer's TRACULA was used to extract FA and MD measures from the selected tracts. Correlations between DTI metrics and dexterity measures were conducted. **Results:** Group differences were found on MT only for left hand during reaching and grasping. For kinematic data, several group differences were found in both hands. For the *right han*d, lower mean values of angular and linear velocities characterized the patient group. Variability of movements (CoVs) with right hand shows low variability for linear velocity but high variability for hand rotation (angular velocity) suggesting disturbed hand rotation. Kinematics for the left hand differed in all actions. Though, results for grasping showed a distinctive pattern in MCI. Associations with DTI indices showed various significant interactions between group and MTs during reaching and grasping. Specifically, reaching times were positively associated with MD in the left UF and CST. **Conclusions:** Patients showed significant differences in MTs and kinematics with left hand, which were further correlated uniquely with DTI indices. The present data offer empirical support to the suggestion that dexterity changes are a characteristic of MCI.

Title: A novel wearable device for motor recovery of hand function in chronic stroke survivors

Authors: S. CHOUDHURY[1], R. SINGH[1], A. SHOBHANA[1], D. SEN[1], S. S. ANAND[1], S. SHUBHAM[1], M. R. BAKER[2], H. KUMAR[1], *S. N. BAKER[2]
[1]Inst. of Neurosciences Kolkata, Kolkata, India; [2]Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: We have previously demonstrated in monkey that reticulospinal connections to hand and forearm muscles are strengthened following corticospinal lesion, contributing to recovery of function (Zaaimi et al, 2012). Reticulospinal neurons can be activated by auditory click stimuli, probably partially via the vestibular apparatus (Fisher et al 2012). Pairing clicks with electrical stimulation of a muscle induces plastic changes in motor pathways (probably the reticulospinal tract) via spike timing-dependent plasticity mechanisms (Foysal et al 2016). In this study, we tested whether pairing clicks with muscle stimulation could improve hand function in stroke survivors. Clicks were delivered via a miniature earpiece, and electrical stimuli at motor threshold were given over the forearm extensor muscles. Stimulation was delivered using a wearable electronic device, as in Foysal et al (2016), which allowed the patient to receive stimulation at home while performing normal daily activities. We recruited 95 patients who had suffered a cortical or sub-cortical stroke at least 6 months previously. Patients were randomised to three groups: 1) wearable device stimulation at ~0.67Hz, where muscle stimuli were given 12 ms before click, 2) wearable device stimulation, where click and shock occurred independently at random, also at 0.67 Hz, 3) standard care. Those allocated to the device used it for at least 4 hours per day, every day for 4 weeks. Hand function was assessed at baseline (week 0), and weeks 2, 4 and 8, using the Action Research Arm Test (ARAT) which has four domains - Grasp, Grip, Pinch and Gross. Severity across three groups were comparable at baseline (mean total ARAT in three groups- 18.09, 10.75, 17.25, p= 0.513). Group 1 improved in the total ARAT (mean week 0: 18.09; week 8: 19.77, p= 0.019) unlike the other two groups. The Grasp sub-score also improved significantly (mean week 0: 5.84, week 8: 7.18, p= 0.004) only in Group 1. Other ARAT sub-domains showed no significant changes in any groups. Only one device related adverse event occurred, which was a contact dermatitis associated with the adhesive surface electrodes; this improved with topical steroid cream with no interruption of treatment. We conclude that a wearable device delivering paired clicks and shocks can produce a significant improvement in hand function in stroke survivors, probably via an action on the reticulospinal tract. Title: Aging impairs the use of explicit cues for anticipatory modulation of digit placement for dexterous manipulation

Authors: *P. J. PARIKH[1], N. RAO[2]
[2]Hlth. and Human Performance, [1]Univ. of Houston, Houston, TX

Abstract: Dexterous manipulation depends on our seamless ability to control digit contact points and digit forces. Young adults demonstrate anticipatory modulation of their digit contact points and digit forces based on explicit verbal or visual cues about object property such as weight and center of mass (CM). Older adults, in contrast, demonstrate an impaired ability to use explicit color cues about object property for anticipatory modulation of digit forces. However, whether older adults are able to modulate their digit contact points based on explicit color cues about object CM remain to be known. Five older adults (65+) and six young adults performed a novel visuomotor task that required them to identify object center of mass using a color cue and to apply appropriate torque on the object at lift onset to minimize tilt over 60 trials. The application of CM-appropriate torque required fine modulation of digit contact points and digit forces. We found that older adults were slower in acquiring novel color-torque associations, a finding consistent with previous studies. Further analysis found that older adults failed to demonstrate anticipatory modulation of digit contact points based on the color cues about object CM when compared with young adults. Older adults were also impaired in applying CM-appropriate digit forces when compared to young adults. These finding suggest that the slower rate of arbitrary visuomotor learning in older adults resulted from impaired anticipatory modulation of both digit contact points and digit forces based on explicit color cues about object CM.

Title: Forced aerobic exercise paired with motor task practice optimizes upper extremity motor recovery post-stroke

Authors: *S. LINDER[1], A. ROSENFELDT[2], S. DAVIDSON[3], N. ZIMMERMAN, 44195[3], J. LEE, 44195[3], A. PENKO, 44195[2], J. L. ALBERTS[2]
[1]Cleveland Clin., Olmsted Twp, OH; [2]Biomed. Engin., [3]Cleveland Clin., Cleveland, OH

Abstract: OBJECTIVE: To determine the effects of forced- and voluntary-rate aerobic exercise on the recovery of motor function in individuals with hemiparesis due to stroke.
BACKGROUND: The effects of aerobic exercise (AE) training in improving cardiovascular function post-stroke is well-documented. The potential role of AE in facilitating motor recovery following stroke, however, has not been systematically evaluated. Aerobic exercise is known to induce neurophysiologic responses in the brain, some of which may be exploited to enhance motor recovery. It has been shown in healthy adults that intensive AE administered immediately prior to motor task practice enhances motor skill acquisition. We have conducted preliminary studies investigating whether AE can enhance the motor learning benefits associated with task practice to improve motor recovery post-stroke. Two modes of AE, voluntary and forced, were evaluated and compared to a time-matched control group. Forced exercise (FE) is a mode of AE in which the participant's voluntary exercise rate during lower extremity cycling is augmented; thus, FE was used to overcome the deficits in motor and cardiovascular output commonly seen post-stroke.
DESIGN/METHODS: Two prospective, three-arm randomized clinical trials were conducted in which each group underwent a 45-min session of upper extremity repetitive task practice. Immediately preceding task practice, one group completed a 45-min session of forced aerobic exercise (FE, n=16), one group completed a 45-min session of voluntary aerobic exercise (VE, n=16), and one group completed a 45-min session of stroke-related education (EDU, n=8). Participants attended 3 times per week for 8 weeks. Outcomes included the Fugl-Meyer Assessment (FMA), Wolf Motor Function Test (WMFT), and Action Research Arm Test (ARAT).
RESULTS: The FE, VE and EDU groups improved significantly on the FMA from baseline to end of treatment by a mean of 11, 5, and 9 points, respectively. Post-hoc analysis revealed that change in the FMA was greater for the FE group compared to VE and EDU ($p=0.001$). On the WMFT, the FE group demonstrated significant improvement on all outcomes (total time, fine motor, gross motor, and functional ability score), while the VE group improved in two of the scores and the EDU group improved only in the functional ability score. All 3 groups improved significantly on the ARAT, with only the FE group improving significantly in all 4 subscales.
CONCLUSIONS: FE preceding motor task practice resulted in greater improvements in upper extremity motor recovery. Pairing AE training with task practice may enhance motor recovery and should be incorporated into stroke rehabilitation.

Title: Non-paretic hand exercise to task-failure increases functional connectivity to paretic hand in chronic stroke

Authors: *Q. DING, T. MCGUIRK, P. S. ELLIOTT, C. PATTEN
Sch. of Medicine, Dept. of PM&R, UC Davis, Sacramento, CA

Abstract: We previously observed acute neural adaptations in the ipsilesional hemisphere of chronic stroke survivors in response to non-paretic hand exercise to task failure (ETF). These robust adaptations were sustained for up to four hours and accompanied by facilitation of paretic hand maximal voluntary contraction (MVC) and improved dexterity. These behavioral effects are consistent with the phenomenon known as 'cross-transfer'. Here we sought to determine the locus of these adaptations and how ETF affects functional connectivity between the central nervous system and non-exercised paretic limb. Intermuscular coherence (IMC) has been used to assess the strength of functional connectivity between the central nervous system and effector muscles. Activity in specific frequency bands is argued to arise from different neural loci (e.g., alpha (range 8-12 Hz): spinal reflexes; beta (range 15-30 Hz): corticospinal tract, subcortical & cortical; gamma (range 30-60 Hz): cortical). We investigated IMC using surface EMG from first dorsal interosseous and opponens pollicis in 12 individuals with chronic stroke (upper-extremity Fugl-Meyer assessment: 28-64/66, age: 65±7 (53-79) years, 11 males) who performed ETF with repeated submaximal non-paretic hand isometric power grip. Powergrip MVC, dexterity (Box and Blocks Test, BBT), and IMC were tested at baseline, immediately post-ETF, and every 45 min until 4 hours post-ETF. IMC in beta and gamma bands at baseline was significantly lower in the paretic than non-paretic hand ($p's<0.05$). IMC in alpha, beta and gamma bands increased in the exercised non-paretic hand immediately revealing peaks at 0 (alpha) and 45 (beta, gamma) min after ETF ($p's<0.05$). In the non-exercised paretic hand, IMC increased significantly only in

beta and gamma bands, revealing peaks at 90 and 135 min after ETF, respectively (p's<0.05). Paretic hand BBT improved (4-24%) in 10/12 participants at ≥1 point post-ETF. The magnitude of increased paretic hand beta band IMC correlated positively with paretic hand BBT facilitation (r^2=0.47, p=0.02). These parallel increases in paretic hand beta band IMC and BBT were greater in higher-functioning individuals (p's<0.05). In response to ETF functional connectivity to the exercised, non-paretic hand increased from all levels of the central nervous system. Crossed-effects in the non-exercised paretic hand, however, reveal increased functional connectivity primarily from supraspinal levels which are associated with behavioral facilitation. Our findings suggest that non-paretic hand ETF could potentially be an alternative rehabilitative intervention for motor recovery post-stroke.

Title: Forced-use therapy after sensorimotor cortex lesions restores contralesional hand preference in macaca mulatta

Authors: *W. G. DARLING[1], K. S. STILWELL-MORECRAFT[3], J. GE[3], D. L. ROTELLA[1], M. A. PIZZIMENTI[2], R. J. MORECRAFT[3]
[1]Dept. of Hlth. and Human Physiol., [2]Anat. and Cell Biol., Univ. of Iowa, Iowa City, IA; [3]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: We previously showed that after unilateral lesions to the arm/hand area of M1, lateral premotor cortex (LPMC), S1 and rostral part of the superior parietal lobule, fine digit motor function of the more affected hand recovers to variable levels. This recovery occurred despite reductions in strength of the corticospinal projection from spared ipsilesional supplementary motor cortex (M2) (Morecraft et al. 2015 J Comp Neurol 523:669). The lesion was always induced in the hemisphere contralateral to the preferred hand as identified using a hand preference test (Nudo et al. 1992, J Neurosci 12:2918). When allowed to choose, monkeys with these lesions would primarily use the ipsilesional (less affected) hand when picking up small food objects even after good recovery, demonstrating a form of learned nonuse (LNU) of the contralesional hand. We now test the hypothesis that forced-use therapy of the more affected hand can restore this hand to preferred hand status for a fine motor task. Six monkeys received

unilateral sensorimotor cortex (F2P2) lesions contralateral to the preferred hand. Two monkeys (SDM93, SDM94) received forced-use therapy beginning two weeks after the lesion. Therapy was provided three days/week using a device that allowed only the contralesional hand to successfully acquire small food objects without any constraint of the ipsilesional limb. On average, each animal successfully grasped and retrieved 400-450 small food treats during each rehabilitation session. Similarly, two motor testing devices were used that allowed testing of both hands for the duration of the survival period (Morecraft et al. 2015). A LNU test was performed on the same post-lesion schedule in four lesioned monkeys that did not receive therapy and hand preference was computed based on the last 3 post-lesion LNU tests. The two monkeys receiving therapy performed a hand preference test during the last post-lesion month for comparison to the pre-lesion hand preference test. Both monkeys that received forced-use therapy during recovery showed a stronger post-lesion hand preference to the contralesional hand than in the pre-lesion test (i.e., handedness index increased from 26.4 to 32 in one case and from 0.4 to 4 in the other). In contrast, the monkeys that did not receive therapy all strongly preferred the ipsilesional, less impaired, hand (average handedness index of 78.7) in the last 3 LNU testing sessions. Thus, forced use therapy restored hand preference after impairment by sensorimotor cortex lesion. Future research will establish whether the descending projections from ipsilesional M2 are maintained by this type of therapy.

Title: Lack of interlimb transfer following visuomotor adaptation in a person with congenital mirror movements

Authors: *S. BAO, A. M. MORGAN, J. WANG
Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: Learning a motor adaptation task can generalize across the arms, although the extent of interlimb transfer is typically limited (30-50%). In this exploratory study, we examined the extent of interlimb transfer following visuomotor adaptation in an individual with congenital mirror movements (MM), which refer to contralateral involuntary movements that mirror voluntary movements. To confirm our subject's condition, we provided transcranial magnetic stimulation (TMS) on the primary motor cortex (M1) and recorded electromyographic activity from the first dorsal interosseous (FDI) muscle of both hands. We observed motor-evoked

potentials (MEPs) elicited in response to TMS in the FDIs both ipsilateral and contralateral to the stimulated M1, although the magnitude observed on the ipsilateral FDI was substantially smaller than that observed on the contralateral FDI. Following that, we had the subject perform targeted reaching movements first with the left arm under a novel visuomotor condition in which the visual display was rotated 30 degrees counterclockwise about the start circle, and then with the right arm under the same visuomotor condition. The results showed that initial adaptation with the left arm did not facilitate subsequent performance with the right arm at all, in terms of either the initial amount of transfer or the rate of adaptation. This finding is surprising, given that neurologically intact adults have demonstrated approximately 50% of transfer from the left to the right arm under the same visuomotor condition (cf. Lei and Wang, 2014). Based on the finding that the magnitude of ipsilateral MEPs was substantially smaller than that of contralateral MEPs, this subject seems to have adapted to his condition (i.e., MM) by learning to unconsciously inhibit ipsilateral corticospinal projection, so that he can perform activities of daily living that requires asymmetrical bilateral movements. Indeed, this subject is capable of performing asymmetrical bilateral movements without too much difficulty. Such adaptation to the given condition, in turn, may have influenced the way information is transferred between the two limb/hemispheric systems, thus resulting in lack of interlimb transfer.

Title: Effect of coil orientation on motor evoked potentials examined during grasping

Authors: *H. JO[1,2], M. A. PEREZ[1,2]
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Bruce W. Carter Dept. of Veterans Affairs Med. Ctr., Miami, FL

Abstract: We recently showed that the latency of corticospinal responses elicited by different orientations of the transcranial magnetic stimulation (TMS) coil change after spinal cord injury (SCI). The extent to which these differences are preserved during behaviorally relevant motor

behaviors after the injury remains unknown. Here, we used TMS over the hand representation of the motor cortex to elicit motor evoked potentials (MEPs) in an intrinsic finger muscle during precision grip and power grip in humans with and without (controls) cervical incomplete SCI. The TMS coil was oriented to induce currents in the brain in the latero-medial (LM) direction to activate corticospinal axons directly and in the posterior-anterior (PA) and anterior-posterior (AP) directions to activate the axon indirectly through synaptic inputs. We found prolonged MEP latencies in individuals with SCI in all coil orientations and in both tasks compared with controls. The latencies of MEPs elicited by AP relative to LM stimuli were consistently longer during power grip compared with precision grip in controls but not in SCI participants. PA relatively to LM MEP latencies were shorter in SCI than controls but similar between tasks across groups. Our results demonstrate that differences between corticospinal responses elicited by AP and PA induced currents during grasping behaviors were not preserved in humans with SCI and suggest that neural structures activated by AP currents, which are particularly relevant for power grip in uninjured controls, changed largely after the injury.

Title: Changes in the silent period evoked by transcranial magnetic stimulation during different coil orientations

Authors: *F. D. BENAVIDES[1,2], M. A. PEREZ[1,2]
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Bruce W. Carter Dept. of Veterans Affairs Med. Ctr., Miami, FL

Abstract: A motor evoked potential (MEP) elicited by transcranial magnetic stimulation (TMS) during voluntary activity is followed by a silent period (SP). Although it is known that the duration of the SP is prolonged in humans with spinal cord injury (SCI), the neural mechanisms contributing to this effect remain unknown. To address this question, we used TMS over the hand representation of the primary motor cortex to generate input-output MEPs recruitment curves in an intrinsic finger muscle using posterior-anterior (PA) and anterior-posterior (AP)

induced currents in the brain during isometric index finger abduction in humans with and without chronic cervical incomplete SCI. We found that the duration of the SP elicited by PA and AP currents was prolonged in SCI compared with control subjects in the ascending part of the recruitment curve but similar at higher stimulus intensities. The size of MEPs elicited by PA and AP currents was positively correlated with the duration of the SP in both groups in the ascending part of the recruitment curve but not at higher intensities. MEPs elicited by AP compared with PA currents have longer SP duration in controls but not in humans with SCI, regardless of the stimulus intensity. Our findings show that differences in SP duration elicited by AP and PA induced currents were not preserved in humans with SCI, supporting the view that neural structures activated by AP currents largely change after SCI.

Title: Grip force output is related to somatosensation and self-reported ADHD symptoms in young women with and without ADHD

Authors: *J. TUCKER[1], A. N. MERIDA, 16802[2], C. R. N. DAHM, 16802[3], A. J. N. GROFF, 16802[3], D. DIMERCURIO, III[4], N. ETTER[4], K. A. NEELY[5]

Abstract: The goal of this work was to examine how grip force output is related to tactile somatosensation in young women with and without Attention-Deficit/Hyperactivity Disorder (ADHD). Previous work involving young women with ADHD is limited, possibly because many women are not diagnosed until late adolescence or adulthood. This work is motivated by previous investigations from our group that demonstrate that adults with ADHD produce more force than adults without ADHD during visually guided grip force (Neely et al., 2016; Neely et al., 2017). Here, we extend that work by evaluating visually guided grip force at seven force amplitudes in concert with tactile somatosensation at the finger, thumb, and palm. Consistent with our previous work, we hypothesized that women with ADHD would produce more force

than women without ADHD. We further hypothesized that those that produced more force would have reduced tactile somatosensation. Thirty-nine female participants (19 ADHD), were recruited from a larger ongoing study. Participants produced force during four 30-second blocks. Within each force block, participants produced force for 4s separated by 2s of rest, for a total of five trials within each block. Participants completed seven force amplitude conditions ranging from 5% to 50% of their precision grip maximum voluntary contraction. Somatosensory assessments included tactile detection and discrimination threshold estimates, as well as two-point discrimination. The results demonstrated that women with ADHD produced more force than women without ADHD in 6 of the 7 amplitude conditions. A trend was observed such that women with ADHD had a slower rate of force production compared to females without ADHD. We then evaluated bivariate correlations between mean force, the rate of force production, tactile somatosensation, and self-reported ADHD symptoms. Participants with a slower rate of force production in the 5% MVC condition had larger two-point discrimination thresholds for the right index finger. Similarly, participants that produced higher force in the 10, 30, and 40% MVC conditions had larger two-point discrimination thresholds for the right index finger. Further, slower rates of force production, and larger overall force output, were associated with more severe ADHD symptoms. These findings suggest that a slower rate of force production and greater force production may be due to reduced tactile somatosensation in the index finger. Additionally, slower rates of force production and higher overall force output may be reliable quantitative measures to indicate the severity of ADHD in young women.

Title: Functional brain mechanisms of sensorimotor control in individuals with autism spectrum disorder

Authors: *K. UNRUH[1], L. M. SCHMITT[3], Z. WANG[4], L. MARTIN[5], A. FOX[6], M. W. MOSCONI[2]
[1]Life Span Inst., [2]Univ. of Kansas, Lawrence, KS; [3]Div. of Developmental and Behavioral Pediatrics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [4]Dept. of Occup. Therapy, Univ. of Florida, Gainesville, FL; [5]Hoglund Brain Imaging Ctr., Univ. of Kansas Med. Ctr., Kansas City, KS; [6]Univ. of Kansas Med. Ctr., Kansas City, KS, KS

Abstract: Background: Socio-communicative deficits and restricted, repetitive behaviors and interests comprise the core diagnostic features of autism spectrum disorder (ASD). However, abnormalities in sensorimotor behavior are also present in the majority of individuals with ASD and associated with a variety of clinical issues, including social and cognitive deficits. Cortico-cerebellar and cortico-striatal networks that control sensorimotor behavior have been implicated in ASD, but little is known about the functional alterations that contribute to these atypicalities. The purpose of this study was to identify differences in patterns of neural activation during feedback-guided motor behavior in ASD compared to typically developing controls.
Methods: Individuals with ASD (11-30 years; N = 18) and age-matched controls (N = 15) completed a visuomotor task of feedback-guided precision gripping during fMRI. Participants pressed with thumb and forefinger on a force transducer while viewing a white FORCE bar on a screen that moved upwards with increased force toward a fixed green TARGET bar and were instructed to maintain FORCE at TARGET level for 24 seconds. Force levels were set at 20% and 60% of the participant's maximum voluntary contraction (MVC).
Results: Participants with ASD showed increased force variability compared to controls only at 60% MVC (p = .049, d = .74). Across force conditions, ASD participants showed increased activity in the cortico-cerebellar visuomotor network for regions involved in sensory (S1, PPC), motor (M1), and sensory-feedback (cerebellum) processes, even in the absence of increased motor error (20% MVC), suggesting hyper-reactivity of this circuit to visual sensory information. ASD participants also showed greater activation in regions supporting internally-guided motor behavior (putamen, SMA).
Conclusions: Increased force variability during force output in ASD suggests impaired processing of visual sensory feedback to guide precision motor behavior, converging with imaging results that suggest hyper-responsivity of sensory processing and sensory feedback cortico-cerebellar circuits. This dysregulation of cortico-cerebellar circuitry may result in a decreased ability to effectively utilize sensory feedback information and therefore greater reliance on internally-generated mechanisms, including those supported by fronto-striatal brain systems. Our findings that brain mechanisms involved in continuous sensory processing are hyper-active during basic precision motor behaviors indicates sensory hyper-reactivity in ASD also may contribute to deficits of more complex motor and non-motor mechanisms.

Title: Brain morphometry differences associated with sex and ADHD symptom severity in young adults

Authors: *D. B. ELBICH[1], C. HUANG-POLLOCK[3], S. SCHERF[2], K. A. NEELY[4]
[2]Psychology, [1]The Pennsylvania State Univ., University Park, PA; [3]Pennsylvania State Univ., University Park, PA; [4]Sch. of Kinesiology, Auburn Univ., Auburn, AL

Abstract: Previous work examining brain structure in Attention-Deficit/Hyperactivity Disorder (ADHD) is inconsistent and focuses mainly on children and adolescents. Further, work examining adults often uses a large age range. The current work examines brain structure and symptom severity in young adults ages 18 to 25. The goals of this project were to examine 1) potential atypicalities in the volumetric properties of motor and sensory cortical regions in young adults with ADHD; 2) whether such atypicalities are associated with self-reported ADHD symptoms; 3) if these effects are modulated by biological sex. ADHD was confirmed using a semi-structured interview and the Connors' Adult ADHD Rating Scale (CAARS). Ninety-six participants (49 ADHD, 47 non-ADHD controls) were scanned with MRI to generate T1-weighted high-resolution structural images (192 volumes, 1 mm^3 voxels). The images were reconstructed, preprocessed, and parcellated using Freesurfer. We extracted volume, thickness, and area for cortical regions, and total volume of subcortical structures. We conducted a 2 (Male, Female) by 2 (ADHD, CTRL) multivariate analysis of variance to identify possible interactions between sex and diagnosis. Volumes in the left pallidum and medial orbitofrontal cortex and right pars opercularis were larger in adults with ADHD than adults without ADHD. Critically, there was a positive association between volume in the left medial orbitofrontal cortex and symptom severity as indexed by the CAARS subscales for Inattention/Memory Problems, Hyperactivity/Restlessness, and ADHD Index. Unlike previous findings, non-ADHD controls exhibited greater thickness in right medial orbitofrontal cortex and volume across all subcortical regions measured than ADHD adults. This is relevant because there was a negative relation between subcortical volume and symptom severity as measured by the three subscales of the CAARS. We observed an interaction between diagnosis and sex for left pars orbitalis thickness, right frontal pole volume, and right frontal pole area. Independent samples t-tests for sex differences within diagnostic groups revealed that frontal pole volume and area were greater for

females than males, only among adults with ADHD. In contrast, left pars orbitalis volume was greater for males than females in adults without ADHD. This work reveals notable differences in volumetric properties of regions related to motor and sensory function, which may be indicative of symptom severity. Most important, this work demonstrates the need to include males and females to evaluate the interaction between sex and diagnosis in ADHD.

Title: piReach: An open source, automated skilled reaching task platform

Authors: *S. LEEMBURG
Univ. of Zurich, Zuerich, Switzerland

Abstract: ***Aims:*** Skilled reaching tasks, such as single pellet reaching and the pasta matrix, are widely used to assess fine motor function in rodents. These tasks reliably show motor deficits in rodent models of brain damage and neurodegeneration, but training and testing the animals and performing detailed, objective quantification of their forelimb movements is very labor intensive. piReach is a low-cost, open source system for automated and standardized testing and quantification of rat forelimb function in these tasks.
Methods: piReach consists of a wifi-enabled module that houses of a pasta matrix or single pellet reaching task and 3 cameras for high-speed video recording of forelimb movements. This module is connected to a PC serving as a control hub for multiple reaching modules, showing real-time training results for each cage. A separate software package can then be used for offline quantification of reaching movements.
Results: The system automatically detects successful or failed reaching attempts and blocks access to the reaching target when a predetermined number of trials is completed or when the maximum training duration has been reached. Reaching success, forelimb trajectories, speed and accuracy are then calculated for each trial.
Conclusions: piReach enables transparent and replicable behavioral analyses, as well as high-throughput training and testing in rodent skilled reaching tasks. The system allows researchers to perform sophisticated quantification of forelimb movements, without requiring extensive computational experience or expensive equipment.

Title: Heterogeneous correlation between neural activity in motor cortex and aspects of movement reorganizes during learning

Authors: *Z. MA[1], H. LIU[2], A. PETERS[2], T. KOMIYAMA[2], R. WESSEL[1]
[1]Physics, Washington Univ. In St. Louis, Saint Louis, MO; [2]Ctr. for Neural Circuits and Behavior Rm 304, UCSD, La Jolla, CA

Abstract: Neural circuits in motor cortex are known to reorganize during motor learning. Such reorganization raises important questions concerning (i) the dynamics, coordination, and stability of neural activity in recurrent cortical circuits, and (ii) the potential malleability and degeneracy of the relation between neural activity and different aspects of movement.
To address the two questions, we monitored via population calcium imaging the activity of pyramidal neurons in L2/3 and L5 of both primary (M1) and premotor (M2) cortex of head-fixed mice during motor learning. Specifically, we trained water-restricted mice daily for up to 50 minutes/day on a lever-press task for approximately 14 days, during which the activity of the same neuronal populations was recorded. We obtained the discrete calcium events and the inferred spike probability from approximately 200 neurons per mouse for the duration of each recording/training session. We analyzed the population activity with respect to (i) changes in the statistical properties of neural activity and network states, and (ii) the relation between motor cortex neural activity and movement parameters, such as lever position, velocity and speed. These analyses revealed two important features of motor cortical activity.
First, population activity rearranged during motor learning. The correlations among pairs of pyramidal neuron activity changed across motor learning sessions. Concurrently, cortical circuits maintained the overall network state, as evaluated with respect to criticality using neuronal avalanche analysis.
Second, the correlation between motor cortex neural activity and lever movement parameters, such as position, velocity, and speed, was significantly heterogeneous across neurons, and changed across learning sessions, (In addition, the number of movement-related neurons increased with learning. Despite the observed heterogeneity, changes, and differences in cortical activity, all tested subjects performed similarly well in learning the lever-press task, as quantified

by the number of obtained rewards.
In conclusion, these results support the hypothesis that neural activity in cortical circuits rearranges during learning within the constraint of a stable network state, yet with a vast number of activity configurations at its disposal that each is consistent with a given behavior. It is tempting to speculate that the observed neural diversity may assist populations of neurons to combine different functions more flexibly to execute motor action.

Title: The effect of forced limb training for recovery of motor paralysis in a photochemically induced thrombosis model of cerebral ischemic stroke in rats

Authors: *C. SATO[1], K. AKAHIRA[1], S. KOEDA[1], K. SUMIGAWA[1], M. MIKAMI[1], J. YAMADA[2]
[1]Hlth. Sci., Hirosaki Univercity, Hirosaki city, Japan; [2]Dept. of Comprehensive Rehabil. Sci., Hirosaki Univ. Grad Hlth. Sci., Hirosaki, Japan

Abstract: Ischemic stroke often causes hemiplegic motor dysfunction, greatly impairing patient quality of life. Post-stroke rehabilitation can reduce the degree to which physiological and neurological function is impaired. A number of rehabilitation strategies exist. For instance, constraint-induced movement therapy is regarded as an effective treatment for impaired upper limb movement after stroke in humans and animals. Additionally, the forced impaired limb use (FLU) task has been found to improve neural function, while the reaching task component of the motor skills training (MST) program has been found to promote neural plasticity in the central nervous system. Despite the variety of approaches, the optimal method for treating motor dysfunction has not been established. Furthermore, few studies have examined the associated mechanisms of neural change in ischemic stroke models. The aim of this study was to investigate the effects of the FLU using the MST for upper limb function in a rodent model of cerebral ischemic stroke. We positioned deeply anesthetized male SD rats in a stereotaxic device and performed a craniotomy to open a window in the skull. After an intravenous administration of rose bengal through the caudal vein, we conducted photo illumination with a 540-nm green laser directed at the brain area controlling upper limb function. The beam of light was delivered

through the dura mater for a duration of 10 min. The rats were divided into three groups: a non-exercise group (non-Ex. group, n = 9) and two exercise groups. One of the exercise groups was trained using the single-pellet reaching and FLU tasks (FLU+MST group, n = 9), and the other group was trained using only the FLU task (FLU group, n = 9). Rehabilitation took place on days 4-10 after the surgery. We assessed motor function using the wire hang test, forelimb-placing test, beam-walking test, and single-pellet reaching test. All tests were performed before surgery and at day 1, 4, 10, 14 after surgery. The animals in all groups were severely paralyzed on day 1 after surgery. Data from the beam-walking test, which served as an assessment of hindlimb function, indicated no differences among the groups after rehabilitation. The scores on the wire hang and forelimb-placing test were higher in the FLU+MST group compared with the FLU and non-Ex. groups ($P<0.05$). These data indicate that the FLU+MST promotes recovery of upper limb function. Particularly, the MST appears to be effective for treating gross motor dysfunction but not fine motor dysfunction.

Title: A center-out sequence task for studying multiple multiple forms of motor learning in non-human primates

Authors: *A. L. ORSBORN, B. PESARAN
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Mastering a motor skill involves different forms of learning distributed across the brain. Understanding the brain mechanisms of motor learning therefore depends on analyzing behaviors with multiple co-occurring learning mechanisms in concert with neural recordings spanning large neural networks. We present a task for non-human primates to parse multiple learning mechanisms. Analyzing behavior in such a task can go beyond identifying a single form of learning to differentiate potentially distinct learning mechanisms. Primate behavioral models combined with large-scale neural measurements and manipulations can then facilitate investigation of underlying neural mechanisms. Sequence learning is hypothesized to involve both action selection learning (identifying the order of actions) and execution learning (refining the movements themselves). Existing work suggests these are distinct forms of learning mediated

by different neural circuits. We trained one monkey (macaca mulatta) on a form of the serial reaction time task, which is a center-out variation of the sequence task from Matsuzuka et al. 2007. At the start of each trial, a grey target array (center and 7 peripheral targets spaced in a circle) was presented on a touchscreen. The monkey was trained to make a series of 3 center-out reaches to receive a reward. Sequence elements were cued by color changes. Targets could be acquired prior to cues. Cue timing was used to encourage sequence learning and probe sequence order knowledge. Motor execution of sequence elements were studied using motion tracking of 5-8 retroreflective markers placed on the monkey's arm and hand. Initial training employed a task condition in which peripheral targets were randomly chosen and cued with short delays (150-200 ms). Subsequent training employed a condition with predictable sequences of peripheral targets with interleaved short and long (up to 1500 ms) cue delay trials. Cue colors were changed between conditions. Over 6 daily training sessions, the fraction of targets acquired prior to the cue increased from 22.7% to 60.5%, reflecting explicit sequence learning. Median trial execution times decreased from 5.78 ± 0.14 s to 3.20 ± 0.03 s, which may be due to both sequence knowledge (i.e. not waiting for the cue) and motor execution improvements (increased speed). We will present analyses of movement kinematics (reach speed, accuracy) and task behavior to test whether execution-related improvements are distinct from acquisition of the sequence. Dissociating behavioral measures of learning, in concert with large-scale neural recordings, will provide insights into how neural circuits support distinct forms of learning.

Title: Temporally precise vagus nerve stimulation (VNS) enhances motor learning and performance of a skilled forelimb reach task

Authors: *J. L. HICKMAN, X. PENG, D. DONEGAN, C. G. WELLE
CU Anschutz Med. Campus, Aurora, CO

Abstract: Vagus nerve stimulation (VNS) paired with execution of a motor behavior has been shown to increase cortical plasticity and improve rehabilitation following motor impairment. However, the influence of temporally-paired VNS on motor outcomes in healthy animals has not been fully explored. Here, we implement a novel chronic VNS mouse model to study the effects on motor learning in a healthy animal. Wildtype C57B6 mice were implanted with a flexible

silicon cuff with an internal diameter of 100 µm (Cortec, MicroSling) on the left cervical vagus nerve. Following a two-week recovery, mice were trained to perform a dexterous forelimb reach to obtain a food pellet. VNS (30 Hz, 0.3mA, 100 µs pulse width) was applied immediately following a successful completion of a reach during either the learning process (n = 5) or in an animal already proficient in the task (n=5). To investigate the circuit mechanism responsible for effects of VNS on skilled motor learning, a separate cohort of mice expressing an immediate-early gene-driven(cfos) destabilized GFP (B6.Cg-Tg(Fos-tTA,Fos-EGFP*)1Mmay/J; n = 3) received VNS, and brain and brainstem tissue were collected 1 hour later. In a third experiment, alterations to cortical circuit dynamics during VNS were investigated in mice expressing a calcium indicator in motor cortex neurons (C56BL/6J-Tg(thy1-GCaMP6 GP5) imaged while freely-moving using a miniscope (UCLA Miniscope).
VNS paired with reach success increases performance throughout all phases of learning: early (days 1-4, $p<0.001$), middle (day5-9, $p<0.05$), and late (10-14, $p<.01$). In addition, paired VNS improves the performance of the dexterous reach in previously trained animals by 20% ($p<0.001$). Histological analysis of cfos expression shows neuronal activation in NTS (where vagal afferents terminate), locus coeruleus (a noradrenergic nucleus) and basal forebrain (a cholinergic nucleus), suggesting that VNS may mediate motor learning through activation of ascending cholinergic and/or noradrenergic afferent projections. Analysis of neuronal firing during VNS revealed decorrelated spiking in superficial motor cortex neurons. These results suggest that temporally-paired VNS can influence the learning and performance of a skilled motor task, and this effect may be mediated by neuromodulatory influence on motor cortex circuit dynamics.

Title: Sex differences in paw-reaching behavior of mice

Authors: M. A. BRADY[1], J. C. BOYER[2], *D. R. MCPHERSON[4], T. BAZZETT[3]
[1]Neurosci., [2]Biochem., [3]Psychology, SUNY Geneseo, Geneseo, NY; [4]SUNY-Geneseo, Geneseo, NY

Abstract: Reach-to-grasp tasks are commonly used in rodent models to study coordinated motor skills as affected by neurodegenerative disorders and stroke. The present study examined sex

differences in mouse (*Mus musculus*) paw reaching behavior using a novel automated operant chamber. This particular chamber is designed to quantify latency to begin reaching, total reach attempts, successful pellet retrieval, and total number of pellets consumed. Operant measures were collected from male (n=20) and female (n=16) C57BL/6J mice beginning at 18 weeks of age and continuing through adulthood. Tests were conducted as 15-minute sessions, twice per week. Our preliminary results show that males perform significantly better than females in all measures. Similar sex differences in more rudimentary reach-to-grasp tasks have been previously reported, and they suggest that sex-related differences may become amplified when the age at which operant training begins is increased. Sex differences have also been observed in some human neurodegenerative disorders that are marked by impaired motor function. For example, females who inherit the gene allele responsible for Huntington's disease (HD) are typically diagnosed with symptoms at an earlier age than their male counterparts. In contrast, Parkinson's disease (PD) is more prevalent among males than females. Mouse models for such neurodegenerative disorders are frequently used for experiments in which researchers attempt to quantify the motor skill declines resulting from brain lesions, genetic aberrations, and normal aging. The present results suggest that sex differences may be pertinent to the interpretation of those experiments, and particularly when using skilled limb movement analysis such as the reach-to-grasp task. Additional studies are currently underway to assess correlations between paw reaching behavior and grip strength measures in these mice. Future research using these techniques will be designed to evaluate motor decline and sex differences in mouse models of HD and PD.

Abstract: The corticospinal (CS) circuit is an essential neuronal pathway for voluntary and skilled movements. However, its organizational and functional connectivity still remains unknown. Here we map the connectivity between CS neurons and various spinal interneurons in mice, and demonstrate that distinct CS-interneuron circuits control specific aspects of skilled movements. By using a set of neuronal tracers and genetically modified mice, we identify subpopulation of CS neurons which have different cortical locations and connectivity. Especially, the neurons positioned in the medial motor and lateral sensory cortex project axons topographically to the ventral and dorsal areas of the spinal cord, respectively. Each CS fiber subtype has connections with specific types of genetically encoded spinal interneuron. CS neurons in the motor cortex innervate axons onto premotor interneurons including Chx10+ V2a neurons, whereas sensory CS neurons connect with sensory-related neurons including Vglut3+ dorsal interneurons . Ablation or chemogenetic inhibition of neuronal population involved in the motor and sensory CS circuits exhibits different deficits during reaching and grasping behaviors. These findings reveal that CS neurons in the motor and sensory cortex differentially control skilled movements through distinct CS-spinal interneuron circuits. Our results indicate that the CS circuit is a neuronal complex integrating multiple functional modules to conduct fine skilled movement.

Abstract: The primary motor cortex (M1) is the final cortical output region important in motor planning and execution of movements. A main challenge is to bridge the gap between formal descriptions in the language of system's motor control theory, and the actual mechanistic biophysical understanding of sensory-motor coding. Towards this end we developed an

integrated unique experimental setup combining a rich behavioral paradigm of head-fixed hand-reach motor tasks, chronic optical calcium imaging measurements of network and dendritic activities in identified neuronal subtypes and opto- and chemogenetic tools. Importantly, we access key cellular network elements according to their projection targets using novel viable functional retrograde viral vectors. We characterized the coding of layer 2-3 and layer 5 pyramidal track (PT) neurons during the hand reach motor task. We find that while the activity of PT neurons was mostly movement related, the activity of layer 2-3 neurons was both movement and sensory parameter related.

Title: Circuit investigation of the GABAergic neurons of the zona incerta

Authors: *Z. LI, A. MERLI, K. TAN
Biozentrum, Univ. of Basel, Basel, Switzerland

Abstract: The diencephalic Zona Incerta (ZI) is a region where investigations has been largely neglected over the past century. Recent anatomical tracing studies show direct projections from the ZI to the centers of many (dopaminergic, noradrenalinergic, and serotonergic) neuromodulatory systems, highlighting its potential importance in influencing locomotion, motivational behaviors, and arousal. Past investigations suggested that the ZI could promote ingestive and locomotor behaviors. However, these findings are still controversial given the crude nature of the manipulations, the lack of targeting specificity, and the proximity to the hypothalamus and the subthalamic nucleus, which have been extensively shown to influence both behaviors respectively.
One of the main obstacles in investigating the ZI is its highly heterogenous cell populations, which could be overcome by advancements in transgenic lines and viral targeting approaches. Here, we investigate the most populous GABAergic neurons. Using cell type specific reporter lines and molecular assays, we examine the localization of different GABAergic markers across the ZI. By selectively expressing viral tracers labeled with fluorescent proteins in cell type specific transgenic mice lines, specific connectivities of ZI GABAergic neurons can be identified. Lastly, optogenetic manipulations of ZI GABAergic neurons are used to elucidate its

functional role in behavior. Collectively, our systematic approach provide insights on the ZI GABAergic neurons across many levels.

Title: Genetic and functional characterization of rubral pathways

Authors: *G. RIZZI[1], M. COBAN[2], A. MERLI[1], M. A. OCAÑA[2], K. TAN[2]
[1]Biozentrum, [2]Univ. of Basel, Basel, Switzerland

Abstract: The Red Nucleus sustains the integration and correct modulation of somatosensory feedback and fine motor coordination. Although two anatomical sub-divisions have been identified (magnocellular and parvocellular segments) and participate in segregated afferent and efferent circuits, a characterization of different cell classes within the Red Nucleus at a genetic and functional level is lacking. Using single molecule mRNA in situ fluorescent hybridization (smFISH) we have identified a rubral cell population that while expressing the calcium binding protein parvalbumin (PV) it largely co-expresses the excitatory Vesicular glutamate transporter (Vglut2). At the anatomical level the boundaries of this cell cluster are markedly delineated by the encircling expression of the inhibitory Vesicular GABA transporter (Vgat). Optogenetic activation of Vglut2 rubral neurons induces robust postural deficits and heavily impairs locomotion, whereas optical ablation of the Red Nucleus severely impairs fine motor coordination leaving locomotion marginally affected. Pathway specific modulation of Vglut2 containing rubral neurons could prove instrumental in ameliorating motor deficits characterized by abnormal muscle tone and dyskinesias in pathological conditions resistant to classical Parkinsonian syndrome treatments.

Title: Signatures of proprioception and vision relevant to corrective motor responses in primate

Authors: *T. FISHER[1], E. M. TRAUTMANN[2], X. SUN[1], D. J. O'SHEA[1], S. RYU[3], K. V. SHENOY[4]
[1]Stanford Univ., Stanford, CA; [2]Stanford Neurosciences, San Francisco, CA; [3]Dept Neurosurg, Palo Alto Med. Fndn., Palo Alto, CA; [4]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: Visual and proprioceptive feedback are both crucial for motor control. Differences in primary motor cortex (M1) and premotor cortex (PMd) response latencies provide some indication that proprioception and vision have unique roles in guiding corrective movements. However, how these complementary signals may be separately encoded in the motor cortical areas is not well understood.
Here, a rhesus macaque (U) was trained to maintain a cursor within a centrally located visually defined target by manipulating a haptic device. Following either a mechanical perturbation or a cursor jump, corrections were required to complete a successful trial. We recorded neural activity from three 96 channel Utah arrays implanted in M1 and PMd.
We designed this task to leverage the consistent neural response latency difference between these two modalities. Perturbation trials were either combined mechanical and visual, or visual only. Critically, firing rate changes in these motor areas after a mechanical perturbation begin at ~20ms, leading the responses to a visual perturbation which begin at ~150ms. This task design has the following advantage: activity just following a combined perturbation is primarily mechanical, whereas activity just following a visual perturbation is predominantly visual.
We found neural population dimensions that separate activity by perturbation modality using dPCA. In order for our analysis to be agnostic to the fixed latency difference between modalities we aligned activity to the neural response onset following the perturbation. We found that they are very similar. A dPC that explains over 40% of the total variance is modality-independent suggests a common signal shared by both modalities.
However, dPCA also isolates dimensions capturing modality-specific variance which differs

between visual and mechanical perturbation responses. This indicates that visual and mechanical errors are differentially encoded in motor cortical populations beyond simple differences in latency.
More broadly, this work can help to elucidate the mechanisms by which neural circuits can fuse information from diverse sensory modalities to facilitate dextrous feedback control.

Title: Systematic changes of neural population activity during curl force field adaptation

Authors: *X. SUN, D. O'SHEA, T. FISHER, M. GOLUB, S. RYU, K. SHENOY
Stanford Univ., Stanford, CA

Abstract: Motor learning is thought to proceed as networks of neurons change their population activity in order to generate new behaviors. Previous neurophysiological studies of motor learning, using force-field adaptation paradigms, have characterized single neuron tuning properties in PMd and M1 and discovered that individual neurons adapt their responses to compensate for the learned force field[1, 2]. However, these single-neuron response changes are heterogeneous and hard to interpret mechanistically. Here, we explore the changes in neural population dynamics that underlie adaptation to curl force fields as well as the spatial generalization of adapted behaviors. We trained monkeys to adapt to a curl force field, active only during reaches to a single “adaptation” target in a ring of 12 targets. In addition, reaches to adjacent, non-adapted targets using an “error clamp” were interleaved with the curl field adaptation trials. Behaviorally, monkeys showed a Gaussian-like spatial generalization pattern: the level of hand force compensation decayed as a function of target angle away from the adaptation target. We recorded neural activity in PMd and M1 during adaptation and found gradual changes in population activity patterns both before movement initiation and during movement execution. First, within a 2D subspace of the overall neural population activity state

space, where preparatory activity is radially organized according to reach direction, the preparatory state for the adaptation target shifted towards that of the adjacent target opposite the direction of the curl field (as measured before adaptation). The preparatory states for nearby targets showed similar shifts towards their adjacent target states; the shifted amount diminished with a similar spatial profile as the behavioral generalization. Second, during adaptation, preparatory states for all targets shifted in a third dimension away from the baseline states. This result is intriguing because it also occurred for reaching targets far from the adaptation target for which no behavioral adaptation was observed. These findings are a first step towards identifying a mechanism for how neural population activity change systematically to facilitate adaptation to novel arm dynamics. This in turn may elucidate how neural circuits learn to adapt their activity patterns in response to changing task demands. [1] Li et al., 2001, Neuron. [2] Cherian et al., 2013, J. Neurophys.

Title: Population dynamics of proprioceptive error signals in motor cortex

Authors: *D. J. O'SHEA[1], E. M. TRAUTMANN[2], S. RYU[3], K. V. SHENOY[4]
[1]Stanford Univ., Stanford, CA; [2]Stanford Neurosciences, San Francisco, CA; [3]Dept Neurosurg, Palo Alto Med. Fndn., Palo Alto, CA; [4]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: An expansive body of behavioral and neurophysiological evidence suggests that primary motor (M1) and dorsal premotor (PMd) cortices serve as key nodes in a brain network

that drives goal-directed feedback control. Mechanical perturbations of the arm evoke cortical responses within 20-50 ms which have been characterized in individual neurons (Evarts and Tanji, 1976; Pruszynski et al. 2014). However, the population structure of motor cortical responses to proprioceptive error remains poorly understood.

To address this question, we recorded simultaneously from 288 channels across 3 Utah arrays implanted in M1 and PMd in a macaque engaged in a center-out reaching task. The reaches were performed while holding the handle of a haptic feedback device. During a random subset of trials, we delivered a step-force mechanical perturbation through the device that pushed the hand along one of eight directions. Perturbations evoked robust responses in M1/PMd neurons (251/288 channels modulated within 100 ms, $p < 0.01$, ANOVA). These responses varied smoothly in magnitude with respect to perturbation direction. Across the population, perturbation-driven deflections in population neural trajectories were radially organized according to the direction of perturbation.

If error-evoked responses in motor cortex are structured so as to counteract applied forces, we would expect these responses to cancel out in opposite directions. Instead, averaged across the 8 perturbation directions, perturbations drove a net increase in most channels' firing rates (mean changes > 10 threshold crossings/sec in 179 / 251 modulated channels). Across the neural population, perturbation direction-independent changes captured > 50% of the variance of the total evoked responses. A single dimension identified with DPCA displayed identical responses across all perturbation directions and captured > 20% of the total variance. This large, perturbation direction-independent response could facilitate generation of a corrective response to perturbation. It may play an analogous role in orchestrating corrective movements as the large reach-direction independent signal reported by Kaufman et al. (2016) may serve in initiating visually guided reaches.

Our results begin to elucidate the input-driven dynamic computations by which motor cortex participates in motor feedback control, beyond its relatively better-explored role in movement initiation and execution. More generally, perturbation experiments can help to dissect the mechanisms by which neural populations process sensory feedback to achieve dextrous behavior.

Title: Neural population dynamics of motor preparation following rapid adaptation to modified reach forces

Authors: *E. TRAUTMANN[1], D. J. O'SHEA[2], T. FISHER[2], S. RYU[3], K. V. SHENOY[4]
[1]Stanford Neurosciences, San Francisco, CA; [2]Stanford Univ., Stanford, CA; [3]Dept Neurosurg, Palo Alto Med. Fndn., Palo Alto, CA; [4]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: Movements are thought to be prepared prior to execution [1]. Numerous studies have illustrated the relationship between neural preparatory state and subsequent behavior [2-4]. In this study, we test the relationship between neural preparatory state and the muscle forces generated during a reach, following adaptation to modified environmental dynamics.
We trained rhesus monkeys to perform reaches with a robotic haptic device. In alternating blocks of 70-100 trials, we applied a velocity dependent drag force, opposing the direction of motion, requiring the monkey to rapidly update an internal model and generate approximately 2.5 times as much force as in non drag reaches. Following a block switch, we observe behavioral adaptation within 5-8 trials, and find significant behavioral differences on miscued trials delivered during drag and non-drag blocks. Together, these behavioral results indicate the monkey is preparing different reaches after adaptation.
We used demixed principal components analysis (dPCA) to look for dimensions in neural population state space during the preparatory period prior to movement that explain variance associated with the forces generated on a given reach. Surprisingly, this dimension explains only 0.8% of neural variance during preparation, compared with 21.7% variance explained by the dimension that best separates target location. At the level of individual multiunit channels, only 20 of 288 channels (6.9%) have significant but modest differences in delay period activity between reaches with a heavy drag and those without.
Despite a significant behavioral perturbation and rapid adaptation to external loads, we find only very small differences in delay activity prior to movement, suggesting that an updated internal model presumed to be present in the brain is not reflected robustly in PMd and M1 neural activity. These results help to constrain optimal feedback models of motor control, and suggest a less direct connection between neural preparatory state and muscle force than prior models.

Title: Motor cortical preparatory activity is causally involved in visuomotor learning

Authors: *S. VYAS[1], D. J. O'SHEA[2], E. TRAUTMANN[4], F. WILLETT[3], K. V. SHENOY[5]
[1]Bioengineering, [3]Biomed. Engin., [2]Stanford Univ., Stanford, CA; [4]Stanford Neurosciences, San Francisco, CA; [5]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: Previous studies suggest that delay period activity in premotor cortex (PM) is critically involved in motor preparation. A recent study (Vyas et al., Neuron 2018) found that visuomotor learning is correlated with systematic changes in motor cortical preparatory activity. Despite such findings, the mechanism by which preparatory activity facilitates motor learning, if at all, remains unknown. Here, we causally disrupted delay activity in PM, to assess its role in visuomotor learning. We first hypothesized that additional time during the delay period could correlate with increases in speed of visuomotor learning. Consistent with this hypothesis, we found that monkeys adapted to a 45-degree visuomotor rotation faster if they were given more time to prepare during a delay period spanning 300-500ms before the go-cue ($p < 1e-3$). This benefit was only present if additional time was granted during the delay period, and not at any other point in the trial. Neural population analyses revealed that during learning, the motor system continually optimized the preparatory neural state intra-trial if additional time was given to prepare, in contrast to saturating quickly after target onset ($p < 0.01$). To causally evaluate these effects, we performed block-wise subthreshold intracortical microstimulation (ICMS) of PM delay activity right at the go-cue (333Hz, 60ms duration, bimodal pulses with 150us cathodal followed by 150us anodal pulses separated by 250us). We found that ICMS at the go cue was sufficient to disrupt and slow down learning ($p < 1e-5$). In separate sessions, we randomly interleaved ICMS and non-ICMS trials during learning, and measured per-trial learning progress, defined as the decrease in error on the current trial relative to the previous trial. Surprisingly, we found no difference in learning progress between ICMS and non-ICMS trials, but instead we found that trials which immediately followed ICMS trials showed significantly less learning progress than trials following non-ICMS trials ($p < 1e-3$). This suggests a mechanism where

ICMS of PM delay activity actually disrupts motor learning, rather than indirectly affecting learning by disrupting behavior on individual trials. To test whether any manipulation at all during the delay period is sufficient to disrupt learning, we performed ICMS at 300ms post-target onset followed by 350-600ms of additional delay time pre-go-cue. We found no disruption in learning, suggesting that allowing the network to reset the preparatory state post-ICMS abolishes learning deficits. Our results provide the first ICMS-causal evidence for the role of motor cortical preparatory activity in visuomotor learning.

Title: Role of primary motor cortex in saccadic and vergence eye movements

Authors: *C. W. TYLER[1], L. T. LIKOVA[2]
[1]Smith-Kettlewell Brain Imaging Ctr., [2]Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Introduction. The eye movement control pathway is generally considered to be driven by signals from the Frontal Eye Fields (FEF) to the superior colliculus (SC) and thence to other subcortical oculomotor structures, with concomitant involvement of parietal regions such as the lateral intraparietal sulcus (LIPS). Unlike reaching hand movements, no involvement of primary motor cortex (M1) is generally recognized, although trace activation of M1 may be seen in in most functional MRI (fMRI) studies of eye movements. Here we ask whether the M1-specific activation shows differential properties relative to those of the FEF activation as a whole during saccadic and vergence eye movements. Methods. Functional MRI of human observers at 3T in a whole-brain paradigm, when morphed to the MNI 152 brain coordinates, was used to assess the activation in attentionally non-demanding tasks consisting of repetitive left-right saccade and near-far vergence (each involving only two eye muscles per eye). Results. 1) At least two M1 sites located within the overall face region showed differential activation during saccades and vergence. 2) There was no activation, or even suppression, in adjacent somatosensory (S1) sites, excluding any possibility of artifactual sulcal cross-talk from sensory stimulation of facial structures such as the eyelids during the eye movements. 3) While the inferior M1 site was

activated for both saccades and vergence, the superior M1 site was activated for vergence and suppressed for saccades. 4) In a L/R saccadic directional paradigm, the activation in the inferior M1 site was specific to saccade direction, whereas the FEF and the superior M1 site showed no directional specificity. Conclusion. Although the eye muscles represent only a very small proportion of the ~650 muscles of the body as a whole, our fMRI evidence suggests that local regions of the M1 homunculus mapping play an unrecognized, direction-specific role in oculomotor control, a function that is usually assigned to the FEF. The suppression seen during vergence is consistent with the fact that vergence movements are much slower than saccades, implying that the interocular coupling of the oculomotor control system is optimized for saccades to the exclusion of symmetrical vergence movements. Thus, vergence eye movements involve less-optimal brainstem circuitry requiring the saccadic control signals to be bypassed during vergence activation.

Title: Emergence of neuron clusters in mouse motor cortex during learning

Authors: *K. LI, J. K. P. IP, M. SUR
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: The superficial layers of the mouse motor cortex is connected with both sensory areas and motor thalamus. It is essential for mouse motor learning, and both synaptic strength and temporal activity patterns have been found to change in the motor cortex following motor learning. However, it is yet unclear what computation is carried out in the motor cortex to facilitate learning, and what principle underlies the changes in motor cortex connectivity following learning. To examine the neuronal correlates of motor learning, we performed two photon Ca^{+} imaging of gCaMP6s- or jR-GECO-expressing neurons in the forelimb representation in the motor cortex of wildtype mice while training them on a simple lever push task with water restriction (Peters, Chan and Komiyama, 2014). The mice were trained to hold a lever still, then push it forward on an audio signal for water, or get punished with white noise and extra wait time.

During training, the mice first learned to start the push at the signal, then gradually refined the push trajectory to make a smooth “expert” push. When clustering the trials by dynamic time warping linkage of their trajectories, the “expert” push cluster started to appear around day 5 of training, and grew with training to include most trials towards day 14. The other clusters representing different push trajectories, while initially seen in similar numbers of trials as the “expert” push, gradually shrank in number and started to disappear after day 11. Wildtype mice were trained to perform the “expert” push reliably within two weeks, and we could track the same 20-30 layer 2/3 neurons between regular imaging sessions during training. We first examined the functional connectivity among tracked neurons as measured with “noise” correlations while the animal was not moving. The neurons initially increased the strength of both positive and negative noise correlations indiscriminately during training. From day 10 to day 13, the same time-period when the mice transitioned to use the “expert” push, two clusters formed among the recorded neurons, where correlations within clusters grew more positive and noise correlations grew more negative between the clusters. When classifying the neurons by their correlation with the “expert” push at the end of training, almost all neurons belonging to one cluster were push-correlated, while the other cluster had all neurons with negative or no correlation.
These results suggest that the reorganization of the motor cortex during learning involves the formation of neurons clusters with strong interconnections, which are also activated during movement.

Title: Patterns of astrocytic microdomain activity in the motor cortex during motor learning

Authors: *J. SHIH[1], C. DELEPINE[2], M. SUR[2]
[1]Brain and Cognitive Sci., MIT/Picower Inst. for Learning and Memory, Cambridge, MA; [2]Brain and Cognitive Sci., MIT/Picower Inst. For Learning and Memory, Cambridge, MA

Abstract: Excitatory neurons of the primary motor cortex (M1) function as part of neuronal ensembles, which are populations of neurons whose activity becomes correlated as an animal learns a stereotyped movement pattern. Astrocytes, the main type of glial cell in the cortex, have

been shown to respond to and influence neuronal activity by transiently increasing their intracellular Ca2+ levels. Astrocytic Ca2+ transients have diverse spatiotemporal characteristics and can spread through the entire astrocyte cell body or be limited to primary branches or fine processes. Emerging evidence suggests that different types of astrocytic Ca2+ activity are associated with different types of neuronal activity and signaling by different neurotransmitter systems. However, definitive correlation between astrocyte Ca2+ activity and defined patterns of neuronal activity has not been established. Here, we focus on Ca2+ microdomain activity in astrocyte fine processes, which are closely associated with synapses and are well-positioned to respond to and influence neuronal activity. We trained mice on an auditory tone-cued lever push task, a behavioral paradigm that incorporates associative learning aspect as well as the acquisition of a stereotyped motor movement. Manipulation of astrocyte mechanisms suggest that altered astrocytic Ca2+ signaling influences neuronal activity during motor learning, leading to decreases in task performance. We hypothesize that a stable pattern of M1 astrocyte Ca2+ activity in microdomains develops during acquisition of a stereotyped motor movement, is correlated with neuronal ensemble formation and motor learning, and is potentially causal for learning. We use chronic two-photon imaging of astrocyte Ca2+ microdomain activity *in vivo* to test this hypothesis and show that distinctive patterns of astrocyte microdomain activity emerge as an animal learns the lever push task. Our results so far suggest that Ca2+ activity in microdomains may encode an astrocyte "signature" that is associated with motor learning, and thus identifies a novel neuron-astrocyte interaction that occurs during motor behavior.

Title: Critical contribution of astrocytes to motor learning *in vivo*

Authors: *C. DELEPINE[1], M. SUR[2]
[1]Brain and Cognitive Sci. Dept., [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Astrocytes, long thought to operate only as a support network for neurons, are now emerging as key players in the modulation of brain information processing. Astrocytes influence synaptic transmission via glutamate transporters, and respond to, as well as modulate, neuronal activity with calcium signaling. However, many questions remain in understanding the

contribution of astrocytes in vivo to complex behaviors and cognition. During motor learning, primary motor cortex (M1) is functionally and structurally reorganized. The learning of a new movement is associated with changes in neuronal activity and dendritic spine turnover. We hypothesize that astrocytes are modulators of learning-associated neuronal network reorganization by influencing synaptic strength through glutamate clearance and calcium signaling. Here we investigate the role and plasticity of cortical astrocytes in a motor learning, lever-push task *in vivo*. Using the engineered human muscarinic G protein-coupled receptor DREADD-hM3Dq activated by low doses of clozapine-N-oxide (CNO), we find that modulation of astrocyte calcium activity perturbs performance of the animal in the lever-push task (causing decreased lever push responses to a cue sound). Moreover, we use a transgenic mouse line in which the expression of the glutamate transporter GLT1 can be inhibited locally in M1 and show that decreasing astrocyte glutamate clearance prevents learning of smooth motor trajectory. Using genetically encoded calcium indicators and high-resolution two-photon imaging, we then show that perturbation of astrocyte calcium activity modulates the correlation structure of neuronal population activity. In contrast, GLT1 knockout increases neuronal activity and prevents the formation of correlated neuronal ensembles normally associated with the motor learning. This ongoing project utilizes cutting-edge imaging techniques, and novel technologies for manipulating astrocyte activity, to unravel astrocyte function during a physiologically relevant task involving motor cortex plasticity.

Title: Sustained effects of an exercise program on dynamic balance control

Authors: *D. SHIBATA
Univ. of New Mexico, Albuquerque, NM

Abstract: Balance control requires central processing of multi-sensory feedback and motor commands responsible for force production. An exercise program was designed to realign spinal curvature, and its effect on balance control immediately after the intervention was documented. To examine the efficacy of the exercise program on balance control over two weeks post-

intervention, the center of gravity (CoG) sway was measured. Subjects (n = 20) were randomly assigned into one of two groups: exercise on a cylinder-shaped tube (Ex-T group, n = 10), and a control group that rested on a flat surface (n = 10). The exercise program consisted of three preparatory positions and seven small motions, and each session lasted approximately 15 min. Subjects in the Ex-T group performed the exercise program twice a day for one week (Day 1-7), while those in the control group lay supine on a flat surface for 15 min twice a day, followed by one week of no intervention (Day 8-14). On Day 0, all subjects underwent baseline CoG sway measurement. On Day 1, CoG sway was measured immediately after either the intervention (Ex-T) or laying on a flat surface (Control). On Days 7 and 14, follow-up CoG sway measurements were taken. CoG sway was measured while standing on a balance system platform (Biodex Medical Systems, Shirley, NY, USA) under both static and dynamic conditions. During the static condition subjects were asked to stand still and the platform was held stationary (e.g., no tilt). During the dynamic condition the platform was allowed to tilt in response to changes of CoG and subjects were asked to maintain the platform in a horizontal position. Five trials of each test condition, for 20 s each were performed. The hypotheses were: a) the decrease in Ex-T group CoG sway on Day 1, 7, and 14 after the intervention would be significantly greater than in the Control group, and b) the decrease in CoG sway during the dynamic platform test condition would be significantly larger than during the static platform test condition.
Mixed-design ANOVAs were used to examine changes in average CoG sway and group differences. There were no significant changes in average CoG sway for the static platform condition. During the dynamic platform condition, CoG sway significantly decreased from baseline on Day 1, 7, and 14 in the Ex-T group ($p < 0.05$), but not in the Control group. These findings indicate that the 1-week exercise intervention improved dynamic, but not static balance control, and the improvement persisted after a 1-week cessation of the intervention. It is speculated that the exercise program enhances processing of sensory feedback and motor commands for dynamic balance control, which sustains without the intervention for 1 week.

Title: Inter-limb coordination patterns during external versus internal asymmetric tasks

Authors: *M. MUKHERJEE, L. BOWMAN, T. RAND
Dept. of Biomechanics, Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Aging and pathology, e.g. strokes, may result in asymmetrical gait in the spatial and/or temporal domains. Asymmetrical walking patterns can be induced through several different tasks including unilateral limb loading and split-belt adaptation. However, these two methods induce asymmetrical walking patterns through different mechanisms. While unilateral limb loading (an external weight added to a limb), is perceived as one limb being heavier than the other (internal perception), the split-belt with the two belts of the treadmill moving at different speeds, is perceived as an external change. Determining how spatial and temporal components of gait are effected due to an internal versus an external coordination task may give important insight into developing rehabilitation programs for those with asymmetric sensorimotor abnormalities. In addition, Virtual reality (VR) affects various domains of gait, but it is unclear how VR affects spatial and temporal symmetry during asymmetrical walking.Thirty-eight young adults participated in this study. Twenty subjects walked on a treadmill while adapting to a unilateral limb load (5% of body weight) strapped to their left ankle. Another 18 subjects adapted to a split-belt treadmill paradigm. Half of all subjects were exposed to VR.To compare interlimb coordination, the symmetry index (SI) was calculated for step length and step time. The SI of any gait variable was defined as a ratio of the difference between the variable for the fast/loaded and slow/unloaded limbs to the sum of the variable for the two limbs. Three-way mixed model ANOVAs showed that limb loading and split-belt adaptation, both altered gait in the spatial and temporal domains (condition effect; $p<0.001$). However, the effect of each task on these domains were different ($p<0.05$). specifically, limb loading and split-belt effects during early and late adaptation were significantly different from each other. Limb loading and split-belt were similarly effected by VR for all comparisons except step time ($p<0.05$). When visual feedback was absent, transitioning from loaded to unloaded condition causes significant temporal effects on gait, however, optic flow through VR allows smoother transitions such that gait patterns are not significantly altered.

Title: Quantifying the spatial smoothness of knee movement by a three-dimensional curvature

Authors: *K. TAKEDA[1], Y. ASANO[2], K. HORI[2], S. SONODA[2,3]
[1]Sch. of Hlth. Sci., Fujita Hlth. Univ., Toyoake, Aichi, Japan; [2]Nanakuri Mem. Hosp., [3]Dept. of Rehabil. Med. II, Sch. of Med., Fujita Hlth. Univ., Tsu, Mie, Japan

Abstract: A novel evaluation method based on spatial smoothness has been proposed to quantify movement irregularities of the affected hand in stroke patients (Osu et al., J Neuroeng Rehabil 2011). In the present study, we investigated how to apply this method to the evaluation of knee motion. Four healthy participants participated in the pilot study. The participants sat on a chair and were asked to raise their knee (hip flexion) as fast as possible and as high as possible. This motion was repeated five times in a row. Three-dimensional (3D) coordinates of hemispherical markers attached to the lateral epicondyle of the femur (knee marker) and the greater trochanter (hip marker) were recorded at 60 Hz sampling rate using KinemaTracer (Kissei Comtec Co. Ltd., Japan). For the absolute coordinate position of the knee marker and the relative coordinate position of the same marker with respect to the hip marker, the 3D curvature at each time point was computed. The median of the -log of curvature (MLC), which indicates the spatial smoothness, was calculated in the flexion and extension phases of the knee, respectively. The differences of the mean MLC across the participants were investigated between the absolute and the relative coordinate positions, and between flexion and extension phases. All the participants showed higher MLC in the absolute coordinates than that in the relative coordinates and showed higher MLC in the extension phase than that in the flexion phase. In the absolute coordinates, MLC might be estimated highly because the change in the position of the knee might be contaminated with the movement of the whole body including the trunk. In the evaluation of the stroke patients, this contamination may be more pronounced because the patients often involve compensating trunk motion. Unlike the previous study which focused on the hand reaching motion in the horizontal plane, the knee motion is in the vertical direction. Therefore, participants can drop the knee simply by releasing force, and the motion might be estimated to be smoother in the hip extension phase, consequently. Since continuous force control is difficult for stroke patients, it is highly possible that they adopt the force release strategy in the extension phase. The evaluation of the hip extension phase may not accurately assess the spatial smoothness of the motion of stroke patients. These results suggest that it is important to focus on the flexion phase in the relative coordinates of the knee with respect to the hip in evaluating the spatial smoothness of the knee motion of stroke patients.

Title: Developmental changes in postural movement patterns during bilateral arm flexion in children

Authors: *T. KIYOTA[1], K. FUJIWARA[2], K. KUNITA[3], K. ANAN[4], C. YAGUCHI[5]
[1]Dept. of Child Care and Educ., Osaka Univ. of Comprehensive Children Educ., Osaka-Shi, Japan; [2]Kanazawa Gakuin Univ., Kanazawa, Japan; [3]Fac. of Sports & Human, Sapporo Intl. Univ., Sapporo, Japan; [4]Sapporo Intl. Univ., Sapporo, Japan; [5]Dept. of Rehabil., Japan Hlth. Care Col., Eniwa, Japan

Abstract: We investigated the developmental changes in postural movement patterns during bilateral arm flexion in children. A total of 174 subjects participated in this study from 4 to 12 years old (number of subjects (n): 4 years: n = 30; 5 years: n = 36; 6 years: n = 41; 7-8 years: n = 21; 9-10 years: n = 15; 11-12 years: n = 31). In response to a visual stimulus presented at 2-4 s after a warning signal, the subjects initiated the bilateral arm flexion as quickly as possible and then stopped their arms voluntarily at a horizontal position. After 5 practice trials, 10 test trials were performed. Movement angles of the trunk and leg joints during the arm flexion were analyzed, based on the small reflective markers placed over the following positions: head of the fifth metatarsal, external malleolus, knee, trochanter major, and vertebra prominence. Young children mainly extended the trunk rather than the ankle during the arm movement, while older children leaned the whole body backward. The postural movement patterns were categorized on the basis of the movement angle of the foot-leg and leg-trunk into the following three patterns: hip extension (HE), hip flexion (HF), and backward leaning (BL) types. More than half of children aged 4-6 years were categorized as HE (4 years: 76.7%; 5 years: 77.8%; 5 years: 61.9%). BL gradually increased from aged 7-8 years and older. The percentage distribution of each type at aged 11-12 years differed with younger children. The percentage of HF (41.9%) and BL (45.2%) were significantly larger than HE (12.9%). These results suggested that the postural movement pattern during bilateral arm flexion would change with age.

Age groups	Number		Postural movement pattern		
			HF	BL	HE
4	30	%	6.7	16.7	76.7
		Standardized Residual	-1.9	-0.5	1.9
5	36	%	16.7	5.6	77.8
		Standardized Residual	-0.4	-2.4	2.3
6	41	%	17.1	4.9	61.9
		Standardized Residual	-0.4	-2.8	2.6
7-8	21	%	9.5	28.6	61.9
		Standardized Residual	-1.2	1.0	0.1
9-10	15	%	20.0	40.0	40.0
		Standardized Residual	0.1	2.0	-1.7
11-12	31	%	41.9	45.2	12.9
		Standardized Residual	3.6	3.8	-6.0

Title: Detecting balance deficits in Parkinson's disease using a novel MRI compatible balance simulator

Authors: *E. PASMAN[1], M. J. MCKEOWN[2], T. W. CLEWORTH[1], J. T. INGLIS[1], M. G. CARPENTER[1]
[1]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Pacific Parkinson's Res. Ctr., Vancouver, BC, Canada

Abstract: BACKGROUND AND AIM: Postural instability is a debilitating symptom of Parkinson's disease (PD) which is not alleviated by most pharmacological and surgical treatments for PD. Identifying the neural substrates contributing to postural instability in PD is made difficult by the need to be supine, or have the head fixed, for most neuroimaging techniques. Motor imagery offers a solution but has been shown difficult to use in PD patients [1] and may be limited for studying non-volitional sensorimotor tasks such as balance. Therefore, we aimed to develop and validate the use of an MRI compatible balance simulator to study static and dynamic balance control in PD patients and healthy controls.
METHODS: We developed an MRI compatible balance simulator (adapted from [2]) that allows subjects to actively balance an inverted pendulum by activating postural muscles around the ankle joint while supine (average load stiffness was 60% of normal stance). Two studies were performed to compare balance performance between upright stance (US), and simulated stance (SS), in PD patients and healthy controls (HC). Study 1 (14 PD; 20 HC) required subjects to maintain static balance during US and SS for 120 s with eyes open and closed. In study 2 (21 PD; 22 HC), subjects repeated the static balance task (90 s, eyes closed only), and also completed a dynamic balance task which required maintaining balance while experiencing random anterior-posterior (AP) perturbations applied to the trunk/pendulum. Angular displacements of the body/pendulum were recorded using angular velocity sensors (Swaystar, study 1) and Optotrak motion capture (study 2) and used to calculate Root Mean Square (RMS) and Mean Power of Frequency for static trials, and peak and time-to-peak for dynamic trials.
RESULTS: During static balance, PD patients had larger amplitude (RMS) of sway in both US and SS compared to HC, independent of vision (study 1). These group differences were replicated in US and SS in study 2. During dynamic balance, PD patients had larger peak and time-to-peak of SS angular displacements, compared to HC. These results followed previous observations in US [3].
CONCLUSION: Deficits in static and dynamic balance control can be detected in PD patients using a novel MRI compatible balance simulator. This technique will allow for functional neuro-imaging to be combined with balance-relevant tasks, and provide new insights into the neural substrates contributing to postural instability in PD.

Title: How does the conscious of self-attractiveness change walking motion

Authors: *H. TANABE[1], N. KANEKO[2], K. FUJII[3], H. YOKOYAMA[4], K. NAKAZAWA[2]
[1]Sci. and Engin., Aoyamagakuin Univ., Kanagawa, Japan; [2]The Univ. of Tokyo, Tokyo, Japan; [3]Riken Ctr. for Advanced Intelligence Project, Osaka, Japan; [4]Tokyo Univ. of Agr. and Technol., Tokyo, Japan

Abstract: INTRODUCTION: Based on the Sexual Strategies Theory, attractiveness of biological motion reflects individual's healthy and fertile potential. Walking movement, which is daily physical exercise, could be appealing to people. Runway modeling is a specialized walking style for fashion commercialism, which transmits the information regarding motion attractiveness. In this study, we aimed to investigate the biomechanical features of walking motion generated by the one who are conscious of self-attractiveness and the information transmitted by attractiveness-oriented biological motions. Extracted biomechanical parameters were also analyzed for seeking the meaning of the motion based on Laban movement analysis.
METHODS: Seven female runway models and ten female non-models participated in this study. The participants walked on a treadmill for 7 minutes with a speed of 3.6 km/h under 2 footwear (barefoot/high-heel) × 2 conscious (normal/attractive) conditions. During attractive walking condition, participants tried to walk as attractive as possible. Whole body joint motions data was obtained by using a 3D motion capture system. Joint motion time series were segmented into each gait cycle started from right foot contact, which was calculated by using heel marker position data. Each joint motion profile was then compared between groups × footwear × conditions.
RESULTS: LEG: Models' knee joints were significantly more extended during stance phase compared with non-models. Non-models extended their knees during attractive conditions much more than that during normal condition but not so much as models. Hip adduction was larger for models during stance phase, which reflects "catwalk", and became much larger when the models were conscious of beauty of the movement. TRUNK: For both groups, being conscious of attractiveness led them to bend their back and neck backward and forward, respectively. Such features of the trunk shape was much more significant for models compared with non-models. ARM: Arm swing of models was smaller than non-models and the swing motion of models

moved backward during attractive walking condition.
DISCUSSION: The conscious of self-attractiveness propelled non-models to extend their knees, laterally swing their hips, bend backwards, and pull their chins. Such walking motion could make the whole body shape look "extended", which can be translated as "self-confidence" based on Laban movement analysis. Walking motion of runway models was an exaggeration of such features of non-models during attractive-conscious condition, suggesting that runway walking motion could be based on biologically affective human body movement.

Abstract: Transcutaneous spinal direct current stimulation (tsDCS) is a one of technique to modulate excitability of central nervous system (CNS). Recently, we reported that the tsDCS preceding motor task could modulate the performance in maximal effort sprint cycling by improving the fatigue in later phase of it. The improvement would be attributed in modulation effects of tsDCS on neural populations generating motor output to their muscles. In contrast, it is known that neural population involved in generation of its locomotive pattern was not fully identical depended on the locomotion speed. Therefore, we investigated whether the tsDCS could modulate rhythmicity of submaximal cycling cadence.tsDCS was applied to 10 subjects by using 2 electrodes (35 cm2) which were located over the vertebral column (Th11 to L1) as stimulation electrode and the other was located on the right shoulder as a reference. Polarity of the stimulus and reference electrodes were cathodal and anodal respectively. The stimulus

intensity was 3 mA and the duration were 15min with 15-s ramp-up and -down periods, while the current was immediately ramped-down after reaching the maximum current in sham stimulus condition. Prior to tsDCS, subjects were asked to perform constant cadence leg cycling at 60 rates per minutes (rpm) for 180s with closed eyes as pre-stimulus task. The load of the cycling task was set at 0.02 kp / kg body weight. During first 60s of the task, subjects were presented auditory click sound with 1Hz to secure correct cycling rhythm. Following the feedback period, the sound was converted into white noise for last 120s. The cycling task was also repetitively performed 4 times every 10min from just after tsDCS as post-stimulus tasks. In cathodal tsDCS, the cadences at no auditory feedback period in all post-stimulus tasks were increased compared to that in pre-stimulus task. In contrast, the changes of cycling cadence at same period did not occurred in sham tsDCS. There were also significant differences of the cycling cadences between cathodal and sham stimulus condition. These results would imply that the tsDCS could modulate the neural population generating motor output at low level of cadence in cycling.

Abstract: [*INTRODUCTION*] Movement disorders due to cortical damage are one of the main problems after stroke. Movement disorders are directly linked to the impairment of daily activities, such as sit-to-stand. Sit-to-stand often fails due to sit-back at the seat-off, and the support surface cannot be transferred to the foot located in front of the trunk. We examined how

the trunk movements of chronic stroke patients are adaptively controlled; thereby contributing to the basic knowledge that helps predict the adaptive process of the nervous system from the resulting movement. [*METHODS*] Sit-to-stand was performed by four chronic stroke patients, three healthy elderly subjects, and three healthy young subjects. We obtained kinematic data using a three-dimensional motion analysis system and calculated three sagittal plane parameters, as shown in the results. We compared each parameter by performing a t-test (Bonferroni correction) between the groups. The resulting statistical significance level was set at $p < 0.01$. [*RESULTS*] (1) The temporal pattern of the thoracic-distal and pelvic-proximal powers relative to the internal waist extension moment were strongly antiphase in all groups (average of cross correlation coefficients: -0.95). However, in stroke patients, (2) the amplitudes at seat-off were smaller than those of the other two groups. Furthermore, (3) the negative work (time integral of power) from the distal end of the pelvis to the internal hip extension moment decreased to a value below that of the other two groups. [*DISCUSSION*] The anterior tilt of the pelvis that occurs at the beginning of the sit-to-stand reflects the positive power (the delivery of mechanical energy from the lumbar extension muscle to the pelvis). By the anterior tilt of the thorax stopped acceleration from the external force (negative power) is synchronized with the anterior tilt of the pelvis, lumbar extensors achieves isometric contraction. This improves the energy transfer efficiency from the lumbar extensor to the pelvis. In stroke patients, the nervous system is adaptively controlled to achieve seat-off by (1) maintaining this temporal coordination while (2) decreasing the amplitudes. In the lower limbs, the anterior tilt of the pelvis antagonizes the internal hip extension moment (negative work). The hip extensor muscle therefore absorbs the mechanical energy. Stroke patients with (3) a small amount of this absorption may be at a disadvantage during hip extension after seat-off (energy release). Considering that the lower limb muscles may compensate for this energy deficiency, we also present muscle synergies and interpret adaptive control.

Abstract: [Introduction] Post stroke survivors have an asymmetric gait, which is caused by certain impairments that may increase dependence on the nonparetic limb. Despite the presence of these impairments, it is necessary to ask why patients who usually walk asymmetrically are capable of walking symmetrically. In most studies on the split-belt walking paradigm, in which two belts are driven independently of each other, the adaptability of human bipedal locomotion was demonstrated using models and shown to induce adaptation in stroke patient. The purpose of this study was to investigate the commonality of kinetic symmetry between stroke patient and healthy subject during adaptation in split-belt locomotion.[Methods] Eight chronic stroke patients with hemiparesis (age = 71.5 ± 5.2) and eight healthy young adults walked on a split-belt treadmill under symmetric and asymmetric conditions. We investigated the changes in stance time, step length, and vertical angle between the line from center of pressure (CoP) to center of mass (CoM) and vertical line from CoM (CoM-CoP angle) at heel strike using motion capture system. All parameters were corrected for three periods, which were in belt velocity symmetry condition (tied-belt period), immediately after belt velocity asymmetry condition (split-belt period), and 5 min after asymmetry condition (adaptation period). The ratios from the three periods were analyzed using ANOVA with repeated measurements. Post hocanalyses were performed using Tukey's honest significant difference test when ANOVA yielded significant results ($p < .05$).[Results] Both the stroke patient and the healthy groups showed stance times with significant differences between the tied-belt and the other periods ($p < .05$). Both groups showed a step length that was not significantly different between the tied-beltand adaptation periods ($p = 0.05, 0.34$). The CoM-CoP angles for stroke patients were also dissimilar but not significantly different between the same periods ($p = 0.19$).[Discussion] By continuing split-belt locomotion, stroke patients re-established baseline step length asymmetry. Similarly, they also re-established the relative positions of CoP and CoM in the adaptation period. Despite the step length asymmetry of the patients, the position of the leading leg relative to CoM was almost symmetrical at heel strike. These phenomena were in common with the healthy subjects. In other words, the asymmetry of spatial parameters for the stroke patients is only an apparent asymmetry. The landed leading leg of stroke patient relative to whole body maintains symmetry equivalent to that of a healthy subject and possibly contributes to locomotor adaptation.

Title: Exploring lower extremity force modulation while jumping in childhood cancer survivors

Authors: *R. A. CREATH[1], V. GRAY[1], T. YORK[2], V. MARCHESE[1]
[1]Physical Therapy & Rehabil. Sci., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Pediatrics, Univ. of Maryland Med. Ctr., Baltimore, MD

Abstract: Background: Children with acute lymphoblastic leukemia (ALL) receive extensive medical treatments consisting of neurotoxic chemotherapy agents such as vincristine and methotrexate. Vincristine causes peripheral neuropathy and muscle weakness in distal extremities while methotrexate causes central nervous system neurotoxicity leading to motor processing and developmental delays. Musculoskeletal effects include decreased strength and limited ankle ROM, while neuromuscular effects may be expressed as motor delays, coordination deficits and poor balance.
Purpose: The inability to quickly generate muscle force in ankle plantarflexors and knee extensors while jumping has been identified in children as a predictor of strength and functional mobility limitations. The purpose of this pilot study was to explore countermovement jump performance in ALL childhood cancer survivors (CSS) to identify force modulation and timing deficiencies.
Methods: 12 children (6 males, 7-16 years), 6 ALL CCS and 6 age/gender matched controls, performed three countermovement jumps. Measures included full body kinematics and ground reaction forces. Subjects were compared by: 1) maximum center of mass (COM) jump height; 2) ankle, knee, and hip torques determined by inverse dynamics; 3) synchronization of peak ankle, knee and hip torques. Effect sizes were determined using Cohen's d. Statistical comparisons were performed by unpaired t tests on mean values. Standard deviations were compared using F tests (alpha=0.05).
Results: ALL CCS average jump height was significantly less than controls (0.711 (±0.034) vs 0.761 (±0.031), normalized to height). There were no significant group differences for normalized hip, knee, or ankle torque. Time durations to reach peak COM acceleration and joint torques were not significantly different between the two groups, although the time to reach peak COM acceleration effect size was large, d=0.815 (ALL=0.399 (±0.055) seconds vs controls=0.447 (±0.063) seconds). There were no significant between-group differences for peak

joint torque synchronization.
Conclusions: Differences in COM jump height reflect lower-body force modulation deficits in ALL CCS, but the lack of significance in peak joint torque comparisons indicates the deficiency does not correlate to a specific joint. Intersegmental timing for jumping is not deficient in ALL CCS as indicated by: 1) similar times to achieve peak joint torques; and 2) similar peak joint-torque synchronization for hip, knee and ankle joints. Neural deficits manifest as force modulation rather than motor delays, coordination deficits or poor balance for countermovement jumping in ALL CCS.

Title: Sports exercise effect on changes in motor evoked potentials of the first dorsal interosseous muscles while maintaining neck flexion position

Authors: *K. KUNITA[1], K. FUJIWARA[2], T. KIYOTA[3], K. ANAN[1]
[1]Fac. of Sports & Human, Sapporo Intl. Univ., Sapporo, Japan; [2]Kanazawa Gakuin Univ., Kanazawa, Japan; [3]Dept. of Child Care and Educ., Osaka Univ. of Comprehensive Children Educ., Osaka-Shi, Japan

Abstract: The present study applied transcranial magnetic stimulation (TMS) to the motor area of the first dorsal interosseous (FDI), and investigated sports exercise effect on changes in motor evoked potentials (MEP) of the FDI while maintaining neck flexion position. Subjects were classified into two groups: sports experience group that has belonged to sports club for 4 years or more (SE group, n = 10) and sports inexperience group that has never belonged to any sports club (SI group, n = 15). The experimental protocols were approved by our institutional ethics committee. All subjects provided written informed consent after receiving an explanation of the experimental protocols. The motor area of the FDI was determined as the site at which MEP was elicited by TMS. MEP was measured with the chin resting on a stand (chin-on condition) and with voluntary maintenance of neck flexion (chin-off condition) at 80% maximal neck flexion angle. Significant difference between these postural conditions was examined in the latency and amplitude of MEP, by using a one-sample t-test. The alpha level for statistical significance was set at $p < 0.05$. In SE group, MEP latency shortened 0.27 ± 0.35 ms ($t_9 = 2.32$, $p < 0.05$) and MEP amplitude increased 60.9 ± 43.0% ($t_9 = 4.12$, $p < 0.01$) in the chin-off, compared with the chin-on condition. On the other hand, in SI group, no significant difference in latency and

amplitude of MEP was found between these postural conditions. These results suggested that the brain activation with maintaining the neck flexion position enhanced the excitability in the motor area of the FDI, and furthermore, that sports experience will be effective in the brain activation to the motor area of the FDI.

Title: Effect of static stretch of the calf muscles on the postural orientation and equilibrium during human quiet standing

Authors: *S. SASAGAWA[1], K. YAESHIMA[2], H. SEKIGUCHI[3]
[1]Dept. of Human Sciences, Kanagawa Univ., Yokohama, Kanagawa, Japan; [2]Kanagawa Univ., Yokohama, Japan; [3]Jobu Univ., Isesaki-Shi, Japan

Abstract: Neural control of human posture has two principal behavioral goals, such as postural orientation and postural equilibrium. The purpose of this study was to investigate the effect of static stretch of the calf muscles on the postural orientation and equilibrium during quiet standing, especially focusing on its time-dependent characteristics.Six healthy women (20-21 yrs.) participated in the study. In pre-stretch condition, participants maintained 60-s quiet standing (QS) on a flat, firm surface with eyes closed for 5 times. After the pre-stretch condition, participants first stood for 3-min on a stretch board that imposes a 25 deg of dorsiflexion stretch of the left and right calf muscles simultaneously. Immediately after the stretching, they maintained 5-min QS on the flat surface with eyes closed. The participants repeated these stretching and QS tasks for 5 times with no interval between them (the post-stretch condition). During QS, ground reaction forces were measured with a force platform. From ground reaction forces, we calculated the anterior-posterior position of the center of pressure (CoP) and the anterior-posterior acceleration of the center of mass (CoM_{acc}) as measures of postural orientation and equilibrium, respectively. To examine the time-dependent characteristics of the effect of static stretch, we divided a single 5-min QS trial in the post-stretch condition into 15 time periods (20-s long each) and evaluated the time course of the above-mentioned two variables, i.e., CoP and CoM_{acc}. We found a significant anterior shift of the mean CoP position (0.95±0.15 cm, mean ± standard error) during the 1^{st} period of the post-stretch QS when compared to the

pre-stretch condition. At the same time, the participants exhibited increased CoM_{acc} during the 1st period of post-stretch QS (1.69±0.20 cm/s^2 as the root mean square value) as compared to the pre-stretch condition (1.28±0.10 cm/s^2). Interestingly, these two variables showed different time course after the 2nd period of the post-stretch QS. That is, the mean CoP position kept showing posterior shift until the 15th period of the post-stretch QS and it did not return to a value observed in the pre-stretch condition even in the end of 5-min trial. On the other hand, the CoM_{acc} immediately fell to the level found in the pre-stretch condition during the 2nd period of the post-stretch QS and was almost unchanged until the 15th period. Our results suggest that the effect of static stretch on the postural orientation and equilibrium have different time-dependent characteristics. To reveal the neural basis responsible for such difference, further investigation with electro-physiological techniques is needed.

Title: Dynamic balance training in persons with multiple sclerosis

Authors: *T. ONUSHKO[1], T. BOERGER[2], A. LONG[1], L. RIEM[1], N. GREGG[1], B. D. SCHMIT[1]
[1]Biomed. Engin., [2]Physical Therapy, Marquette Univ., Milwaukee, WI

Abstract: Impaired balance control interferes with walking and increases fall risk in persons with multiple sclerosis (MS). Rehabilitation interventions to improve standing balance emphasize the use of sensory strategies to challenge the balance system to adapt to environmental tasks. However, gait therapies often provide aids, such as handrails or assistive devices, reducing the need for the person to control their balance. Therefore, the purpose of this pilot study was to evaluate the effects of a gait-training paradigm aimed at challenging balance while walking on dynamic balance and walking outcomes in persons with MS. In this preliminary study, we evaluated nine persons with MS who participated in the training protocol. For the training protocol, participants walked at their self-selected pace on our treadmill system 30 minutes per day, 3 days per week, over 4 consecutive weeks. Using a motion base system, we controlled the motion of the entire treadmill to move in an unpredictable manner in the medio-lateral (ML) direction to challenge balance while walking. To test if integrating balance

challenges while walking improves balance and walking, we quantified dynamic balance and walking function prior to and following completion of the training. We performed clinical measures of dynamic balance (functional gait assessment, FGA), over ground walking speed (10 Meter Walk Test), and balance confidence (Activities-specific Balance Confidence (ABC) Scale). We also performed kinematic measures of dynamic balance and walking function while participants walked on a stable (non-moving) treadmill. We quantified the ML margin of stability (ML-MoS), step width, step length, and step frequency. Prior to training, persons with MS walked with a cautious gait pattern, by taking shorter, wider and quicker steps to limit center of mass movement (i.e. higher ML-MoS). Following training, persons with MS walked with decreased step width (2.8% decrease), increased step length (14.3% increase), decreased step frequency (3.0% decrease) and lower ML-MoS (15.8% decrease). From the clinical assessments, we observed increased FGA scores (+2.3 points), faster over ground walking speeds (+0.1 m/s for self-selected and fast-as-possible walking speeds), and increased ABC scores (+5%). These preliminary findings suggest that challenging balance while walking can improve dynamic balance, increase walking speed and increase balance confidence in persons with MS.

Title: Potential parameters for wrist-worn single accelerometer and gyrosensor in functional evaluation of upper extremity in hemiplegic stroke

Authors: *H. NAM[1], W. LEE[1], H. SEO[2], M. W. SMUCK[3], S. KIM[1]
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Rehabil. Med., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [3]Stanford Univ., Redwood City, CA

Abstract: Previously many studies on accelerometers and gyrosensors were performed for upper extremity movements in stroke, yet there exist no standardized methods with significant clinical relevance. We aimed to determine parameters and appropriate tasks that may serve as potential clinical outcome measures, which can be measured with a single sensor on the wrist. Ten healthy volunteers and nine patients with hemiplegic stroke were recruited to perform Action Research

Arm Test (ARAT) and selected activities of daily living (ADL), with wearable multiple IMU sensor based motion capture system. Acceleration of the wrist and hand sensors in three global orthogonal directions and Euler angles of sensors in each segment of the upper limb with reference to their proximal segment were measured. ARAT score and Brunnstrom stage were evaluated for all patients. Average amplitude and maximum amplitude of the movement segments, logsum and logsum per time was extracted and analyzed. Logsum was defined as integration of all displacements or changes for corresponding measurements. Of the parameters that showed significant differences between healthy subjects and patients and also significant correlation with clinical measures, average amplitude of forearm supination/pronation angle during ARAT domain 4 tasks demonstrated significant decline of the value in severely impaired patients compared to normal subjects (29.83%) and profound difference between severely and mildly impaired patients (48.46%). During ADL tasks, logsum per time for supination/pronation showed significant difference between severity levels (38.33%). Average amplitude of acceleration in x-axis (left-right) and z-axis (up-down) of hand and wrist sensors during ARAT tasks demonstrated a range of 45 to 62% value compared to healthy subjects, with 21.6 to 35.1% difference along the severity spectrum. Although accurate measurement with single wrist sensor may not be possible, specific parameters may play a significant role in simple or serial functional evaluation as an important predictor of clinical outcome measures.

Title: Quantitative stretch reflex measurement using motor system for the elbow joint

Authors: *T. ARAKI, H. MURAMATSU, Y. ITAGUCHI, S. KATSURA
Fac. of Sci. and Technol., Keio Univ., Yokohama-Shi, Japan

Abstract: Abstract
Introduction: The spasticity is one of aftereffects of a cerebrovascular disease. Symptom of the spasticity is occurrence of abnormal resistant torque at a specific angle through joint movement. The spasticity makes a daily living activity difficult because it becomes hard to move a limb as desired. Accordingly, an evaluation method of the spasticity is necessary to rehabilitate the patients properly. Therapists have evaluated the degree of the spasticity qualitatively by examining a torque response of a patient limb during passive movement. However, the qualitative evaluation is insufficient for the proper rehabilitation because of individual different recognitions. The purpose of this study is to measure the degree of spasticity quantitatively with a measurement system. In this study, the stretch reflex properties of healthy subjects were quantitatively examined because the spasticity is caused by sthenia of the stretch reflex. The elbow-joint-measurement system composed of a direct drive motor, which does not contain extra mechanical elements such as gears, enables high-accuracy angle and torque measurements.
Methods: Resistant torques of three healthy subjects were measured with elbow extension motion in a sitting posture. The exercise commands were set to 1.0, 2.0, 3.0, 4.0, 5.0, 6.0 rad/s constant velocity movements to imitate the real measurement because the evaluation of the spasticity is performed by moving a patient target part at constant velocity. The range of motion was 80 degrees. Before the measurements, the subjects were directed to make the arm relaxed.
Results: According to the experimental results, the resistant torque occurred in the countering direction and the stretch reflexes occurred twice in each experiment. Mean latent periods of the stretch reflexes were 62 ms (SD=5) and 143 ms (SD=25) after the extension motion started. Mean torque responses of the first reflex and the second reflex were -2.37 Nm (SD=0.43) and -1.59 Nm (SD=0.75) for all conditions. Each mean torque response of the second reflex was -0.58 Nm (SD=0.18), -0.76Nm (SD=0.19), -1.63 Nm (SD=0.48), -2.25 Nm (SD=0.37), -2.18 Nm (SD=0.30), and -2.09 Nm (SD=0.31) at 1.0, 2.0, 3.0, 4.0, 5.0, and 6.0 rad/s, respectively.
Discussion: We found the three stretch reflex properties quantitatively. (1) The latent periods of the two stretch reflexes occurred at 62 ms (SD=5) and 143 ms (SD=25). (2) Since the standard deviation was small as SD=0.43, the torque responses of the first stretch reflex were

approximately constant torque -2.37 Nm regardless of the movement velocity. (3) The torque of the second reflex varied at the movement-velocity threshold between 2.0 and 3.0 rad/s.

Title: Age-dependent differences in neuroplastic response to daily home-based treadmill training in children and adults with cerebral palsy

Authors: *J. B. NIELSEN, J. LORENTZEN, M. WILLERSLEV-OLSEN
Univ. Copenhagen, Kobenhavn N, Denmark

Abstract: Improved toe-lift and heel strike in children with Cerebral palsy (CP) following daily home-based treadmill training is accompanied by increased beta and gamma band coherence between populations of dorsiflexor motor units. This indicates that plastic changes in the central drive to dorsiflexors may be responsible for improved gait in the children. In the present study we investigated whether these plastic changes are age-dependent by comparing changes in gait function and coherence following daily treadmill training in 35 children and adults with CP covering an age span from 3 to 65 years of age. Coherence was estimated from two separate EMG recordings over the Tibialis anterior muscle in the swing phase of gait. Toe lift and heel strike were estimated from 3-D kinematic video analysis. For children below the age of 12 years we observed a significant training-related increase in beta and gamma band coherence, which was closely correlated to improved lift of the toes in late swing. For children and adults above the age of 12 years no change in coherence and only limited change in toe lift was observed. These findings suggest that plastic changes in the central drive to dorsiflexor motor neurons are easier to induce through training in children below the age of 12 years than later in life. This may be related to the normal maturation of gait function in children.

Title: Enhanced unidirectional motor cortex to muscle connectivity in beta and gamma bands during voluntary gait task in humans

Authors: *H. YOKOYAMA[1], N. KANEKO[2], Y. MASUGI[3], T. OGAWA[2], K. WATANABE[4], K. NAKAZAWA[2]
[1]Tokyo Univ. of Agr. and Technol., Koganei-shi, Japan; [2]The Univ. of Tokyo, Tokyo, Japan; [3]Tokyo Intl. Univ., Saitama, Japan; [4]Waseda Univ., Tokyo, Japan

Abstract: INTRODUCTION: Modification of ongoing walking movement requires accurate voluntary control, which is dependent on the environmental situation. In cat studies, it has been established that the motor cortex has crucial roles for precisely adjusting muscle activity during gait modification. In humans, however, it is unclear whether and how the motor cortex contributes to adjustments of locomotor muscle activity during gait modification. In this study, we examined effective connectivity between the motor cortex and leg muscles during voluntary gait modification and compared the connectivity with that during steady state walking.
METHODS: Twelve males participated in this study. The participants performed two different walking tasks on a treadmill: 1) normal walking and 2) precision stepping that forced the participants to step on pre-specified positions on the treadmill. In the precision stepping, the stepping position was projected on the treadmill by a projector and was randomly presented based on 5 and 3 predetermined positions in the anteroposterior and mediolateral directions, respectively. We measured electromyographic (EMG) activity from the tibialis anterior (TA) and the soleus (SOL) muscles and electroencephalographic (EEG) signals from 63 electrodes over the scalp. Effective connectivity (i.e., directional information flow) between the motor cortex and leg muscles was examined by estimating full-frequency Directed Transfer Function (ffDTF), which is a frequency-domain estimator of causal interaction utilizing a multivariate autoregressive model, between an EEG signal from Cz electrode and the EMG signals.
RESULTS: In both muscles and both walking tasks, significant effective connectivity was observed from the motor cortex to the leg muscles, while not from the muscles to the motor cortex. For the TA, the cortex to muscle connectivity increased in the gamma band (30-40 Hz) in the swing phase during precision stepping compared to that during normal walking. For the SOL,

the connectivity increased in the high-beta band (26-30 Hz) and decreased in the alpha band (8-12 Hz) in the stance phase during precision stepping than normal walking.
DISCUSSION: The present results strongly suggest that the motor cortex is effectively involved in modification of locomotor muscle activity. It has been suggested that corticomuscular connectivity in the alpha band contributes automatic movements and that in the beta and gamma bands is involved in movements that require high attentional demand. These functional differences among the frequency bands would be related to the changes of the effective connectivity during precision stepping.

Title: Asymmetry in neuromuscular control for damping behavior during object transport in healthy young individuals

Authors: *S. A. WINGES[1], A. SONG[2], M. J. MACLELLAN[2]
[1]Sport and Exercise Sci., Univ. of Northern Colorado, Greeley, CO; [2]Louisiana State Univ., Baton Rouge, LA

Abstract: Anticipatory control of grip force and coordinated movement of upper limb movements counterbalance inertial forces while walking and transporting objects. In addition to maintenance of a secure grasp through anticipatory adjustment of grip force on the transported object, the vertical displacement of the object relative to trunk displacement is limited. However, it is still unknown how the muscles function to produce the damping behavior during object transport. The purpose of this study was to identify the neuromuscular control of the upper limb used to transport an object and to determine if any asymmetry is present between the patterns of muscle activation in the dominant (DO) and non-dominant (NDO) arms. Whole body kinematics were recorded, along with bilateral activations of eight upper limb muscles in seven healthy young right-handed adults. A damping ratio was computed as the peak-to-peak vertical displacement of C7 and the object when the object was transported with the right or left hand. The average damping ratio across participants did not differ between the DO and NDO object transport conditions ($p = .311$). However, only one participant had damping ratios that were very similar between dominant and non-dominant hands. Three participants had NDO damping ratios that were 30-89% larger than DO, while three other participants exhibited 13-34% less damping

in the NDO compared to DO condition. Muscle synergies derived using non-negative matrix factorization revealed two temporal patterns during which proximal arm muscles peaked just prior to heel contact while forearm and hand muscles reached peak activation approximately at heel contact of the contralateral leg. These preliminary results suggest that the shoulder and elbow joints were stabilized first by the recruitment of the upper arm muscles prior to heel contact, followed by the wrist and finger muscles, to maintain the stability of the object against the perturbation caused by the impact of heel contact. However, examination of individual muscles patterns and peaks reveal subtle asymmetries across limbs that may explain the differences in damping behavior.

Title: Mice learn to modulate intra- and inter-limb paw kinematics with training on a novel locomotor behavioral paradigm

Authors: *K. P. NGUYEN[1], A. SHARMA[2], S. M. CHASE[2], A. H. GITTIS[3]
[1]Biomed. Engin., [2]Ctr. for the Neural Basis of Cognition, [3]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: A critical feature of the motor system is its ability to adapt movements to constantly changing environments. This is especially true for locomotor control. Historically, the majority of focus on locomotor control has been on understanding how central pattern generators within the spinal cord regulate coordinated movements. Recent studies, however, have demonstrated that the subcortical circuits of the basal ganglia and cerebellum are necessary for locomotor learning. Despite the importance of locomotion in our daily lives, the roles that these subcortical circuits play in mediating the acquisition and expression of skilled locomotor behavior remain unclear. This is in large part due to the lack of behavioral paradigms which assess complex motor tasks with sub-second precision during rapid perturbation of genetically-defined neurons. Thus, we have established a novel hardware and software infrastructure that provide the groundwork for disentangling how targeted neural circuits give rise to distinct locomotor features. More specifically, we designed and constructed a two-wheel running paradigm for rodents in which body and paw kinematics can be tracked at up to 500 frames per second,

providing a high degree of spatial and temporal behavioral readout during skill learning. Here, we demonstrate that mice learn to perform on our custom running wheel over a period of several days. Improved performance correlates with a forward shift in body center position on the wheel when both wheels are driven at a fixed speed. To run at a particular speed, stride length and step frequency must be constrained to a coupled set of values we term the optimal solution space. Over the course of training, we note that mice change their strategy within this optimal solution space by taking quicker and shorter steps. Moreover, we observe an increase in stance-phase stride length and stride frequency as the wheel moves faster, similar to gait patterns previously characterized on a flat terrain in quadrupeds. Finally, wheel training is also correlated with the development of regular interlimb coordination patterns. These data suggest that mice learn to modulate intra- and inter-limb paw kinematic strategies to mediate successful wheel running with training. In summary, the data collected from our custom running wheel system provides a unique and powerful approach to extracting the piecewise gait components for studying how distinct neural mechanisms and loci enable locomotor skill acquisition.

Title: Visual perturbations between immersive virtual reality modalities on healthy and multiple sclerosis participants' balance control

Authors: *L. I. RIEM[1,2], T. ONUSHKO[2], S. RAAB[2], S. A. BEARDSLEY[3], B. D. SCHMIT[4]
[1]Marquette, Milwaukee, WI; [2]Biomed. Engin., [3]Dept. of Biomed. Engin., Marquette Univ., Milwaukee, WI; [4]Dept. of Biomed. Engin., Marquette Univ. Dept. of Biomed. Engin., Milwaukee, WI

Abstract: In this study we examined the impact of disrupted visual feedback within a virtual reality (VR) environment on balance compensation in persons with multiple sclerosis (MS). Balance impairment is the second most common symptom in MS, however, the sources of disruptions in postural control and the influence of visual inputs are not well understood. The objective was to characterize the impact of applying medial-lateral (ML) shifts in the VR visual scene on balance in subjects with MS. Disruptions were examined during embodied (EB) and out of body (OB) perception in two types of fully immersive VR environments using ML visual perturbations applied at different frequencies. Subjects participated in three VR test conditions (counterbalanced across subjects): (1) a 270degree Christie Cave system with active stereoscopic

glasses (EB), (2) the same cave system, but with blinders attached to the glasses to restrict visual feedback to out of body perception, and (3) the HTC Vive headset (OB). During each test condition, subjects underwent two 5-minute trials. Within each trial, 20 second intervals of quiet standing were followed by 10 cycles of a sinusoidal 1m ML visual displacement at frequencies varying from .3-.95 Hz. The participant's center of pressure (COP) over time was obtained using time-frequency analysis and compared to their position relative to the visual stimulus. Temporal fluctuations in subjects' COP increased from rest (0.12 Hz), and became phase-locked with displacement frequencies up to 0.7 Hz. For sinusoidal visual displacements presented at 0.7 Hz, mean ML sway in the COP, velocity, area, and excursion all showed significant increases relative to quite standing ($t(12)$, $p<0.05$). Analysis of the change in COP showed that MS subjects experienced an increased reaction to visual displacements applied in the Vive VR environment. In conjunction with phase locking and increased postural sway, significant increases were observed in COP mean ML sway, velocity, area, and excersion ($t(12)$, $p<0.05$) during visual perturbations for both EB and OB perceptions. Tests with healthy young adults revealed similar responses, albeit with more continuous changes in postural control. The increase of peripheral visual flow provided in out of body conditions elicited stronger postural mechanisms. These results demonstrate that in persons with MS, there is an increased reaction and predisposition to a more immersive virtual environment. MS subjects matched their sway to the displacement of the visual scene and at a higher frequency compared to healthy participants. This increased reliance on visual feedback could enable rehabilitation via a low-cost head mounted VR system.

Title: Lower- and upper-body control during standing balance for individuals with incomplete spinal cord injury

Authors: *J. W. LEE[1,2], J. YOO[1,2], K. CHAN[2,3], J. UNGER[2,3], K. MUSSELMAN[2,3,4], K. MASANI[1,2]

Toronto, ON, Canada; [3]Rehabil. Sci. Institute, Univ. of Toronto, Toronto, ON, Canada; [4]Dept. of Physical Therapy, Univ. of Toronto, Toronto, ON, Canada

Abstract: Individuals with incomplete spinal cord injuries (iSCI) often have an impaired ability to maintain balance during standing. For able-bodied (AB) individuals, it is known that the ankle joint control as well as the lower- and upper-body coordination play important roles in stabilizing the whole body. We hypothesized that individuals with iSCI do not sustain this coordination, causing difficulties in maintaining their standing balance. In this study, we investigated the coordination of the lower- and upper-body during standing for individuals with iSCI. Eleven young AB individuals (ABy) (5 female and 6 male; 25.1±5.3 years old), eleven individuals with iSCI (7 female and 4 male; 58.6±11.5 years old) and twelve age- and sex-matched AB individuals (ABm) (9 female and 3 male; 60.1±9.7 years old) participated. The participants were instructed to perform quiet standing for 150 seconds with their eyes open. Using a motion capture and a force platform system, we measured kinematic and kinetic data. We calculated the center-of-mass (COM) of the lower-, upper- and whole-body, as well as the corresponding segment angles. The root-mean square of the linear and angular acceleration data was used to quantify body fluctuations. We also evaluated the coordination between the two segments using the coordination index, based on our previous study. The analysis of variance (ANOVA) with Tukey's test, as the post-hoc analysis, was used to compare the measures among the three groups. The whole-body COM linear accelerations were significantly different among the three groups (ANOVA: $p=0.007$). The post-hoc analysis revealed that the whole body COM acceleration in participants with iSCI was significantly larger than the other two groups (ABy vs iSCI: $p=0.0126$ and ABm vs iSCI: $p=0.0180$), indicating that participants with iSCI have compromised balancing abilities. We also found that the lower body angular acceleration was larger for individuals with iSCI than for AB participants (ANOVA: $p=0.01$; ABy vs iSCI: $p=0.0088$ and ABm vs iSCI: $p = 0.0293$). On the contrary, the upper body fluctuation was larger in iSCI compared to only ABy (ANOVA: $p=0.042$; ABy vs iSCI: $p=0.0455$ and ABm vs iSCI: $p=0.121$). The coordination index was not different among the three groups (ANOVA: $p=0.984$). We demonstrated that individuals with iSCI sway more during standing, indicating that they have compromised ability to maintain balance. Despite this instability, the lower- and upper-body coordination was statistically equivalent to AB participants. Therefore, the instability in individuals with iSCI must be related to the reduced control in their ankle joint control.

Title: Using genetic algorithm to control tendon-driven systems with unknown structure

Authors: *A. MARJANINEJAD[1,2], R. ANNIGERI[2], F. J. VALERO-CUEVAS[1,3]
[1]Biomed. Engin., [2]Electrical Engin., [3]Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: Understanding the neural control of movement in detail requires that we confront the same mechanical problem the brain faces: controlling multiple tendons. This problem has two simultaneous features: it is redundant when it comes to the control of tendon forces, but over-determined when controlling the lengths and velocities of muscles pulling on those tendons. Here we address the latter problem by using a genetic algorithm to solve the over-determined problem of finding the time-history of muscle lengths to produce smooth and accurate movements in a simulated human arm.
Methods: We use a Genetic Algorithm to find a series of muscle excursion values to move the limb in a desired trajectory accurately. Our proposed method works without prior knowledge of the structure of the system, and does not require linearity. The method was tested on a 3 tendon 2 DOF system with posture-dependent moment arm values.
Results: We were able to accurately track the predefined goal trajectory (a circle at the endpoint of the limb) without prior knowledge about the structure of a nonlinear tendon-driven system. We believe that this, and similar approached will enable us in controlling tendon-driven systems with unknown parameters with high accuracy. However, smoothness requires a much more refined control. The average execution time to find the desired excursion values was long (seconds) which precludes its real-time application. Therefore, adding biomechanical constraints as well as trying other Machine Learning algorithms can help extend this approach into a real-time controller for this problem. This highlight the fact the moving smoothly and accurately is neither simple nor a forgiving task for tendon-driven systems with afferented muscles.[1,2]

Title: The effects of two types of variable assistance on motor learning of a novel swing phase trajectory

Authors: *A. DOMINGO[1], E. RAMIREZ[2]
[1]Doctor of Physical Therapy Program, [2]Bioengineering Program, San Diego State Univ., San Diego, CA

Abstract: Robot-assisted therapies have been developed to improve gait function in patients with motor disorders. It is not clear how best to use these robotic devices to maximize motor learning and functional outcomes. The Ekso is a commercially available wearable robotic exoskeleton used for gait rehabilitation after neurological injury. It contains motors at the hips and knees that provide assistance at these joints in the sagittal plane during ambulation. The Ekso is able to provide variable assistance, meaning that when the user follows an assigned swing phase trajectory, the device's software reduces the motor assistance, with the goal of increasing engagement and effort of the user. It has two variable assistance modes, Adaptive (where the movement is continuous and users are given feedback on the percentage of motor assistance) and Fixed (where the movement is interrupted if the user is not contributing a minimal level of their own power to the movement). The purpose of this study was to compare if either mode is better for motor learning of a novel swing phase trajectory in able-bodied subjects. We hypothesized that subjects that trained in the Fixed mode would learn the trajectory faster during training, because it would provide more opportunities for error detection and correction. 20 able-bodied subjects were randomly assigned to either the Adaptive or Fixed mode while walking in a linear path (18 m in length) 10 times followed by a second day (24-48 hours later) to assess retention of learning. Learning was measured by the assistance required from the motors to maintain the assigned swing phase trajectory. Preliminary results show that there no differences between groups in the assistance given by the robot at baseline (P=877). Both groups were able to learn the novel swing phase trajectory and significantly lowered assistance from the device from the beginning to the end of training(P<.001), but there were no differences between groups (P=.271), and no interactions (P=.182). There were also no differences in retention of learning between groups (P=.513). For able-bodied subjects, either type of feedback was helpful for learning a

novel swing phase trajectory. For those with compromised motor and/or sensory function, one type of variable assistance mode may be superior.

Title: The neural correlates of continuous gait adaptation to the split-belt treadmill are influenced by gait pattern characteristics: An ^{18}F-FDG PET Study

Authors: *D. HINTON[1,3], A. THIEL[2,4], L. J. BOUYER[5], C. PAQUETTE[1,3]
[1]Kinesiology and Physical Educ., [2]Neurol. & Neurosurg., McGill Univ., Montreal, QC, Canada; [3]Ctr. for Interdisciplinary Res. in Rehabil. of Greater Montreal (CRIR), Montreal, QC, Canada; [4]Lady Davis Inst. for Med. Res., Jewish Gen. Hosp., Montreal, QC, Canada; [5]Rehabil. Dept-CIRRIS, Univ. Laval Fac Med., Quebec, QC, Canada

Abstract: Gait alterations on a split-belt treadmill (SBT), where each leg is driven at a different speed, highlight the nervous system's ability to quickly adapt the locomotor plan to its environment. However, specific contributions from the brain to this motor adaptation remain unknown. The fact that participants with cortical strokes, hemispherectomy, and even infants prior to independent stepping, have the ability to make changes to their gait cycle within 5 steps of walking on a SBT suggest that a distributed network may be involved. Here we establish if cerebral and cerebellar brain regions change activation during continuous gait adaptation to the SBT compared to typical treadmill walking in healthy adults and how the gait pattern influences these changes. Methods: Directly following bolus injection of ^{18}F- fluorodeoxyglucose tracer, 10 healthy adults walked on a treadmill for 30 minutes. In the tied-belt (TB) condition, both belts were maintained at a comfortable speed. On a separate occasion, the continuous adaptation (CA) condition changed the speed ratio between treadmill belts every 15 seconds. Positron emission tomography (PET) images of cerebral glucose metabolism of each condition were compared to assess for clusters with significant changes in metabolism when continuous, unexpected gait pattern changes are required. A multiple linear regression predicted participants' peak activation change within each significant cluster based on their cadence, number of steps taken and step length variability. Results: A significant increase in metabolism during CA was only found in 4 main clusters: the left supplementary motor area (SMA), the right posterior parietal cortex

(PPC), the anterior cingulate cortex (ACC) and the left anterior cerebellum ($p<0.05$). Of these four clusters, participants' peak Z values in the PPC and the Cerebellum could be predicted from gait characteristics. The change in cadence, a temporal measure of gait, was the only predictor of peak activation within the PPC ($R^2=0.725, p<0.01$), whereas step length variability, a spatial measure of gait, was the only predictor of peak cerebellar activation ($R^2=0.528, p<0.05$). Conclusion: Our results suggest that complex control of temporal and spatial aspects of the gait cycle increase metabolism in anatomically separate areas of the brain and imply a parieto-cerebellar network could be required for continuous locomotor adaptation. A lack of change in metabolism of the PFC indicates that executive function may not play a substantial role while activation of the ACC independent of gait characteristics signals the need to sustain increased task directed attention in this complex walking task.

Title: The effects of transcranial direct current stimulation on age and race implicit association tests during complex motor tasks

Authors: E. P. KELLER[1], *C. J. KETCHAM[2]
[1]Biol., [2]Exercise Sci., Elon Univ., Elon, NC

Abstract: Humans exhibit attitudes towards groups of people different than themselves, some they may be aware of and some not so aware of. This group identity leads to stereotyping others and creating unconscious assumptions, which control human behavior (Greenwald & Krieger, 2006). However, inhibitory control in the prefrontal cortex is critical to controlling activation of these biases (Sellaro *et al.,* 2015). It is unknown if implicit biases are amplified when engaged in a high motor load task, or if it can be mitigated by an external stimulation treatment. Engagement in a dual motor task may draw attention away from the usage of the prefrontal cortex to modulate bias (Schmader, Johns & Forbes, 2008). This project investigated if the use of noninvasive brain stimulation via transcranial direct current stimulation (tDCS) in conjunction with evidence based excerpts of the effects of implicit bias, will positively influence bias, specifically racial bias. Twenty-one participants (age = 19.8 ± .98), who self-identified as white college students, completed four Implicit Association Tests (IAT), which is a computer based reaction task where participants responded to images of stimuli for age and race that were paired with words of good verses bad. Participants were randomly assigned to either tDCS stimulation (1mA.40 min) or sham (1mA.30 sec) conditions at the dorsolateral prefrontal cortex. The IAT software produced

an IAT score. The first IAT participants took was a baseline followed by another IAT while balancing on a Biodex Balance System. The participants then completed training with tDCS stimulation while reading and writing reflections on a series of excerpts from literature based books while balancing on a stability ball. The written reflections were compiled as a qualitative result of how participants describe and understand their explicit biases. This was followed by a post training IAT and a one-week post training IAT. Results of the IAT showed that a high motor load has no effect on implicit racial or age bias ($p<0.05$). Further research should continue to consider motor load as a mediating factor that could influence bias.

Title: Neural correlates of human dual-task gait: Effect of secondary task difficulty

Authors: *H.-T. GOH, S. EWING, D. MARCHUK, A. NEWTON, I. NYANGANI
Physical Therapy, Texas Woman's Univ., Dallas, TX

Abstract: Dual-tasking has a detrimental impact on human gait and is an important index for fall risk. Both Dorsolateral Prefrontal Cortex (DLPFC) and Supplementary Motor Area (SMA) have been shown to be involved in dual-task gait. Our previous work showed that 5Hz repetitive transcranial magnetic stimulation (rTMS) applied to SMA, but not DLPFC, improved dual-task gait speed in young healthy adults, supporting the role of SMA in dual-task gait. One possible explanation was that the level of difficulty imposed by the secondary task mediated the differences between SMA and DLPFC. Subsequently, the purpose of the current study was to determine whether the secondary task difficulty modulates the neural correlates of dual-task gait. Eighteen young healthy adults (7 males, mean age = 27.6 ± 6.3 years) participated in the study and were equally divided into 2 groups (Easy or Difficult secondary task group). Gait speed was assessed under single- (walk only) and dual-task (walk and count backward) conditions. The Easy group counted backward by 3 from a given number (ranged from 40-100) while the Difficulty group counted backward by 7. Both groups put priority on the counting task during dual-task walking. Each participant received a 5Hz-rTMS protocol (90% resting motor threshold, 1200 stimulations) applied to left DLPFC, SMA or primary motor cortex (M1) at 3 different sessions (~ 1 week apart) in a pseudo-randomized order. Gait and counting performance was assessed before and after rTMS application. Counting backward by 7 was significantly more difficult than counting backward by 3 as evidenced by more correct counting responses were observed in the Easy group than the Difficult group (p =. 00). rTMS applied to SMA led to a

significant increase in dual-task gait speed (p = .01) regardless of secondary task difficulty (p= .70). rTMS applied to DLPFC and M1 did not lead to reliable changes in dual-task gait speed. Gait speed under the single-task condition was not altered by either rTMS application. In conclusion, SMA plays an important role in mediating dual-task walking in humans and its role appears to be independent from the secondary task difficulty. Future work will investigate the effect of rTMS to SMA and DLPFC on dual-task gait in individuals with brain damage.

Title: Is it possible to perform independent rhythmic movements with the upper and lower limbs?

Authors: *W. QI[1], K. KATO[2], M. SAKAMOTO[3], T. NAKAJIMA[4], K. KANOSUE[2]
[1]Sport Sci., Waseda Univ., Saitama, Japan; [2]Fuculty of Sport Sciences, Waseda Univ., Saitama, Japan; [3]Kumamoto Univ., Kumamoto, Japan; [4]Kyorin Unversity Sch. of Med., Mitaka City/Tokyo, Japan

Abstract: The rhythmic movements of daily life, such as tapping and walking, appear in many forms. Complex movements may involve the performance of two or more rhythms simultaneously. The present study focused on whether two rhythmic movements could be produced independently. Eleven subjects performed rhythmic finger tapping concurrently with four different lower limb movements; 1) self-paced walking (SW), 2) walking at a given pace (GW), 3) alternative bipedal heel tapping while sitting (BT), and 4) unipedal heel tapping while sitting (UT). Subjects first performed the foot movement more than 60 times (self paced in the SW task and with a 600 ms interval in the other tasks). Then metronome sounds (375 ms interval) were given to the subjects to synchronize finger tapping with the sounds and keep pace with the foot movements. After another 60 foot movements, the metronome for finger tapping was stopped, and the subjects were required to continue the two rhythmic movements without external stimuli during the period in which the subjects did foot movements at least 60 times. Performance was evaluated by the distribution of the relative phase of finger tapping and foot movement. The task was considered successful if the relative phase was evenly distributed. In the SW and GW tasks, the number of relative phase distributions was not beyond the chance level, indicating independency of the walking
and tapping rhythms. On the other hand, for the BT and UT tasks, relative phase distribution was significantly above the chance level around 0° (360°) and 180°, and was significantly below the

chance level around 90° and 270°. This indicates that the relative phase of finger and foot movements dropped to a 2:1 rhythm (the subject failed to perform independent movements of the finger and feet). We attribute successful performance of the SW and GW tasks to the existence of two control mechanisms, one in the supra-spinal brain (for finger tapping) and the other in the locomotion-related neural circuits of the spinal cord (for walking). We attribute failure of the BT task and UT tasks to be due to the control of both finger and leg movements by supra-spinal mechanisms which conflict with each other. We conclude that two separate rhythmic movements can be independently performed only if they were controlled by discrete neuronal mechanisms.

Title: Motor cortex activity during locomotion and postural corrections in the mouse

Authors: *I. N. BELOOZEROVA[1], E. F. CABRALES[2], Z. MIRZADEH[2]
[1]Neurobio., [2]Neurosurg., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Neuronal activity in the motor cortex is modulated with the rhythm of strides in diverse species including humans, non-human primates, cats, rabbits, and rats. It was shown that in humans, cats, and rabbits, it is also modulated by postural corrections after a perturbation. In mice, however, where genetic tools have facilitated the neurophysiological study of various behaviors, the role of the motor cortex in locomotion and postural corrections was not investigated. In this study, we recorded the activity of single neurons in the motor cortex of head-fixed male and female C57BL/6J mice that were standing, walking, and balancing on a floating ball. We found that the activity of neurons in cortical layer 5 was profoundly modulated by both locomotion and balancing movements. Specifically, the activity of most individual neurons was higher during one phase of the stride and postural correction and lower during another phase. Different neurons are active during different phases of the behavior. The entire population was slightly more active during the swing phase of the stride and the limb extension phase of the postural correction. Our findings suggest that the motor cortex of the mouse, similar to that of higher mammals, is involved in control of locomotion and posture.

Title: Flexibly switching postural responses between structured visual stimuli depends on the temporal determinism of the stimuli

Authors: *Z. MOTZ[1,2], T. SADO[2], W. DENTON[2], M. MUKHERJEE[2]
[1]Univ. of Nebraska At Omaha, Omaha, NE; [2]Biomechanics, Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Healthy postural sway is characterized by the ability to respond to changes in the environment, and adapting to these changes allows us to maintain balance while performing different tasks (e.g. on a ship at sea or in space). However, when such environmental conditions quickly change among several different conditions, whether we can flexibly adjust our postural responses, is not clear. Studying such flexibility patterns could provide insight into alleviating abnormal sensorimotor recalibrations and enhancing adaptation to ever-changing stimuli in dynamic environments. The purpose of this study was to test the ability of flexibly switching postural entrainment from one stimulus structure to another. Seven healthy participants were recruited to voluntarily shift medial-laterally and attempt to match their sway to a moving visual stimulus. Both deterministic (periodic and chaotic) and non-deterministic (random) stimuli were tested individually (baseline) and in combination. The combination trials comprised of either 20 second sections of the random stimulus followed by 20 seconds of the periodic stimulus, repeating for three minutes or the same structure with the chaotic stimulus instead of the periodic. The degree of center-of-mass (COM) – target stimulus coupling was quantified using cross-recurrence quantification analysis (cRQA) which represents duration of coordination and cross-sample entropy (cSE) which represents the repeatability between the two signals. Mixed-factor ANOVA statistical design was used to determine main effects of section, condition and interaction. Results show significant section, condition and interaction effects ($p<0.001$) for both baseline and combination trials. Postural entrainment to the random stimulus was significantly different from periodic and chaotic stimulus across early to late trials. Across baseline and combined signals, the unpredictable stimulus showed an increase in repeatability and coupling duration across trials; and as a group had lower repeatability and coupling duration than the deterministic stimuli. Coupling to deterministic stimuli at a frequency similar to normal postural sway (0.24 Hz), shows strong entrainment with a reduced learning effect. The study showed the

ability to flexibly switch between characteristically different patterns of visual stimuli depends on their temporal determinism. Future directions should test higher velocities to tease out adaptive flexibility across different deterministic stimuli and explore the transition points to determine uncoupling-coupling characteristics.

Title: Pain during learning reduces retention of a strategic locomotor learning task

Authors: *J. E. GALGIANI, S. M. MORTON
Physical Therapy, Univ. of Delaware, Newark, DE

Abstract: Certain forms of motor learning and retention can be influenced by non-motor elements, including attention, cognition and other factors. Pain is one potential factor that may affect motor learning, but to date, this has not been systematically studied. Of note, several cortical brain regions involved in pain processing overlap with those responsible for motor learning and consolidation, indicating that the two processes have the potential to interact. We compared the learning and retention of a strategy-based locomotor learning task between two groups of young healthy individuals, randomly assigned to either a ‘no pain’ or a ‘pain’ group. Individuals in the pain group received a painful stimulus induced by the combination of capsaicin and heat applied to the skin. All participants learned to alter their step lengths differently on each leg by watching a screen showing real-time feedback of their steps, displayed as a dynamic bar graph. For each step, a target step length was displayed, based on the average step length. During learning on Day 1, the feedback display was gradually distorted over 10 minutes, encouraging participants to take increasingly longer steps with one leg and increasingly shorter steps with the other, resulting in a newly learned asymmetric gait pattern. The pain group had the experimental pain delivered to one of the lower legs during the Day 1 learning period only. Twenty-four hours later, we tested retention of learning by assessing step lengths during the first few trials of walking with the same distorted feedback as at the end of Day 1. We found that while there was no difference in learning on Day 1, individuals in the pain group showed reduced retention of learning, demonstrated by initially less asymmetric stepping on Day 2. Our

results suggest that pain during strategic learning may interfere with the consolidation process of learning, resulting in poor retention. This work is significant because it provides novel insight into brain mechanisms of consolidation and retention and because it has important implications for application of rehabilitation interventions utilizing motor learning strategies in patients who have pain.

Title: The performance cost of postural biofeedback

Authors: *J. L. BAER[1], R. G. COHEN[2]
[2]Dept. of Psychology & Communication Sci., [1]Univ. of Idaho, Moscow, ID

Abstract: Background: Maintaining an upright sitting posture in the workplace may help reduce or prevent neck pain. The recent development of biofeedback interventions, which draw attention to postural feedback cues, raises the question of a possible trade-off between attention to posture and attention to task performance, such that maintaining upright posture may negatively affect task performance.
Approach: To investigate this possible trade-off, we assessed upright posture (based on neck length) and score on a 10-minute computer game, played with and without biofeedback in counterbalanced order.
Results: When participants used biofeedback, their postural alignment was significantly improved and their game performance was significantly worse than when they played without biofeedback, demonstrating a dual task cost. The magnitude of the dual-task cost was positively correlated with neck shortening while using biofeedback, indicating that participants who were worse at maintaining upright posture (and thus would have greatest need for biofeedback) had greater task performance decrements when using biofeedback.
Conclusion: Developers of biofeedback systems would be well-advised to consider individual differences and possible dual-task costs when designing training protocols.

Abstract: We have proposed a novel task design (*visual feedback distortion)*, in which the both step lengths are measured during treadmill walking and displayed as two vertical bars, and the length of only one bar is distorted. Our previous work demonstrated that subjects spontaneously modulated gait symmetry in response to the distortion. Thus, the use of the visual feedback distortion may involve *sensory prediction error-based learning*, in which the motor system cannot tolerate differences between a prediction of motor commands and the execution perceived through visual feedback, thereby leading to gait adaptation.
We further investigated how gait adaptation may be compromised in two different modalities of feedback distortion; 1) visual graph feedback and 2) digit feedback. For the first trial, the visual graph feedback represented the step length with a semi-circle (Fig. A). As the right step length is longer than the left step length, the semi-circle moves left and vice versa. For the second trial, the digit feedback displayed a number percentage off from step symmetry with information of which side of the leg is longer (Fig. B). Our pilot trials consisted of 5 minutes treadmill walking. The distortion level increased 2% on the right side for every 30 seconds up to 14% after the first one minute. All participants were aware of the distortion and instructed to walk normally while looking at the visual feedback. Subjects made spontaneous modulations away from actual symmetry in response to the feedback distortion, no matter the modality (Fig. C & D). Despite the simple graph or digital feedback distortion of gait symmetry, it appears to still cause adaptation possibly through sensory prediction error-based learning, which does not necessarily rely on visually-guided feedback of movements.
Figure. Illustrate of visual graph feedback (A) and digit feedback (B), and gait symmetry change in response to the graph feedback distortion (C) and the digit feedback distortion (D). The symmetry ratio (%) was measured by 2*(R-L)/(R+L) and the symmetry change was referenced to the base line (the first one minute).

Title: Application of real-time marker-based motion capture for the kinematic analysis of freely behaving mice

Authors: *A. KUCK, B. M. IGNATOWSKA-JANKOWSKA, M. Y. UUSISAARI
Neural Rhythms in Movement Unit, Okinawa Inst. of Sci. and Technol., Onna, Japan

Abstract: Movement analysis in freely moving rodents is of high importance in systems neuroscience as well as research of motor behavior and disorders. However, since most of the current state-of-the-art tools for movement analysis in freely moving rodents employ marker-less motion tracking techniques, they require cumbersome off-line analysis and are limited in their precision of kinematic tracking. To overcome these limitations and to allow for high-resolution recording of limb positions simultaneously with neural recording and stimulation, we employed a marker-based motion capture system to track limb and body kinematics of freely moving mice in real time. The system consists of seven high-precision motion capture cameras (Oqus 7, Qualisys AB, Göteborg, Sweden), tracking the position of several permanently attached, custom-made retroreflective motion capture markers. Markers were positioned on both hind- and forelimbs as well as hip and back of the animal, enabling tracking of limb kinematics, body orientation and posture in 3D with sub-millimeter precision at a sampling rate of up to 1kHz. To demonstrate the capabilities of the system, we showcase the kinematics of mice locomoting

freely on open field, vertical climbing wall and on a horizontal rope. We extract a rich set of kinematic variables, to describe the animals' behavior during gait, reaching, climbing, grooming and exploration. The data allows detecting subtle differences in movement and behavior, as a response to pharmaceutical, environmental, optogenetic or other types of interventions. We show that the employment of such a marker-based kinematic system in freely moving, unrestrained rodents is possible and suggest its great potential to a range of neuroscience fields. The high-precision kinematic analysis of rodents' behavior as well as the possibility of movement-driven, real-time, closed loop experimental protocols opens new paths to dissecting the neural circuitry underlying motor behavior and dysfunction.

Abstract: Rapid attentional switching from sensory information and/or an ongoing task to a postural disturbance is an important function for postural control. However, few studies have used neurophysiological methods. In this study, relationships between the timings of attentional switching and postural preparation were investigated using a choice-reaction paradigm with transient floor translation (S2), with the direction indicated by a warning auditory signal (S1). Thirteen healthy young adults participated in this study. S2 started 2 s after S1 onset while standing on the platform. The platform moved forward when S1 was a high tone, and backward when S1 was a low tone. In the S1-S2 period, attentional switching was evaluated by P3 component of event-related potentials. A shift in the center of pressure in the anteroposterior direction (CoPap) or a continuous increase in postural muscle activation toward S2 was recognized as postural preparation. Changes in postural muscle activation were found just before the CoPap shift. P3 was observed about 250-650 ms after S1. Onset of postural preparation was significantly later (about 200 ms) than latency of P3 ($p < 0.001$) (Figure 1) and correlated strongly with P3 latency (forward: $r = 0.81$, backward: $r = 0.74$, $p < 0.01$). Postural preparation for S2 was demonstrated to start after attentional switching from S1 to S2.

Title: A simple neural mutation that generates reward from rhythmic audible vestibular jolts fully explains all aspects of human bipedal gait development, including cerebral palsy gaits

Authors: *M. RIGGLE
Causal Aspects, Charlottesvle, VA

Abstract: The human bipedal gait starts with toddlers walking by clubbing the floor with their feet, then years of development until the adult heel-strike gait. Our gait has often been assumed to require unique structures in the motor control neural areas -- presumably placed there by evolution. However, a simple alternative to needing motor control changes is a neural change that produces an internal reward from the sensation of rhythmic audible vestibular jolts (RAVJ). If RAVJ is rewarding, we can show that all human gaits from the initial toddler gait to the adult gait, and even the cerebral palsy toe strike gaits, arise as learned via operant conditioning.

Normal human gaits generate RAVJ because of foot impacts to the floor which create a shockwave that travels to the head via the skeleton. That shockwave at the head produces a strong vestibular jolt and it is audible. As the gait matures, the gait must produce RAVJ but is also modified to reduce slips, trips, and collisions because they can be painful (learned modifications). We show the gait modifications from toddler to the adult allows more time for recovery from a trip or for avoiding obstacles but still generates strong RAVJ. As a rewarded behavior, walking is well practiced and thus becomes automatic.
Additionally, during the first week of walking, toddlers have learned to avoid slip falls by using muscles to stop the forward motion of the swing leg prior to floor contact (which requires a reflex development). With cerebral palsy, stopping the swing leg accurately by muscle is not reliable and they must instead use a foot strike that produces RAVJ but also reliably stops the foot to prevent a slip fall. That foot strike is often a skeleton damaging toe-strike and this theory suggests possible solutions.
There is additional evidence supporting that RAVJ is rewarding in humans but is not rewarding in non-human primates; this includes rhythmic headbanging and infant movement responses to rhythmic music.
We review published data from many areas to support this theory.

Title: Human-exoskeleton adaptation: Predicting individualized adaptability from sensorimotor & cognitive factors

Authors: *A. GUPTA[1], R. J. MCKINDLES[3], L. A. STIRLING[2]
[1]Hlth. Sci. & Technol., [2]Dept. of Aeronautics & Astronautics, MIT, Cambridge, MA;
[3]Bioengineering Systems and Technologies, MIT Lincoln Lab., Lexington, MA

Abstract: Individualized adaptation timelines and natural adeptness of exoskeleton operators may be predicted by their underlying perceptual, cognitive, and motor abilities. Until recently, the research and development being carried out by academic and industry groups focused on exoskeleton mechanical and material design or control methods with the goal of improving neurorehabilitation, enhancing human performance, and preventing injury. These researchers noted high variability in human adaptation and technology adoption with no current explanation. Our overarching study begins to quantify these individualized user differences that will inform (1) identification of adept exoskeleton operators, (2) creation of training methodologies, and (3) exoskeleton control architectures. Here we investigated which perceptual, cognitive, and motor capabilities best predict short term exoskeleton adaptation. We hypothesize that the rate of adaptation of a naïve exoskeleton user will be correlated to sensorimotor and cognitive function. This pilot study focuses on the development and validation of two novel tasks. The first focused on a known executive function task (i.e. Simon Task) typically performed as a visual, upper extremity response task and translating it to a tactile, lower extremity response task. The experiment included visual and lower extremity tactile stimuli that were either congruent or incongruent. Subjects (n=20) were asked to respond as quickly as possible by either a button press or foot tap. Though response times were on average slower for foot taps ($p<0.05$) and tactile stimuli ($p<0.05$), the results confirmed our hypothesis that the Simon task could be translated to lower extremity studies. For the second task, we developed and tested a self-paced, treadmill walking paradigm that examined user adaptation to a goal-directed walking task. Subjects (n=4) were asked to reach and maintain target speeds of 0.5, 1.0, and 1.5 m/s for 60 second trials on a self-paced treadmill (Motekforce Link). Results showed that there were varied responses to using the self-paced treadmill, characterized as speed overshoot (range 0-1.01 m/s) and time to steady state (range 1.1-18.6 seconds). In the next phase of this study, we will examine how these tests and other metrics of perception, cognition, and motor skills may help predict human-exoskeleton adaptation. DISTRIBUTION STATEMENT A. Title: Prefrontal cortical activity in Parkinson's disease decreases during dual tasks and is not associated with cognitive effort

Authors: *A. PANTALL[1], L. KAPA[2], R. VITORIO[4], S. STUART[5], L. ALCOCK[3], L. ROCHESTER[3]
[1]Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Psychology, [3]Neurosci., Newcastle Univ., Newcastle, United Kingdom; [4]São Paulo State Univ., São Paulo, Brazil; [5]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Background: Cholinergic networks, from the pedunculopontine nucleus in the brainstem and the subcortical nucleus basalis of Meynert, influence postural control, gait and cognition [1]. Most activities involve dual tasks (DTs), such as walking and talking. Optimal DT performance requires both networks to be functional. However, in Parkinson's disease (PD), postural control, gait and cognition, specifically executive function, are often impaired. Executive function includes attention and allocation of cognitive reserve and is associated with the prefrontal cortex (PFC) [2]. Analysis of PFC activity and cognitive task (CT) errors during DTs may provide insight into mechanisms underlying cognitive cost of DTs in PD.
Aims: (1) to evaluate the effect of PD on PFC activity when performing DTs compared to a single task; (2) to investigate the relationship of PFC activity with CT performance.
Methods: 60 participants were recruited – 30 with PD (68.5±14.0 years), 15 healthy older adults (OA) (74.1±6.9 years) and 15 healthy younger adults (YA) (23.5±2.9 years). PFC activity was recorded using a wireless functional near infra-red spectroscopy device (Oxymon, Artinis Medical Systems). Participants performed two tasks for 300s: a) alternating 30s bouts of standing still (SS) and standing whilst performing a CT (SSCT); b) alternating 30s of usual walking (UW) with walking plus the CT (DTW). The CT involved recalling how many odd or even numbers were spoken during 30s. The averaged normalised fNIRS differences between SS and SSCT and between UW and DTW were calculated. Statistical analyses used linear mixed models and Pearson's correlation test with significance set at $p<0.05$.
Results: PFC activity decreased for DTW task compared to UW ($p=.009$) for PD whereas no change was found for OA and YA. No change was observed in PFC activity from SS to SSCT whereas OA and YA increased activity. CT performance differed significantly between groups ($p<.001$) with lowest performance recorded for the PD group. The task effect was significant

only for the PD group (p=0.002) with better CT performance during DTW compared to SSCT. No significant correlation was observed between PFC activity and task performance in PD (p=0.085).
Conclusions: People with PD display different neural activation patterns during DTs compared to healthy adults. PFC activity decreased in DTW although this change was not related to lower CT performance. Decreased PFC activity during DTW may explain why people with PD experience difficulty performing dual task activities.

Title: A phase-independent balance shift is generated by phase-dependent muscle activation in response to galvanic vestibular stimulation during walking

Authors: *H. REIMANN[1], T. D. FETTROW[2], E. D. THOMPSON[4], D. GRENET[2], J. J. JEKA[3]

Abstract: To maintain upright posture of the body during locomotion in the frontal plane, the central nervous system has to activate muscles to push against the ground to stabilize the position of the center of mass and the orientation of the body. Several studies have reported balance responses in the lower body that strongly depend upon the phase of the gait cycle, whereas responses in the upper body are usually only weakly phase-dependent. We hypothesize that there might be an underlying control mechanism for balance which is phase-independent. To test this hypothesis, we perturb the balance system during locomotion and observe the responses of the motor system. Subjects walked on a self-paced, split-belt instrumented treadmill, surrounded by a virtual reality environment projected onto a domed screen. Balance was perturbed by bipolar, binaural Galvanic vestibular stimulation for 600ms with an amplitude of 0.5mA every 6-9 strides. Stimulation was triggered by heelstrike of the right foot, and started after a randomized phase delay of 0, 150 or 450ms. Results show that in response to the stimulus, the center of

pressure shifts in the direction of the perceived fall relative to the center of mass. The onset of this CoP shift occurs approximately 250-350ms after the stimulus onset, independent of the phase delay. In the 450ms delay condition, the CoP response cannot be realized by the current stance foot as it shifts to swing. Instead, the CoP shift transfers to the opposite foot as it enters stance, preserving the balance response. EMG results show that in the first post-stimulus step, the stance leg peroneus longus EMG is increased for a perceived fall away from the stance leg in the 0 and 150ms delay conditions. In the 450ms condition, a similar peroneus longus EMG modulation occurs during the second step in the contralateral leg, which is then in stance. These results indicate that there is a functional balance response to the GVS in the form of a CoP shift, driven by modulation of the stance foot peroneal muscles. Although the activation of the underlying musculature is phase-dependent, the functional response of the CoP is phase-independent with respect to the gait cycle.

Title: Greater visual attentional demands during saccadic eye movements do not improve postural sway

Authors: M. A. YEOMANS, A. V. MICHEL, K. MOORE, T. DIAZ, J. JOHNSON, J. SCHIPPER, S. YAN, *J. M. HONDZINSKI
Kinesiology, Sch. of Kinesiology; Louisiana State Univ., Baton Rouge, LA

Abstract: The purpose of this study was to better understand the effects of saccadic eye movements on postural control. By performing visually guided saccades during quiet stance, people can attenuate standing postural sway compared to fixating on a stationary target. Although such postural control may stabilize the visual system, it may increase attentional demands for whole body control or provide external cues for such control. We questioned whether self-paced saccades to imagined targets in a dark environment would attenuate sway relative to fixation. Performing self-paced saccades eliminated external cueing of a metronome and additional attentional cues. We also questioned whether increased attention on targets during visually guided fixation or saccades would attenuate sway relative to visually guided fixation or saccades on targets requiring less attention. Young adults were asked to stand still on a force plate and either stare at a fixation point (FP) target or to perform saccadic eye movements (SAC) to targets. An imagined target was used in a DARK environment, while a real target, either a 2 cm diameter DOT or a randomly presented 2 cm number/letter (NL), was presented on a

computer screen for non-DARK trials. Target presentation for SAC was at an 11 degree visual angle. Increased attentional demands were achieved by having participants name each number or letter orally (NLoral) or to themselves (NL). They performed 6 trials (3 FP and 3 SAC) in each condition while standing on a force platform (AMTI, Watertown, MA). Gaze position was tracked with a mobile Eye Tracker (SMI, Teltow, Germany). Analyses performed on several sway measures for the center of pressure revealed the following. In visually guided conditions (i.e., DOT, NLoral, and NL), SAC frequently attenuated sway relative to FP. Visually guided conditions also produced less sway compared to DARK, especially when considering SAC trials. NLoral and NL conditions did not differ from sway measures for the DOT condition. Results of the present study match previous work, which showed saccades can attenuate standing sway when visual guidance is provided. Decreasing visual attentional demands with no external cueing can increase sway compared to provision of external visual cues. Providing additional visual attentional demands, associated with reporting a number/letter during fixation and saccades like those performed in this study, does not improve postural sway. Thus, external cueing alone cannot explain attenuated sway associated with saccades. Data support that the external cueing associated with visually guided saccades improves postural control and gaze accuracy needed to stabilize the visual system.

Title: Motor-cognitive interference in older adults walking with a visual verbal Stroop task

Authors: *B. WOLLESEN[1], C. VOELCKER-REHAGE[2]
[1]Univ. of Hamburg Fac. of Educ. Psychol, Hamburg, Germany; [2]Inst. of Human Movement Sci. and Hlth., Technische Univ. Chemnitz, Chemnitz, Germany

Abstract: Gait performance depends on sensorimotor and cognitive function. To identify people's susceptibility to adopt impaired gait patterns, often resulting in an increased risk of falling, the cognitive processing of locomotion in dual- or multi-tasking situations, (e.g. crossing the street while observing traffic flow, Faulkner et al., 2007); is important. In order to better understand the multiple requirements of motor skills and cognition, the Dual-task paradigm (DT) has become prominent to analyze cognitive-motor interference (CMI) in old age. Different models try to explain the contradictory results for the DTC (Wollesen et al., 2016). The aim of this observational study was to compare the differences of demographics, comorbidities and

physical functioning of older adults with positive and negative DTC while walking with a visual-verbal Stroop task. **Methods** A total of 241 participants (72.3 ± 5.4 years) performed a ST and a DT condition (visual-verbal Stroop task) while walking on a treadmill in randomized order. Gait parameters (step length, step width, gait line) were measured at 100 Hz. DTC were calculated by the formula (ST-DT/ST *100). Demographics, comorbidities and physical functioning were assessed (SF-12, FES-1, hand grip force, MMST, SPPB). An ANOVA was used to reveal subgroup differences of the baseline characteristics by using SPSS 24. **Results** We found DTC for step with and step length from 1% (step length) und to 2% (step width) with a SD between 8-15% for the 241 participants. Three subgroups with n=57 with positive (DTC-1) and n= 66persons with negative DTC (DTC-2) and n=118 persons with DTC for step length or step width (DTC-3) were distinguished. The baseline characteristics between the subgroups showed significant differences in age (DTC-1 73.7 ± 5.9; DTC-2 70.7 ± 5.2 and DTC-3: 72.6 ± 5; $F_{(2,233)}$=5.092, p=0.007) and concerns of falling (DTC-1: 20.4 ± 4.4; DTC-2 22± 5.4; DTC-3: 20 ± 3.4;$F_{(2,233)}$=3.732,p= .026). No differences were found for hand grip force, SPPB, MMST, SF-12. **Conclusions** The results showed that a huge number of participants cannot be clearly specified into a group with positive or negative DTC. A trend from differences in baseline characteristics (SF-12, FES-I, hand grip force, MMST, SPPB) between negative and positive DTC performer was observed. Interestingly, the main differences cannot be explained by older age. The persons with neg. DTC showed more motor and cognitive deficits in comparison to the participants with positive DTC. These results should be further analyzed to gain recommendations for interpreting dual-task assessments or training studies.

Title: Dissociation of muscle and cortical response scaling to balance perturbation acceleration

Authors: *A. PAYNE[1,2], G. HAJCAK[3], L. H. TING[2]
[1]Georgia Tech., Atlanta, GA; [2]Biomed. Engin., Emory Univ., Atlanta, GA; [3]Psychology and Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Reactive balance recovery engages sensorimotor control centers throughout the nervous system, but the role cortical activity in online control of balance is unclear. Cortical EEG activity during reactive balance recovery reveals a robust negative peak of activity (N1) over the supplementary motor area at ~150ms latency, but its relationship to concurrent and subsequent balance-correcting automatic postural responses (APR) in muscle is not understood. Prior work on averaged responses suggest that muscle and cortical responses share modulation by somatosensory inputs (Dietz 1984b, 1985a/b; Berger 1987; Staines 2001). We hypothesized the balance N1 shares somatosensory inputs with the initial burst (IB) of the muscle APR in order to monitor the simultaneous brainstem-initiated balance response and to influence later balance-correcting muscle activity. Because perturbation acceleration modulates the amplitude of the initial burst of the muscle APR (Lockhart 2007), we predicted that the balance N1 amplitude would also scale with perturbation acceleration and correlate to the muscle APRs on a trial-by-trial basis. We recorded EEGs during perturbations to standing balance that were unpredictable in timing, direction, and acceleration magnitude. Across subjects, we found much weaker acceleration-dependence of cortical responses (R^2=0.022) compared to muscle responses (R^2=0.323). Only half of individuals showed acceleration-dependent cortical responses despite acceleration-dependent muscle responses in all individuals. Variation of balance N1 amplitudes between subjects (R^2=0.528) was much greater than variation within subjects, with larger amplitudes in shorter subjects (R^2=0.412). Z-transformed balance N1 and muscle APRs were weakly correlated (R^2=0.075), in part due to differences in acceleration-dependence, but also due to a greater reduction in amplitude across trials of the balance N1 (R^2=0.047) compared to muscle APRs (R^2=0.015). Importantly, balance N1 was larger on trials in which subjects took a step to recover balance (two-way T-test, $p<0.0001$), and was correlated with longer-latency muscle activity (R^2=0.039). We conclude that the balance N1 receives the sensory inputs driving the muscle APR IB, but its amplitude depends more on the individual and recent experience, which may relate to known influences of attention and perceived threat. Our data further highlight a possible relationship between the balance N1 and stepping behavior, suggesting a potential influence of the cortex on longer latency muscle activation related to changes in strategy.

Title: Human cortical response to sensorimotor perturbations measured with high-density electroencephalography

Authors: S. M. PETERSON[1], *D. P. FERRIS[2]
[1]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI; [2]Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: Human balance requires precisely-timed coordination between sensory information and motor control. Studies have shown that improving cognitive function improves the ability to maintain balance, suggesting that cortical activity may be an informative biomarker of balance performance (Bherer 2015). We studied the responses of 30 healthy young adults (15 female/15 male; age 22.5±4.8 years, mean±SD) to sensorimotor perturbations that challenged their balance. Subjects performed four 10 minute conditions total of tandem stance and tandem gait while either being mediolaterally pulled or viewing brief 20 degree field of view rotations in virtual reality. We recorded 136-channel high-density, source-localized electroencephalography (EEG) clustered across all subjects. Based on previous research (Varghese et al. 2014; Wagner et al. 2016), we hypothesized that both the physical pull and visual rotation perturbations would elicit time-frequency fluctuations in theta (4-8 Hz) and beta (13-30 Hz) bands, with increased occipito-parietal activity during the visual rotations compared with the physical pull perturbations. Our results confirmed this hypothesis. For both visual and pull perturbations, we found early theta band synchronization and late alpha-beta (8-30 Hz) band desynchronization following perturbation onset (Figure 1). This pattern was strongest in occipito-parietal areas during visual perturbations and strongest in sensorimotor and anterior cingulate areas during pull perturbations. These results indicate that electrocortical patterns when humans respond to sensorimotor conflict are similar for both visual and physical perturbations.. Local field potential recordings in the subthalamic nucleus show similar time-frequency activity during visual conflict (Zavala et al. 2016). This common electrocortical pattern may have important implications for assessing balance control in both healthy adults and individuals with motor disabilities.

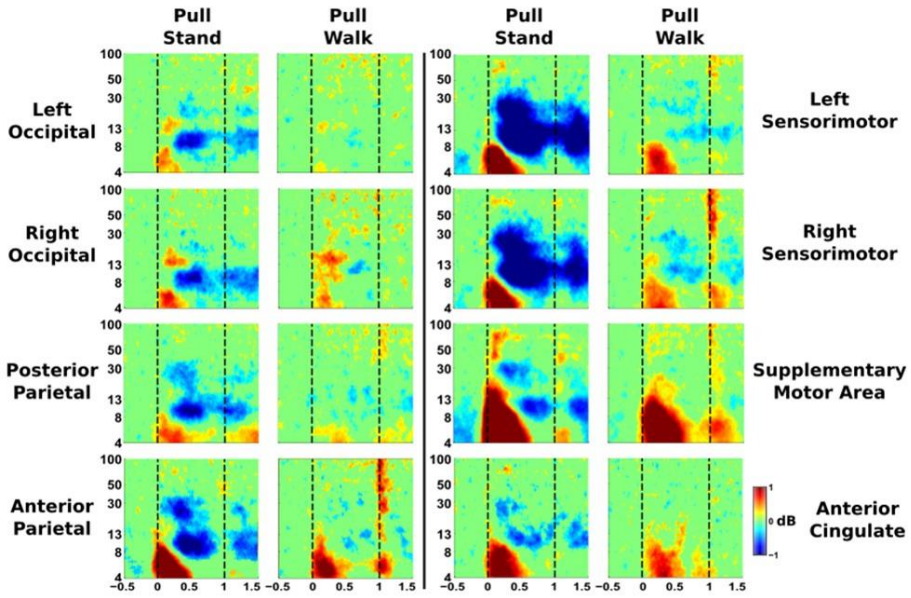

Figure 1. Time-frequency EEG activity in response to the physical pull perturbation (onset at 0 sec) during tandem standing (columns 1 and 3) and tandem walking (columns 2 and 4).

Title: A quantitative, objective, and synchronized dual movement/cognitive task; pilot study in autism spectrum disorder

Authors: T. L. SIMMONS[1], L. CHUKOSKIE[2], J. TOWNSEND[3], *J. SNIDER[4]
[1]Res. on Autism and Develop. Lab., UC San Diego, La Jolla, CA; [2]UCSD, LA Jolla, CA; [3]Dept Of Neurosci, [4]Inst. for Neural Computation, UCSD, La Jolla, CA

Abstract: It is common to isolate a single cognitive or motor task in laboratory studies, but the reality of our everyday experience is that we engage in multiple tasks simultaneously, e.g. walking while talking (or texting) on our phones. We designed a task to simultaneously quantify balance, fine motor skill, and cognitive ability with objective outcome measures. The system's

temporal precision and modular design also allow for the incorporation of other sensors as needed, like EEG or heart rate variability. We tested the task on a pilot cohort of children with autism spectral disorder (ASD) and matched controls. The system consists of a glove programmed to accurately record finger tapping, a forceplate, and a microphone. The glove has conductive pads on the fingertips that act as switches as participants pinch their fingers and thumb together. The forceplate records center of pressure data at 100Hz. The microphone allows the participant to interact with the task verbally, since their hands may be occupied with tapping. We use custom plugins to the WorldViz Vizard VR development platform to coordinate presenting the task and simultaneously recording multiple data streams.In our pilot study, participants performed a vocally-triggered N-back task, while simultaneously executing combinations of standing and finger tapping. Participants demonstrated their balance control by attempting to remain erect while standing still. We also recorded a measurement of speeded finger tapping. Our pilot study compared the performance of young adult males with autism spectrum disorder (ASD) with normal to high IQ (WASI II) to the performance of typically-developing young adult males with similar IQs. We hypothesized that the additional demands of the balance and speeded finger-tapping task would further degrade motor performance in the simultaneous conditions, but not impact N-Back performance. Movement data was evaluated by comparing the change of each group across 3 levels of cognitive load (0-, 1-, and 2-back). N-Back performance was similar across both experimental and control groups. However, ASD participants were shown to have increased amounts of sway, as well as a slower ability to correct their movements back to center relative to the control group. Similarly, finger tapping speed also decreased more substantially for ASD participants. These results indicate that our task taps into a neural resource shared between cognitively demanding tasks and basic movement tasks.

Title: Error-related brain dynamics predict step adaptation in a challenging gait task

Authors: *J. WAGNER[1], R. MARTINEZ-CANCINO[1], G. R. MUELLER-PUTZ[2], S. MAKEIG[1]
[1]Inst. for Neural Computation, Univ. of California San Diego, La Jolla, CA; [2]Computer Sci. and Biomed. Engin., Graz Univ. of Technol., Graz, Austria

Abstract: Gait is not merely automated motor activity but requires attention and other executive function (EF). Relationships between age- and disease-associated declines in cognitive function and mobility are of increasing interest. A growing body of evidence using dual-task walking paradigms indicates a pivotal role of EF in gait control and fall prevention in the elderly and Parkinson's subjects (Mirelman, 2012). EF may compensate for age-associated decline in motor function, however evidence suggests that EF itself is involved in challenging gait tasks (Potocanac, 2014). In a recent gait study using EEG imaging (Wagner, 2016), we provided direct proof of involvement of EF and prefrontal control in gait adaptation. To further pinpoint the roles of cognitive control processes in gait adjustments we examined the source-resolved EEG dynamics of participants attempting to step in time to an auditory tone sequence. Participants had to adapt their step length and rate to shifts in tempo of the pacing stimulus (e.g., following unpredictable shifts to a faster or slower pacing tempo). Analysis revealed a negative potential in the source-resolved EEG, localized to dorsomedial prefrontal cortex (DMPFC) 200-300 ms after onset of the tempo-shift marking stimulus (Figure 1). Multiple regression analysis shows that single-trial amplitude of this negative deflection predicts the size of the subsequent step adaptation for tempo re-adjustment ($R^2 = 0.2$) beginning 500 ms after the shift-marking cue. Negative scalp event-related potential peaks over DMPFC ~250 ms after incorrect button presses, described as error-related potentials, have been associated to control functions including error correction (Holroyd & Coles, 2002). Our results suggest that error-correction processes are directly involved in gait adaptation allowing flexible adaptation of steps to changing external requirements. Future research will investigate age- and disease-associated impairments of these control processes in gait disorders to develop biomarkers for fall risk prediction, e.g. in early-stage Parkinson's.

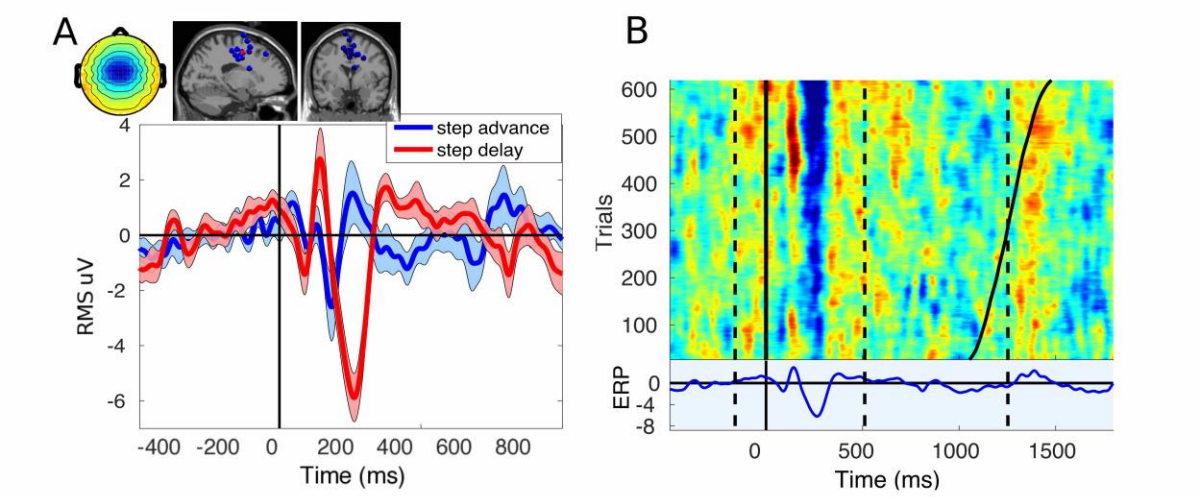

Figure 1: A) Cluster mean scalp projection and cluster single equivalent current dipoles and average ERPs relative to the tone cueing step advance and step delay perturbation. B) Single trials of all 14 subjects for step delay perturbations sorted by the normalized size of the adptation step. The solid vertical line at zero represents the beep indicating the tempo shift; dashed vertical lines are median step latencies. The curved line around 1200ms indicates the relative length of the adaptation step. A larger negative amplitude in the EEG potential predicts a larger adaptation step producing a better adptation to the new tempo (adptation step is defined as inter-step interval (ISI) between 2nd and 3rd steps following the tempo shift expressed as percentage change in pre-shift ISI)

Title: Avoiding pedestrians while walking in physical and virtual environments

Authors: M. A. BÜHLER[1], *A. LAMONTAGNE[2,1]
[1]Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada; [2]Feil and Oberfeld Res. Centre, Jewish Rehabili, Laval, QC, Canada

Abstract: Virtual reality provides a unique opportunity to safely assess and train people with disabilities under ecological conditions. While appealing to research and clinical practice, its usefulness is limited by the extent to which it can elicit natural behaviours. To date, this assumption has little supporting evidence, especially when considering complex locomotor tasks such as the avoidance of pedestrians. Objectives were to compare circumvention strategies in response to static and moving pedestrians in a virtual (VE) vs. a physical environment (PE). Twelve participants were assessed while walking towards a target and avoiding a collision with interferers in a PE vs. VE (random order). The VE, viewed in VR goggles, simulated the PE which was the gait laboratory. In the static obstacle condition, participants avoided one interferer that remained static at 3 or 3.5 m from the participants' starting position. In the dynamic obstacle condition, one interferer randomly approached from the left, middle or right (± 40°, 0°), towards a theoretical point of collision located 3.5 m ahead of the starting position. Compared to the PE, circumventing static and moving pedestrians in the VE was characterized by slower walking speeds ($\Delta = 0.14 \pm 0.04$ m/s (mean ± 2SE); $p < .0001$), larger obstacle clearances ($\Delta = 0.10 \pm 0.04$ m; $p < .0001$) and larger mediolateral path deviations ($\Delta = 0.10 \pm 0.04$ m; $p = 0.0002$). No significant differences were observed between environments for the preferred side of circumvention ($p = 0.33$) and onset distance of trajectory deviation ($p = 0.44$). The larger clearances around the interferers and slower walking speeds in the VE suggest the use of "safer" avoidance strategies.The similarities in circumvention strategies between the two environments, however, suggest that virtual reality is a valuable tool to study complex locomotor tasks and shows potential as a rehabilitation tool.

Title: Motor impairment in mice with a gain-of-function mutation in retinoic acid receptor beta

Authors: *J. L. MICHAUD, N. LEMMETTI, C. NASSIF
Hôpital Sainte-Justine, Montreal, QC, Canada

Abstract: Retinoic acid (RA) signalling is required for the development of several organs, including the eye and the brain. In target cells, RA binds to heterodimeric receptor complexes that function as ligand-activated transcription factors. We previously described several patients with microphthalmia, cognitive impairment and dystonia who carried *de novo* mutations in the

retinoic acid receptor beta gene (*RARB*). We found that these mutations enhance RA-induced transcriptional activity 2- to 3-fold over the wild-type receptor in an in vitro assay, suggesting a gain-of-function (GOF) mechanism.
Dystonia is typically caused by dysfunction of the striatum. RA signaling plays an important role in the generation of striatal neuronal types. Loss of *Rarb* leads to a reduction of striatonigral neurons due to premature differentiation of their progenitors and motor abnormalities in mice. Thus, loss of *Rarb* function may cause motor deficits by disrupting early development of striatal circuits. *We hypothesize that the motor impairment of patients and mice with RARB GOF mutations is caused by increased RARB signaling in the striatum, possibly disrupting homeostatic control of the same pathways as those affected by decreased Rarb signaling*.
In order to investigate this hypothesis, we used CRISPR-Cas9 to introduce p.R394C, the equivalent of the recurrent p.R387C GOF mutation found in some patients, at the *Rarb* genomic locus in mice. We generated 2 independent lines of $Rarb^{R394C/+}$ mice. Behavioral assessment at 2 months of age showed a specific motor phenotype characterized by a short stride, normal strength in the hanging test, increased activity in the open field test, and dramatically reduced motor coordination in the rotarod paradigm. This motor phenotype is reminiscent of that of mouse models of dystonia. We are currently determining when these motor abnormalities first appear and whether they worsen with age. $Rarb^{R394C/R394C}$ mice are born at the expected mendelian ratio but they show a waddling gait, their growth is compromised and they die between birth and 3 weeks of life. In order to understand the cellular basis of the motor impairment associated with p.R394C, we are currently characterizing the striatum of $Rarb^{R394C/+}$ and $Rarb^{R394C/R394C}$ mice using molecular markers.

Title: Investigating sensorimotor integration in the trunk motor cortex in adult rats

Authors: *B. NANDAKUMAR[1], G. H. BLUMENTHAL[2], K. A. MOXON[3]
[1]Univ. of California Davis, Davis, CA; [2]Drexel Univ., philadelphia, PA; [3]Dept. of Biomed. Engin., Univ. of California, Davis, CA

Abstract: While there exists extensive information about sensorimotor integration in the forelimb, hindlimb and barrel cortex, little is known about details of trunk cortex. Since volitional control of trunk musculature is essential for postural stability and weight supported locomotion, understanding sensorimotor integration in the trunk cortex is useful for studies of

neurological injury or disease where the somatotopic organization of cortex changes. The trunk is especially important for the impact of mid-thoracic spinal cord injury where reorganization of the trunk motor cortex is necessary for the recovery of function. To understand sensorimotor integration in the trunk cortex, we first assessed the extent of trunk motor representation using intracortical microstimulation (ICMS). Then, we examined somatosensory representation in the trunk motor cortex by recording evoked responses to peripheral electric stimulation of forelimb, hindlimb and trunk. **Methods:** Naïve Sprague Dawley rats were anesthetized and a craniotomy over the medial post Bregma area (MPBA) and the caudal forelimb area (CFA) exposed most of the motor cortex. EMG electrodes were implanted in the trunk muscles at different levels of the vertebral column along with hind limb and forelimb muscles. Low impedance Tungsten electrode was slowly lowered to layer 5 of the cortex, in predefined locations. Movement representations were evaluated at the minimum current required to elicit movement/EMG response. Neuronexus probes were then inserted into fixed locations spanning the motor cortex. Evoked responses to peripheral electric stimulation of limbs and trunk were measured. **Results:** Activation of trunk muscles in response to ICMS at threshold current extended from +0.75 to -2.25mm rostrocaudally and from 1.0 to 2.25mm medial from Bregma. However, exclusive activation of trunk musculature is small and medial, and the locations were not consistent across animals. More likely, the trunk motor representation contained 3 distinct coactivation zones: 'synergistic trunk', characterized by unilateral synchronous activation of the forelimb & the hindlimb; 'hindlimb trunk', characterized by co-activation of the hindlimb & trunk musculature and 'forelimb trunk', characterized by co-activation of forelimb and trunk muscles. Evoked responses to both forelimbs hind limbs and trunk were found in the trunk motor cortex, suggesting there is extensive sensorimotor integration within the trunk motor cortex. **Conclusion:** This knowledge from normal animals can be used for greater insight into the reorganization of the trunk motor cortex after spinal cord injury.

Title: Do performance errors and environmental switches regulate generalization of learned locomotor features across contexts?

Authors: *D. DE KAM, W. STARING, G. TORRES-OVIEDO
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Movement patterns learned in one context partly generalize to untrained contexts. This generalization is limited by contextual cues, such as large performance errors, that promote linking of motor patterns to the context in which they were learned. We investigated if different strategies to reduce error size promote generalization of locomotor learning to a similar extent. Human locomotor learning was induced by a split-belt treadmill eliciting initial asymmetry in step lengths and subsequent adaptation towards symmetric gait. The control group experienced large performance errors through a semi-abrupt split-belt perturbation (40 strides ramp). Performance errors were reduced in two other groups through distinct learning strategies: 1) by explicitly reducing performance errors (step length asymmetry) using visual feedback, or 2) by implicitly (subconsciously) reducing errors through a gradual split-belt perturbation (600 strides ramp). Generalization was quantified by step length asymmetry after-effects upon removal of the perturbation during overground walking. Smaller errors during adaptation resulted in reduced overground after-effects (gradual, $p=0.025$, feedback $p=0.024$). This was surprising given previous work showing a negative association between error size and generalization (Torres-Oviedo 2012). We reasoned that there were two possible reasons for these contrasting results: 1) a non-linear effect of error size during adaptation and generalization (less generalization if errors during adaptation are too large or too small) or 2) errors experienced upon removal of the perturbation (catch trial) induce less generalization because they facilitate switching between split and regular walking patterns. Thus, we contrasted the generalization of our control group to: 1) an abrupt group experiencing a sudden introduction of the split perturbation, inducing performance errors larger than controls and 2) a catch group that experienced the same perturbation profile as controls but also a catch. Overground after-effects were substantially reduced compared to controls in the catch group only ($p<0.01$). Our results indicate that error size plays an important role in generalization of motor learning from trained to untrained contexts. However, errors experienced when the perturbation is introduced (positive errors) or removed (negative errors) have opposite effects on generalization. Positive errors facilitate generalization possibly because they induce more learning, whereas negative errors mitigate generalization because they enable subjects to recall the appropriate motor pattern according to the context at hand.

Title: Split-belt walking similarly changes active step length perception at different speeds and step lengths

Authors: *C. J. SOMBRIC, M. GONZALEZ-RUBIO, G. TORRES-OVIEDO
Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Stroke induces motor deficits (e.g., asymmetrical stepping) that limit patients' mobility. Some stroke subjects do not recover symmetric stepping due to additional perceptual deficits, or impaired awareness of their own asymmetrical stepping (Wutzke et al., 2015). Thus, there is a clinical interest to understand if the perception of step lengths can be altered. It is already known that split-belt treadmills, which drive the feet at different speeds, induce shifts in belt speed perception (Vazquez et al., 2015). Therefore, we hypothesized that split-belt walking induces step length perceptual shifts that will vary with walking speed, and thus step length, similarly to motor after-effects (Vasuvaden et al., 2009). We used a virtual reality headset (Oculus Rift) to block visual cues while subjects walked on a treadmill and received feedback about the target step length and their actual step lengths. With this feedback, subjects learned to take three distinct step lengths (short, comfortable, and long). Subject's step length accuracy when feedback unexpectedly only showed 35% of their step length error was used as a proxy for active step length perception. Each subject's perception was measured on the treadmill with both belts moving the same speed before and after two treadmill walking trials: tied- (both belts 1m/s) and split-belt (fast leg 1.5 m/s, slow leg 0.5 m/s). Three groups (n=7 each, 24.4±5 y.o.) differed only in the perception task in order to distinguish the effect of speed and step length on active perception: (1) comfortable (1m/s) walking with short steps, (2) comfortable (1m/s) walking with long steps, and (3) slow walking (0.5m/s) with short steps. Subjects had perceptual shifts such that they overshot all targets with their fast leg and undershot all targets with their slow leg following split, but not tied, walking ($p<0.01$). All groups had similar perceptual shifts ($p=0.99$) indicating that perception doesn't contextualize based on speed or step length, perhaps implying that peripheral sensors or circuits mediate perceptual shifts. Importantly when performance was assessed without visual feedback after training and after split-belt after-effect extinction, all subjects maintained the learned step lengths ($p=0.28$). Unlike perception, motor after-effects (measured step length difference across legs during a short tied-belt trial during adaptation) are larger at slow walking speeds ($p=0.02$; Vasuvaden et al., 2009) even though all groups adapted similarly ($p=0.35$). These results are promising because they imply that split-belt protocols can be tuned for motor outcomes while maintaining perceptual shifts to robustly improve patient's mobility.

Title: Unifying model of savings, interference, and generalization of motor learning in locomotion

Authors: *G. TORRES-OVIEDO, A. SALATIELLO, D. M. MARISCAL
Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Split-belt walking, in which legs move at different speeds, can improve patients' mobility by correcting their gait asymmetry (e.g. Reisman et al 2013). For this strategy to be effective it is necessary to maximize the retention of motor memories acquired on the treadmill and their generalization to over ground walking. It has been shown that errors drive the sensorimotor adaptation process, but also the recall of past motor memories (Herzfeld et al. 2014; Ingram et al. 2017). Here we ask if errors could also serve as contextual cues to develop distinct motor memories within the same environment. To address this question we developed a computational model in which the error experienced when a split perturbation was introduced (i.e., positive error) or removed (i.e., negative error) created distinct motor memories. We found that our model was able to reproduce empirical observations of savings, interference, and generalization in the context of locomotor adaptation. More specifically, it reproduced 1) the faster adaptation rate upon experiencing multiple repetitions of the same perturbation (a.k.a., Savings), 2) the slower adaptation rate when two repetitions of the same perturbation were separated by an opposite perturbation in between (a.k.a., Interference) and 3) the reduced adaptation effects when walking over ground (i.e., untrained context) compared to those walking on the treadmill (i.e., training context). In sum, our results indicate that errors are relevant for the development of motor memories, but also their recall when switching between walking environments.

Title: Computational modeling investigation of phase-dependent responses of spinal motoneurons to afferent stimulation during fictive locomotion

Authors: *S. FUJIKI[1], S. AOI[2], K. TSUCHIYA[2], S. M. DANNER[3], I. A. RYBAK[4], D. YANAGIHARA[1]
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Kyoto university, Kyoto, Japan; [3]Dept. for Neurobio. and Anat., [4]Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Animals walk adaptively in diverse environments by appropriately modulating locomotor behavior based on the sensory information. Locomotion involves the reciprocal activation of flexor and extensor muscles and physiological studies have suggested that these activities are produced by the central pattern generator (CPG) in the spinal cord. Stimulation of peripheral nerves in the legs during fictive locomotion can alter motoneuron burst durations and induce a transition between extensor and flexor motoneuron activities. The difference between these responses mainly depends on the timing of the stimulation (phase dependency). The aim of this study was to elucidate the mechanism of the phase dependency during fictive locomotion in terms of dynamic system theory. We used a previously developed computational model of the CPG consisting of networks of neurons modeled in the Hodgkin-Huxley style to simulate fictive locomotion in the cat. We showed that the model can reproduce the phase-dependent response to the applied stimulation as observed in the physiological experiments. The model was used to investigate and mathematically analyze the mechanism that determines the phase-dependent response through the dynamical structure of the governing equations, such as the changes in the nullclines, the positions of the fixed points, and the eigenvalues around the fixed points.

Title: Interactions between spinal circuits and afferent feedback to control locomotion at different speeds: Insights from computational modeling

Authors: *S. M. DANNER[1], S. AOI[2], S. FUJIKI[3], D. YANAGIHARA[3], I. A. RYBAK[1]
[1]Dept. for Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Aeronautics and Astronautics, Grad. Sch. of Engin., Kyoto Univ., Kyoto, Japan; [3]Dept. of Life Sciences, Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: To survive in a complex, fast-changing environment, legged animals, including mammals, need to be able to quickly change locomotor speed and gait to express required behavior and adapt it to the environment. Recent optogenetic studies in mice have shown that slow locomotion observed during exploration behavior and fast locomotion observed during escape are differently controlled by supraspinal and spinal neural circuits. Yet, differences in control of slow vs. fast locomotion, including interactions between spinal circuits, afferent feedback, and biomechanical properties of the musculoskeletal system, remain poorly understood. We have developed a neuromechanical computational model of hindlimb locomotion in mouse and used it to study the mechanisms of sensorimotor integration and the role of different afferent pathways in the stabilization of locomotion at different speeds and in different environmental conditions. The model includes a neural network model of the spinal circuits controlling and coordinating limb movements, coupled with a 2D musculoskeletal model of the mouse hindlimbs (3 joints and 7 muscles per limb). Each limb is controlled by a two-level central pattern generator (CPG) consisting of a rhythm generator (RG), and pattern formation (PF) network, as well as circuits, mediating basic reflexes and motoneurons actuating hindlimb muscles. In our model, the RGs control the basic locomotor oscillations, commissural interneurons (CINs) mediate left-right interactions between the CPGs, and PF circuits form motor synergies and generate muscle-specific activation patterns. The velocity- (Ia), force- (Ib) and length-dependent (II) feedback from each muscle as well as cutaneous feedback modulate the operation of each CPG, their interactions via CINs, motor synergies formed at the PF level,

and motoneuronal activities. CMA-ES (covariance matrix adaptation evolution strategy) was used to find a pattern of afferent feedback connections to the spinal circuits that provide stable locomotion at different speeds during level and slope walking. The proposed connectome of spinal circuits and the organization of afferent feedback allowed the model to closely reproduce characteristics of mouse locomotion with slow (exploratory) and fast (escape) speeds and to adapt locomotion to unpredictable changes in the environment. Analysis of locomotor disturbances and failures in the model following selective removal of individual intraspinal, commissural or feedback pathways allowed us to suggest the specific role of these pathways in different forms of locomotor behavior and in providing stable locomotion under different conditions.

Title: Computational modeling of brainstem circuits controlling locomotor speed and gait selection

Authors: *N. A. SHEVTSOVA[1], V. CAGGIANO[2], J. AUSBORN[1], S. M. DANNER[1], I. A. RYBAK[1]
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Computat. Biol. Ctr., IBM Res., Yorktown Heights, NY

Abstract: Locomotion is an essential motor activity allowing animals to explore and to survive in complex environments. Depending on the environmental context and current needs quadruped animals including mice can switch locomotor behavior from slow left-right alternating gaits, such as walk and trot (typical for exploration), to higher-speed synchronous gaits, i.e. gallop and bound (specific for escape behavior). Recent studies have shown that the above distinct types of gaits and locomotor behaviors are differently controlled by two brainstem nuclei: the cuneiform nucleus (CnF) and the pedunculopontine nucleus (PPN) (Caggiano et al. 2018). Glutamatergic (Glu) neurons within both of these nuclei contribute to the control of slow, alternating-gait movements, whereas only stimulation of CnF is able to elicit high-speed, synchronous-gait

locomotion. Neurons from both of these regions project to and activate spinal locomotor circuits via descending reticulospinal tracts including the lateral paragigantocellular nucleus (LPGi) (Capelli et al. 2017).
To model and computationally investigate the brainstem control of locomotion, we built upon our previous model of spinal circuits, consisting of four rhythm generators (RGs, each controlling one limb) interacting via networks of local cervical and lumbar commissural interneurons (CINs) and long propriospinal neurons (LPNs) connecting cervical and lumbar compartments (Danner et al. 2017). This model was able to reproduce the experimentally observed speed-dependent gait transitions, but did not include the supraspinal control provided by brainstem circuits. We extended the model to incorporate the bilaterally interacting CnF and PPN circuits and their LPGi-mediated descending pathways to the spinal cord. The suggested organization of synaptic inputs from these pathways to the spinal RGs, CINs and LPNs allowed the model to reproduce the experimentally observed effects of stimulation of excitatory (Glu) and inhibitory neurons within CnF, PPN, and LPGi. Using the model we investigate (a) the involvement of CnF and PPN in the control of low-speed alternating-gait locomotion, (b) the specific role of CnF in the control of high-speed synchronous-gait locomotion, and (c) the roles of inhibitory neurons from the above areas in slowing down and/or stopping. Specifically, the model shows that the suppression of PPN during the CnF stimulation-evoked locomotion leads to the experimentally observed shift of the speed-dependent transition between trot and gallop/bound to lower locomotor speeds.
The model provides important insights into the brainstem-spinal cord interactions and supraspinal control of locomotion.

Title: Intermitted in-phase activity of the crustacean locomotion circuit

Authors: *C. R. SMARANDACHE-WELLMANN[1], L. SCHLAEGER[1], C. ZHANG[2]
[1]Univ. of Cologne, Cologne, Germany; [2]Dept. of Mathematics, Univ. of Arizona, Tucson, AZ

Abstract: Coordination of central pattern generators (CPG) is an important feature accomplished by the nervous system and is responsible for many forms of effective locomotion. Crayfish and other long-tailed crustaceans swim by rhythmically moving limbs called swimmerets. Movements of adjacent swimmerets maintain an approximate quarter-period phase difference, independent of frequency, with the more posterior limbs leading the cycle. The crayfish swimmeret system is one of the very few, if not the only, locomotor systems in which the structure and properties of both the CPG and its coordinating circuit have been clearly identified at the neuron *and* synaptic level, and therefore it provides an excellent model system to investigate the coordination of distributed neural oscillators.
The four pairs of crayfish swimmerets are innervated by a chain of four abdominal ganglia. In each segment (a hemiganglion), a half center oscillator (HCO), consisting of two interneurons with mutual inhibition, controls motor neurons to activate the limbs in alternating cycles of power-stroke and return-stroke. The intersegmental network comprises in each segment three types of neurons: two spiking Coordinating Neurons (ASC_E and DSC) and one Commissural Neuron (ComInt1); together they synchronize the activities of the HCO chain such that neighboring HCOs maintain a quarter-period phase difference.
Recently, we found that the application of 4-Aminopyridine (4-AP), a K^+-channel blocker, on a well-coordinated isolated nerve cord disrupted the normal quarter-period phase-locked coordination pattern and produced intermittent in-phase activity, i.e., the activity switched between periods of tonic activity and periods of in-phase activity of the motor neurons in all segments. Two major changes in the coordinating circuit were observed and analyzed in this condition: first, there was no longer activity in the DSC (the descending coordinating neuron that projects posteriorly), while the activity of ASC_E (the ascending coordinating neuron that projects anteriorly) was intact with the correct timing; second, there was no longer a gradient of synaptic strength from different segmental ASC_E's to ComInt1. Using a mathematical model with added noise, we found that each of the two changes led to a significant decrease in the phase-lag between neighboring segments, and together they replicated the observed in-phase coordination pattern.
The above result suggests that the blocking of K^+ channels in the crayfish swimmeret neural circuit could lead to a complete shift in its coordinating pattern from the natural quarter-period phase-locking to an intermittent in-phase synchronization.

Title: Principles underlying the feedforward control of multi-jointed limbs

Authors: *V. BHANDAWAT[1], C. T.-C. HSU[2]
[1]Biol., [2]Duke Dept. of Biol., Durham, NC

Abstract: The precise control of multi-jointed limbs is central to our ability to perform a vast array of behaviors. Multi-jointed limbs allow an animal to tune its motor output finely, but controlling the many degrees of freedom resulting from multi-jointed limbs is a well-recognized challenge. A central question in motor control is how the nervous system transforms larger behavioral goals into the complex computations necessary for the moment-by-moment control of multi-jointed limbs. Here we employ genetics, *in-vivo* electrophysiology, and quantitative analysis of leg kinematics to determine the respective contribution of circuits in the brain, circuits in thoracic ganglia, and sensory feedback to the generation of limb movements. By manipulating central control and sensory feedback under diverse preparations, we come to four conclusions regarding the control of leg movements in *Drosophila*. First, without sensory feedback from the environment, inter-leg coordination is almost completely disrupted. Second, in contrast to inter-leg coordination, many aspects of intra-leg coordination remain intact. In particular, retraction-protraction (RP) and extension-flexion (EF) are flexibly coordinated by central circuits such that a vast majority of movement epochs can be classified into a small number of discrete movement-types. Third, maintaining this structured movement requires descending inputs from the brain. Fourth, feedback from the environment seems critical for eliciting levation-depression movements which in turn structures movement into alternating stance and swing phases. We use this framework to underpin the role of descending neurons (DNs) from two different parts of the brain in shaping motor output by recording from them while measuring leg kinematics. We find that one class of DNs mediate sensorimotor transformation: they respond to sensory stimuli and mediate movement in a subset of legs. A second class of DNs do not perform specific sensorimotor transformations: they do not respond to any sensory stimuli, and their activity is not dependent on the identity of the leg that is moving. Rather, they respond only when a particular type of movement is executed. In sum, there is a division of labor between feedforward and feedback which represents an elegant solution to the “degrees of freedom” problem.

Title: Activation timing and order in the sequence during rhythmic burst is dependent on cell type of inspiratory neurons in the pre-Bötzinger complex of the mice medulla slice

Authors: *Y. OKE[1], F. MIWAKEICHI[3], Y. OKU[2], J. HIRRLINGER[4], S. HÜLSMANN[5]
[1]Dept. of Physiol., Hyogo Col. of Med., Hyogo, Japan; [2]Hyogo Col. of Med., Nishinomiya, Japan; [3]Dept. of Statistical Modeling, The Inst. of Statistical Mathematics, Tachikawa-Shi, Japan; [4]Univ. of Leipzig, Leipzig, Germany; [5]Georg August Univ. Goettingen, Goettingen, Germany

Abstract: The pre-Bötzinger complex (preBötC) is an important medullary region, which generates spontaneous respiratory rhythm. In the preBötC of rodent medullary transverse slices, rhythmic burst activities can be recorded as local field potential (LFP) as well as using calcium imaging. Interestingly, the activation-order of inspiratory neurons changes stochastically cycle-by-cycle but with loose regularity where a subset of inspiratory neurons appear to cover the initial part of the activation sequence. To analyze the timing of activation and to understand the observed loose regularities, we tested how the neuron type influences its position in the activation sequence using double-transgenic mice expressing EGFP in glycine transporter 2 (GlyT2)-positive neurons and tdTomato in glutamic acid decarboxylase 65 (GAD65)-positive neurons. Based on the maximum cross-correlation (maxCC coefficient) between the neuronal calcium signal of each cell (7 x 7 pixels ROI) and the LFP, we identified 5 groups of inspiratory neurons, that showed, in principle, a different time of activation. We found two groups of respiratory neurons, which showed a large calcium signal with clear waveform (regular type neurons). (1) GlyT2-/GAD65- neurons : regular type excitatory neuron (R-Ex) and (2) GlyT2+/GAD65-: regular type glycinergic neuron (R-Gly). Additionally, there were three groups of neurons showed a small maxCC coefficient and small and short waveform during the rhythmic burst (irregular type neuron): (3) GlyT2-/GAD65-: irregular type excitatory neuron (Irr-Ex) (4) GlyT2+/GAD65-: irregular type glycinergic neuron (Irr-Gly) (5) GlyT2+/GAD65+: irregular type cotransmitting neuron (Irr-Cotrans). Activation of Irr-Ex and Irr-Gly tended to

occur much earlier (e.g. before the peak of LFP) than those of R-Ex and R-Gly. Activation occurrences of Irr-Cotrans spread widely throughout the rhythmic burst and were detected often late. When investigating the order of activation, Irr-Ex was the major cell type activated during the initial phase of the sequence, when many of Irr-Gly were also activated. Activation of R-Ex and R-Gly were rarely observed in this initial phase, while Irr-Cotrans neurons were also activated late in the sequence. We conclude that the stochastic activation-sequence of preBötC-inspiratory neurons depends on the neuron types.

Title: Modulation of spike timing of specific interneurons critical for phase termination by multiple neuropeptides in a small network

Authors: W.-D. YUAN[1], G. ZHANG[1], K. YU[1], Z.-W. LE[1], S.-Y. YIN[1], E. C. CROPPER[2], K. R. WEISS[2], *J. JING[1,2]

Abstract: Neuropeptides are often present in projection interneurons that modulate the excitability of pattern generating (CPG) interneurons which are responsible for terminating specific phases of multiphasic motor programs. Thus, they can alter the nature of the motor output. However, in complex networks, more than one CPG interneuron can be responsible for phase termination. How neuropeptides may target these different CPG interneurons and alter spike timing is not well understood. We address these issues in the feeding circuit of Aplysia. Feeding behavior is biphasic, each cycle consists of radula protraction-retraction phases. Previous work has identified two CPG interneurons, B64 and CBI-5/6, both of which normally fire during retraction, and when activated, terminate protraction. In addition, several neuropeptides, such as FCAP and ALKs, increase B64 excitability to shorten protraction.

However, it is unknown whether and how CBI-5/6 is modulated by neuropeptides. We sought to study apSPTR-GF-DP2, which has recently been shown to shorten protraction, not by acting on B64, but by increasing the excitability of B20. However, B20 is active during protraction and its effects are indirectly mediated. Here, we show that apSPTR-GF-DP2 exerts a direct action by enhancing CBI-5/6 excitability, and by advancing the spike timing of CBI-5/6 during CBI-2-elicited programs. Moreover, when either CBI-12, which contains apSPTR-GF-DP2, or B20 is stimulated together with CBI-2, protraction becomes shorter and CBI-5/6 activity is phase advanced. Both CBI-12 and B20 also increase the excitability of CBI-5/6. Thus, CBI-12 and its peptide (apSPTR-GF-DP2) act both directly (on CBI-5/6) and indirectly (on B20) to shorten protraction, providing an example of a feedforward loop of peptidergic actions. In contrast, neither FCAP nor ALKs enhance the excitability of CBI-5/6. On the other hand, we demonstrate that ALKs advances spike timing of B64 during CBI-2-elicited programs. We conclude that different neuropeptides target distinct interneurons to alter their excitability and change their spike timing, and ultimately, the motor parameters of feeding programs. These findings highlight critical roles of peptidergic modulation of both excitability and spike timing of CPG interneurons in generating diverse motor outputs.

Title: Recruitment of Dbx-1-positive spinal neurons encode speed-dependent behavioral states

Authors: *C. BELLARDITA[1], A. TALPALAR[2], O. KIEHN[2]
[1]Dept. of Neurosci., Copenhagen Univ., Copenhagen N, Denmark; [2]Dept. of Neuroscience, Karolinska, Stockholm, Sweden

Abstract: Dbx-1 positive commissural interneurons (INs) are divided in two subpopulations, the $V0_D$ and the $V0_V$ INs, that are required for left-right alternation at slow speeds of locomotion corresponding to walk or higher speed locomotion corresponding to trot (Talpalar et al. Nature 2013; Bellardita and Kiehn 2015). However, how exactly $V0_D$ and $V0_V$ INs encode left/right alternation during locomotion remains unknown.
To address this issue we have applied combined techniques that allow examination of the

relationship between spatially and temporally coordinated neuronal activity of these interneuron populations during rhythmic locomotor activity. First, we used intersectional mouse genetics and clarity for revealing the anatomical location of the $V0_V$ and $V0_D$ INs in the lumbar spinal cord in E17.5 mice. $V0_V$ INs appeared to have a ventro-lateral position in the ventral horn while the $V0_D$ INs were located dorso-medially. Thereafter, we used calcium imaging and optogenetics in the isolated preparations of the lumbar spinal cord to visualize V0 INs activity and to drive them at different frequencies of fictive locomotion. The calcium dynamics and the optogenetic activation of V0 INs revealed a speed-dependent mode of operation of the spinal circuitries involved in alternation. The majority of the $V0_D$ were activated at low speeds of locomotion followed by the activation of the $V0_V$ at higher speeds of locomotion. Optogenetic activation of V0 neurons strongly modulates rhythm-generation at low speed and this effect tends to decrease as the speed of locomotion increases.
In conclusion, the speed-dependent alternation of limbs necessary for alternating gaits in mice is supported by the speed-dependent recruitment of the V0 INs. A sequential recruitment of the $V0_D$ and $V0_V$ INs support a modular organization of the left-right alternating circuits. The decreased ability of modulating locomotor output by V0 neurons as speed increases support a role of these cells directly modulating the core rhythm-generating circuits.

Title: Diversity of glycinergic V0d interneurons and their function in the zebrafish locomotor circuit

Authors: *L. D. PICTON, R. BJÖRNFORS, A. EL MANIRA
Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: An intrinsic feature of locomotion is the ability to transition between different speeds while maintaining appropriate alternation of limb and axial muscles. While key circuit mechanisms for speed control have been revealed in adult zebrafish, those controlling reciprocal alternation remain unclear. A study in mice has suggested that inhibitory commissural interneurons (V0d) control limb alternation at slow speeds, whilst excitatory commissural interneurons (V0v) take over at faster speeds. In adult zebrafish, most V0v interneurons are recruited only during fast swimming, yet little is known about the adult V0d population. Here,

we characterise the glycinergic V0d population in zebrafish. There were ~10 V0d interneurons per spinal hemi-segment, significantly fewer than other interneurons in the swim network. Targeted patch-clamp recordings in larvae revealed a majority of V0d interneurons to be recruited only during fast swimming. By contrast, in adult zebrafish, our analysis revealed three main V0d classes - fast, intermediate, and slow - which are recruited at their respective swim speeds and displayed partially overlapping electrophysiological profiles. However, we found an overall predominance of slow-type V0d interneurons, in contrast to the larva. Furthermore, the axon projections and dendritic trees of adult V0d interneurons were heterogeneous, even within classes, suggesting both functional and anatomical changes during development. To test the overall function of the adult V0d population we performed 2-photon ablations of 20-40 V0d interneurons across 5 spinal segments and recorded contralateral, back-labelled motoneurons (MNs). Preliminary evidence showed that midcycle inhibition was sustained only briefly during a swim episode, before reducing in amplitude such that MN firing became tonic and a coordinated swim pattern collapsed. Finally, our analysis identified two distinct, apparently specialised, V0d subtypes in the adult. Each occupies a specific position in the outermost (dorso-medial and ventro-lateral) locations of the spinal cord, and displayed a stereotyped morphology, electrophysiological profile, and activity pattern that all indicate that they may be specialised for escape. Overall, we show that the zebrafish V0d interneuron population undergoes considerable developmental changes in function and morphology, from a relatively homogenous population contributing to fast swimming, to a more heterogeneous population largely involved in slow swimming but supplemented by specialised subtypes. In the adult, the V0d population appears to be critical for the appropriate maintenance of locomotion.

Title: Coordinated control of locomotor speed, arousal, and hippocampal theta rhythms by the nucleus incertus

Authors: *L. LU, Y. REN, T. YU, Z. LIU, L. TAN, J. ZENG, Q. FENG, R. LIN, R. WANG, Y. LIU, Q. GUO, M. LUO
Natl. Inst. of Biol. Sci., Beijing City, China

Abstract: When navigating at fast speed through a complex environment, an animal not only needs to execute locomotor programs but also requires higher arousal to attend to rapidly changing environmental cues and retrieves spatial associations from memory that is often associated with hippocampal theta oscillations. However, it remains unclear how these important behavioral and physiological processes are coordinately controlled. Here we show that the neuromedin B (NMB) neurons in the nucleus incertus (NI) of the dorsal pons coordinately control locomotor speed, pupil-linked arousal levels, and hippocampal theta rhythm. Cell type-specific fiber photometry revealed that the activity of NI NMB neurons is tightly correlated with mouse locomotor speed, pupil size, and hippocampal theta power. These processes were reversibly suppressed by optogenetic inhibition and rapidly promoted by optogenetic activation of NI NMB neurons. Finally, anatomical and physiological dissections revealed that the NI NMB neurons provide mainly GABAergic output and form reciprocal connections with several subcortical areas associated with arousal, motivation, and premotor processing. Our experiments thus suggest that the NI—an evolutionarily conserved brainstem nucleus—is strategically located within the neural circuit for navigation control according to particular brains states.

Title: Assessment of parkinson`s disease through clinical and demographic data

Authors: *A. SAIKIA[1], V. K. PANDEY[1], S. PAUL[1], M. HUSSAIN[2], A. R. BARUA[3]
[1]Biomed. Engin., North Eastern Hill Univ., Shillong, India; [2]Dept. of Neurol., North Eastern Indira Gandhi Regional Inst. of Hlth. and Med. Sci., Shillong, India; [3]Dept. of Neurol., Guwahati Neurolog. Res. Ctr., Guwahati, India

Abstract: Parkinson disease (PD) is a progressive neurologic condition that causes motor and non-motor manifestations. Treatment provides symptomatic benefit but no current treatment has been proven to slow disease progression. Research studies of PD require a means of rating the

severity of disease by measurement of motor manifestations, assessment of ability to perform daily functional activities, and symptomatic response to medication. The work presented in this paper emphasize on some of the clinical and demographic data's collected from 16 subjects out of which 8nos were PD subjects and 8nos were control subjects. Different rating scales like Mini mental State Examination, Webster Scale, Geriatric Depression Scale, and Unified Parkinson's Disease Rating Scale were used for the clinical assessment of the subjects. Some of the demographic data's were also collected. They were: age, gender, occupation, and exposure to environmental factors like well water drinking, dietary habit, smoking, intake of alcohol, insecticides, pesticides etc, and family history of PD. It was found that above mentioned scales are very much useful with combination of demographic data to detect Parkinson's disease in the early stages and that can lead to benefit for modern diagnostic tool.

Title: Streptozotocin-induced diabetes causes crucial morphological changes in abdominal motoneurons and muscles of rats

Authors: *N. OSHIRO[1], K. MURAMATSU[1], T. TAMAKI[2], M. NIWA[1]
[1]Kyorin University, Fac. of Hlth. Sci., Mitaka-city, Tokyo, Japan; [2]Hlth. Sci. Univ., Yamanashi, Japan

Abstract: Diabetic neuropathy (DN) is a major complication of diabetes. Although it is well-established that DN targets sensory and autonomic nerves, little is known about its influence on motor disorders. This study investigated morphological alterations in abdominal (Abd) motoneurons and muscles of experimental type I diabetic rats. Alterations in the number and size of Abd motoneurons were studied using retrograde labeling techniques in diabetic rats 6 or 14 weeks after injection of streptozotocin (diabetic group). Age-matched control animals were labeled at 6 or 14 weeks after saline injection (control group). Further, the thicknesses of the external oblique, internal oblique, transversus abdominis (TA), and rectus abdominis (RA) muscles were similarly examined and the cross-sectional area of the TA myocytes was measured. The mean number and the mean soma diameter of labeled Abd motoneuorns tended to decrease

in diabetic group. The mean number in L1 and mean size of cell bodies in T13 and L1 significantly decreased in the diabetic group compared with the control group ($P < 0.05$). In the diabetic group, there was a clear decrease in muscle thickness except for RA muscle and in the cross-sectional area of the TA myocytes ($P < 0.05$). The main component of these alterations might be loss of the cell bodies of larger motoneurons, or shrinkage of the cell bodies of larger motoneurons and loss of smaller motoneurons. We suggest that the hyperglycemia could induce the reduction of number and size of Abd motoneurons and caused an atrophy of Abd muscles. Therefore, it could be expected that disorders will start at 6 weeks of diabetes and be related to a wide range of disorders such as those involved with expiratory, defecation function, and trunk movement.

Title: miR-138 controls motor behavior and neuronal spine morphology *in vivo*

Authors: *M. ÅKERBLOM[1], J. CHERONE[2], C. BURGE[2], M. MCMANUS[3]
[1]UCSF Diabetes Ctr., San Francisco, CA; [2]MIT, Cambridge, MA; [3]Univ. of California, San Francisco, San Francisco, CA

Abstract: Dendritic spines are small protrusions from the neuronal dendritic shaft that receives inputs from excitatory axons. Neuronal spines are dynamic, heterogeneous in morphology and play a role in synaptic plasticity. Understanding how spine morphology is regulated is crucial for determining how neurons integrate and generate information. miR-138 is highly expressed in the mouse central nervous system, yet the *in vivo* role of miR-138 has not been investigated. In this work we describe the generation and characterization of miR-138-1/miR-138-2 double knock out (DKO) mice. DKO mice exhibited a number of phenotypes and importantly, performed less well compared to WT controls in a set of motor behavioral tests. To further characterize these defects, we analyzed tissues at the whole mount and histological level. DKO brains weighed significantly less than age-matched controls and sectioning of the DKO brains revealed a thinner width of the motor cortex. Although we detected no differences in number of cells in the motor cortex, the number of stubby spines was significantly greater in DKO mice, and the total number of thin spines decreased. RNA sequencing of motor cortex from WT and DKO mice revealed differences in RNA levels, laying a solid foundation for exploration of molecular mechanism. We hypothesize that the observed motor deficiencies might be due to alterations in spine

morphology in the brain, particularly in the motor cortex. Spine alteration is an important substrate in the pathogenesis of motor disorders as well as neurological disorders such as amyotrophic lateral sclerosis, schizophrenia and Alzheimer's disease. New findings on spine morphology regulation may provide insight into etiologies and therapy. Overall, these data demonstrate an important and as-yet undefined role for miR-138 in the mammalian brain and raise important questions about noncoding RNA roles in human disease.

Title: Gender and age peculiarities of electromyographic indices in qualified rowing athletes

Authors: *E. V. KOLOSOVA[1], A. V. GORKOVENKO[2]
[1]Natl. Univ. of Physical Educ. and Spor, Kyiv, Ukraine; [2]Movement Physiol., Bogomoletz Inst. of Physiol., Kyiv, Ukraine

Abstract: Introduction. At the present time the problem of educating locomotory skills draws researchers attention due to the large amount of novel facts of brain motor cortex and spinal cord structures plasticity. Electromyographic (EMG) study allows to assess peculiar pattern of inhibition and excitation processes in intrasegmental systems and also to determine the kind of descending influences from motor cortex to segmental spinal motoneuronal pool. It was reported that there were certain specificities of the EMG indices shown by athletes performing different sports. At the same time, influence of gender and age factors on neuromuscular apparatus state remains insufficiently studied. **Purpose.** The objective of the research was to assess gender and age-related peculiarities of EMG indices in qualified rowing athletes. **Materials and methods.** Fifty two athletes-rowers (27 men and 25 women, 17-33 years of age, M_{age}=21.4, SD=3.9) took part in this EMG-study. The method of H (Hoffmann) reflex of soleus muscle and the median nerve conduction velocity (NCV) method were performed at both body sides using neurodiagnostic complex Nicolet Biomedical Viking Select (Viasys Healthcare, USA). Three-factor analysis of variance considering two between-subjects factors (sex and age) and one within-subjects factor (body side) was carried out in the SPSS 17.0. **Results and discussion.** It was found that the sex factor had significant effect on values of the H- and M-responses thresholds (F=5.736, P=0.021; F=7.632, P=0.008 respectively), which were higher in women than in men. This might be due to thicker subcutaneous fat tissue in female body. The sex factor also had effect on values of the H- and M-responses magnitudes (F=5.336, P=0.026; F=7.317,

P=0.010), which were smaller in women than in men. This might be the evidence of less muscle weight and muscle fiber volume in women comparing with men. In young athletes the gender difference of the M-responses magnitude was greater than in adults (the interaction of sex and age factors F=4.071, P=0.050). Although all three factors had no significant effect on median motor NCV, median motor proximal and distal amplitudes were higher at the right side of the body (F=4.950, p=0.032; F=11.247, p=0.002 respectively). Such differences might be due to adaptative neuromuscular system reactions under the influence of longterm physical activity. **Conclusion.** Obtained data demonstrate plasticity of neuromuscular system structures, associated with genetical determination and adaptative reactions to a physical exercise. It is assumed that gender and age should be considered during the electromyographic investigation of human neuromuscular system.

Title: Sensory innervation of the human soft palate

Authors: *J. CHEN[1], L. MU[2], J. LI[2], T. NYIRENDA[2], S. SOBOTKA[2,3]
[1]Res., [2]Biomed. Res., Hackensack Univ. Med. Ctr., Hackensack, NJ; [3]Otolaryngology and Urology, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The human soft palate plays an important role in respiration, swallowing, and speech. These motor activities depend on reflexes mediated by sensory nerve endings. To date, the details of human sensory innervation to the soft palate have not been demonstrated. In this study, eight adult human whole-mount (soft palate-tongue-pharynx-larynx-upper esophagus) specimens were obtained from autopsy. Each specimen was bisected in the midline, forming two equal and symmetrical halves. Eight hemi-specimens were processed with Sihler's stain, a whole-mount nerve staining technique. The remaining eight hemi-soft palates were used for immunohistochemical study. The soft palatal mucosa was dissected from the oral and nasal sides and prepared for neurofilament staining. Our results showed that the sensory nerve fibers formed a dense nerve plexus in the lamina propria of the soft palatal mucosa. There was a significant difference in the innervation density between both sides. Specifically, the oral side had higher density of sensory nerve fibers than the nasal side of the soft palate. The mean number and

percent area of the sensory nerve fibers in the mucosa of the nasal side was 78% and 72% of those in the mucosa of the oral side, respectively (P <0.0001). The data presented here could be helpful for further investigating the morphological and quantitative alterations in the sensory nerves in certain upper airway disorders involving the soft palate such as obstructive sleep apnea (OSA) and for designing effective therapeutic strategies to treat OSA.

Title: Modulation of post-contraction potentiation in the central nervous system

Authors: *T. ISHII[1], S. SASADA[2], S. SUZUKI[3], T. KOMIYAMA[1]
[1]The United Grad. Shcool of Educ., Tokyo Gakugei Univ., Tokyo, Japan; [2]Dept. of Food and Nutr. Science, Sagami W, Sagamihara/Kanagawa, Japan; [3]Hlth. Sci. Univ. of Hokkaido, Hokkaido, Japan

Abstract: Surface electromyogram (EMG) activities of the biceps brachii (BB) during a weak elbow flexion are reported to increase immediately after a strong (25 or 50% maximum voluntary contraction [MVC]) elbow flexion is exerted. This phenomenon is called “post-contraction potentiation (PCP)” and has been thought to be driven by an acute modulation in the central nervous system. However, the underlying mechanisms have not been determined. To address this issue, we investigated the PCP phenomenon using transcranial direct current stimulation (tDCS). A total of 44 healthy volunteers, aged 21–30 years and with no history of neurological diseases, were enrolled in this study. In Experiment 1 (Exp 1), the participants were asked to consecutively perform 2 % (test contraction, TEST 1), then 25, 50 or 100 % (conditioning contraction [CC]), and again 2 % (TEST 2) MVC contraction with a visual feedback of force. EMG was recorded from the right biceps brachii (BB). In experiment 2 (Exp 2), the CC was performed only at a 50 % MVC, but the sequence of contractions was the same as that in Exp 1; before the task, tDCS was applied to the BB area of the motor cortex (2 mA) for 15 min with 3 different polarities (anodal, cathodal, and sham). In experiment 3 (Exp 3), the sequence of contractions was the same as that in Exp 2, but the participants were asked to perform 2 % EMG (TEST 1 and 2) with a visual feedback of the BB EMG. In Exp 1, in three different CC conditions, the EMG activity was significantly increased during TEST 2 compared with during TEST 1. However, there was no significant difference in the EMG activity for TEST

2. In Exp 2, the EMG activity during TEST 2 was decreased after anodal tDCS but increased after cathodal tDCS, compared with after sham tDCS. In Exp 3, when the visual feedback of the BB EMG was administered during the task, the force was significantly decreased during TEST 2 compared with during TEST 1. Frequency power spectrum analysis showed that the power of 10 Hz and 20 Hz band was significantly increased during TEST 2 compared with during TEST 1. The present findings suggest that the motor cortex plays a role, at least partially, in generating PCP and that the change in the excitability in the central nervous system may modify the firing rate of the motor unit.

Title: The ergogenic effects of caffeine depend on neuronal $A_{2A}R$

Authors: *A. S. AGUIAR, JR[1], A. E. SPECK[2], P. M. CANAS[3], R. A. CUNHA[4]
[1]Hlth. Sci., Univ. Federal de Santa Catarina, Araranguá, Brazil; [2]Pharmacol., Univ. Federal de Santa Catarina, Florianópolis, Brazil; [3]Ctr. for Neurosci. and Cell Biol., [4]CNC -Center For Neurosci. and Cell Biol., Univ. of Coimbra, Coimbra, Portugal

Abstract: Ergogenic aid is a substance or method used for enhancing exercise and sports performance. The efficacy of many of these techniques is controversial. Caffeine is the most used ergogenic aid for amateur and professional athletes; the ergogenic effects of caffeine are clear and very well documented. However, the mechanisms of action have not yet been clarified, currently limited to three hypotheses. The increased (1) intracellular Ca^{+2} mobilization and (2) cAMP activity were only demonstrated at toxic mM concentrations. At non-toxic concentrations (uM), caffeine acts as an antagonist of adenosine receptors. First, we evaluated the ergogenic and thermogenic effect of caffeine (a non-selective antagonist of $A_{2A}R$) and SCH-58261 (a selective antagonist of $A_{2A}R$) on WT mice. Then we confirm the role of $A_{2A}R$ in forebrain knockout mice. Thirty-four adult male mice (23±0.4 g body weight, 10-12 weeks old) from a forebrain $A_{2A}R$ knockout colony were used. The animals underwent a period of familiarization on the treadmill (3 days x 10 min, 15 cm/s, 5°, saline i.p) for ergospirometry (running power and respiratory

gases - O_2 and CO_2) on the 5th day. Caffeine (15 mg/kg, i.p., -15 min) and SCH 58261 (1 mg/kg, i.p., -15 min) were administered on the 4th day of open field behavioral task (15 min) and on the 5th day of ergospirometry. The animals ran at increasing speeds until they reached exhaustion. The temperature at rest and after exercise was evaluated by IR thermography. The animals were perfused for immunohistochemistry of prefrontal cortex. Caffeine and SCH-58261 were psychostimulant (distance and average speed) for WT animals in the open field, but not for forebrain-A_{2A}R-KO animals. Caffeine and SCH-58261 were ergogenic for WT mice, that is, they increased 41.4±7.2% and 57.2±10.7% the running performance on the incremental running test. In addition, caffeine and SCH-58261 also increased 37±8.3% and 36.4±13.3% $\dot{V}O_2$max in WT mice, respectively. $\dot{V}CO_2$ had similar kinetics. But caffeine unchanged running power, submaximal and maximum $\dot{V}O_2$ and $\dot{V}CO_2$ of forebrain-A_{2A}R-KO animals. Acute physical activity increased cFos density in the prefrontal cortex of the animals. The different genotypes and treatments did not modify the body and tail temperature at rest and exercise-induced hyperthermia. Extracellular electrophysiology and high-resolution respirometry in striatum slices demonstrated the psychostimulant effects of caffeine. Our results suggest that the ergogenic effects of caffeine are mediated by A_{2A}R in the central nervous system.

Title: Neuronal preservation and reactive gliosis attenuation following neonatal sciatic nerve axotomy by a fluorinated cannabidiol derivate

Authors: *A. L. OLIVEIRA[1], M. PEREZ[2], L. P. CARTAROZZI[3], G. CHIAROTTO[4], F. S. GUIMARAES[5]
[1]Univ. of Campinas - Lab. of Nerve Regeneration, Campinas, Brazil; [2]Unicamp, Campinas, Brazil; [3]Anat., UNICAMP, Campinas, Brazil; [4]Univ. of Campinas, Campinas, Brazil; [5]Sch. Med. Ribeirao Preto-Usp, Ribeirao Preto, Brazil

Abstract: Lesion to the immature peripheral nervous system, such as the transection of a peripheral nerve, results in extensive degeneration of motoneurons and dorsal root ganglia (DRG) sensory neurons, mostly by apoptotic events. We have previously shown that cannabidiol

(CBD), the most abundant non-psychotropic molecule present in the *Cannabis sativa* plant, exhibits neuroprotective action when daily administered at a dose of 15mg/Kg. The present work shows that the use of 4'-fluoro-cannabidiol, HUF-101, a fluorinated synthetic version of CBD, significantly improves neuronal survival by 2-fold with only one-third of the dose. Furthermore, we show that HUF-101 administration significantly upregulates anti-apoptotic genes and block pro-apoptotic nuclear factors expression. Two-day-old Wistar rats were subjected to a unilateral section of the sciatic nerve and daily treated with HUF-101 (1, 2.5, 5 mg/Kg/day, i.p.) or vehicle solution for five days. The results were evaluated by Nissl staining, immunohistochemistry, and qRT-PCR. Neuronal counting revealed 47% rescue of spinal motoneurons and 79% of DRG neurons (HUF-101, 5mg/Kg). Such survival was associated with complete depletion of p53 and an elevation of 60-fold of BCL2 like 1 gene expression. Also, peroxisome proliferator-activated receptor gamma (PPAR-gamma) gene expression was downregulated by 80%. Neuronal preservation was coupled with a reduction in astroglial and microglial reaction evaluated nearby spinal motoneurons present in the ventral horn of the lumbar intumescence, and also higher preservation of synaptic covering. Overall, the current data strongly indicates the HUF-101 has potent neuroprotective effects, and such properties are particularly related to anti-apoptotic protection and reduction of astrogliosis.

Title: Activation of 5-HT_{2A} receptor enhances function of GluN2A-containing NMDA receptor via Src kinase in dendrites of rat jaw-closing motoneurons

Authors: M. DANTSUJI[1], S. NAKAMURA[1], K. NAKAYAMA[1], A. MOCHIZUKI[1], S. PARK[4], Y. BAE[4], M. OZEKI[2], *T. INOUE[3]

Abstract: Jaw-closing masseter motoneurons (MMNs) receive both glutamatergic and 5-HT input, though the effect of 5-HT on glutamatergic input to MMN dendrites remains unknown. We examined the effects of 5-HT on glutamatergic responses in the dendrites of MMNs evoked by single- or two-photon laser photolysis of caged glutamate in brainstem slice preparations obtained from neonatal rats on postnatal day 2-5. Application of 5-HT induced membrane depolarization and enhanced glutamate responses. Furthermore, the 5-HT_{2A} receptor (5-HT_{2A}R) agonist TCB-2 mimicked enhancement of those glutamate responses, which was antagonized by ketanserin, a 5-$HT_{2A/2C}$R antagonist. In contrast, the 5-HT_{2B}R agonist BW723C86 and 5-HT_{2C}R agonist MK212 had no effect on glutamate responses. Blockade of NMDA receptors (NMDARs) by APV, but not AMPA receptors by NBQX, abolished 5-HT-induced enhancement. Furthermore, incubation with 5-HT significantly increased Src phosphorylation at tyrosine residue 416, while addition of the Src kinase inhibitor PP2 reduced 5-HT-induced enhancement. TCB-2 also enhanced NMDAR currents evoked by glutamate uncaging, whereas TCB-2-induced enhancement of NMDAR currents was abolished by the GluN2A antagonist PEAQX, but not the GluN2B antagonist ifenprodil. Additionally, glutamate responses evoked by two-photon uncaging of glutamate were enhanced when the uncaging loci were restricted to the vicinity of the puffed loci of TCB-2. Electron microscopic immunohistochemistry findings revealed that NMDARs and 5-HT_{2A}Rs were in close proximity to each other in the same dendrite. These results suggest that activation of 5-HT_{2A}Rs enhances the function of GluN2A-containing NMDAR in the vicinity via Src kinase. Such enhancement of glutamate responses by 5-HT may contribute to wide-ranging regulation of contractile forces of jaw-closing muscles.

Title: Structural changes in spinal cord of newborns with muscle hypertonia after antenatal hypoxia-ischemia in rabbit cerebral palsy model

Authors: *A. DROBYSHEVSKY, S. SYNOWIEC, I. GOUSSAKOV
Pediatrics, Northshore Univ. Hlth. Syst. Res. Inst., Evanston, IL

Abstract: Newborn rabbit kits after global antenatal hypoxic-ischemic (H-I) injury exhibit motor deficits similar to humans with cerebral palsy, including muscle hypertonia. We previously reported that muscle hypertonia in newborns increased was associated with spinal circuit excitability and injury to descending white matter tracts. In the current study we tested several putative mechanisms previously implicated in spinal hyper- excitability in perinatal brain and spinal cord injury. Newborn P1 rabbit kits after E25 global hypoxic-ischemic brain injury with and without muscle hypertonia and naïve controls were used. Newborn kits received intramuscular injection of cholera toxin fluorescent conjugates to investigate primary afferents and motor neurons morphology. Motor neurons dendritic tree was examined using Sholl analysis on Golgi staining. Microglia activation and astrogliosis was examined on immune-stained cord sections with stereological methods. PCR and western blot of KCC2 transporter expression was performed during normal development at several time points and in newborns after injury. We found that motor neuron soma sizes and primary afferent density were not different between rabbit kits with and without hypertonia, either in neurons projecting to flexor or extensors muscles, in cervical or lumbar cord. Length of dendritic tree and ramification index were also not changed after H-I. Initially low KCC2 protein content in fetal naïve rabbit increased 6 fold after birth, reached maximum around P5-P11 and then declined with maturation. At P1, gene expression of KCC2 was lower in hypertonic kits, but the protein content was not different between the control and hypertonic groups either in cervical or in lumbar cord. While microglia was mostly present in activated form in control and hypertonic kits, we did not find difference in microglia numbers between the groups. There was a significant increase in astroglia in hypertonic group. In conclusion, we did not find structural evidence for increased primary afferent or dendritic tree size branching or motor neuron soma size that may explain spinal excitability and muscle hypertonia in rabbits after antenatal H-I. Since the phenotype is observed already in newborns we conclude that KCC2 is also unlikely related to motor deficits in the rabbit model, as previously suggested mechanism of spasticity in spinal cord injury. Astrogliosis, observed in hypertonic kit, may play a role in muscle hypertonia.

Title: Predicting disease stage specific spinal motor neurons and glia in sporadic ALS

Authors: *F. SONG[1], F. DACHET[1], J. LIU[1], J. M. RAVITS[2]
[1]Dept. of Neurol. and Rehabil., Univ. of Illinois at Chicago, Chicago, IL; [2]Neurosciences, Univ. of California San Diego Dept. of Neurosciences, La Jolla, CA

Abstract: Background: Recent observations of the location and spread of motor neuron degeneration in sporadic amyotrophic lateral sclerosis (sALS) patients suggests that neurodegeneration is radially graded, and regions of minimal motor neuron loss are remote from site of onset. Increasing evidence shows that neuroinflammation mediated by activated glia and infiltrated immune cells is involved in the progression. However, the mechanism of interaction between activated glia and motor neuron degeneration is unclear. **Objectives:** To determine the relationship between disease stage specific motor neurons and glial activation in sALS. **Methods:** We applied new bioinformatics tools to identify transcriptional profiles established by exon microarrays of motor neurons collected remote from site of onset with glia in the very close surrounding microenvironment by laser capture microdissection. We identified the relationship between motor neurons and glia from 12 sALS and 10 control patients. **Results:** Due to highly consistent and exact - inverse patterns of gene cluster being observed, we identified 5 clusters of co-expressed genes in sALS samples and 3 clusters in controls. Cellular interactome showed three stages of motor neurons interacting with different glia. Stages 2 and 3 motor neurons and groups 1 and 2 microglia/macrophage presented in sALS patients. While increased microglia/macrophage1 correlated best with decreased stage 2 motor neurons, the increased microglia/macrophage2 correlated best with decreased stage 3 motor neurons in 12 sALS patients. Increased MHC class II genes positively correlated with these increased groups 1 and 2 microglia/macrophage, suggesting they are activated. Tissue staining confirmed significantly increased microglia/macrophages activation in connection with motor neurons in the less affected microenvironment in sALS. The disease course in individual sALS patients inversely correlated with the quantity of stage 3 motor neurons. Identified gene pathways and biological changes included antigen processing and presentation and immune cell activation in microglia/macrophages, and induction of apoptosis and protein phosphorylation in stage 3 motor neurons. **Conclusions and discussion**: While the exact mechanism of how activated microglia/macrophages promote neurodegenerative progression is unclear, the new findings support the hypothesis that neuro-glia physical interactions are important in the ALS pathologic process, and targeting stage specific motor neurons and/or glia could be a useful therapy to slow disease progression in patients with sALS.

Title: Effects of pharmacological agents administered for swallowing disorders on swallowing motor activity in nerves innervating infrahyoid and laryngeal muscles

Authors: T. MORIYA[1], K. NAKAYAMA[2], S. NAKAMURA[4], *A. MOCHIZUKI[3], T. SHIROTA[1], T. INOUE[5]
[2]Dept. of Physiol., [3]Dept. of Oral Physiol., [1]Showa Univ. Sch. of Dent., Tokyo, Japan; [4]Showa Univ., Tokyo, Japan; [5]Showa Univ. Sch. Dent., Tokyo, Japan

Abstract: Swallowing disorders are associated with increased risk of aspiration pneumonia, and often occur following acute cerebral infarction as well as in individuals with Parkinson's disease. Delayed triggering of the swallowing reflex has been reported in patients with damaged basal ganglia, who also exhibit impairments of dopamine and substance P metabolism. Thus, pharmacological agents that elevate dopamine and substance P concentrations have been suggested to prevent aspiration pneumonia and improve impaired swallowing processes. However, little is known about the effects of such agents on swallowing activities induced in motor nerves innervating the pharyngeal muscles. In the present study, we examined the effects of imidapril hydrochloride and cilostazol, often prescribed for swallowing disorders, on swallowing motor activity. Experiments were performed using arterially perfused decerebrate rats aged from postnatal day 21-33. We recorded efferent nerve activity in the vagal nerve (VN), hypoglossal nerve (HGN), and phrenic nerve (PN) using suction electrodes. Inspiratory motor discharges in each of those nerves were observed and occurred in a synchronous manner. Injection of 2.7 ml of distilled water into the oral cavity consistently inhibited inspiratory discharges in all of those nerves, and evoked synchronized swallowing burst discharges in the VN and HGN. Administration of imidapril (60 ng/ml) or cilostazol (2.5 μg/ml) to the perfusate increased the mean peak amplitude of orally evoked swallowing discharges in the VN, while the peak amplitude in the VN decreased over time in the non-administration group. The mean peak amplitudes of swallowing discharges normalized according to the amplitude of discharges preceding drug administration in both the imidapril and cilostazol administration groups were

significantly greater as compared to the non-administration group [imidapril (n=5): 116.0±15.6%, *P* = 0.017; cilostazol (n=8): 112.6±13.0%, *P* = 0.005; non-administration (n=5): 70.2±17.6%]. In contrast, neither imidapril nor cilostazol caused a significant change in swallowing activity frequency or burst duration. These results suggest that both imidapril and cilostazol administrations may improve impaired swallowing increasing pharyngeal muscle activities.

Title: Intramuscular injections of botulinum toxin cause axotomy-like changes in C-boutons on spinal motoneurones of adult rats

Authors: *C. F. MEEHAN, S. KLINGENBERG, D. B. JENSEN, K. P. DIMINTIYANOVA, J. WIENECKE
Univ. of Copenhagen, Kobenhavn N, Denmark

Abstract: Large cholinergic boutons (C-boutons) on α-motoneurones are important modulators of neuronal excitability. Their activation increases excitability by decreasing action potential afterhyperpolarization (AHP). Experiments indicate that axotomy results in loss of C-boutons, which is consistent with studies reporting a prolongation of the AHP in fast spinal motoneurones following axotomy. Similar electrophysiological changes are also observed after intramuscular injections of Botulinum Toxin (Botox), including a prolongation of the AHP. The aim of the current experiments was therefore to investigate whether similar changes in C-bouton number or size could explain the AHP prolongation following intramuscular Botox administration.
In one group of 7 adult male Wistar rats, unilateral injections of Botox (mixed with the tracer Cholera Toxin subunit B conjugated to Alexa Fluor 488) were made into the gastrocnemius muscle. In a second group of 7 rats, the tibial nerve was dissected and the tracer was injected into the cut distal stump. Immunohistochemistry for vesicular acetylcholine transporter was used to detect C-boutons of labelled spinal motoneurones under these conditions and contralateral gastrocnemius motoneurones were used as internal controls. C-boutons were analysed on 102

axotomized motoneurones with 92 contralateral control motoneurones and 135 Botox motoneurones with 118 contralateral controls. All analysis was performed with blinding.
At 2 weeks post-axotomy we observed a significant decrease in C-bouton number by 40.4% ($P<0.0001$, n=194 cells). Linear regression confirmed that the number of C-boutons was influenced by soma size which itself was significantly decreased for axotomised motoneurones by 7.9% ($P=0.001$). The elevation of these regression slopes (soma size X C-bouton number) was significantly different confirming that the reduction in C-bouton number occurred irrespective of soma size. A significant difference was also found with respect to both C-bouton surface area by 23.4% ($P<0.0001$) and volume by 31.6% ($P<0.0001$). At 2 weeks post-Botox administration there was no significant difference in the number of C-boutons ($P=0.17$) but there were significant reductions in C-bouton surface area by 12.2% ($P=0.001$) and volume by 18.6% ($P=0.0008$).
This demonstrates that Botox administration results in somewhat similar but less extreme changes to C-boutons than observed post-axotomy. This is consistent with the electrophysiological changes in AHP that have been reported following both interventions.

Title: The role of fscn1 in peripheral nerve regeneration

Authors: *T. OMURA[1], D. XU[2], Y. MIHARA[1], T. BANNO[1], A. OKAMOTO[1], Y. MATSUYAMA[1]
[1]Hamamatsu Univ. Sch. of Med., Hamamatsu, Shizuoka, Japan; [2]Orthopaedic Surgery, Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Through phenotypical analysis if axonal growth and full-genome expression profiling of nine genetically diverse inbred mouse strains, we found the potential role of fascin actin-bundling protein 1 (fscn1) in peripheral nerve regeneration. The purpose of the study was to examine the role in fscn1 using dorsal root ganglion (DRG) primary cultured neuron. Naïve and conditioned (sciatic nerve transection 5 days prior to harvest) L4 and 5 adult DRG from 8 weeks old C57BL/6 were grown and assayed on laminin coated plates. To evaluated whether fscn1 is necessary for axonal growth, we cultured conditioned DRG neurons for 15 hours in the presence or absence of FASCIN-G2(Xcess Biosciences In), a potent fscn1 antagonist at a concentration of

25, 50 (IC50), 75μM. Total axonal growth per neurons, longest neurite length and number of sprouting axons were cells were analyzed using NeuroMath and compared between the fscn1 treated group and the vehicle control group. With naïve DRG neurons, we confirmed significant reduction of total axonal growth and the longest neurite length with 50 and 75μM in a dose dependent manner. Similarly, conditioned neurons also exhibited significant decrease of total axonal growth longest neurite length with a concentration of 50 and 75μM. However, the number of sprouting axons was not affected by the inhibition of fscn1. The loss of function study using fscn1 inhibitor revealed that fscn1 is required for axonal elongation, but does not affect axonal sprouting. This is essential for clinical application as the increase in the total length and the extent of axonal growth is critical for faster innervation and improved recovery for the treatment of peripheral nerve injury, but additional sprouting may cause misdirection and co-contraction. We conclude that fscn1 is important for peripheral nerve regeneration.

Title: Fatigue-associated changes in estimates of persistent inward current in human motor neurons

Authors: C. T. COMPTON, N. K. CECIRE, *J. M. KALMAR
Dept. of Kinesiology, Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: Neuromuscular fatigue is associated with reduced supraspinal drive. Similarly, intracortical facilitation and muscle activation are reduced following concussion. Both fatigue and mild traumatic brain injury are associated with increased noradrenergic and serotonergic activity in animal models. Given that monoaminergic-dependent persistent inward currents (PIC) set spinal motor neuron (MN) gain, we speculate that PIC will increase during fatigue to compensate for supraspinal hypoexcitability and that this will be more pronounced in people with concussion. PURPOSE: To assess spinal MN excitability during fatigue in people with concussion and healthy controls. METHODS: 20 participants (10 concussion, average age 22.05 ± 2.25) completed two experimental sessions on two separate days (fatigue and rest, randomized and counterbalanced). On the fatigue day, paired motor unit analysis was used to estimate soleus

motor neuron PIC, before, during, and after an isometric plantarflexion fatigue protocol (5 sets of 50 3-s ankle plantarflexion contractions at 50% of maximal voluntary contraction). Excitability of the soleus motor neuron pool was assessed at rest using slopes of the H reflex recruitment curve before and after the protocol. On the rest day, estimates of PIC and H reflexes were made at the same time points, but the fatiguing contractions were omitted. A mixed ANOVA (group x day x time) was used to quantify the effects of fatigue and concussion on PIC and H reflexes, and a Fisher's LSD post-hoc analysis was used to detect differences between means. RESULTS: Soleus motor neuron PIC and resting H reflexes in people with concussion were not different from the controls at any time point. When the groups were collapsed, maximum voluntary torque declined to 92.6±8.67% ($p<0.001$) by the end of the fatigue protocol. PIC increased by the 3rd ($p<0.01$) and 4th ($p=0.026$) set of fatiguing contractions, returning to baseline by the end of the fatigue protocol ($p=0.562$). The slopes of the H reflex recruitment curves did not change. CONCLUSIONS: Although PIC may function to compensate for reduced drive or contractile failure early in the fatigue protocol, it does not appear to compensate for hypoexcitability in people with concussion. It is likely that increased monoaminergic drive seen during exercise activates soleus motor neuron PIC to enhance motor output. The increased gain provided by PICs may serve to enhance motor output during fatiguing muscle activity.

Title: Motoneuron output during voluntary activity in humans with spinal cord injury

Authors: *R. VASTANO[1,2], M. A. PEREZ[1,2]
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Bruce W. Carter Dept. of Veterans Affairs Med. Ctr., Miami, FL

Abstract: Evidence has shown that the excitability of resting spinal motoneurons increases in humans with spinal cord injury (SCI). The extent to which motoneuron excitability changes during voluntary activity after SCI remains largely unknown. To address this question, the ulnar

nerve was stimulated supramaximally at the wrist to evoke F waves in the first dorsal interosseous (FDI) and adductor digit minimi (ADM) muscles at rest and during 5% and 30% of maximal voluntary contraction into index finger abduction and little finger abduction in humans with and without chronic cervical SCI. In addition, we stimulated corticospinal axons directly by using high current electrical stimulation over the cervicomedullary junction to elicit motor evoked potentials (CMEPs) during the same conditions. We found higher persistence and amplitude of F waves at rest in the ADM compared with the FDI in controls. After SCI, both muscles showed higher persistence and amplitude of F waves compared with controls but to a similar extent. With increasing levels of voluntary contraction the amplitude of F waves and CMEPs increased in SCI participants but to a lesser extent than in control subjects in the muscles tested. These results indicate that the responsiveness of the motoneuron pool decreases during voluntary activity following SCI, which could alter the generation and strength of voluntary muscle contractions.

Title: Relative contributions of corticospinal and reticulospinal pathways to strength adaptation in non-human primates

Authors: *I. S. GLOVER, S. N. BAKER
Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: It is well established that in addition to muscle hypertrophy, resistance training generates neural adaptations which may partially underlie strength gains. Previous work has focussed on changes in the corticospinal tract and intracortical inhibitory networks in M1. However, subcortical pathways could also play a part in neural adaptions. In this study, we investigated the changes in corticospinal and reticulospinal outputs during a period of unilateral strength training.
Two female rhesus macaques were trained to pull a loaded handle towards the body using their right hand; initial training used no additional loads, such that <5N was required to move the handle. Monkeys were then implanted bilaterally with EMG electrodes in 8 upper limb muscles as well as electrodes in M1, the pyramidal tract (PT) and medial longitudinal fasciculus (MLF)

for stimulation.
Recording sessions were carried out daily. A session involved performing 50 trials of the task without load, while M1, PT and MLF electrodes were stimulated in pseudorandom sequence. The monkeys then performed 50 trials at high load (up to 64N) without stimulation. The session ended with a further 50 trials while stimuli were given but without load.
The two animals completed 8 or 9 weeks of this protocol, preceded and followed by 2-week periods in which only unloaded trials were performed. We refer to the first week of strength training as week 0. Muscle responses to stimulation were assessed from averages of rectified EMG, and quantified as the area under the curve above baseline. Monkey L demonstrated a significant suppression of responses early in the training period (week 0 to 5), followed by a facilitation which started at week 6 and continued until the end of recordings. The observed changes were in a similar direction for M1, PT and MLF, but were proportionally much larger for the MLF stimulus (maximum increase 261% for MLF, 31% PT, 27% M1). In monkey N, we observed a similar early suppression for the M1 and PT stimuli (weeks 1 to 10), but not for MLF; there was no evidence of the late facilitation.
Our results suggest that changes in M1 responses may reflect underlying alteration of the spinal efficacy of both corticospinal and reticulospinal projections. The initial suppression of responses was unexpected, but robust in two animals. This may indicate that spinal circuits become transiently less dependent on descending drive to activate motoneurons in the early phase of strength training. The later response facilitation was seen in only one animal; it may reflect a secondary adaptation, rather than result from the strength training itself.

Title: Regulation of micturition by the activity of the anterior cingulate cortex in mice

Authors: *T. MOCHIZUKI[1], S. MANITA[2], T. MITSUI[1], M. TAKEDA[1], K. KITAMURA[2]
[1]Dept. of Urology, [2]Dept. of Neurophysiol., Univ. of Yamanashi, Yamanashi, Japan

Abstract: Brain injury patients tend to have pollakisuria. Therefore, it has been believed that the cerebrum suppressed micturition in the storage phase and this suppression was released in the voiding phase. Recently, human imaging studies have shown that several brain regions including the anterior cingulate cortex (ACC) and the periaqueductal gray matter (PAG) were associated with micturition. Although the role of PAG has been extensively studied, it remains unclear how

ACC controls micturition. In this study, to elucidate the mechanisms for the control of micturition by ACC, we examined the change in the micturition interval time (MIT) induced by electrical and optogenetic stimulation of ACC in mice. MIT was defined as the time interval between peaks of voiding pressure. To measure MIT, we carried out cystometry through bladder catheter. First, we examined the contribution of ACC to MIT by lesion experiments. Electrodes were inserted into bilateral ACC, and we found that MIT was shortened by either the electrode insertion (N = 4 mice) or electrical lesion (N = 6 mice). These results are consistent with human pollakisuria induced by brain injury. Next, in order to further examine the contribution of ACC to micturition, we injected a $GABA_A$ receptor agonist, muscimol into both sides of ACC. After the injection of muscimol, MIT was extended (N=6 mice). Finally, we employed optogenetic stimulation of ACC neurons in order to directly demonstrate the causal relationship between the activity of ACC neurons and micturition. We found that photostimulation of excitatory layer 5 pyramidal neurons in ACC using channelrhodopsin-2 reliably induced micturition (N = 5 mice). On the other hand, photostimulation of parvalbumin-positive inhibitory interneurons in ACC significantly prolonged MIT (N = 6 mice). These results indicate that micturition could be induced by the activation of ACC. In contrast, the activation of parvalbumin-positive inhibitory interneurons in ACC causes extension of MIT. In conclusion, our results suggest that ACC plays a crucial role for the control of micturition and that the balance of excitation and inhibition in ACC may regulate micturition.

Title: Can motor noise account for force variability?

Authors: *A. NAGAMORI[1], C. M. LAINE[1], G. E. LOEB[2], F. J. VALERO-CUEVAS[1,2]
[1]Div. of Biokinesiology and Physical Therapy, [2]Dept. of Biomed. Engin., USC, Los Angeles, CA

Abstract: Involuntary force variability is an inherent property of motor behavior. When exacerbated, it is a key contributor to performance errors and a feature of several neurological

conditions. Some propose that involuntary force variability arises primarily through the conversion of motoneuron firing patterns into muscle force, i.e. “motor noise.” This mechanism has been tested using a model of recruitment and rate coding developed by Fuglevand et al. (1993). However, this model has several drawbacks that limit its ability to simulate force variability. First, it was not designed to model explicitly the fusion of force twitches with increases in firing rate and concomitant saturation of calcium binding to troponin. Second, the model lacks a series elastic element (i.e., tendon), which damps out the effects of fluctuations of motoneurone firing by changing its length and, thereby, causing shortening and lengthening of the muscle fibers of what is an otherwise externally isometric system. We addressed these limitations by combining some elements of the Fuglevand model with physiological and mechanical features from a model by Song et al. (2008). This new model yields improved predictions of force and force variability. Upon close inspection, we show the amplitude and spectral features of force variability are significantly influenced by the passive viscoelastic properties of musculotendons. Importantly, this more physiological model of motor units produces a lower amplitude of force variability than previous models. Also, the spectral features of this new model resemble more closely what has been observed experimentally. These results question current thinking attributing the majority of involuntary force variability to peripheral motor noise, and highlight the importance of closed-loop behavior including afferent feedback, passive viscoelastic properties and voluntary error corrections.

Title: Neural and muscular dynamics of behaving Hydra under different environmental conditions

Authors: *W. YAMAMOTO[1], S. HAN[2], R. YUSTE[1]
[2]Biol. Sci., [1]Columbia Univ., New York, NY

Abstract: To understand the neural code, i.e., the relation between the activity of a nervous system and the behavior it generates, we study *Hydra vulgaris*, which, as a cnidarian, represents

some of the earliest nervous systems in evolution. Indeed, *Hydra* has a simple nervous system of 600-2,000 neurons, organized in three independent nerve nets in the ectoderm and endoderm, and which are distributed through the body of the animal but without any cephalization or ganglia. In recent work, we have genetically engineered the calcium sensor GCaMP6s in every neuron (Dupre and Yuste, 2017) or every muscle cell (Szymanski and Yuste, in prep.) of transgenic Hydra, and developed machine learning method to systematically analyze its behavior (Han et al, 2018). This makes it possible to reconstruct the entire neuronal and muscle activity of *Hydra* during behavior and analyze these databases to decipher the neural code. As a step in this direction, we have explored how freely-behaving *Hydra* responds to environmental stimuli and conditions that affect its survival, while measuring its entire neural and muscle activity dynamics. Experimental conditions include high osmolarity (50mM sucrose), high temperature (30 degree Celsius), scarce of food (1 week starvation), and smaller body size. We acquired movies using calcium imaging and then processed and analyzed the data to extract neural and muscle activity during spontaneous contraction and elongation using custom ImageJ and MATLAB code. To study changes in neuronal and muscle activity during different conditions, we focused on two previously identified non-overlapping circuits (Dupre and Yuste, 2017): contraction burst (CB) neurons that trigger body wall contractions and rhythmic potential 1 (RP1) neurons whose firing correlates with elongation. We found that activation of the muscle correlates to the activity of CB neurons during contraction and there was no difference in number of contractions or frequency of RP1 firing under different conditions. However, the frequency of CB firing decreased in high temperature or high osmolarity, (n = 3-7 replicates). These results indicate that *Hydra's* nerve net possess intrinsic control mechanisms to respond and adapt to the environment.

Title: Functional and Structural profile of abdominal-projecting motoneurons of rats submitted to sustained hypoxia

Authors: *M. P. SILVA[1], D. J. A. MORAES[1], L. G. H. BONAGAMBA[1], A. S. MECAWI[2], J. RODRIGUES[1], W. A. VARANDA[1], B. H. MACHADO[1]

[1]Sch. of Med. of Ribeirão Preto, Ribeirão Preto, Brazil; [2]Federal Rural Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Expiratory motoneurons work as an integrative center translating the complex brainstem neuronal respiratory inputs to effective muscles contraction, but their profile was not yet explored. Here, we characterized the abdomen-projecting motoneurons regarding their electrical, molecular and morphological profile using *in vitro* and *in situ* preparation from control and rats submitted to sustained hypoxia (SH), an experimental model presenting active expiration. Whole-cell patch clamp reveled two sub-populations of cells: spontaneous and silent motoneurons. SH (FiO2 0.1, 24 hours), selectively changed the excitability of spontaneous motoneurons: a) depolarization of the resting membrane potential (-69.3 ± 0.9 mV vs -66.5 ± 0.7 mV), b) enhancement of the firing frequency (7.6 ± 1 Hz vs 16.8 ± 3 Hz, n=18), and c) a reduction in the input resistance (0.35 ± 0.05 GΩ vs 0.18 ± 0.03 GΩ). However, these changes were abolished by synaptic blockers and were due to increases in the frequency (6 ± 1 Hz vs 2.2 ± 0.6 Hz, n= 11), as well in the amplitude (97 ± 10 pA vs 31 ± 5 pA) of excitatory postsynaptic currents. Three-dimensional reconstruction of spontaneous motoneurons revealed that hypoxia increased the surface area (349.4 ± 81 μm^2 *vs* 1119 ± 115 μm^2, p =0.013), soma volume (922.5 ± 109 μm^3 *vs* 4606 ± 1115 μm^3, p= 0.02), branching complexity (9892 ± 3542 *vs* 45800 ± 11760, p= 0.03) and the number of nodes of spontaneous motoneurons (3.25 ± 1 *vs* 13.6 ± 3, p=0.03). Interesting SH induced dendrites spines formation, which is absent in control conditions suggesting structural plasticity, which may contribute to changes observed in the electrophysiological properties of spontaneous motoneurons. These findings contribute for a better understanding of how abdomen-projecting expiratory motoneurons process the electrical inputs to ensure an appropriated respiratory activity in the control and mainly under hypoxic challenges.

Title: SorCS2 in motor neuron development and integrity

Authors: *P. B. THOMASEN[1,3], H. LOGIN[1], K. KJAER-SOERENSEN[2], J. TRANBJERG-JENSEN[1], S. BEEL[3], P. VAN DAMME[3], C. OXVIG[2], A. NYKJAER[1]
[1]Biomedicine, [2]Mol. Biol. and Genet., Aarhus Univ., Aarhus C, Denmark; [3]Neurosciences, KU Leuven, Leuven, Belgium

Abstract: Motor neuron development is dependent on several mechanisms including axon guidance, growth cone collapse and synapse formation, and has been highly studied, yet all the proteins and pathways involved in this process and their interplay are still not fully described. Accumulating evidence implicates axon guidance proteins in neurological diseases such as amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy demonstrating that improper wiring during development may be lead to disease later on in life. Axon guidance proteins are not only important during development but also play a role in regeneration of nerves after injury. Further studies of axon guidance proteins and their function may clarify how dysregulation cause disease and could help towards developing new therapeutic strategies.
In my PhD project the function of the sorting receptor SorCS2 in motor neuron development and integrity is being studied through *in vitro* and *in vivo* studies in zebrafish and mice. We have found that SorCS2 is expressed in motor neurons in both zebrafish and mice. To study the role of SorCS2 in motor axon guidance we have knocked down expression of SorCS2 in zebrafish embryos by morpholino injections. We find that knockdown of SorCS2 results in abnormal length and aberrant branching in the primary motor neurons. Furthermore, acetyl choline receptor clustering is altered in knockdown embryos suggesting changes in neuromuscular synapse formation. Using the technique facial nerve crush injury, we similarly find that nerve outgrowth of SorCS2 knockout mice are significantly slower than wildtype mice. Together, the data suggests that SorCS2 plays an important role for motor neuron development and integrity, and ongoing studies aim at elucidating the molecular mechanisms underlying these phenotypes.

Title: Spinal cord motor columns targeted by Foxp2 V1 interneurons

Authors: A. R. LANE[1], L. GOMEZ-PEREZ[1], J. B. BIKOFF[2], J. T. ANDERSON[1], T. M. JESSELL[3], *F. J. ALVAREZ[1]
[1]Physiol., Emory Univ., Atlanta, GA; [2]Dept. of Developmental Neurobio., St. Jude Children's Res. Hosp., Memphis, TN; [3]Neurosci., Zuckerman MBBI, Columbia Univ., New York, NY

Abstract: Spinal V1 interneurons (V1s) are a diverse population of ventral horn inhibitory interneurons (INs) arising from the p1 domain and that transiently express the transcription factor En1 once they become postmitotic. V1s influence motoneuron (MN) activity and therefore motor output, but the distinctive V1 subpopulations remain to be fully characterized. Foxp2 V1s are one group that represents around 65% of all V1s when lineage labeled by intersectional genetics using $Foxp2^{flpo}$ :: $En1^{cre}$ mice with one R26 allele containing a dual conditional GFP and the other the Ai9 LSL-tdTomato (tdT). Because the tdT transgene in the Ai9 line is cre dependent but also is deleted by Flpo recombination, Foxp2 V1s only express GFP. In these animals 34.5% of V1s are tdT(+) Foxp2(-), 51.2% GFP(+) Foxp2(+) and 14.3% dual GFP/tdT labeled. We interpret dual GFP/tdT neurons as arising from transient expression of Foxp2 in embryo, while GFP "only" V1s represent neurons that upregulate Foxp2 during neurogenesis and many maintain expression until early postnatal age efficiently deleting tdT. All Foxp2 V1s have a fast spiking phenotype and are divided into lateral and medial groups according to timing of neurogenesis. Lateral Foxp2 V1s are further divided into dorsal and ventral groups, respectively expressing OTP and Foxp4 transcription factors. To gain insight into their function we identified their synapses by immunolocalizing VGAT to their genetically labeled axons and analyzed the targeting of different motor columns in the lumbosacral enlargement (T12 to S2) after counterstaining with choline acetyltransferase immunolabeling. The results show that Foxp2 V1s constitute ≥50% of the V1 input on the cell bodies of the lateral and medial motor columns (LMC and MMC) from lumbar (L)1 to L6, but contribute little input to the hypaxial motor column (HMC) in upper lumbar and lower thoracic segments. They also give few synapses to preganglionic sympathetic and parasympathetic neurons. Interestingly, most Foxp2 V1 synapses over autonomic MNs are GFP/tdT dual labeled. Overall, autonomic MNs received significantly lower density of V1 synapses than somatic MNs. We compared this pattern to calbindin V1 Renshaw cells (RC). RC synapses represent around 50% of all V1 synapses on the cell body of all upper lumbar (L1-L2) motor columns but were less abundant than Foxp2 V1 synapses on the lower lumbar (L4-L6) LMC and MMC and were absent on LMC distal motor pools (dorsolateral L6 MNs). Similarly to Foxp2 V1s, RCs did not significantly project to autonomic MNs. The results suggest that Foxp2 V1s mainly target somatic MNs and give significant input to both LMC and MMC, but not HMC MNs.

Abstract: The NeuroLINCS Center is an NIH-funded multi-site collaborative effort between research groups with expertise in iPSC technology, disease modeling, imaging, OMICS methods, and computational biology focused on ALS. The NeuroLINCS team has generated a rich data set from RNA, protein, and epigenomic analyses using ALS and control iPSC-derived motor neurons. Gene level quantification of transcriptomic and proteomic data reveal specific cell signatures between C9orf72 and control iPSC-motor neurons even at the earliest timepoint. We further analyzed differential exon usage and alternative splicing to quantify transcript isoforms and ncRNA levels including: lnc-, circ-, and miRNAs in ALS and control samples. DeepBind motif analysis identified RNA binding proteins (RBPs) that could contribute to the altered exon usage and alt-splicing. The motifs of RBPs mislocalized in ALS autopsy tissue are highly represented, including: SRSF and hNRNP genes. Mislocalization and disruption of the normal function of these RBPs could play a role in the transcriptomic dysregulation seen in the i-MNs from *C9ORF72* ALS patients. Predicted protein isoforms are also analyzed in the matching proteomics data set to determine if isoforms were translated and if there were quantity changes between *C9ORF72* ALS and control. WGS was carried to identify genetic variants that could be associated with or modifying our ALS disease signatures. eQTL analysis is being used to 1) identify genetic variant that could be confounding our gene expression signatures 2) stratify our ALS samples by uniquely modifying the signatures 3) as prior knowledge for anchoring nodes for network-based causal inference modeling. Another way we are integrating the genomic data with other data sets is to investigate if DNA coding variants are expressed in i-MNs and if these predicted protein isoforms were sequentially identified based on the actual peptide sequence within the proteomic data to confirm that genetic variants are being expressed and assess their

proportional representation among other proteins. This approach to OMICS data integration helps us understand how genetic SNPs impact the cellular protein milieu. These approaches are being extended to samples generated through Answer ALS, which is creating 1,000 unique stem cell lines from ALS patients and healthy controls. We show preliminary data on the first 500 lines using RNASeq and SWATH proteomics.

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult onset neurodegenerative condition in which loss of upper and lower motor neurons occurs due to cell death, which ultimately leads to impaired muscle function and eventually death. iPSC derived motor neurons allow for the interrogation of the discrete molecular effects of specific genetic perturbations within the context of ALS. The goal of this study was to identify disease specific proteomic signatures using three different timepoints along differentiation as a means to identifying the minimal or initiating ALS pathways. We carried out cell wide proteomic analysis (data independent acquisition-MS, DIA-MS) on iPSC derived motor neurons generated from patients with a single homogenous genetic driver (C9) and compared those to control lines (n=4 for each) at three differentiation time-points: Day 18, Day 32 and Day 90. Of the DDA-MS peptide library consisting of ~ 5000 cell specific proteins, DIA-MS data quantified ~3700 proteins across the three timepoints. In addition, there were 84, 322 and 924 differentially expressed proteins in Day 18, 32 and 90, respectively. Of these, 11 proteins overlapped at all three time points, with just over half of the Day 18 differentially expressed protein being unique to that timepoint. Importantly the proteome signature at day 18, comprised of nuclear pore and ECM proteins were observed and expanded in

the later more complex differentiations. With longer differentiation times, there was an enrichment in the number of known ALS associated proteins, as well as proteins associated with the nuclear pore and cytoskeleton. We speculate that the large increase in the number of differential proteins with the length of the differentiation protocol may reflect i) disease progression, ii) neuronal cell maturity or iii) appearance of other cell types (development of a microenvironment). Moreover, this initial proteomic signature is already present at Day 18, suggesting early cellular dysfunction as a result of mutations in C9.

Abstract: The Answer ALS project entails creating 1,000 unique stem cell lines from ALS patients and healthy controls. These stem cells and their derived brain and spinal cord cells can then be used *in vitro* to model the disease in a large scale. We have been optimizing the differentiation protocols and in this study asked the question: what is the effect of increasing the time and complexity of the differentiation protocol on phenotypic differences seen between ALS and control lines? We used 12 lines for this study, that included sporadic ALS patients (n=4), familial ALS patients with a C9ORF mutaion (n=2), C9ORF isogenic corrected controls (n=2) and healthy controls (n=4). The first motor neuron protocol was performed in three different stages: (Stage 1) Neuroepithelial induction using base media supplemented with CHIR99021, SB431542, and LDN193189, (Stage 2) motor neuron precursor generation using Retinoic Acid to induce caudalization, (Stage 3) terminal motor neuron maturation using neurotrophic growth

factors such as GDNF and BDNF. Motor neuron cultures were collected at 18, 32 and 60 days of differentiation. In addition, a longer differentiation protocol was used that included embryoid body formation, rosettes, sphere expansion and platedown of cells for 21 days of motor neuron maturation. At the end of each protocol, differentiated motor neurons were collected and distributed to 5 collaborating sites: Thompson lab at the University of California, Irvine for RNA analysis, Fraenkel lab at the Massachusetts Institute of Technology for DNA/Epigenetic analysis, Finkbeiner Lab at the University of California, San Francisco for imaging analysis, Rothstein Lab at Johns Hopkins University for perturbation analysis and Van Eyk lab at Cedars-Sinai for protein analysis. Here, data is presented from this collaborative study aimed at determining the optimal time of differentiation for detecting phenotypic differences between ALS and control lines.

Title: Answer ALS iPSC and Motor Neuron Repository at the Cedars-Sinai RMI iPSCCore

Authors: *L. PANTHER, H. TROST, R. CHENG, E. GOMEZ, C. LIU, L. ORNELAS, J. ORTIZ SANCHEZ, M. BANUELOS, S. HUANG, K. KUROWSKI, D. WEST, I. PSC CORE, M. N DIFFERENTIATION CORE, A. NSWER ALS CONSORTIUM, C. SVENDSEN, D. SAREEN
Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: The Answer ALS project entails creating 1,000 unique stem cell lines from ALS patients and healthy controls. These stem cells and their derived cells of the brain and spinal cord can be used to model the disease on a large scale. This allows scientists a deeper look at the mechanisms of a fatal neurodegenerative disease like ALS.
The iPSC Core at Cedars-Sinai is leading the generation of these unique iPSCs and their derived motor neurons (MNs) from samples collected across multiple clinical sites in the US along with deep clinical data. These cells are being utilized in big data projects and large-scale omics investigations. The iPSC Core has already received 692 unique patient blood samples. Over 600

of these samples were collected from ALS patients with mutations like *C9ORF72, SETX* and *SOD1,* while others were from healthy controls without any neurological diseases and some with diseases such as primary lateral sclerosis and spinal muscular atrophy. We have successfully reprogrammed over 300 PBMCs into iPSCs; over 66 of these lines are control samples, 17 with C9ORF72 ALS, 3 with SOD1 ALS while the remaining lines are from sporadic ALS patients. The PBMCs are reprogrammed using non-integrating episomal plasmids and undergo extensive testing and optimization to ensure their pluripotency, quality and genetic integrity. After we have completely reprogrammed the Answer ALS samples, the iPSC Core will have one of the largest biorepositories of ALS iPSC lines which, along with the de-identified clinical data, will be available for distribution throughout the world.
Of the 300 iPSC lines, 126 have been successfully differentiated into MNs; 42 being controls and the remaining 84 are from ALS patient iPSC lines. The method used to differentiate iPSC lines into MNs involves an 18-day process split into 3 different stages: neuroepithelial induction using media supplemented with CHIR99021, SB431542, and LDN193189 (Stage 1), MN precursor generation using Stage 1 media with Retinoic Acid for inducing caudalization (Stage 2) and terminal MN maturation using media supplemented with neurotrophic factors such as GDNF and BDNF (Stage 3). At the end of the protocol differentiated neurons are collected and distributed to 5 collaborating sites; Thompson lab at the University of California, Irvine for transcriptomics (RNA-seq), Fraenkel lab at the MIT for epigenomics (ATAC-seq), Finkbeiner Lab at the UCSF for longitudinal imaging analysis, Rothstein Lab at Johns Hopkins University for perturbation analysis and Van Eyk lab at Cedars-Sinai for proteomics.

California, Irvine, CA; [7]Regenerative Med., Cedars-Sinai Med. Ctr., West Hollywood, CA

Abstract: Amyotrophic lateral sclerosis (ALS) and Frontotemporal Dementia (FTD) comprise a spectrum of neurodegenerative diseases. ALS is characterized by a loss of neurons in the spinal cord, brainstem and cortex. Specific cortical neuron subtypes are implicated, including deep layer V pyramidal neurons that project to the spinal cord, as well as layer II/III interneurons that regulate the excitatory activity of projection neurons. In contrast, FTD is characterized by a loss of neurons in the frontal and temporal cortices. Mutations in the gene C9*orf*72 have been identified as playing a role in both diseases. In a collaborative effort across three Institutes (NeuroLINCS), we have used 3 protocols to differentiate 12 human induced pluripotent stem cell (iPSC) lines (6 C9*orf*72 ALS, 2 isogenic-corrected C9*orf*72 ALS, and 4 control) into robust and reproducible cortical forebrain neurons. Here, we compare differentiation protocols, each of which employ varying components and time in culture. We first use immunocytochemistry to assay the diversity of cell types produced with each protocol, including deep layer pyramidal neurons, interneurons and glia. We also evaluate the neuronal cultures for their transfection efficiency and the ability to perform longitudinal single-cell imaging. In addition, we perform RNA-seq and protein analysis for di-peptide repeats, which are pathologically produced in ALS and FTD patients. Finally, we evaluate the signatures present in the C9*orf*72 patient-derived cortical neurons compared to control cell lines. Our work presents a platform for future, multi-omic evaluation of neurodegenerative diseases. This project paves the way to extend our integrated analysis beyond ALS to assess FTD and other neurodegenerative disorders like Alzheimer's Disease. This will position NeuroLINCS as a resource for the broader scientific community.

Title: Spatial reconstruction of the spinal cord from iPSC models of ALS with single cell RNA-seq

Authors: *R. HO[1], M. J. WORKMAN[1], M. KELLOGG[2], V. MONTEL[2], M. G. BANUELOS[1], S. HUANG[1], D. WEST[1], I. KHREBTUKOVA[2], L. WATSON[2], K. TAYLOR[2], C. N. SVENDSEN[1]

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disorder characterized by motor neuron (MN) death, typically presented in late adulthood, and resulting in an average lifespan of five years after diagnosis. Of ALS cases, 90 percent are of unknown genetic cause (sporadic ALS), and ten percent are attributed to genetic mutations (familial ALS). Onset of motor symptoms is variable among patients, presumably due to differing rates of degeneration among MN sub-types. Living central nervous system tissue is not accessible from patients to perform functional genomic and molecular research, which hinders pinpointing genetic or environmental mechanisms that cause MN degeneration. *In vitro* modeling of ALS with patient-derived induced pluripotent stem cells (iPSCs), which harbor the relevant genetic context of patients, can potentially capture the underlying causes of ALS in a patient-specific manner. We published that iPSC-derived MNs differentiated *in vitro* exhibit bulk transcriptomic expression profiles that globally resemble *in vivo* fetal spinal tissues. However, these bulk transcriptomic techniques represent averaged gene expression profiles among heterogeneous cell types and thus may not accurately reflect distinct pathologies of individual cells. Here, we describe our application of single cell RNA-seq (scRNA-seq) to assay individual cell transcriptomes with the goal of producing a high-resolution, three-dimensional anatomical map of cellular identities and physiologies within iPSC-derived spinal tissue cultures in ALS patient and control samples. This cellular atlas of the human spinal cord will provide 1) a valuable resource for stem cell and neuroscience research communities, 2) new avenues of investigation to resolve variable clinical phenotypes of ALS, and 3) specific molecular mechanisms to target by specialized treatment options for patients. Classifying iPSC-differentiated cells as *in vivo* spinal cell types using individual transcriptomes enables discovery of dysregulated pathways occurring in distinct MNs or other cell types. This single-cell approach with patient-specific iPSC models of ALS may resolve the variable motor deficits among patients, improve understanding of disease etiology and progression, and thus enable precision treatments for ALS.

Abstract: Answer ALS was conceived and organized as a comprehensive multi-omics approach to ALS to ascertain, at a population level, the various clinical-molecular- biochemical subtypes of ALS. This national program was initiated to identify and follow 1000 ALS and ALS/FTD patients nationwide along with a cohort of >100 matched control patients. Patients were recruited at 8 national ALS centers and followed longitudinally over one year. In addition, a smartphone-based system was employed to collect deep clinical data including fine motor activity, speech, breathing and linguistics/cognition. In collaboration with IBM Watson, analytics of speech pattens reveals a strong correlation between clinical progression indices and speech. In parallel, iPS motor neurons were blood-derived from each patient and these cells underwent multi-omic analytics including: whole genome sequencing, RNA transcriptomics, ATAC-Seq, proteomics, metabolomics, high content imaging and longitudinal high throughput single cell analysis. HIPPA compliant cloud data bases were employed to store all data. Open access to early raw data is being instituted as well. More than 750 ALS patients have already been enrolled and > 400 iPS cell lines have already been generated from these patients, along with > 350 whole

genomes sequenced. Integrated clinical and biological signatures are now being generated using bioinformatics, statistics and computational biology to establish patterns that may lead to a better understanding of the underlying mechanisms of disease. We hope to begin identification of biological subgroups from the first 130 sALS and fALS iPS motor neuron lines. Interestingly, definite subgrouping was readily identified even with an initial small subset of ~30 patients and appears to be influenced by co-analyses of clinical and biological data sets. C9 patients were found have prominent defect in nuclear transport, chromatin remodeling and RNA metabolism as fundamentally altered pathways with candidate pathways modulating drugs identified. For some subgroups, antisense oligonucleotides targeting relevant pathways could mitigate molecular injury- reverting cells towards control patient profiles. Relevant pathways and molecular targets are being verified in post mortem brain tissue as well as fly models. A web portal for open source sharing of all data are being developed for widespread community based data analytics. These studies demonstrate distinct reliably identifiable subgroups among the sporadic and familial patients and the great utility in iPS based approaches to disease pathophysiology and therapy discovery.

Title: VCP is involved in axonal mitochondrial motility

Authors: *A. E. GONZALEZ
Neurosciences, Stanford Univ., Stanford, CA

Abstract: In neurons, mitochondria must be transported sizable distances through the axon to localize to areas like the bouton, where synaptic growth, signaling, and Ca2+ buffering require mitochondria for energy. Mitochondrial transport is especially critical in motor neurons as the axon can extend up to a meter in length. Movement of mitochondria along the axon is mediated by Miro, which anchors mitochondria to a motor complex and to microtubules. Miro responds to diverse cellular signals to dynamically mediate the movement of mitochondria. These signals include intracellular Ca^{2+}, glucose, and mitophagic triggers including PINK1 and Parkin

interactions, which link Miro to neurodegenerative disease. We have recently discovered a connection between Miro and VCP/p97. VCP is a highly conserved, ubiquitous, essential, and abundant ATPase. The hexameric structure and enzymatic activity of VCP enables it to perform mechanical work in cells, with its most widely studied function being facilitation of protein degradation through the ubiquitin-proteasome system (UPS). VCP function has been implicated in a mitochondrial process called mitophagy, the selective autophagy of damaged mitochondria. This process is regulated by the PINK1/Parkin pathway which tags outer mitochondrial membrane (OMM) proteins and initiates mitophagy. VCP is required for the removal and degradation of OMM protein Mitofusin2 (Mfn2) which is an essential step required to complete mitophagy. VCP also localizes to mitochondria and regulates Mfn2 levels in healthy conditions. While VCP disease mutants have been studied in artificially damaged conditions, the function of VCP in mitochondrial pathways remains unstudied in healthy conditions. We looked at the role of VCP in axonal mitochondrial transport, hypothesizing that VCP may regulate Miro similarly to Mfn2. We found that while VCP does not play a role in regulating the speed of individual mitochondria, it does play a role in the number of mitochondria in axons. We hypothesize that loss of VCP function reduces the number of mitochondria transported from the cell body into the axon by lowering Miro levels, and thus reducing anchoring of mitochondria on microtubules. Our results suggest that VCP has a role in regulating Miro in healthy conditions. Further, the long axons of motor neurons that are particularly susceptible to mitochondrial transport defects could suffer most from the molecular dysregulation of VCP and Miro. As evidence of defective mitochondrial dynamics continues to emerge in ALS and other neurodegenerative disease research, our research on the basic biology of VCP may enlighten us to VCP functions important for disease pathogenesis.

Title: Does time make a difference? The effect of the administration of follistatin on re-innervated skeletal muscle fiber recovery after 3 vs 6 months of denervation

Authors: *M. S. SHALL[1], J. E. ISAACS[2], S. MALLU[2], G. PATEL[2]
[1]Physical Therapy, MCV/VCU, Richmond, VA; [2]Orthopaedic Surgery, Virginia Commonwealth Univ., Richmond, VA

Abstract: The objective is to evaluate the effect of Follistatin on the recovery of skeletal muscle strength and skeletal muscle fiber diameter after different periods of denervation time and re-innervation.
Rationale: Functional recovery following traumatic peripheral nerve injury is often suboptimal despite appropriate treatment. Due to the slow rate of axonal regeneration (1-3 mm/d), the target muscle may undergo significant atrophy before the axon attempts reinnervation. Follistatin influences muscle regeneration at several levels including directly inhibiting myostatin, a signal transduction protein that regulates muscle mass by inhibiting muscle regeneration. As a result, Follistatin stimulates muscle fiber hypertrophy and hyperplasia in normal animal models.
Methods: Transection of the tibial nerve in the hindlimb of Sprague-Dawley rats, followed by delayed (3 or 6 month) repair (utilizing microsurgical nerve suturing with nerve graft) induced partial recovery of the muscle with mild or moderate residual strength deficits due to irreversible atrophy. Recombinant protein and recombinant DNA were synthesized (and the DNA packaged in adeno-associated viral vectors) in the Virginia Commonwealth University (VCU) Biological Macromolecule Core Facility. The Follistatin protein was delivered, after reinnervation, to the gastrocnemius muscle utilizing an Alzet (Cupertino, CA, USA) implantable drug delivery system. Treatment effects on the muscle were evaluated by cryosectioning the muscles after evaluation of muscle force. Muscle fiber types identified with Immunohistochemistry allowed differential evaluation of three primary muscle fiber types.
Results: The muscles of the animals that were denervated 3 months and repaired, followed by Follistatin treatment, exerted about the same force as experimental animals without Follistatin treatment and had about the same size muscle fibers. Muscles that were denervated 6 months before reinnervation and treatment with Follistatin protein developed significantly more force than denervated animals without treatment. The muscle fibers expressing type IIa and IIb myosin heavy chains were larger in diameter in the experimental animals that were treated with either type of Follistatin than control animals that received no Follistatin.
Conclusions: In this rodent model of delayed peripheral nerve repair, we found that Follistatin, administered 1 month after reinnervation had a greater facilitating effect after 6 months than 3 months of denervation on the recovery of type IIa and IIb muscle fibers and muscle force.

Title: Early life stress and neurodevelopment: Contributions of glucocorticoid plasticity to maturational timing

Authors: *L. D. GODOY[1,2], N. GARCIA-CAIRASCO[1], K. G. BATH[2]
[1]Physiol. Department, Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]CLPS Dept., Brown Univ., Providence, RI

Abstract: Early life stress (ELS) is associated with increased risk for later emotional disturbance and precocious development of the HPA-axis. ELS leads to an earlier emergence of contextual fear inhibition (Pattwell et al., 2012) and accelerated maturation of the hippocampus. We posit that corticosterone (CORT) plays a functional role in regulating the timing of maturation of regions underlying threat learning and expression, including the hippocampus, amygdala, and prefrontal cortex. Our working hypothesis is that elevations in plasma levels of CORT can impact the timing of maturational processes, and that blocking elevation in CORT associated with ELS will buffer against ELS effects on the timing of brain and behavioral maturation. To test those hypotheses, we used a limited bedding model of ELS from P4-P11. Control and ELS animals were administered either saline (Naïve) or metyrapone (MET; 50mg/kg) on P12. At P18, P21 or P28 separate groups of mice were exposed to a single session of fear conditioning followed 24 h later by a single context test (Bath et al.,2016). Analysis of freezing behavior in the context test revealed that MET treatment blocked the acceleration in contextual fear inhibition in ELS reared mice at P22, with no diference between groups at P19 or P29. This effect was observed in both female and male mice. Interestingly, in control male pups treated with MET a significant reduction in freezing was observed at P22 and increased freezing at P29 when compared to Naïve, indicative of MET effects on typical development.
We discuss these data in the context of complementary approaches assessing ELS and MET effects on the timing of neurotrophic factor and glucocorticoid receptor expression in the brains of these mice. Based on the current results, CORT is likely playing an important role in the timing of both typical development and ELS-associated shifts in behavior and brain maturation. Importantly, blocking the ELS-associated increase in CORT in ELS mice may represent an interesting strategy to buffer stress effects on the timing of brain maturation and possibly decrease risk for pathological emotional outcomes.

Title: The ^{1}H MRS study for the measurement time dependency of acute stress response

Authors: *Y. HWANG[1], M.-H. LEE[2,3], C.-S. YUN[1], Y. KIM[4], H.-M. BAEK[4], B. HAN[1], D. KIM[1]
[1]Yonsei Univ., Wonju, Korea, Republic of; [2]Wayne State Univ. Sch. of Med., Detroit, MI; [3]Children's Hosp. of Michigan, Detroit, MI; [4]Gachon Univ., Incheon, Korea, Republic of

Abstract: Proton magnetic resonance spectroscopy (^{1}H-MRS) has been widely used in study for the acute stress (AS) response. This response to AS is a complicated process that varies depending on the individual characteristics, which may cause variation of the amount of each metabolite over individuals measured at the same time after AS exposure. However, most stress studies using ^{1}H-MRS have been performed based on the measurement at particular time. Therefore, the existing measurement method of MRS data for AS study needs to be improved to reflect the individual differences in AS response. There has not yet been an assessment of AS and its impact on the brain's metabolic response over time, which is critical to deepening our understanding of brain metabolism. In this study, we explore the physiological response to AS by quantifying metabolites in the hippocampus over time using ^{1}H-MRS. Twenty-four C57BL/6N mice (18-25g, 6~7 weeks, and male) were involved in this study and randomly assigned into control (12 mice) and AS (12 mice) groups. In order to examine the AS response, the each mouse in AS group was physically restrained in 50mL conical tubes for 2 hours. The MRS data were acquired in the hippocampus at 9.4T Bruker MRI/MRS system with PRESS. Data acquisitions were performed at 30min, 60min, 90min and 120min after AS exposure. The data were analyzed using Linear Combination Model (LCModel) with a simulated basis set including 17 metabolites and group comparisons were carried out employing the nonparametric t-test for each data obtained at particular time and repeated measure analysis of variance for all data. Our findings are as follows: The stress group shows significantly higher concentration than control group in Alanine (Ala) and Glutamate (Glu) at 30min, Ala, Glu, and total Creatine (tCr) at 60min, Ala at 90min, and Glucose (Glc) at 120min ($p<0.05$). In the group analysis for all data, the stress group shows significantly higher concentration in only Glu and Ala than control group ($p<0.05$). The findings of present study show that the results of MRS data analysis vary depending on the measurement time. Therefore, this study suggests that the analysis through the measurements over time is required in the AS studies using ^{1}H-MRS.

Title: Chronic lead exposure promotes epigenetic changes in serotoninergic receptors and aggressive behavior in mice

Authors: *L. G. GARCIA-LARA[1], A. J. HERNÁNDEZ-CORO[1], J. MARTÍNEZ-LAZCANO[2], B. E. SÁNCHEZ-HERNÁNDEZ[3], S. MONTES[1], C. RÍOS CASTAÑEDA[1], F. PÉREZ-SEVERIANO[1]

Abstract: Exposure to lead (Pb), during early stages of life, affects the normal brain development causing neuronal and behavioral changes, such as aggressiveness, hyperactivity and learning impairments. Previously, we have demonstrated the interaction between a decreased serotonin turnover (5-HT) and the aggressiveness in mice exposed to Pb. To elucidate the mechanism that leads to the alteration of the 5-HT1A and 5-HT1B receptors by exposure to Pb from pregnancy to different postnatal ages (P7, P14, P28 and P72). We set breeding litters of C57BL6 mice and they were given *ad libitum* either tap water as control or lead acetate solution (250 ppm) and we dissected the hippocampus and cortex of both groups for protein and RNAm detection levels of 5-HT1A and 5-HT1B receptors. Furthermore, methylation levels were analyzed in the 5-HT1A and 5-HT1B promoter region and we found low methylation especially in the 5-HT1B promoter. For the evaluation of the aggressive behavior, the resident-intruder test was performed on mice of both groups at P72 and we found that the mice exposed to Pb with respect to the control show higher aggressive behavior. Therefore, chronic lead exposure from the gestation to an adult stage predisposes to an aggressive behavior probably due to the methylation and expression impairments that could affect the response of 5HT1A and 5HT1B receptors.

Abstract: Maternal stress before and during pregnancy (prenatal stress, PS) is a key risk factor affecting in utero and postnatal child development. We hypothesized that PS impacts the heart rate variability signature of autonomic nervous system (ANS) stress axis activity in mother and fetus. We recorded abdominal electrocardiogram (aECG) in a cohort of stressed (n=49) and non-stressed (n=55) pregnant women, identified by Cohen Perceived Stress Scale questionnaire (PSS-10) administered on 28th week of gestation. Using validated mathematical algorithms, we extracted maternal (mECG) and fetal (fECG) signal from aECG. We then studied maternal and fetal ECG-derived heart rate variability (HRV) properties, a measure of fetal autonomic nervous system (ANS) activity, using a novel multidimensional HRV analysis approach (DYNAMO). Traditional HRV measures from HRV Task Force were calculated for comparison (SDNN, RMSSD, SDSD, pNN50, IQRNN and HTI). Maternal hair cortisol was measured at birth: Cortisol levels from 3 cm hair reflected up to three months of prior chronic stress exposure. (Clinical Trials NCT 033891 78). Maternal hair cortisol levels differed significantly between both groups objectifying the results of PSS-10. We show that such HRV approach distinguishes stressed from non-stressed fetuses one month following PSS-10 assessment. Notably this result

is best seen in fetal HRV and less clearly in maternal HRV. The traditional HRV measures did not provide a clear separation of the two groups. This suggests a direct transgenerational transmission of PS onto fetal ANS and stress axis. Our finding show a persistent effect of PS identified in the last trimester. Our study provides a proof-of-principle for deploying non-invasive aECG technology for early identification of mothers and fetuses at risk of altered neurodevelopmental trajectories to allow for planned early postnatal interventions

Title: Drd3 signaling in the lateral septum mediates early life stress-induced social dysfunction

Authors: *S. SHIN[1], H. PRIBIAG[2], V. LILASCHAROEN[3], D. KNOWLAND[4], X.-Y. WANG[2], B. LIM[3]
[1]Dept. of Biol. Sciences, Neurobio., [3]Biol. Sci., [2]UCSD, La Jolla, CA; [4]UCSD, San Diego, CA

Abstract: Children exposed to adverse experiences (e.g., physical abuse, emotional neglect, etc.) during a critical period in their development are more likely to have social dysfunction later in life. Those experiences, collectively referred to as early life stress (ELS), can induce psychiatric symptoms associated with diseases like autism spectrum disorder (ASD), schizophrenia, and major depression. Little is known, however, about the relevant molecular signaling within a specific neural substrate that governs ELS-induced social dysfunction. Here, we identify dopamine receptor 3 (Drd3)-expressing-LS ($Drd3^{LS}$) neurons as a critical component mediating the detrimental effects of ELS on social behavior. Employing an early social deprivation (ESD) stress paradigm, we found that Drd3 signaling in the LS is significantly down-regulated in mice exposed to ESD stress, and that this is accompanied by abnormal social behaviors such as reduced social preferences and severe communication deficits. Using in vivo Ca^{2+} imaging, we

found that social stimuli produce significantly less activity in $Drd3^{LS}$ neurons of ESD mice than in controls. Notably, optogenetic activation of $Drd3^{LS}$ neurons rescues this ESD-induced social impairment. Pharmacological treatment with the Drd3 agonist PD128907, which increases the activity of $Drd3^{LS}$ neurons, also normalizes the abnormal social behaviors of ESD mice. Taken together, our findings identify Drd3 signaling in the LS as a critical mediator of the ELS-induced social impairments in adulthood. Drd3 in the LS may therefore constitute an important therapeutic target for the treatment of the severe social impairments commonly observed in numerous neuropsychiatric disorders.

Title: Effects of birth and birth-mode on markers of inflammation in the mouse brain

Authors: *A. CASTILLO-RUIZ, M. MOSLEY, Y. C. HOFFIZ, R. BURCH, N. G. FORGER
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Birth is an inflammatory event, with the onset of parturition marked by inflammation at the fetal/maternal interface. As the fetus traverses the vaginal canal and enters the outside world, it experiences changes that under any other circumstance could elicit an immune response: hypoxia, mechanical pressure, and a new environment filled with microorganisms. In agreement, we previously found that perinatal mice show dynamic changes in peripheral pro-inflammatory cytokines, with TNF-α showing high levels pre- and postnatally, and IL-6 showing highest levels just before birth. In contrast, the anti-inflammatory IL-10 tripled within 3h of birth. Whether this peripheral response extends to the brain's immune system, and whether the inflammatory response to birth is altered by birth mode has not been addressed. To answer these questions, we focused on microglia, the resident immune cells of the nervous system. Microglia respond to immune challenges by increasing their soma size and morphing into an activated, amoeboid state. We examined microglial soma size at embryonic day (E)18.5 and E19 and *ex utero* at postnatal day (P)0 (3h after birth), P1, and P3 in mice born vaginally or by Cesarean section. Brains were immunohistochemically stained for the microglial marker ionized calcium binding adaptor molecule 1. We found a significant increase in microglial soma size between E19 and P1 in vaginally-born animals that was sustained at P3 in the paraventricular nucleus of

the hypothalamus, a region with a central role in the stress response and brain-immune interactions. Remarkably, this effect was prevented in mice born by Cesarean section. Given that soma size is a marker of microglial activation, our findings suggest that microglia in Cesarean born mice are less activated. We are currently assessing whether these results extend to other brain regions and are examining brain cytokine expression in mice born vaginally or by C-section. In addition, to test the role of the peripheral IL-10 peak seen 3h after birth (above) on the brain's immune system, we are examining brain cytokine expression and microglial soma size in perinatal IL-10 knockout mice. Taken together, our results indicate that vaginal birth triggers an immune response in the newborn's body and brain and that some aspects of this response are altered by birth mode.

Title: The impact of stress on the dopamine system is dependent on the state of the critical period of plasticity

Authors: *F. V. GOMES[1], X. ZHU[1], A. A. GRACE[2]
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA

Abstract: Background: Unregulated stress exposure occurring during sensitive periods of development leads to the emergence of circuit deficits consistent with schizophrenia in the adult. If accurate, one would predict that re-opening the sensitive period in the adult could make it susceptible to a similar disruption. **Methods:** Male rats were submitted to a combination of footshock (FS) and restraint stress (RS) during adolescence (PD31-40) or adulthood (PD65-74). The activity of dopamine neurons in the ventral tegmental area (VTA) and the pyramidal in the ventral hippocampus (vHipp) were evaluated 1-2 or 5-6 weeks post-stress. We also evaluate if the administration of the HDAC inhibitors valproic acid (VPA; 300mg/kg) and SAHA (25mg/kg), which are known to re-instate the critical period in adults, would recreate an adolescent phenotype of susceptibility to stress. **Results:** The adolescent stress increased VTA dopamine population activity 1-2 and 5-6 weeks post-stress, these changes seem to be driven by an increased vHipp activity. FS+RS in adult rats decreased dopamine population activity 1-2 weeks post-stress, but not after 5-6 weeks. Interestingly, VPA treatment altered the impact of

adult stress. When rats were treated with VPA or SAHA, FS+RS increased VTA dopamine population activity, similar to that observed with adolescent stress. **Conclusion:** Timing of the stress is a critical determinant of the pathophysiology that is present in the adult. While adolescent stress could led to changes that recapitulates the MAM model of schizophrenia, adult stress induced changes observed in animal models of depression. Re-opening the sensitive period in the adult restores vulnerability to stress-induced pathology resembling schizophrenia.

Title: Embryonic GABAergic proliferation as a contributing mechanism in prenatal stress effects

Authors: *J. J. DEWITT, S. J. LUSSIER, E. C. MENEZES, J. S. ARMER, H. E. STEVENS
Univ. of Iowa, Iowa City, IA

Abstract: *Background*: Prenatal maternal stress increases risk for psychiatric outcomes in offspring, such as autism spectrum disorder (ASD), schizophrenia, Tourette syndrome, and ADHD. One mechanism that has been implicated both as an effect of prenatal stress and in psychiatric pathology is the alteration of the GABAergic neuron development. Human studies also implicate increased neuronal progenitor proliferation in macrocephalic ASD, but it is unclear if this is affected by prenatal stress. This study evaluates the effects of prenatal stress on GABAergic progenitor proliferation, developing striatal GABAergic populations, and striatal-dependent behaviors. *Methods*: A standard prenatal stress protocol used three times daily restraint stress beginning on embryonic day 12 in CD1 mouse dams bred to CD1 males heterozygous for a GAD67GFP transgene. Male offspring performed habit-learning, motor learning, and motor activity as adults. We examined GAD67GFP+ cellular outcomes in embryonic and postnatal brain using immunocytochemistry. With *in vivo* and *in vitro* methods, we manipulated maternal stress physiology, placental growth factors upregulated by stress, and embryonic GABAergic progenitor proliferation and assessed outcomes. *Results*: Motor activity

and motor and habit learning were disrupted in in adulthood. These behavioral changes correlated with increased GABAergic neuron density in mature caudate putamen, a region dominated by inhibitory neuronal populations. In embryonic brain, prenatal stress resulted in increased GABAergic progenitor proliferation, ganglionic eminence proliferative zones, and ventral GABAergic populations. Repetitive maternal exposure to interleukin-6 (IL6) but not corticosterone, also increased GABAergic populations in embryonic brain. These findings were matched in neurospheres. Neurosphere cultures were also used to develop methods for increasing GABAergic proliferation *in vivo*. *Conclusion*: Motor activity and habit learning were altered in male offspring after prenatal stress, reflecting what is seen in children with ASD and Tourette syndrome. These behavioral changes were associated with significant differences in GABAergic populations in the caudate putamen after prenatal stress, neurobiology implicated in several psychiatric disorders. Prenatal stress and maternal and placental physiological stress factors perturbed proliferation of GABAergic progenitors. These findings implicate interactive mechanisms in maternal and placental physiology during stress in disrupting the normal control of embryonic growth and represent important contributions to psychiatric disorders.

Title: Effects of early life stress on infantile amnesia and early development

Authors: *R. A. APONTE-RIVERA[1], A. JOHNSEN[1], G. MANZANO NIEVES[1], S. N. BASKOYLU[1], K. G. BATH[2]
[1]Neurosci., [2]CLPS, Brown Univ., Providence, RI

Abstract: Early life adversity is associated with increased predisposition for mental health disorders later in life. By looking at development, we can determine how early life adversity may alter neurodevelopment in ways that increase susceptibility to affective disorders. This experiment focuses on the development of memory as a means of probing for differences in emotional learning between typical and adverse-life subjects. Mouse models of early life stress (ELS) can carry crucial translational implications on memory formation in the traumatized brain,

especially in the ability to transition from child-like (infantile) to adult-like forms of memory. In order to visualize this transition behaviorally, we consider the period of infantile amnesia in order to compare development between ELS and control mice. We subjected mice to a limited-bedding paradigm as a model for ELS and measured fear recall of a tone-shock pairing at 17 (within the typical infantile amnesia window) days of age. Current results demonstrated the absence of infantile amnesia in 17-day-old ELS mice, suggesting a shortened period of infantile amnesia and an acceleration towards adult-like memory in ELS mice. In corroborating this biologically, ELS mice demonstrate higher levels of neurogenesis in the amygdala. From this data, we conclude that ELS mice demonstrate accelerated memory development, and that the greater tonic levels of neurogenesis in ELS mice are responsible for the accelerated, "strengthened" memory effect.

Title: The effects of early life stress on central and peripheral immune development in male and female mice

Authors: *M. E. GALLO[1], T. CAMPBELL[2], A. OLANIYAN[3], K. G. G. GALLO, 02901-1821[4]
[1]Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI; [2]Neurosci., Brown Univ., Brown University, RI; [4]CLPS, [3]Brown Univ., Providence, RI

Abstract: Exposure to early life stress (ELS) increases the lifetime risk for pathology and profoundly impacts neural development. To model ELS, we take advantage of a limited bedding and nesting (LBN) paradigm to induce alterations in maternal behavior and stress in the pups. To further characterize the behavioral effects of this ELS model on mother-pup interactions, we utilize a 24/7 video monitoring setup over the entire ELS manipulation to assess maternal behaviors including nesting, eating, drinking, kicking and walking. Critically, we observe LBN dams expressed increased interactions with their nest as indexed by nest entries/exists and circadian dependent differences in time spent on nest during the dark-light transition and the light period. Utilizing this model, we assess the effects of ELS on central and peripheral immune development. Recent work has linked chronic exposure to stress to regional changes in neuron-

microglial activation and changes in inflammatory responses, positing a role for the activation of the immune system in the sculpting of neural development. Utilizing immunohistochemistry, we assess the effects of ELS on microglia/macrophage specific binding protein (IBA-1) expression in regions implicated in maternal and social behaviors at postnatal days 8, 12 and 16 (during and following our LBN manipulation). Using real time qPCR, we characterize expression of relevant proinflammatory responses, including IL-6, IL-1 and CD34, in these regions. To assess peripheral immune responses, we quantify peripheral blood lymphocytes during and following the LBN manipulation.

Title: Prenatal stress affects communication patterns and modulates corticosterone and pro-inflammatory responses to an adult social stressor in male and female mouse offspring

Authors: ***N. D. OSBORNE**[1,2], T. CHARLTON[4], C. GROULX[4], K. CONNOR[5], M.-C. AUDET[1,2,4,3]
[1]Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [2]Cell. and Mol. Med., [3]Nutr. Sci., Univ. of Ottawa, Ottawa, ON, Canada; [4]Neurosci., [5]Hlth. Sci., Carleton Univ., Ottawa, ON, Canada

Abstract: Early life experiences may affect behavioral and cognitive development and modulate responses to stressors encountered later in life. In rodent models, adult social stressors known to promote depressive- and anxiety-like behaviors elicit stress hormone hypersecretion, gut microbiota changes reflective of a pro-inflammatory gut environment, and pro-inflammatory cytokine activation in circulation and in stress-sensitive brain regions. The objective of this study was to investigate whether a prenatal maternal stressor would modulate inflammatory activation and membrane permeability status along specific regions of the gut-brain axis in adult males and females exposed to an acute social stressor. Communication patterns in the developing offspring were also examined. Pregnant C57BL/6 mice experienced physical restraint (30 minutes, three times daily) during the second trimester of their pregnancy or were left undisturbed. Ultrasonic vocalizations were recorded at early (postnatal day [PD] 2) and late (PDs 9-11) neonatal stages and before weaning (PD21). In adulthood, male and female offspring experienced an acute social

stressor or were not manipulated (no stressor condition) and were sacrificed 90 minutes after for the determination of plasma corticosterone levels and mRNA expression of pro-inflammatory cytokines and tight junction proteins in the prefrontal cortex and the jejunum. Prenatally stressed litters emitted more ultrasonic vocalizations than non-stressed litters at PD2, while the calls produced had comparable peak maximum frequencies. As pups from both prenatally stressed and non-stressed litters aged, call rates decreased while peak maximum frequency increased. Elevations of plasma corticosterone levels and of prefrontal expression of interleukin (IL)-6 apparent after the adult stressor were limited in prenatally stressed males, but not in females. Curiously, prefrontal expression of the tight junction protein claudin-5 was upregulated in prenatally stressed males (irrespective of whether they experienced an adult social stressor) but was reduced after the adult social stressor only in females. In the jejunum, IL-1β and IL-6 mRNA was increased in prenatally stressed offspring, an effect that appeared limited when these mice were acutely stressed in adulthood. These findings suggest that prenatal stress may alter offspring's communicative development and modulate corticosterone as well as gut and brain cytokine responses to a subsequent stressful experience in a sex-specific fashion.

Title: Maternal separation induces long-lasting changes in anxiety and protein expression in specific brain regions, but not conditioned place preference to methamphetamine

Authors: *J. N. HAMDAN[1], S. SAUCEDO[2], G. A. LODOZA[1], J. A. SIERRA FONSECA[2], R. J. FLORES GARCIA[3], L. E. O'DELL[4], K. L. GOSSELINK[5]
[2]Biol. Sci., [3]Psychology, [1]Univ. of Texas at El Paso, El Paso, TX; [4]Univ. Texas at El Paso, El Paso, TX; [5]Univ. of Texas at El Paso Dept. of Biol. Sci., El Paso, TX

Abstract: Maternal deprivation is a strong psychological stressor that can cause long-lasting neurological and behavioral changes which may lead to difficulties with social integration; subsequent outcomes can include school- or work-related challenges, increased criminal behavior, and even the manifestation of mental illness. The goal of this study was to determine long-lasting changes in the brain and behavior of rats that result from maternal deprivation in the

form of maternal separation (MatSep). Male Wistar rats were removed from their dams for 3h/d from postnatal day (PND) 2 to PND14 and were assessed in adulthood (PND 70-95). Proteins involved in dopaminergic signaling [dopamine transporter (DAT), dopamine receptor-1 (D_1), dopamine receptor-2 (D_2), tyrosine hydroxylase (TH)] or synaptic plasticity [D_1, post-synaptic density 95 (PSD95), NMDA receptor-1 (NMDAR), and α-synuclein] were evaluated by Western blot. Brain regions in which the levels of these proteins were quantified included the prefrontal cortex (PFC), hippocampus, caudate-putamen (CPu), and the nucleus accumbens (NAcc). Rats were also exposed to a light-dark box test for anxiety-like behavior, and for conditioned place preference to different doses of methamphetamine (1.0 mg/kg and 0.1mg/kg). Preliminary data show a significant increase in the expression of D_1 and PSD95 in the NAcc ($p=0.040$ and 0.016, respectively), a significant decrease in the expression of NMDAR in the CPu ($p=0.026$), a significant decrease in the expression of DAT, D_1, and D_2 in the hippocampus, and a significant increase in the expression of D_2 in the PFC. No changes were seen in drug sensitivity caused by MatSep, but a significant decrease was seen in stressed rats in the amount of time spent in the light side of the light-dark box. Together, these data suggest that plasticity and reward systems can undergo significant changes without affecting certain relevant behavioral outputs. The impacts of early life stress are long-lasting and can be seen in multiple brain regions in adult animals, months after the stress was experienced. This study will also include a more in-depth analysis of changes caused by MatSep on protein expression and behavior following the administration of methamphetamine.

Title: Social isolation in early adolescence induces long-term changes in dopaminergic system and increases the susceptibility to food addiction in adulthood

Authors: *C. LAMPERT[1], N. S. COUTO-PEREIRA[1], D. M. ARCEGO[1], A. S. VIEIRA[1], E. GARCIA[1], D. A. VENDITE[1], R. M. M. DE ALMEIDA[2], M. E. CALCAGNOTTO[1], C. DALMAZ[1]
[1]Biochem., [2]Psychology, Univ. Federal do Rio Grande do Sul - UFRGS, Porto Alegre, Brazil

Abstract: Exposure to early life stress, such as social isolation (SI), is able to prompt changes in sensitive brain circuitries, essentially in the mesolimbic dopaminergic system and increase the risk for psychiatric disorders later in life. SI can stimulate the consumption of rewarding substances, like drugs of abuse and palatable foods. However, most studies analyze long periods of SI and very little is known about the effects of a brief social isolation in a sensitive period of development and its association with palatable foods on the reward system sensitization. Therefore, the aim of this study was to analyze the effects of a short period of SI combined with a chronic access to a high sugar diet (HSD) on sweet food seeking behavior, and possible alterations in dopaminergic parameters and synaptic function in the nucleus accumbens (NAc). We used female Wistar rats that were socially isolated from post-natal days (PND) 21 to 35 and received chronic HSD until PND 60. After five days of washout, on PND 65, the habituation protocol of the sweet food seeking task (using Froot Loop®) was performed. The habituation session lasted 5 days under food restriction, and the test session was conducted on the 6th day in a fed state. During the habituation and test sessions, we analyzed the latency to reach the food, the latency to start eating and the amount consumed. Another subset of animals was killed on PND 65 to determine the dopaminergic parameters on NAc using western blotting. In addition, the excitatory synaptic transmission on NAc neurons was studied in slices using Whole cell-patch clamp. We found that animals that were socially isolated after weaning increased sweet food seeking (p=0.004) as well as the amount of Froot Loop® consumed (p=0.025) in a fed state, indicating a binge eating-behavior. In the same way, SI animals showed a reduced basal immunocontent of D2R (p=0.024) in the NAc, indicating an increase in dopaminergic signaling in the NAc. The electrophysiological properties of synaptic transmission are still being analyzed. This study highlights that a short post-weaning social isolation is able to induce long-term changes in the NAc dopaminergic system and increase sweet food seeking behavior. These results emphasize the importance of stressful experiences during a short period of development on reward circuit programming and susceptibility to food addiction later in life.

Title: Early life stress induces retinal microglia activation and retinal layer alterations across the lifespan of female rats

Authors: *M. CHAVEZ[1,2], M. GRIGORUTA[1], J. SIERRA[2], K. L. GOSSELINK[2], A. MARTINEZ[1]

Abstract: Early life stress (ELS) in mammals is associated with neuronal and glial alterations in central nervous system (CNS). ELS has different consequences including learning, memory, behavior, and morphological disorders during brain lifespan, depending on sex. Early Maternal Separation (MatSep) is considered as an ELS chronic model for newborns and is associated with proinflammatory immune response activation. Several studies indicate that MatSep-stressed animals experience both microglia and proinflammatory cytokine activation in adolescent and adulthood life. Retinal tissue is part of the CNS but MatSep stress effects have not yet been described. The objective was to evaluate MatSep-stress effects in retinas from female rats of three different ages: adolescence, adulthood, and aged. Newborn pups were separated from their mother for 3 hours per day on 13 consecutive days (PND 2-14), then were grown to three different age groups: 49 (adolescent) or 75 (adult) days old, or 17 months old (aged). Rats were sacrificed, their eyes enucleated and treated for immunofluorescence analysis. Retinal sections (12 µm) were cut on a cryostat and incubated with antibodies for 1) microglia activation: IBA-1, CD45; and 2) neuroprotective function: DJ-1. To evaluate the retina architecture, retinal layer thickness was determined for Control and MatSep groups at different ages. 10 retinal sections per animal (N=3 animals for group/age) were stained with DAPI. The thickness of the outer nuclear layer (ONL), inner nuclear layer (INL), and total retina was measured with Zen Blue® 2011 software. Results are shown as mean ± SEM. Our results suggest that retinas from the MatSep group have higher IBA-1 and CD45 expression depending on age. Maximum expression of both markers was observed in the aged group. On the other hand, DJ-1 expression in Control and MatSep groups was similar in adolescent and adult retinas but decreased in aged rats. Moreover, retinal thickness for the MatSep group showed more than 30% reduction in adult and old rats. MatSep-stress is a condition that affects retinal architecture predominantly in adult and aged rats, which also increase the expression of microglia activation mediators.

Title: Long-term neurobiological effects of early-life challenges on cognition and stress responsivity in adult female rats

Authors: *M. H. KENT[1], M. BROOKS[1], D. KOVALEV[1,3], S. SCAROLA[3], D. VAVRA[2], K. POKORNY[2], K. G. LAMBERT[1]

Abstract: In humans, poverty and unpredictable environments have been associated with negative socioemotional and developmental outcomes (Blair et al., 2016). Accordingly, the current study utilized a rodent model to assess the effects of restricted resources and unpredictable threats [simulating a poverty/low socioeconomic status (SES) model] on socioemotional neurobiological functions. In this model, female rats were raised in four different conditions defined by availability of materials for nest building, standard resources for control (CON) and restricted resources for (LOW), along with the presence (T) or absence (NT) of threat (predator cues) throughout the lactation period. Following weaning, offspring were pair-housed, according to group assignments (LOW/NT; LOW/T; CON/NT; CON/T, n=8 each group) in standard housing conditions for 1 year. Female adult offspring were assessed on multiple behavior tasks to assess the cognitive and emotional effects of rearing environment. During a learning task, CON/T rats on average took longer to reach the reward baited well compared to the CON/NT while there was little difference between the LOW groups. The same difference was observed for the percentage of rewards eaten. This difference could indicate a difference in vigilance between the T and NT groups in the CON group. An uncertainty task revealed increased vigilance behaviors in the T rats demonstrated by increased rearing responses. The same trend for increased vigilance--like behavior was seen in a novel environment task where T rats explored more than NT rats. When a novel male confined to a plastic container was introduced the NT rats interacted more with the container and spent more time engaged in nose to nose interactions with the novel male. However, when the female cage mate was placed in the plastic container the T rats spent more time rearing (information gathering) while the NT rats spent time directing attention toward the restricted conspecific (ie, digging). Further, CON/T rats spent the most time interacting with the confined cage mate especially when compared to the CON/NT. Histology data revealed a trend in increased oxytocin-ir in the supraoptic nucleus in

NT rats BDNF-ir was increased in CON rats, specifically in the CA3 area of the hippocampus. Interestingly, lower body weights and longer tail lengths in CON animals were observed in adulthood. In sum, behavioral and neurobiological data suggest long-term socioemotional effects in adult animals exposed to stressful conditions during the limited time of lactation.

Abstract: Perinatal stress (PRS) in rats has an established value as a model for stress-related disorders endowed with face, construct, and pharmacological validity. A comorbidity exists between stress-related disorders and disorders of the extrapyramidal motor system (e.g., Parkinson's disease). We decided to examine how PRS influences neurochemical and behavioral parameters related to basal ganglia motor function. We were surprised to find that adult (4-month old) PRS rats (i.e., the adult offspring of dams exposed to multiple episodes of restraint stress during pregnancy causing reduced maternal care) showed a reduction in depolarization-evoked dopamine (DA) release in the corpus striatum, as assessed by measurement of ^{3}H-DA efflux from superfused isolated synaptosomes, associated with an increase in steady-state DA levels in

the striatum. Immunoblot analysis of the high affinity DA transporter (DAT) suggested that the reduction of DA release found in PRS rats was not due to degeneration of nigro-striatal DAergic terminals. Interestingly, PRS rats showed increased A_{2A} adenosine receptor mRNA levels and A_{2A} receptor-mediated cAMP formation in the striatum, with no changes in the transcripts of mGlu4 and mGlu5 metabotropic glutamate receptors. As a behavioral correlate of these findings, adult PRS rats showed a defective striatal motor performance in the grip strenght, and pasta matrix reaching tests. We extended the analysis to aged (20-month old) PRS rats, which also showed a reduction in the evoked release of ^{3}H-DA from striatal synaptosomes and a defect in striatal motor function (pasta matrix, and ladder rung walking tests) with respect to age-matched unstressed controls. D1 receptor protein levels were also largely reduced in the striatum of aged PRS rats. Our findings suggest that early life stress may cause abnormalities in the basal ganglia motor circuit that could enhance the risk for development of extrapyramidal motor disorders.

Abstract: A double exposure to stressful events during critical developmental periods and later in the adult life is crucial in shaping individual variability in coping strategies. In males, it has been shown that exposure to stressful events in early life strongly programs an individual's phenotype. Here, we extended the study to middle-aged female rats using the model of perinatal stress (PRS). We investigated different outcomes following exposure in later life to an unpredictable chronic mild stress (uCMS) condition for six weeks. We showed for the first time an accelerated ageing in the estrous cycle associated with a reduction in estradiol levels in PRS rats. In middle-aged female rats PRS also reduced motivational and risk-taking behavior, caused an impaired regulation of plasma glucose and insulin levels following a glucose challenge, and disrupted the feedback regulation of the hypothalamic-pituitary-adrenal axis after acute stress. Interestingly, all PRS-induced alterations were modified by exposure to uCMS while controls were not affected by uCMS, except for a slight and transient reduction in body weight. PRS females displayed a reduced body weight gain across the entire duration of the uCMS procedure. Remarkably, the effects of uCMS on PRS females were still observed up to two months after its termination and the females displayed heightened rhythms of locomotor activity and enhanced sensitivity to reward with respect to controls exposed to uCMS. Globally, our findings indicate a mismatch hypothesis for many parameters of the PRS female adult phenotype that are subjected to both an early and late experiences and suggest that early stressed individuals may be programmed with a more dynamic phenotype than non-stressed individuals.

Abstract: Perinatal stress (PRS) in rats has an established value as a model for stress-related disorders which is caracterized by an impaired synaptic activity including glutamatergic transmission with reduced depolarization-evoked glutamate release selectively observed in the ventral hippocampus and reduced expression of SNARE proteins and mGlu5 and mGlu2/3 receptors. The defective glutamate transmission is causally related to reduced risk-taking behavior in several behavioral tests. We wanted to assess the effects of different interventional strategies in reversing this PRS-induced profile on glutamate transmission by chronically treating (3 weeks, i.p.) adult PRS animals with antidepressants (fluoxetine, agomelatine, and the novel AMPA receptor enhancer, S 47445) or by targeting the stress/antistress balance with the oxytocin receptor agonist, carbetocin. We found that the three different treatments reversed the deficit in glutamate release and in the expression in SNARE proteins, and corrected abnormalities in risk-taking behavior, motivational behavior, and cognitive function, as assessed by the elevated plus maze, light-dark box, splash test, and social memory test. There was significant correlation between glutamate release and behavioral changes in the various experimental groups. We are currently performing a glycomic characterization in the hippocampus of PRS rats to unravel the molecular events that drive phenotypic changes focusing on post-translational modifications of proteins. Taken together, our findings suggest that PRS causes long-lasting changes in glutamatergic transmission in the hippocampus that involve, at least in part, modifications in the presynaptic machinery mediating glutamate release. Interestingly, this “glutamatergic synaptopathy” was corrected by antidepressant and anti-stress drugs. These findings support the hypothesis that abnormalities in glutamatergic neurotransmission lie at the core of stress-related disorders.

Title: Effects of early life stress on AMPA receptor composition and cocaine conditioned place preference are sex-specific and driven by TNF

Authors: *P. GANGULY, J. A. HONEYCUTT, J. ROWE, L. RYLL, C. DEMAESTRI, H. C. BRENHOUSE
Northeastern Univ., Boston, MA

Abstract: Early life adversity can contribute to the propensity for developing neuropsychiatric diseases, including substance abuse disorders. In rodents, early stressors such as repeated maternal separation (MS) impact neural development, including important effects on ionotropic glutamate receptors in brain regions critical for behavioral regulation. Notably, previous reports suggest that neuroimmune signaling molecules, including the pro-inflammatory cytokine tumor necrosis factor (TNF), regulates AMPAR subunit composition. Indeed, increased TNF levels are reported to reduce GluA2-positive AMPARs, which are associated with increased excitotoxicity. Since MS can lead to TNF elevation, we hypothesized that AMPAR subunit composition is altered after MS. Furthermore, AMPAR activity in both the prefrontal cortex (PFC) and nucleus accumbens (NAc) contributes to drug-cue association. Therefore, we tested whether MS induced TNF elevations in these regions prompt AMPAR subunit composition changes, thereby affecting cocaine-induced conditioned place preference (CPP). Here, we (a) studied the contribution of MS to selective loss of GluA2 subunit in the PFC and NAc of male and female rats, (b) tested the specific role of soluble TNF in MS-induced GluA2 loss, and (c) examined the role of MS in cocaine-induced CPP and possible amelioration via pharmacological disruption of TNF signaling. Male and female rats were reared either under control or MS conditions. During adolescence (P40), animals were subcutaneously administered soluble TNF inhibitor XPro1595 (Xencor, Inc) or vehicle. Subsequently, they were tested for cocaine-induced CPP. PFC and NAc were extracted for qPCR analysis of TNF, GluA1, and GluA2, and western blot analyses on membrane fractions of GluA1, GluA2, and TNFR1. We observed elevated TNF gene expression in both PFC and NAc of MS males, but not females, compared to controls. GluA2 gene and protein expression were reduced in both regions of MS male rats, and XPro1595 treatment protected against such loss. MS males also formed a greater preference for a cocaine-paired environment, which returned to baseline levels after XPro1595 administration. Taken together,

this work is the first to show a sex-specific mechanistic link between TNF signaling and changes in GluA2 expression and drug-cue conditioning, thereby providing further evidence for a role of MS and neuro-immune activity changes in cortical and striatal AMPARs. Moreover, manipulation of the TNF signaling pathway represents a novel approach for influencing response to rewarding effects of drug use.

Title: Altered corticolimbic connectivity in a rat model of early adversity: Evidence from fMRI and neuroanatomical tracing suggests sex-dependent effects of early experiences

Authors: *J. A. HONEYCUTT[1], C. DEMAESTRI[1], X. CAI[2], R. MEHTA[1], P. P. KULKARNI[2], C. F. FERRIS[2], H. C. BRENHOUSE[1]

Abstract: Adverse early life experiences significantly alter behavioral and neural trajectories, and such disruptions during early developmental periods likely set the course for aberrant brain maturation. Indeed, children with a history of early life stress (ELS) often exhibit deleterious effects, manifesting as maladaptive behaviors, cognitive impairment, and/or increased risk of mental illness later in life. Evidence in ELS human populations points to a role of atypical corticolimbic circuit development leading to changes in connectivity between limbic (i.e. amygdala, hippocampus) and the prefrontal cortex (PFC). Importantly, children with a history of ELS show patterns of precocially mature corticolimbic functional connectivity (FC) which is comparable to adolescent patterns. While these findings indicate compelling influences of early adversity on neural circuit maturation, the underlying neurobiological substrates remain poorly understood. Recent work from our group utilizing a rat model of ELS via maternal separation reveal sex- and age-dependent effects on amygdala-derived axonal innervation of the PFC. Specifically, we have reported that juvenile ELS females show patterns of axonal innervation comparable to adolescent and adult controls, with ELS-dependent changes in males not appearing until later in development. To explore whether these neuroanatomical changes confer alterations in corticolimbic connectivity, we utilized resting state FC and anisotropy assessments

to directly compare ELS and control males and females from juvenility to adolescence. Here, we present data delineating sex- and age-dependent effects of resting FC which suggest thatmay help explain how females with a history of adversity may be more vulnerable to later psychiatric illness resulting from alterations in FC driven by precocial maturation of amygdala-derived PFC innervation. Furthermore, we present behavioral data suggesting that these neural alterations may also be predictive of anxiety-like behaviors mediated by corticolimbic circuitry. Taken together, this data provides evidence for a critical role of early experience, and provides putative preliminary mechanistic insight into the underlying etiology of adversity-induced vulnerability.

Title: Early life stress leads to sex-specific alterations in the formation of perineuronal nets around parvalbumin-expressing interneurons in the developing rat prefrontal cortex

Authors: *K. R. GILDAWIE, J. A. HONEYCUTT, H. C. BRENHOUSE
Psychology, Northeastern Univ., Boston, MA

Abstract: Early life experiences play a vital role in the development of the brain and its molecular components. Consequently, early life adversity can have disruptive effects on behavioral and neural development, especially in the prefrontal cortex (PFC), a late-maturing region with many subcortical connections involved in emotion regulation. Research demonstrates that the formation of extracellular structures, such as perineuronal nets (PNNs), that enwrap certain neuronal subtypes throughout the central nervous system, is essential for proper neurodevelopment. Indeed, PNN formation coincides with the closure of developmental critical periods, potentially playing a role in the emergence of neuropsychiatric disorders. Early life stress via maternal separation (MS) is reported to have sex-specific effects on presence of parvalbumin (PV), which is expressed in fast spiking GABAergic interneurons that PNNs preferentially surround in the PFC. To determine the impact of MS and sex on PNN and PV formation in the PFC, male and female rat pups were separated from their dams for 4 hours per day from postnatal day (P) 2-20. At distinct developmental time points of juvenility (P20), adolescence (P40), early adulthood (P70), and adulthood (P120) rats were perfused and brains

were collected, cryoprotected, and sliced on a freezing microtome to 40 µm slices. Tissue sections containing the prelimbic (PL) and infralimbic (IL) PFC were stained for *Wisteria floribunda* agglutinin, a plant lectin that has an affinity for PNNs, and anti-PV to visualize PV neurons. Z-stacks were obtained (8 stacks per section) using fluorescent microscopy in 4 consecutive sections of the PFC and ImageJ was used to manually count PNNs, PV cells, and PNNs surrounding PV cells in the PL and IL. Results demonstrate sex- and age-specific effects of MS on PNN number in the PFC, where females displayed a distinct reduction in the number of PNNs surrounding PV cells following MS. Notably, this effect is not observed in PNNs surrounding non-PV cells. These findings have implications for the role of aberrant PNN and PV development in neural and cognitive dysfunction seen in humans and animals that have experienced early life adversity.

Title: The association between maternal alcohol consumption in pregnancy and offspring brain morphology: A population-based MRI study

Authors: *T. SHARP[1], E. WALTON[1], C. RELTON[1], T. PAUS[2], L. ZUCCOLO[1]
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Rotman Inst., Toronto, ON, Canada

Abstract: The neurodevelopmental consequences of Foetal Alcohol Spectrum Disorder are well characterised, with microcephaly and cognitive deficits consistently reported resulting from significant prenatal alcohol exposure (PAE). There is a gap in the literature, however, regarding the impact of in utero alcohol exposure in non-clinical populations. Here we describe the results of our exploratory study assessing the association of PAE with global and region of interest (ROI) measures of cortical surface and thickness in two population-based cohorts.
Data from mother-adolescent pairs were meta-analysed from two populations; prospective birth cohort the Avon Longitudinal Study of Parents and Children (ALSPAC, n=455) in the UK and the cross-sectional Saguenay Youth Study (SYS, n=998) in Canada. Data on maternal alcohol consumption were collected via structured questionnaire, and offspring grouped as exposed or unexposed. MRI scans were obtained during adolescence (mean 19.6 years ALSPAC, 15.2 years SYS), and processed using the FreeSurfer v5.3 pipeline. Brain-based outcomes were defined as total cortical surface (tCS), mean cortical thickness (mCT), and 34 regions-of-interest (ROI) in both measures. A wide range of covariates relating to the prenatal and postnatal environment were examined as potential confounders. Our final model adjusted for sex, age and gestational

age of the child, and maternal smoking in pregnancy, parity, and socioeconomic indicators. To allow assessment of a dose-response relationship, additional analyses were conducted in ALSPAC using low (<1 unit/week) and moderate (1 to 6 units/week) alcohol measures. Regression models produced little evidence against the null hypothesis in all analyses. In the adjusted model, exposed offspring showed a 398mm2 difference in tCS in ALSPAC (95% CI -3024mm2 to 3820mm2 p=0.82), and a 492mm2 difference in SYS (95% CI -1835mm2 to 2819.17mm2 p=0.68), with a pooled estimate of 462mm2 (95% CI -1503mm2- 2383mm2 I2< 0.00%). Exposed offspring showed a 0.009mm difference (95% CI -0.014mm to 0.031mm p=0.46) in mCT in ALSPAC, and a 0.003mm difference in SYS (95% CI -0.019 to 0.012 p=0.69), with a pooled estimate of 0.001mm (95% CI -0.012mm to 0.013mm I2=<0.00%). Low and moderate exposure measures were not associated with differences in either tCS or mCT. No ROIs were associated with any alcohol measures after correction for multiple testing.
We found little evidence to suggest PAE is associated with alterations in brain morphology in adolescents in the general population. This analysis will be expanded to incorporate other population cohorts, where increased power may allow detection of evidence of effect.

Title: Transcriptional priming by enduring chromatin modifications after early life stress

Authors: *C. J. PENA[1], Y.-H. E. LOH[1], L. FARRELLY[1], B. GARCIA[2], I. MAZE[1], L. SHEN[1], E. J. NESTLER[1]

Abstract: Child maltreatment and other forms of early life stress increase the lifetime risk of depression and other mood, anxiety, and drug disorders by 2-4 -fold. Studies in humans and animals suggest that early life stress sensitizes individuals to stress later in life, leading to a first appearance or synergistic worsening of depression-like symptoms only after additional stress. To study the molecular correlates of lifelong stress vulnerability, we recently established a “two-hit”

stress paradigm in mice in which early life stress in a sensitive window increases susceptibility for depression-like behavior, but only after experience of an additional stressor in adulthood. This latent behavioral vulnerability is accompanied by latent transcriptional alterations in key brain reward regions that are implicated in depression, including the ventral tegmental area (VTA; Peña et al., *Science*, 2017). We hypothesized that such latent transcriptional alterations would be primed by post-translational histone modifications. In order to profile all possible long-lasting histone modification changes, we performed bottom-up mass spectrometry on isolated histone tail fragments from adult standard-reared and early life stressed male mice. The proportions of 14 histone H3 and H4 modifications were altered by early life stress, a majority of which are associated with permissive gene expression states. Among these, early life stress increased H3K4me3 and H3K4me1, marks of active and primed cis-regulatory elements. ChIP-seq for H3K4me1 revealed 201 differentially enriched peaks (FDR<0.05 and >20% fold-change), a majority of which were increased by early life stress. Interestingly, there is greater correspondence between H3K4me1 enrichment and expression of nearest-genes after additional adult stress than after early life stress alone, in support of a priming hypothesis. This research suggests novel epigenetic mechanisms mediating the long-lasting effects of early life stress within brain reward circuitry.

Title: Unexpected transcriptional programs underlie enduring memory deficits after early-life adversity

Authors: *J. L. BOLTON[1], A. SCHULMANN[1], M. M. CURRAN[1], L. REGEV[1], N. KAMEI[1], A. SINGH-TAYLOR[1], S. JIANG[2], J. MOLET[1], A. MORTAZAVI[2], T. Z. BARAM[1]
[1]Dept. of Anat. & Neurobio., [2]Developmental and Cell Biol., Univ. of California-Irvine, Irvine, CA

Abstract: Premise: Adverse early-life experiences are associated with lifelong cognitive deficits and risk of dementia, yet the underlying mechanisms remain unclear.
Methods: We imposed early-life adversity by rearing rat pups in simulated poverty, assessed hippocampus-dependent memory in adulthood, and probed enduring changes in gene expression and their contribution to memory deficits.
Results: Adversity provoked poor spatial memory in adult male rats, associated with over a hundred differentially expressed (mostly downregulated) genes in dorsal hippocampus. Transcription-factor target enrichment identified the stress-hormone receptor GR (glucocorticoid receptor) and, unexpectedly, the repressor neuron-restrictive silencer factor (NRSF/REST), as candidate upstream regulators. Blocking NRSF function transiently *after* the adversity period rescued hippocampus-dependent memory without influencing other behaviors.
Conclusions: These studies identify a novel role for NRSF-mediated repression of crucial neuronal genes in early-life adversity-induced hippocampal dysfunction and enduring cognitive deficits. A better understanding of these mechanisms will enable the development of better therapeutics and preventative interventions for at-risk children.

Title: Variations in maternal care influence the epigenomic and transcriptomic landscape of the rat dentate gyrus

Authors: *W. I. DOYLE[1], X. WEN[2], C. L. KEOWN[1], J. DIORIO[2], M. MEANEY[3], E. A. MUKAMEL[1], T.-Y. ZHANG[2]

Abstract: Maternal care has profound impacts on the development and function of the brain in mammals. Maternal care in rats affects synaptic plasticity and neurogenesis in the dentate gyrus (DG), a brain region involved in learning and stress-related behaviors. Offspring of high licking/grooming (high LG) mothers have enhanced learning and memory, and decreased

corticosterone response to acute stress, compared to offspring of low licking/grooming (low LG) mothers. We examined the effects of maternal care in the dorsal and ventral DG on gene expression (transcriptome RNA-sequencing). In parallel, we generated DNA methylome (whole genome bisulfite sequencing) and hydroxymethylome (Tet- assisted bisulfite sequencing) data to address the potential epigenomic contribution to the lasting effects of maternal care. RNA-sequencing indicated that maternal care is associated with significant changes in the expression of genes related to synaptic plasticity and function, dendrite complexity, and gene regulation in both the dorsal and ventral DG. These effects were similar in the two poles of the DG. Consistent with our previous work in mice, we also found that the dorsal and ventral DG have substantial differences in gene expression and DNA methylation, with higher levels of methylation at non-CG dinucleotides in ventral compared to dorsal DG. We also identified over 30,000 differentially methylated regions (DMRs) where CG dinucleotides were hypomethylated in the dorsal DG. These results demonstrate that maternal care can lead to changes in expression of genes crucial for proper neuronal activity, which may be in part explained by DNA methylation differences.

Title: Intra-individual methylome signatures distinguish early-life experiences

Authors: *N. KAMEI[1], S. M. JIANG[2], J. L. BOLTON[1], G. A. SANCHEZ[1], A. MORTAZAVI[2], T. Z. BARAM[1]
[1]Anatomy/Neurobiology and Pediatrics, [2]Developmental and Cell Biol., Univ. of California, Irvine, Irvine, CA

Abstract: Premise: Genetic and environmental factors interact during sensitive periods early in life to influence mental health and disease. These influences involve modulating the function of neurons and neuronal networks via epigenetic processes such as DNA methylation. However, it is not known if DNA methylation changes outside the brain provide a predictive ‘epigenetic signature’ of early-life experiences in an individual child that may serve as a marker for vulnerability or resilience to mental illness. **Methods:** To obviate the massive variance among individuals, we employed a novel intra-individual approach by directly comparing two timed samples from the same individual rat in groups exposed to distinct early-life experiences with

defined onset and duration. We have previously established that these diverse experiences provoke specific phenotypic outcomes later in life. Specifically, we imposed 'simulated poverty' by raising pups for a week (from postnatal day [P]2 to P10) in cages with limited bedding and nesting materials (LBN). This manipulation disrupts the care provided by the rat dam to her pups and results in profound yet transient stress in the pups, devoid of major weight-loss or physical changes. This transient experience provokes significant and life-long deficits in memory and generates emotional measures of anhedonia and depression. Genomic DNA was isolated from each buccal swab. Reduced Representation Bisulfite Sequencing (RRBS) libraries were created and analyzed for intra-individual methylome changes using Support Vector Machine learning (SVM) algorithms. **Results:** Methylation levels of samples collected on P10 or P2 reflected the effect of age. However, inter-individual comparisons of P10 samples did not distinguish the early life experience of each individual rat. In contrast, **intra-individual** methylation changes of paired DNA samples from the same individual rat reflected the impact of diverse neonatal experiences. Using a support vector machine learning algorithm, we identified a DNA methylation signature that enabled predicting the type of early life experience of individual rats in a validation cohort. **Conclusions:** Our observations in rats--that distinct early-life experiences generate specific individual methylome signatures in accessible peripheral cells--should be readily testable in humans.

Title: Early life emotional neglect predicts shorter telomere length in adulthood

Authors: *P. CINTORA[1], H. K. LAURENT[2]
[1]Neurosci., [2]Neuroscience, Psychology, Univ. of Illinois at Urbana Champaign, Urbana, IL

Abstract: Telomere length has gained increased attention as a potential risk marker for neuropsychiatric disorders. Telomeres, the protective caps at the end of chromosomes, naturally shorten with cellular aging, eventually leading to cellular dysfunction and death. Acceleration of this shortening process has been associated with early life adversity. However, there are multiple forms of adversity, and most studies to date have narrowly focused on abuse or trauma. Here, we study the associations between childhood maltreatment subtypes of neglect and abuse and

telomere length in a sample of 48 low-income women who took part in a study of mother-infant stress regulation. Self-reported experiences of neglect and abuse on the Childhood Trauma Questionnaire were used to predict mothers' telomere length in saliva samples collected when their infants were 18 months old. Of the five subtypes of childhood maltreatment, only history of emotional neglect predicted shorter telomere length in adulthood [Beta = -.318, p= .027], which was independent of concurrent depression and anxiety symptoms. Our results indicate that emotional neglect may have long lasting impacts that are biologically based as indicated by telomere shortening. Research examining the biological mechanisms by which neglect may accelerate telomere shortening and how that impacts later psychological health are warranted.

Title: Transcriptome analysis of prenatal glucocorticoid exposed offspring demonstrates altered circadian rhythm signaling

Authors: S. THARMALINGAM, S. KHURANA, *T.-C. TAI
Div. Med. Sci., Northern Ontario Sch. Med., Sudbury, ON, Canada

Abstract: Prenatal glucocorticoid (GC) exposure is associated with the development of hypertension in adults. We have previously demonstrated that antenatal dexamethosone (DEX) administration in Wistar-kyoto dams results in offspring with elevated systolic, diastolic, and mean arterial pressure, along with increased plasma epinephrine levels (Nguyen 2015). Permanent molecular programming of the adrenal gland in the hypothalamic-pituitary-adrenal (HPA) axis has been implicated with cardiovascular disorders. In order to elucidate the molecular mechanisms responsible for prenatal DEX-mediated hypertension, whole-transcriptome analysis of the adrenal gland in male offspring of DEX exposed Wistar-kyoto dams were analyzed using Rat Gene 2.0 ST GeneChip (Thermo Fisher Scientific). This array covers over 27,000 protein coding transcripts from 24,000 Entrez genes, with a median of 22 probes per gene thereby providing excellent genome wide coverage. Differential gene expression analysis of DEX exposed offspring compared with saline-treated controls revealed 84 significantly differentially expressed genes; 55 upregulated genes and 29 downregulated genes (criteria: fold-change <-1.5 and >1.5; p-value <0.05; false discovery rate < 0.1). Global network

analysis demonstrated that genes involved in circadian rhythm signaling were most robustly dysregulated. Here, DEX exposed offspring demonstrated 2-fold increased expression of BMAL1 and Npas2, while Per1, Per2, Per3, Cry1, and Cry2 were all downregulated (verified using qPCR analysis). BMAL1 and Npas2 dimerize and function as molecular transcription factors with a wide variety of downstream effects including control of blood pressure regulation. Interestingly, BMAL1 knockout animals demonstrate reduced blood pressure during the active phase. Furthermore, BMAL1-Npas2 complex also increases expression of Per and Cry genes, which are negative regulators of BMAL1 and Npas2. Therefore, these results suggest that the adrenal gland of DEX exposed offspring demonstrate abnormal circadian rhythms. Thus, altered circadian rhythm signaling may provide a mechanism by which prenatal GC exposure may program for hypertension later in life.

Title: Development and characterisation of mice carrying the humanised FKBP5 gene

Authors: V. NOLD[1], N. DENOIX[1], B. HENGERER[1], *K. A. ALLERS[2]
[1]CNS Discovery Res., [2]Boehringer Ingelheim Pharma Gmbh & Co. KG, Biberach An Der Riss, Germany

Abstract: The *fkbp5* gene codes for the protein FKBP51, which is a potent regulator of glucocorticoid and NFkB signaling. A common SNP located in *fkbp5* is rs1360790, which imparts a profound influence on the stress response. This is likely due to an altered chromatin conformation in carriers of the T- allele, resulting in greater transcription upon glucocorticoid response element activation. Furthermore, the risk of developing psychiatric disorders after childhood trauma is higher in carriers of rs1360790-T as compared to carriers of the ‘resilience’ allele (rs1360790-C), as shown by an increased incidence of disorders in carriers of the ‘risk’ allele. This gene × environment interaction is suggested to be mediated via demethylation of *fkbp5*, which further promotes transcription in the already more highly responsive form of *fkbp5*. These SNPs are not present in rodents. In collaboration with Taconic, our aim was to develop humanised mouse lines carrying the ‘risk’ or ‘resilience’ allele. A locus replacement strategy was used: Targeting constructs for either the murine or human gene were obtained by cloning the SNP variants into the sequence. Via homologous recombination, the constructs were inserted in the genome of murine embryonic stem cells (ESC). Construct-positive ESC clones were selected using resistance factors included at the ends of the constructs and confirmed by PCR analyses.

The selected ESC clones were inserted in blastocysts via microinjection to generate chimeric mice. In these chimeras, the resistance factors were deleted in vivo via flip-recombinases. Breeding of chimeric mice with wildtype-mice resulted in heterozygous progeny which was HE × HE mated to obtain homozygous transgenic mice carrying the human *fkbp5* gene containing either the 'risk'-allele rs1360790-T or the 'resilience'-allele rs1360790-A. A well-known feature of *fkbp5* regulation is its induction by glucocorticoid receptor agonists, which makes detection of *fkbp5*-RNA after stimulation of the glucocorticoid receptor an ideal test of a functionally responsive gene. Upon generation of heterozygote mice, primary splenocytes were isolated to test for a functional response upon glucocorticoid stimulation. In this assay, the mouse and human alleles were both stimulated in a dose-responsive manner to an equal extent (~10 fold change). This study demonstrated that the human allele is detectable at basal levels and is also functionally responsive. Hence, this mouse model may provide an ideal system in which to further characterize the gene × environment interactions of the known human SNP rs1360790-T with childhood adversity that impart significant risk for psychiatric disorders.

Title: Epigenetic regulation and gene gxpression analysis of glucocorticoid receptor exon 1f and fkbp5 in adolescent suicide

Authors: *H. S. RIZAVI, D. R. GRAYSON, H. ZHANG, G. PANDEY
Univ. Illinois Chicago, Chicago, IL

Abstract: Suicide has been steadily rising for the past 10 years and is at its highest peak in 30 years, since collection of data began. This rise is particularly high among teens 12-18 and college-age youth. An impaired feedback inhibition of the HPA axis is a strong predictor for suicide. Glucocorticoid receptor (GR), a key mediator of HPA axis regulation and a transcription factor is considered to engage several responsive genes that can drive lasting molecular and cellular changes. GR also directly induces expression of FKBP5 which is a negative regulator for

GR sensitivity to cortisol. Growing number of studies have shown that gene-environment interactions ultimately affect and influence genetic predispositions for suicide. Epigenetic modifications continuously modulate the transcriptional changes that could lead to lasting functional changes. Our aim was to determine the epigenetic modifications occurring at the proximal promoter region of GR-1F and FKBP5 and the regulatory consequence on the respective genes. In addition, we examined the expression of genes that control DNA methylation, DNA methyltransferases (DNMTs), and demethylation, ten-eleven translocation proteins (TETs) and growth arrest- and DNA-damage-inducible proteins GADD45, as potential contributors to the altered levels of DNA methylation (5mC) and hydroxymethylation (5-hmC). We found an increase in 5mC and a decreased level of 5hmC at the GR1F promoter which is accompanied by a significant decrease in expression of GR1F. We also find a decreased amount of 5mC and an increase in the levels of 5hmC at the proximal promoter region of FKBP5, and a total increase in expression of FKBP5. These results are accompanied by an increase in DNMT1 and DNMT3a expression, decrease in TET1 and TET2 and a decrease in Gadd45β. Collectively these results identify possible causes to the disturbed balance that contributes to prolonged activation of HPA axis in PFC and provide insight to the molecular pathology of teenage suicide.

Title: Prevention of aberrant DNA methylation induced by maternal maltreatment in early life

Authors: *N. PHILLIPS[1], T. S. DOHERTY[2], T. L. ROTH[3]
[1]Psychological and Brain Sci., [3]Psychology, [2]Univ. of Delaware, Newark, DE

Abstract: Early life adversity can increase risk for the development of psychological disorders such as depression and anxiety. One prominent form of early life adversity is child maltreatment. Poor maternal care can alter methylation patterns of several genes, and these altered patterns are often followed by maladaptive behaviors later in life Previously, our lab demonstrated that negative caregiving received by rat pups results in aberrant methylation and decreased gene expression of the brain-derived neurotrophic factor (*Bdnf*) gene in the prefrontal cortex (PFC) across the lifespan and that aberrant methylation can be rescued in adulthood via daily administration (7 days) of a DNA methyltransferase inhibitor (DNMTi), zebularine. Further, we and others have found that maltreated pups grow up to maltreat their own offspring. The present

study aimed to investigate whether DNMTi, 5-aza-deoxycytidine (5-azaD), can prevent aberrant methylation of *Bdnf* exon IX in the PFC of Long-Evans (*Rattus norvegicus*) pups if delivered at the time of negative caregiving. Using a scarcity adversity paradigm and a within-litter design, male and female pups were exposed either to normal care from their biological mom, normal care from a nurturing foster dam, or negative care from a stressed foster dam for 30 minutes per day from postnatal days 1-7. Results indicate that a 0.5 mg/kg dose of 5-azaD normalized *Bdnf* methylation such that there were no differences between maltreated pups given 5-azaD and their control counterparts Methylation levels in females given this dose exhibited high variability. Thus, we also tested the effects of a 1mg/kg dose to ensure effectiveness. We found that the 1 mg/kg dose of 5-azaD significantly reduced *Bdnf* methylation in the infant maltreated female PFC, and normalized methylation in the infant maltreated male PFC. These findings indicate that a pharmacological intervention can prevent changes in the epigenome due to early adverse experiences. If this prevention persists into adulthood, it could potentially prevent the development of adversity-induced maladaptive behaviors. Thus, we plan to measure if this prevention of methylation persists into adulthood and if that persistence is associated with the amelioration of adversity-induced behavioral phenotypes. Title: Child abuse, neuroinflammation, and blood-brain barrier integrity: A preliminary postmortem investigation

Authors: *M. WAKID[1], A. TANTI[1], P.-É. LUTZ[2], C. NAGY[1], D. ALMEIDA[1], M. DAVOLI[1], G. TURECKI[1], N. MECHAWAR[1]
[1]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [2]Nociception et Douleur, Inst. Neurosciences Cellulaires Intégratives, Strasbourg, France

Abstract: Introduction: There is increasing evidence supporting the hypothesis that major depression is associated with increased neuroinflammation and permeability of the blood-brain barrier (BBB). Our group recently reported that in the dorsal anterior cingulate cortex (dACC) of depressed suicides, there is a significantly higher proportion of blood vessels surrounded by a high density of macrophages compared to matched controls. The aim of the current project is to examine whether a history of child abuse is associated with even more pronounced changes in

the expression of neuroinflammatory and BBB markers. Methods: Well-characterized postmortem dACC samples from adult depressed suicides with a history of severe child abuse and from matched healthy controls having died suddenly were processed for RNAseq. Results: A preliminary comparative transcriptome analysis revealed a significant downregulation of certain genes coding for tight junction proteins, including tight junction protein 1 (TJP1), tight junction protein 2 (TJP2) and occludin (OCLN) in depressed suicides with a history of child abuse compared to controls. Discussion: Tight junctions, which underlie the physical barrier created by neurovascular endothelial cells of the BBB, provide neuroprotection for complex cellular interactions at the neurovascular unit. Our preliminary finding indicate that some key genes for the establishment and maintenance of tight junctions are disrupted in dACC samples from depressed suicides with a history of child abuse. We speculate that this observation is associated with our previous findings of increased macrophages surrounding blood vessels in the dACC of depressed suicides. Experiments are under way to validate these results, assess their specificity with regards to child abuse, and explore BBB integrity with additional molecular and histological approaches. Keywords: child abuse, major depressive disorder, suicide, tight junction, blood brain barrier, neuroinflammation

Title: Epigenetic programming of chromatin accessibility by stress during puberty

Authors: *K. E. MORRISON, T. L. BALE
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Adverse childhood experiences are one of the greatest predictors for affective disorder presentation for women. However, few animal models exist that address female-specific risk factors or unique periods across the lifespan. As the pubertal transition is marked by dynamic hormonal changes and ensuing reorganization of the brain, it represents a window of sex-specific

vulnerability to adverse experiences. Periods of hormonal flux in the female lifespan, including pregnancy, exacerbate the risk for affective disturbances and promote stress dysregulation, a key feature of affective disorders. We have established a translationally relevant mouse model in which pubertal adversity leads to broad stress dysregulation in adulthood that is dependent upon hormonal status. Our previous work in humans and mice has shown that increases in allopregnanolone are necessary to produce the blunted HPA axis response in stressed females. Allopregnanolone likely acts on a reprogrammed GABA system within the paraventricular nucleus of the hypothalamus (PVN), as RNA-Seq analysis of the PVN during pregnancy revealed alterations to GABA system gene expression by pubertal stress. However, it is unclear what is responsible for long-term reprogramming of the GABA system. Prior RNA-Seq also revealed that females stressed during puberty had increased expression of a host of immediate early genes at baseline during pregnancy. Immediate early gene expression requires that their promoters be accessible to the intracellular cascades that initiate their transcription. These data suggest that, even at baseline, the chromatin in the PVN of pubertally stressed females is in a more open, permissive state. Thus, we utilized ATAC-Seq, a technique which allows for the direct assessment of chromatin openness and interrogation of which genes are available for transcription, to assess pubertal stress-induced epigenetic programming. Female mice were exposed to chronic variable stress from postnatal days 21-34 and were sacrificed during adulthood, either in virgin or pregnant state. ATAC-Seq signal intensity in the PVN was assessed for effects of pubertal stress and hormonal state, allowing for the identification of any alterations to the chromatin accessibility landscape. Together, these studies provide novel insight into the mechanisms underlying female-relevant risk factors for stress dysregulation, a central endophenotype of affective disorders.

Abstract: Paternal preconception exposures to environmental stressors, including metabolic, immune, and perceived threats are associated with increased disease risk in subsequent generations. Studies in rodent models implicate the germ cell transfer of epigenetic information in programming these intergenerational effects. Though the cellular mechanisms responsible for encoding paternal experiences in sperm are still being characterized, small non-coding RNAs (sncRNA) delivered to sperm by extracellular vesicles (EV) seem to play a key role. We have developed a model of paternal preconception stress in which chronically stressed mice sire offspring with a significantly blunted stress response and broad hypothalamic transcriptional changes. In our current studies, we identified a mechanism by which stress alters the sncRNA content of sperm to influence offspring development, focusing on the known role of EVs in delivering RNA cargo to sperm in the male reproductive tract. Analyses of mouse paternal reproductive tissues following stress revealed a convergence in stress-responsive sncRNA between sperm and the caput epididymis, pointing to this tissue as a nexus for somatic cell shaping of sperm sncRNA content. We modeled this *in vitro* using corticosterone treatment of cultured epididymal epithelial cells and found that this 'stress in a dish' reproduced lasting changes in the sncRNA content of secreted EVs. In addition, chronic corticosterone affected the histone codes of these cells, alterations that were also found in our mouse model of paternal stress. Together, these preclinical data support a lasting epigenetic mechanism by which stress experience alters programming of the caput epididymis, transmits this information to maturing sperm via secreted EVs, ultimately influencing early embryo development. To maximize the translational potential of this work, we developed a broad framework to determine the content and variability in EVs and sperm sncRNA over time relative to perceived stress in healthy human subjects. Using proteomics and RNA-sequencing to characterize the sncRNA content of sperm collected monthly from healthy human subjects for 6 months, we examined changes in semen content relative to perceived stress at each donation. Analyses to determine the normal within and between individual variability of sperm RNA content over time and to identify populations of sncRNA that covary with measures of perceived stress were completed. These studies offer an exciting novel mechanism by which the environment dynamically regulates sperm epigenetics, furthering our understanding of paternal contributions to offspring development and disease risk.

Title: Epididymal extracellular vesicles signal paternal stress programming of sperm and offspring neurodevelopment

Authors: *J. CHAN[1], B. M. NUGENT[2], K. E. MORRISON[2], E. JASAREVIC[2], N. V. BHANU[1], B. A. GARCIA[1], T. L. BALE[2]

Abstract: Evidence that paternal preconception exposures can shape offspring behavior and physiology prompts new consideration for the molecular mechanisms underlying offspring neuropsychiatric disease risk. As potential modes of transmission, germ cell epigenetic marks have been described to respond dynamically to stress in the paternal environment and subsequently transmit this information at fertilization. In particular, mechanistic examination has implicated small noncoding RNA populations in sperm, including microRNA (miRs) and tRNA-derived fragments, as causal mediators of offspring programming. Yet, despite the exciting potential for sperm small RNAs, how stress in the paternal environment is signaled from somatic tissues to transcriptionally inert sperm and how these signals may persist remain unknown. Here, we address these questions using our established mouse model of paternal stress, where specific sperm miRs altered by chronic stress reprogrammed adult offspring hypothalamic-pituitary-adrenal (HPA) stress reactivity. In the current studies, we describe the involvement of the caput epididymis, a somatic tissue that secretes extracellular vesicles (EVs) to deliver miRs from epididymal epithelial cells to maturing sperm, in relaying stress signals to sperm. Using an *in vitro* model, we demonstrate that administration of chronic glucocorticoids to DC2 mouse caput epididymal epithelial cells altered EV miR content both acutely and long after treatment ended, mimicking the timing of miR changes in paternal stress sperm. These EV changes corresponded with upstream increases in glucocorticoid receptor (GR) levels and modifications to histone post-translational marks in caput epididymal cells both in DC2 cells *in vitro* and in our mouse model *in vivo*, suggesting a potential mechanism that promotes enduring alterations to EV and subsequently sperm miRs. Further, we demonstrate the crucial role of GR in paternal stress transmission by caput epididymal epithelial-specific transgenic knockdown, which prevented offspring HPA stress axis dysregulation. Lastly, to determine the mechanism by which GR reduction rescued transmission, we analyzed the caput epididymal epithelial-specific translatome and found enhanced mitochondrial capacity and reversal of chromatin-modifying processes as potential modes of cellular resilience to stress. Our studies establish the paternal caput epididymis as an important somatic tissue upstream of offspring brain programming, and provide insight into the cellular mechanisms that can impact and prevent intergenerational transmission of offspring neuropsychiatric disease risk.

Title: The pregnancy gut microbiome as a translational biomarker of maternal adversity and offspring immune programming

Authors: *E. JAŠAREVIC[1], L. HANTSOO[3], C. HOWARD[2], C. N. EPPERSON[4], T. WEINKOPFF[5], T. L. BALE[6]
[1]Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Philadelphia, PA; [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Univ. of Pennsylvania, Philadelphia, PA; [4]Psychiatry, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA; [5]Univ. of Arkansas for Med. Sci., Little Rock, AR; [6]Pharmacol., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Maternal adversity during pregnancy, such as stress, diet, and infection, influence fetal neuroimmune development and is a risk factor for neurodevelopmental disorders, including autism and schizophrenia. To examine the hypothesis that sex-specific neuroimmune development is influenced by early pregnancy stress alterations to the maternal gut microbiome and microbiota-derived metabolites, we used our established mouse model of early prenatal stress (EPS), in which male, but not female, offspring demonstrate lasting health outcomes. Longitudinal modeling revealed that stress experience disrupted gut microbiota. Functional profiling revealed stress disruption of microbial metabolic pathways. Comparisons of amino acids, bile acids, and short chain fatty acids (SCFAs) from embryonic day (E)18.5 maternal and fetal tissues demonstrated parallel stress-mediated decreases in amino acids and SCFAs in maternal cecum and E18.5 brain. As these metabolites regulate innate immune development, we determined how altered metabolite availability impacts the E18.5 fetal brain immune compartment and observed sex-specific alterations in the frequency and activational patterns of resident and infiltrating immune cells. Sex-specific transcriptomes were also examined using RNA-Seq and ATAC-Seq on E18.5 immune cell populations. Reconstitution experiments were used to examine the casual contribution of maternal gut microbiota-derived metabolites to rescue

aspects of the EPS phenotype in adulthood. Finally, to establish the translational relevance of our results, pregnant women who had experienced either a low (<2) or high (>2) number of adverse childhood events (ACEs) during the preadolescent window were recruited at 21 to 32 weeks of pregnancy. Gut microbiota composition, pro-inflammatory cytokine profiles, and cortisol levels following acute stress were measured in low and high ACE pregnant women. Similar to our results in our EPS mouse model, the maternal gut microbiome was significantly altered in high ACE women relative to low ACE women during pregnancy. Further, pro-inflammatory cytokines were positively correlated with inflammation-associated microbiota in high ACE women, providing an important link between early life adversity and peripheral inflammation during pregnancy. Taken together, our results demonstrate stress reprogramming of the neuroimmune compartment via maternal gut microbiota-derived metabolites. Further, as the maternal gut microbiota is readily accessible, these studies demonstrate high translational potential and implicate a novel biomarker of ACEs and subsequent health outcomes in the offspring.

Title: Maternal stress and brain development: Can stress in mice model the stress-induced racial disparity in infant health?

Authors: *Y. M. CISSE[1], B. M. NUGENT[1], J. CHAN[2], N. BHANU[3], B. A. GARCIA[3], T. L. BALE[1]
[1]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Dept. of Biochem. and Biophysics, [2]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Maternal lifetime exposures to perturbations such as stress, infection, and malnutrition increase risk for offspring disease. African American infants in the U.S. have significantly worse health outcomes than non-Hispanic white infants. Increased risk of low birth weight (LBW) and preterm birth (PTB) is correlated with indicators of stress, as well as childhood and lifetime

perceived racism specifically in African American mothers, independent of socioeconomic, medical, and behavioral risk factors. While maternal insults during pregnancy directly impact fetal development, the mechanisms by which lifelong stress experience can alter germ cell programming and affect offspring neurodevelopment are unknown. We have established a model of maternal preconception stress (MPS), where adult female mice were exposed to chronic (4 week) or lifelong (from weaning) stress. Two weeks post-stress, females were mated to naïve male mice. Stress-relevant behaviors and physiological were assessed in adult offspring of MPS dams. Female, but not male, MPS offspring showed enhanced stress reactivity, supporting our hypothesis that stress experienced prior to pregnancy induces long-term changes along the reproductive tract to alter sex-specific fetal development. Transcriptional changes in the placenta regulate sex-specific programming in response to stress, through differential expression of the X-linked gene, OGT (O-glycosyl transferase), and its regulation of the repressive histone mark, H3K27me3. We therefore examined differences in placental histone post-translational modifications (PTMs) using an unbiased mass spectrometry approach. Female placentas from MPS dams showed decreased H3K27 methylation and increased acetylation, suggesting increased broad permissive transcription in response to stress. We then conducted transcriptomic analysis of the placenta and fetal brain via RNA-sequencing to examine the transcriptional consequences of MPS programming. Finally, we investigated the role of the oocyte in encoding the lasting molecular alterations of MPS at the single cell level via RNA-sequencing. Together, these studies bring to attention the importance of female lifetime and preconception experiences on germline, placental, and offspring brain development, and highlight its potential contribution to the stress-induced racial disparity in infant health outcomes.

Abstract: Objective and rationale: Within days of birth, mammals undergo commensal intestinal bacterial colonization that remains throughout life. This commensal colonization is critical for immune function, nutrient processing, and central nervous system (CNS) functioning. One major component of the CNS, the hypothalamic-pituitary-adrenal (HPA) axis, synchronizes the body's stress response system and matures throughout the postnatal period, a time at which intestinal bacterial colonization also occurs. Studies in rodents have demonstrated a bidirectional pathway of communication between the gut and the brain such that gut microbiota program the HPA axis early in life, as well as stress reactivity throughout the lifespan; conversely, stress also alters the integrity of intestinal microbiota. Moreover, behavioral and physiological responses to stressful situations are impacted when the bacterial status of the gut is manipulated, either by infection, treatment with probiotics, or genetic modification. However, all these studies have been conducted in rodents and have relied on short-term samples to assess HPA axis functioning. Though it is established that nursery-reared (NR) monkeys exhibit higher long-term cortisol concentrations than mother-peer-reared (MPR) monkeys, nonhuman primates are notably absent from the literature demonstrating that gut microbiota program the HPA axis early in life. Methods: We tested the hypothesis that gut microbial diversity would relate to chronic HPA axis activity, as measured in hair cortisol concentrations (HCCs), across early development in rhesus monkeys (*Macaca mulatta*, N=19-35; 10-21 female). We obtained DNA samples from rectal swabs and hair samples on the day of birth and at six intervals throughout the first year of life. We used t-tests to explore rearing differences in relative quantities of intestinal bacteria genera, and Pearson's correlations to assess relations between relative percentages of bacteria and HCCs. Results: NR infants had lower relative *Lactobacillus* than MPR infants at 30d ($t(1)=3.39, p=0.002$) and 6mos ($t(1)=1.98, p=0.03$), and higher *Bifidobacterium* at 30d ($t(1)=-2.50, p=0.01$). Relative levels of *Lactobacillus* ($r=0.48, p=0.06$) and *Streptococcus* ($r=0.53, p=0.03$) at 6mos were positively correlated with changes in HCCs from 6-9mos for NR infants. These are the first findings in neonatal nonhuman primates to show that gut microbial diversity, from birth, is associated with altered chronic HPA axis activity. Support: This research was supported by the Legacy Award from the American Society of Primatologists (to AMD), and by the National Institutes of Health (#R24OD011180).

Abstract: The brain is a genomic mosaic due to somatic mutations occurring throughout neural development. Endogenously encoded Long Interspersed Element-1 (LINE-1 or L1) is a mobile element that generate somatic mosaicism in the human hippocampus and other regions. While it has been hypothesized that aberrant somatic L1 activity could mediate environmental factors that contribute to neurological disorders, evidence of L1 activation and the functional consequences of L1 mediated somatic mosaicism has remained elusive. Herein, we investigate the functional role of inflammation-driven somatic L1 retrotransposition in contributing to neurological disorders. Maternal immune activation (MIA) during embryonic neurogenesis increases the risk of developing schizophrenia and autism and correlates with increased L1 copy number in mouse and macaque brain. Here, we demonstrate that MIA induced pro-inflammatory cytokine IL-6 activates transcription and retrotransposition of mouse and human L1 in hippocampal neural progenitor cells. We established an in vivo mouse model to manipulate levels of L1 retrotransposition during MIA. Mice exposed to fetal MIA with high levels of L1 retrotransposition demonstrate impaired sensorimotor gating. Attenuation of L1 retrotransposition during fetal MIA specifically restores sensorimotor gating function. Offspring subjected to fetal MIA while attenuating L1 retrotransposition retain the strong pro-inflammatory immune response. Therefore, somatic retrotransposition specifically mediates attentional abnormalities associated with schizophrenia and autism. We performed targeted single cell DNA sequencing to identify somatic L1-assciated variants (SLAVs) induced by MIA in mouse. MIA results in an increased number of SLAVs in hippocampal neurons, an increased percentage of highly variable neurons harboring 15-60 SLAVs per cell, and enriched genomic variation near genes expressed at the time of MIA. These results suggest that L1 genomic variation mediates an important environmental risk factor for aberrant neural development and that properly tuned levels of somatic mosaicism are essential for healthy cognitive function.

Abstract: Early life stress (ELS) is associated with an increased risk for later development of emotional pathology such as depression and anxiety. The origins of pathology are thought to be rooted in atypical development of circuits regulating emotional responding, including the amygdala. Here we used a mouse model of ELS, in the form of maternal bedding restriction, and tested the effect on amygdala development, and the development of freezing behavior in a tone-associated fear conditioning paradigm. Previous work has established that tone-associated freezing develops as early 15 days of age and stays relatively stable across early development. Here, we found that mice reared under ELS conditions show an unexpected and significant decrease in freezing behavior at 21 days of age. This decrease in freezing behavior was associated with a precocious maturation and an increase in the density of Parvalbumin (PV)-positive cells in the basal amygdala (BA). In addition, we found that ELS mice had a delay in prefrontal to basolateral amygdala projections. To test if the increase in PV-cells was related to suppressed freezing behavior, we took advantage of optogenetic techniques to silence this population of cells in the BA during acquisition and testing phase in the conditioning paradigm. We found that silencing BA PV cell restored normal levels of freezing behavior in ELS reared mice. These results have implications for understanding the effects of ELS on the ontogeny of circuit development and its impact on the development and expression of fear associated responding.

Title: The impact of chronic early life social isolation on receptor expression and receptor tyrosine kinase transactivation in the hippocampus and prefrontal cortex

Authors: N. GONDORA[1], C. POPLE[2], M. ROBINSON[1], J. G. MIELKE[3], *M. A. BEAZELY[4]
[1]Sch. of Pharm., [2]Biol., Univ. of Waterloo, Kitchener, ON, Canada; [3]Sch. of Publ. Hlth. and Hlth. Systems, Univ. of Waterloo, Waterloo, ON, Canada; [4]Sch. of Pharm., Univ. of Waterloo, Sch. of Pharm., Waterloo, ON, Canada

Abstract: Exposing mammals to social isolation in early life can affect brain development and lead to changes in adult behavior. In rats, social isolation during adolescence induces changes reflective of neuropsychological disorders, such as depression. However, the molecular mechanism(s) underlying these outcomes have not yet been elucidated. In the Chronic Early Life Social Isolation Study (CELSI), we explored the impact of social isolation on the expression of key proteins both implicated in neuroplasticity and potentially related to the observed behavioral effects of social isolation: the TrkB receptor and the NMDA receptor. At post-natal day 21, 20 male and 20 female Sprague-Dawley rats were separated into either group (N=3 animals/cage) or isolation housing. After seven weeks, the animals were sacrificed and the hippocampus (HP) and prefrontal cortex (PFC) were extracted, homogenized, and analyzed via immunoblotting. Differences in receptor subunit expression between the control (group housed) and stressed (isolated) animals were observed, including sex-specific and region-specific variation. To explore the relationship between chronic stress (early life isolation) and acute chemical stress, brain slices obtained from the CELSI rats were exposed to corticosterone, a steroid stress hormone. We have previously demonstrated cross-talk signaling between the 5-HT7 serotonin receptor and receptor tyrosine kinases including TrkB. Slices treated with the 5-HT7 receptor agonist, LP 12, or corticosterone, demonstrated increased TrkB receptor phosphorylation. The transactivation pathway is of particular interest because of its potential to harness neuroprotective potential and to buffer against various neuronal insults. We have also demonstrated in the HT22 cell-line, (a hippocampal cell-line) that corticosterone affects both cell-viability and receptor tyrosine kinase (RTK) transactivation. This data will form the basis for

subsequent work to improve our understanding of the molecular neurodevelopmental responses to chronic early-life stress.

Title: Circuitry for water seeking motivation in *Drosophila*

Authors: D. LANDAYAN[1], J. ZHOU[1], *F. W. WOLF[2]
[2]Sch. of Natural Sci., [1]UC Merced, Merced, CA

Abstract: Thirst is an evolutionarily ancient motivational state that is hard-wired and critical for survival. How thirst circuits in the brain coordinate the appropriate goal-directed behavior, and how it can do so in the presence of opposing behavioral states such as hunger, is not well understood. We show that a persistent state of thirst is evoked by the precise activation and inactivation of overlapping central brain neuronal circuit elements in Drosophila. In a neuronal activation screen, we identified a subset of glutamatergic neurons that evoke robust thirst-related behaviors, including water seeking and intake; we named these neurons Durstig, the German for thirsty. These central brain neurons function downstream of sensory input and internal osmotic sensors to drive seeking to either open or inaccessible water. Importantly, activation of Durstig neurons overrides food seeking in water replete but hungry flies. We also identified neuropeptide F receptor (NPFR)-expressing neurons that appear to function as a water seeking homeostat. Neurons expressing NPFR, the invertebrate homolog of the NPY receptor, also promote insatiable hunger and voracious feeding. Like Durstig neurons but independent of them, activation of NPFR neurons overrides food seeking in water replete but hungry flies. Thus, neural circuit elements that regulate hunger and thirst are tightly integrated. These studies provide an entry point for mapping the fundamental homeostatic thirst neurons and the hierarchical wiring of neural circuits that encode opposing motivational states.

Abstract: Water intake is a basic physiological response that restores fluid homeostasis in thirsty animals. Water ingestion is detected in the oral/oropharyngeal cavity and gastrointestinal (GI) tract, and this signal is communicated to the central thirst neurons to quench thirst. This signaling is thought to involve serially connected nuclei including the parabrachial nucleus (PB). However, the key circuit elements and precise circuit organization remain unclear. Here we show that a genetically defined subpopulation of neurons in the PB signals water intake and quenches thirst. By monitoring deep-brain calcium dynamics, we show that the PB neurons are selectively activated by water intake in a time-locked manner. These responses are induced by wet solids or aqueous liquids as well, but not by dry solids or non-aqueous liquids. Interestingly, this activation is stronger when animals are water-deprived, suggesting that animal's internal state is already integrated into the water intake signal at or before the PB. Optogenetic stimulation of the PB neurons selectively suppressed water intake, whereas chemogenetic inhibition of the same population augmented water intake in water-deprived mice. Taken together, our study provides a circuit mechanism to explain how water intake signals from the periphery are transmitted to the thirst centers and quench thirst.

Title: Modulation of drinking behavior through central amygdala GABAergic neurons

Authors: *J. FU, C.-J. SHEN, X.-D. YU, X.-M. LI
Dept. of Neurobio., Zhejiang Univ. Sch. of Med., Zhejiang, China

Abstract: Drinking behavior is a repetitive licking movement with a constant frequency. Recent studies indicate that central amygdala (CeA) play a role in ingestive behavior and the mechanism is still poorly understood. Here, we validated a new circuit from CeA GABAergic neurons to Midbrain nucleus. The activity of this pathway increased during drinking period recorded by fiber photometry in mice. Furthermore, photo-stimulation of this projection effectively induced a licking behavior and promoted water consumption in mice. These results demonstrate that CeA GABAergic projection to midbrain has a crucial role in modulating drinking behavior.

Title: Carbonic anhydrase II deletion confers salt appetite in genetically engineered mice

Authors: M. VARASTEH KIA[1], S. BARONE[1], K. ZAHEDI[1], *M. SOLEIMANI[1,2]
[1]Med., Univ. of Cincinnati Med. Ctr., Cincinnati, OH; [2]Res. Services, VA, Cincinnati, OH

Abstract: Salt appetite, salt craving or salt intake in excess of physiological needs is regulated by a number of physiological mechanisms including neuronal and hormonal pathways. Excess salt intake is a major health problem and a risk factor in the pathogenesis of hypertension, which consequently can lead to heart disease and stroke. Few genetic factors are implicated in the pathogenesis of salt appetite. Here we demonstrate that mice with the genetic inactivation of carbonic anhydrase 2 (CAII) display significant salt appetite as judged by their preference for salted water (280 mM NaCl added to the drinking water) over regular tap water, when both options are provided (daily salted water intake of 2.80 ml in WT and 5.2 ml in CAII KO mice, $p<0.01$, $n=5$). Wild type littermates showed preference for regular water (daily tap water intake of 4.21 ml in WT and 2.15 ml in CAII KO mice, $p<0.03$, $n=5$). The excess salt intake is observed in the absence of any vascular volume depletion or kidney dysfunction in CAII KO mice (as judged by comparable kidney renin expression and blood creatinine and BUN concentration in WT and CAII KO mice). When only provided the salted water (280 mM salt added to the drinking water), CAII null animals showed a robust increase in daily water intake vs. WT mice (20.54 ml/day in KO mice vs. 11.83 ml/day in WT, $p<0.001$, $n=5$) as well as an increase in sodium excretion (0.192 mmol/g in CAII KO vs. 0.0716 mmol/g in WT, $p<.01$, $n=5$). The expression levels of kidney sodium and water absorbing channels ENaC and AQP-2 showed robust increases in response to enhanced salt intake in CAII KO mice vs. wild type littermates despite their lower expression levels under baseline states. The AVP expression levels in pituitary gland significantly increased in CAII KO mice vs. WT littermates when receiving salted water for 10 days ($p<0.05$), despite their comparable expression levels at baseline conditions. When given the option of tap water and salted water, male CAII KO mice exhibited remarkable propensity toward salted water intake vs. female KO mice. Systolic blood pressure after 10 days of salted water intake showed a tendency toward higher values (systolic blood pressure of 145 +/- 3.9 in CAII null mice vs. 135 +/- 3.2 in WT) as verified by a computerized tail cuff method, but did not achieve statistical significance ($p=0.07$). We propose that CAII plays an important role in regulating salt intake and its inactivation can cause salt appetite, specifically in male animals, and may provoke a salt sensitive hypertension.

Title: Estradiol regulation of fluid intake following 24 hour water deprivation

Authors: *J. A. HOWELL, J. SANTOLLO
Biol., Univ. of Kentucky, Lexington, KY

Abstract: Thirst is an essential component of maintaining body fluid homeostasis and is necessary to restore osmolality and volume in cases of dehydration. Estradiol (E2) decreases daily fluid intake and intake in response to dehydration in females, but the mechanism(s) underlying this effect is unclear. To explore the mechanism(s) that underlie E2's inhibitory effect on fluid intake we first aimed to expand the previous finding that E2 decreases water intake stimulated by 24 h deprivation by examining drinking microstructure. Then, we aimed to determine which estrogen receptor subtype mediates the decreases in intake. Because activation of ERα decreases water intake stimulated by the hormone angiotensin II we hypothesized that activation of ERα, but not ERβ, decreases water intake stimulated by 24 h fluid deprivation. Using a repeated-measures design, ovariectomized (OVX) rats (n=9) were injected with estradiol benzoate (EB, 10 µg) or vehicle for two consecutive days. Twenty-four hours after the second injection, rats were water deprived or retained fluid access as a control. The following day, water was returned and total intake was measured for 1 h. In addition, licks during the test period were recorded using a contact lickometer. As expected, after water deprivation EB-treated rats drank significantly less than oil-treated rats ($p < 0.05$). Furthermore, there was no difference in the number of licks per burst. After water deprivation, oil-treated rats had significantly more bursts (defined as at least two licks with an interlick interval of less than 1 s) than EB-treated rats ($p < 0.05$) suggesting that estradiol reduces intake by increasing post-ingestive feedback signals. Next, to investigate the estrogen receptor subtype mediating this effect, a second group of OVX rats (n = 10) were water deprived or retained fluid access as a control. The following morning, rats were injected with 200µg PPT (ERα agonist), 250µg DPN (ERβ agonist) or vehicle and 3.5 h later water was returned from deprived animals and intake and licks were measured for 1 h. Preliminary data suggests no difference in intake after agonist treatment. This could suggest that the anti-dipsogenic effect of E2 after water deprivation is the result of synergistic activation of both ERα and ERβ receptors and ongoing research is testing this hypothesis.

Title: Disinhibition of sodium appetite by Htr2c in the lateral parabrachial nucleus

Authors: *S. PARK[1], C. LIU[2,3], K. W. WILLIAMS[2], J.-W. SOHN[1]
[1]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [2]Intrnl. Med., [3]Dept. of Neurosci., Univ. of Texas Southwestern, Dallas, TX

Abstract: The drive for sodium intake, sodium appetite, is a powerful form of motivation which is required for the maintenance of blood volume. This form of motivation is capable of making animals and humans ingest otherwise aversive concentrations of sodium. However, in the absence of fluid imbalance, this manifestation of sodium appetite is normally suppressed to prevent homeostatic deviations. Although molecular and neural mechanisms underlying the promotion of sodium appetite have received attention recently, those that act to inhibit sodium appetite have remained relatively obscure. Here we report a genetically defined population in the lateral parabrachial nucleus (LPBN), marked by the expression of Htr2c, which acts to inhibit sodium appetite. Chemogenetic inhibition of these neurons leads to increases in sodium intake whereas chemogenetic activation reduces sodium intake during times of sodium depletion. Interestingly, inhibition of these neurons is also capable of increasing food intake but only when sodium is present in the diet. Furthermore we show that Htr2c hyperpolarises these neurons through KATP channels and that removal of Htr2c from LPBN neurons decreases sodium intake in mice. Collectively these results reveal a genetically distinguishable population of neurons in the LPBN that act to suppress sodium appetite. Given the pernicious link between sodium intake and cardiovascular disease, as well as the non-compliancy of patients on low-sodium diets, our study may also provide potential drug targets aimed at inhibiting sodium appetite.

Title: Neural circuits underlying sodium homeostasis

Authors: *S. LEE, V. AUGUSTINE, Y. ZHAO, H. EBISU, Y. OKA
Caltech, Pasadena, CA

Abstract: Maintaining the balance of internal fluid is indispensable for survival. Fluid homeostasis mainly regulates the amount of water and sodium in extracellular fluids to achieve a proper balance. Sodium is the major cation that determines the osmolality of the extracellular fluid. As such, the ingestion of sodium is strictly regulated by both peripheral sensory signals and central appetite signals. However, the underlying neural mechanism is still poorly understood. Recent rodent studies have shown that some types of neurons in the lamina terminalis (LT) and nucleus tractus solitaries (NTS) are causally related to sodium intake. Nevertheless, these studies have highlighted the highly complicated and shared neural circuits between sodium appetite. Here we show the neural population in the hindbrain that exclusively regulates sodium appetite. We will also discuss how these neurons optimizes sodium intake based on peripheral signals.

Title: Functional annotation of molecular cell types in the mammalian thirst system

Authors: *A.-H. POOL[1], Y. OKA[2]
[1]BBE, [2]Caltech, Pasadena, CA

Abstract: Thirst is an instinctive behavioral state that elicits a series of robust behavioral adjustments geared towards restoring body fluid homeostasis. Osmotic stress in mammals is detected by two circumventricular organs - OVLT and SFO - and relayed to higher order brain centers where the need signal is converted to adaptive behavioral and endocrine responses. Here we explored the cellular logic for decoding the need signal at the second order thirst nucleus MnPO. Single cell RNA-seq uncovered 8 distinct transcriptomic cell types within the nucleus. In

functional characterization of these cells we revealed that one of the four excitatory cell types is water deprivation activated and can drive the full thirst behavioral repertoire. Another excitatory cell type encodes heat stress whereas one of the 4 inhibitory neuronal classes is responsible for liquid consumption related suppression of drinking behavior. Anatomical output mapping of the thirst driving cell type revealed a candidate map of only a few hypothalamic and extrahypothalamic targets identifying sites for decoding the thirst signal into behavioral subprograms. Current analysis reveals the logic of decoding physiological cues at the second order thirst relay.

Title: Central angiotensin II induces sucrose intake dissociated from water intake

Authors: *M. H. PAES[1], L. M. CARDOSO[2], L. B. OLIVEIRA[3]
[1]Programa de Pos-Graduacao em Ciências Biologicas, NUPEB, [2]Univ. Federal de Ouro Preto, Ouro Preto, Brazil; [3]Fed. Univ. Ouro Preto - UFOP, Ouro Preto, Brazil

Abstract: Ang II acts on the regulation of different ingestive behaviors, including sucrose intake. However, the increase in sucrose intake could be a consequence of thirst induced by ANG II. Thus, this study aimed to distinguish the effect of Ang II on the thirst from its stimulatory effect on sucrose intake. Therefore, male Wistar rats weighing 300330g were anesthetized with ketamine (80 mg/kg) and xylazine (7 mg/kg) and a stainless steel cannula was implanted directed to the right lateral ventricle (LV) in the animal's brain. During recovery period (five days), water, 2% sucrose solution and food were ad libitum. To the ingestive test, food, water and sucrose were removed and the rats received LV injection of 1 μL of PBS (control) or ANG II (0.4 nmol/μL). After 15 minutes, they had free access to water and its intake was measured at 15, 30, 60, 90 and 120 minutes. At 105 minutes (after water offer) the animals received central injection (1μL on LV) of vehicle or the antagonists (losartan 50nmol/μL or PD 123319 30nmol/μL). 15 minutes later, 2% sucrose solution was also offered to the animals.

Water and sucrose intakes were measured at 135, 150, 180, 210 and 240 minutes. At the end of 4 hours, the animals received food, water and 2% sucrose solution *ad libitum*. The results are expressed as means±SEM. Two way RMANOVA and pos test Tukey's were used for statistical analyses. Differences were considered significant at p&It0.05. In the first two hours of experiment, ANG II, as expected, increased water intake, satiating thirst (PBS 0.5 ± 0.18 vs ANG II 14.5 ± 1.77 mL/120min). After the second injection, sucrose intake in the group receiving ANG II was higher than the control group and this effect was abolished when Losartan or PD 123319 were injected (PBS + PBS 0.5 ± 0.29 vs PBS + ANG II 5.5 ± 1.21 vs losartan + ANG II 0.1 ± 0.10 vs PD123319 + ANG II 0.3 ± 0.28 mL/120min). In the last two hours of the experiment, no differences were observed for water intake among treatments. These results suggest that central ANG II induces sucrose intake independent of its effect on thirst.

Title: Neurons within the subfornical organ that express angiotensin type 1a receptors stimulate fluid consumption and hypothalamic-pituitary-adrenal axis activation

Authors: *A. R. ALLEYNE[1], K. CAHILL[2], Y. TAN[3], A. D. DE KLOET[5], E. G. KRAUSE[4]

Abstract: Circulating angiotensin II elicits behavioral and physiological responses to decreased blood pressure or hypovolemia by activating angiotensin type-1a receptors (AT1aR) in circumventricular organs that lack a blood brain barrier. In particular, the subfornical organ (SFO) contains neurons that express AT1aR and are implicated in the maintenance of body fluid homeostasis. This study used mice with Cre recombinase expression directed to the AT1aR gene to functionally phenotype neurons in the SFO that express AT1aR. Initial studies combined genetic reporting with RNAscope *in situ* hybridization to reveal that the majority of AT1aR neurons in the SFO are glutamatergic. Next, Cre-inducible adenoassociated virus that expresses

channelrhodopsin-2 (ChR2) or enhanced yellow fluorescent protein (eYFP) was delivered into the SFO of AT1aR-Cre mice, and subsequently, a chronic dwelling fiber optic was implanted. Relative to controls expressing eYFP, *in vivo* optogenetic stimulation of AT1aR neurons in the SFO significantly increased water and 0.3M NaCl consumption. Interestingly, optical excitation of the same population of neurons also significantly elevated plasma levels of corticosterone. Taken together, these results suggest that neurons in the SFO that synthesize AT1aR drive water and sodium intake as well as activation of the hypothalamic-pituitary-adrenal axis.

Title: Renal expression of aquaporin 2 in the offspring of rats that consumed sugared water during pregnancy and lactation

Authors: *V. VELAZQUEZ[1], L. NICOLÁS[2], E. CUEVAS[2], A. ORTEGA[3], F. CASTELÁN[4], J. RODRÍGUEZ ANTOLÍN[2]
[1]Univ. Autonoma De Tlaxcala, tlaxcala, Mexico; [2]Ctr. Tlaxcala Biología de la Conducta, Univ. Autónoma de Tlaxcala, Tlaxcala, Mexico; [3]Cinvestav-IPN, Mexico City, Mexico; [4]Inst. de Investigaciones Biomedicas, Univ. Nacional Autonoma De Mexico, Tlaxcala, Mexico

Abstract: The urinary tract achieves the elimination of toxic substances from the organism, particularly in the kidneys. Among the several types of aquaporins (AQPs) expressed in different parts of the organism, seven (AQP1,-2,-3,-4,-6,-7, and -8) are differentially expressed in the kidney. These are highly relevant for the water transport across the renal tubules. Particularly, AQP2 is located on the collecting duct where the urine will be diluted or concentrated because of actions triggered by the anti-diuretic hormone (ADH) including the trafficking of AQP2 containing vesicles to the apical membrane. The high consumption of sugared beverages is related to metabolic diseases, including type 2 diabetes mellitus frequently linked to renal failure. The aim of this project was to determine the effect of sugared water consumption during pregnancy and lactation on the renal AQP2 in the adult male offspring. We use Wistar female rats that were mated and divided in a control group fed with standard diet and tap water, and the experimental group fed with standard diet and 5% sucrose diluted in tap water (sugared water). At weaning, two male rats were randomly selected per litter; one of them had free access to simple water while the other had free access to the sugared water. After four months, male rats were sacrificed and the AQP2 expression was analyzed by immunohistochemistry and Western

blot. In contrast to the group that consumed tap water, the group that consumed sugared water during pregnancy, lactation and postnatal life showed an overexpression of AQP2. It seems that the consumption of sugared water, even in low concentration, is able to modify the renal AQP2 expression. These findings could be directly related to water transport in the renal tubules altering the function of the upper urinary tract.

Title: Pressor and dipsogenic responses induced by central angiotensin II in rats treated with high fat diet

Authors: J. M. SÁ, R. M. BARBOSA, L. A. DE LUCA, Jr., J. V. MENANI, E. COLOMBARI, *D. S. COLOMBARI
UNESP Sch. of Dent., Araraquara, Brazil

Abstract: The activity of the renin-angiotensin system may increase in obesity. We have previously demonstrated that the central blockade of angiotensin type 1 receptor of high fat diet (HFD)-fed rats abolished the increase in arterial pressure observed in these animals. In the present study, we tested the pressor and dipsogenic responses to central angiotensin II (ANG II) in rats fed with HFD. In addition, the effect of HFD on *ad libitum* water intake was also evaluated. Male Holtzman rats (290-320 g) treated with standard diet (SD, 5% calories from fat; n = 5-10/group) or HFD (45% calories from fat; n = 8-15/group) for 6-7 weeks were used. At the end of the 6^{th} week, a group of rats received a stainless steel cannula in the lateral ventricle (LV). A week later, ANG II (25 ng/1 µl) was injected in the LV and water intake was measured for 1 h and expressed in ml/100 g of body weight (b.wt.). Two days later, a catheter was implanted in the femoral artery and in the following day, mean arterial pressure (MAP) was recorded in conscious, freely moving rats, before (baseline period for 20 min) and after injections of saline (1 µl) and ANG II (25 ng/1 µl) into the LV. In another group of rats treated with SD or HFD for 6 weeks, daily water intake was measured and averaged for the week. The peak of the pressor response induced by ANG II injected into the LV was comparable in HFD and SD rats (20 ± 4,

vs SD: 21 ± 3 mmHg), however 20 min after the injection of ANG II into the LV, MAP was still increased in HFD compared to the SD group (19 ± 3, vs SD: 9 ± 3 mmHg, $p < 0.05$). Rats that ingested HFD had a lower daily water intake for the 6 week-period analyzed (5.1 ± 0.3, vs. SD: 8.3 ± 0.7 ml/100 g of body weight at the 6^{th} week, $p < 0.05$), whereas ANG II injected into the LV induced similar intake of water in HFD and SD (3.6 ± 0.4, vs. SD: 3.1 ± 0.4 ml/100 g b.wt.). These results suggest that rats treated with HFD have a sensitization for the pressor response to central ANG II, without changing central ANG II-induced water intake.

Title: Involvement of the medial septal area in the control of sodium intake

Authors: S. P. BARBOSA, L. A. DE LUCA, Jr, P. M. DE PAULA, D. S. A. COLOMBARI, E. COLOMBARI, C. A. F. ANDRADE, D. B. ZOCCAL, *J. MENANI
UNESP, Araraquara, Brazil

Abstract: Angiotensin II (ANG II) and aldosterone are typical facilitatory mechanisms involved in the control of water and/or sodium intake. The deactivation of the inhibitory mechanisms with moxonidine (α_2 adrenergic/imidazoline agonist) into the lateral parabrachial nucleus (LPBN) not only strongly increases 1.8% NaCl intake in sodium depleted rats, but also surprisingly drives hyperosmotic rats to ingest 1.8% NaCl. In the present study, water and 1.8% NaCl intake was investigated in rats treated with intragastric load of 2 M NaCl that received losartan (AT1 antagonist) into the medial septal area (MSA) combined with injections of moxonidine into the LPBN. In addition, it was also investigated water and 1.8% NaCl intake in satiated and normovolemic rats treated with injection of ANG II into the MSA combined with moxonidine into the LPBN. Male Holtzman rats (290-310 g, n= 7-8) with guide-cannulas implanted toward the MSA and the LPBN were used. Rats treated with intragastric 2 M NaCl (2 ml/rat) combined with moxonidine (0.5 nmol/0.2 µl) into the LPBN and saline into the MSA ingested water (11.1 ± 1.8, vs. vehicle: 2.6 ± 1.0 ml/2 h) and 1.8% NaCl (27.0 ± 8.1, vs. vehicle: 0.6 ± 0.3 ml/2 h). The injection of losartan (20 µg/0.5 µl) into the MSA reduced water (6.4 ± 3.2 ml/2 h) and 1.8% NaCl intake (5.3 ± 3.3 ml/2 h) in hyperosmotic rats treated with moxonidine into the LPBN. The

injection of ANGII (10 ng/0.5 µl) into the MSA combined with moxonidine into the LPBN also induced 1.8% NaCl intake (15.7 ± 5.8 ml/2 h) compared to saline + vehicle (0.6 ± 0.4 ml/2 h) or ANG II into the MSA + vehicle (0.6 ± 0.2 ml/2 h). The ingestion of water also increased in rats were treated with ANG II into the MSA + moxonidine into the LPBN (5.1 ± 2.2 ml/2 h) compared to ANG II into the MSA + vehicle (1.5 ± 1.1 ml/2 h) or saline + vehicle (1.0 ± 0.5 ml/2 h). The results suggest that the LPBN strongly inhibits the facilitatory mechanisms for sodium intake activated by ANG II acting in the MSA. In addition, the results suggest that the activation of AT1 receptors in the MSA is an important step to drive hyperosmotic rats to ingest sodium when the inhibitory mechanisms are deactivated with moxonidine into the LPBN.

Title: Central MAPK-Erk1/2 inhibition reduces sodium appetite in spontaneously hypertensive rats

Authors: G. M. F. ANDRADE-FRANZÉ, E. D. PEREIRA, Jr., L. A. DE LUCA, Jr., J. V. MENANI, *C. A. ANDRADE
Sch. of Dent. - FOAr - UNESP, Araraquara, Brazil

Abstract: Excessive salt intake has been associated with the development or worsening of chronic diseases such as hypertension. Spontaneously hypertensive rats (SHR) have a typical increased sodium preference when compared to normotensive strains. In normotensive rats, angiotensin II (ANG II)-induced water intake can be selectively blocked by protein kinase C inhibitors, while ANG II-induced sodium intake is dependent on MAPK-Erk1/2 activation (Exp Physiol 94:130, 2009). However, the effects of MAPK-Erk1/2 inhibition on sodium and water intake in SHR are not clear. Therefore, in the present study, we investigated if selective inhibition MAPK-Erk1/2 pathway would change sodium appetite and water intake in SHR. Spontaneously hypertensive rats (280 - 330 g, 24 weeks old, n = 09) and normotensive Holtzman rats (HTZ, 280 - 330 g, 16 weeks old, n = 07) with stainless steel guide cannulas implanted in the lateral ventricle (LV) were used. Rats with 24 h of water deprivation (WD) had access to only

water during 2 h for partial rehydration (PR) (WD-PR protocol) before receiving LV injections of U0126 (p44/42 MAPK inhibitor, 2 mM; 2 μl) or vehicle (0.9% NaCl:DMSO 20%). Then, the animals had 2 h access to 0.3 M NaCl and water (sodium appetite test). SHR treated with intracerebroventricular (icv) injections of vehicle ingested more 0.3 M NaCl than vehicle-treated HTZ rats (10.4 ± 1.4, vs. 5.3 ± 1.8 ml/120 min, respectively). The icv injections of U0126 in HTZ produced no change in 0.3 M NaCl intake (3.5 ± 1.8, vs. vehicle: 5.3 ± 1.8 ml/120 min) or water intake (1.8 ± 0.7, vs. vehicle: 3.8 ± 2.0 ml/120 min). However, icv injections of U0126 in SHR reduced 0.3 M NaCl intake induced by WD-PR (4.6 ± 1.3, vs. vehicle: 10.3 ± 1.4 ml/120 min) and water intake (2.1 ± 0.9, vs. vehicle: 6.4 ± 1.1 ml/120 min). In addition, the icv injection of U0126 produced no change in basal mean arterial pressure and heart rate, however, reduced the pressor response induced by icv ANG II (25 ρmol/1 μl) in both SHR and HTZ rats. The present results suggest that the inhibition of central MAPK-Erk1/2 ANG II receptor signaling pathway decreases sodium appetite in SHR and the pressor response to icv ANG II in HTZ and SHR rats. **Financial Support:** FAPESP and CNPq.

Title: Perinatal exposure of the rat to high levels of NaCl via mother induces salt sensitivity in later life that depends on enhanced vasopressin secretion

Authors: W. JUNG, Y.-B. KIM, S. LEE, X. JIN, H. KANG, *Y. I. KIM
Dept. of Physiology, Korea Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Salt sensitivity (SS) is a trait of clinical importance because it carries strong prognostic implication for various cardiovascular disorders including hypertension. Whether perinatal exposure to high levels of NaCl via mother induces SS in adulthood has been a subject of several studies, with little evidence for this hypothesis. This study sought to determine whether, in rats, excessive maternal salt intake during gestation and lactation would induce SS in the offspring in later life, and if so, the mechanisms underlying its expression. The 7~8weeks-old male-offspring of dams (Sprague-Dawley rats) provided with 1.5% saline as drinking water

during these reproductive periods (experimental group) had higher systolic blood pressures (SBP) after high-salt challenge, which was given by providing 2% saline as drinking water for 3 days or 8% NaCl-containing chow as the diet for 4 weeks, than the age- and sex-matched rats, the mothers of which were supplied with tap water, instead of 1.5% saline, as drinking water (control group). Furthermore, after the high-salt challenge, experimental rats had greater increases in plasma arginine-vasopression (AVP) level and greater depressor responses to intravenously injected V1a receptor antagonist. In experimental and control rats prazosin lowered SBP to a similar extent both before and after the high-salt challenge. Meanwhile, Na^+-rich ACSF ([Na^+]: 300 mmole/L or 450 mmole/L) injection into the lateral ventricle increased the SBP and heart rate to similar degrees in control and experimental rats. Lastly, after the high-salt challenge, GABA functioned as an excitatory, instead of inhibitory, neurotransmitter in most AVP neurons of experimental rats. These results indicate that perinatal exposure to high levels of NaCl via mother induces SS in adulthood, the expression of which may not depend on enhanced sympathetic outflow, but on increased AVP secretion, which in turn is aided by the inhibitory-to-excitatory transition of GABAergic transmission in AVP neurons. We speculate that, by examining the AVP system, one may be able to detect SS and decipher its nature.

Title: Aldosterone-sensitive HSD2 neurons in the nucleus of the solitary tract: Gene expression and axonal projections in mice

Authors: *S. GASPARINI[1], J. M. RESCH[2], S. V. NARAYAN[1], L. PELTEKIAN[1], G. N. IVERSON[1], J. C. GEERLING[1]
[1]Neurol., Univ. of Iowa, Iowa City, IA; [2]Dept. of Med., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Hyperaldosteronism is linked to increased rates of mood disorders including anxiety and depression and to other broadly dysphoric symptoms, but the neural circuit basis for aldosterone affecting mood remains obscure. Aldosterone boosts the activity of neurons in the

brainstem that contain the enzyme 11-beta-hydroxysteroid dehydrogenase type 2 (HSD2), a hallmark of aldosterone-sensitive cells. To better understand these aldosterone-sensitive neurons and their output projections, we performed immunolabeling, fate-mapping, and Cre-dependent axon tracing in mice. Fate-mapping identified cells throughout the brain with a developmental history of *Hsd11b2* expression, yet in adults expression is limited to neurons in a region of the nucleus of the solitary tract with a leaky blood-brain barrier. Their axons project first to the parabrachial nucleus (PB) and pre-locus coeruleus (pLC), intermingling with AgRP-immunoreactive axons and forming dense terminal fields among FoxP2-immunoreactive neurons. Their axons also extend into the forebrain, intermingling with AgRP- and CGRP-immunoreactive axons and forming a compact terminal field amid GABAergic neurons in the ventrolateral bed nucleus of the stria terminalis (BSTvL). En route to BSTvL, they form sparse branches and boutons in the parasubthalamic nucleus, suprafornical lateral hypothalamic area, central nucleus of the amygdala, and paraventricular hypothalamic nucleus. Dual retrograde tracing revealed that projections to PB or BSTvL originate from largely separate HSD2 neurons. In addition to promoting sodium appetite in BSTvL, we predict from their pattern of output connections that HSD2 neurons promote dysphoric symptoms linked to sodium deficiency and hyperaldosteronism.

Title: Prelimbic prefrontal cortex is necessary to face threats during a motivational conflict guided by learned, but not innate, stimuli

Authors: E. ILLESCAS-HUERTA, *L. RAMÌREZ-LUGO, R. ORDOÑEZ-SIERRA, F. SOTRES-BAYÓN
Inst. of Cell. Physiology, UNAM, Mexico City, Mexico

Abstract: When animals forage for food they are often challenged with a conflict based on opposing signals such as facing threat to obtain food. In such motivational conflict, selecting the appropriate behavioral response to execute is critical for survival. The prelimbic prefrontal

cortex (PL) is implicated in signaling fear-related responses and reward-seeking. It is not clear, however, if PL is necessary when opposing signals compete during motivational conflict. To address this issue, we performed pharmacological inactivations of PL in rats that learned to face a threat (crossing an electrified grid floor signaled by white noise) to obtain a reward (press a bar to receive food signaled by light). We found that PL inactivation decreased the latency of rats to cross the signaled threat to obtain food, suggesting PL is necessary to promote fear-related responses when competing with reward-seeking responses. Interestingly, we found that PL inactivation did not affect the latency to obtain food in the absence of threat (no-conflict trials) and did not affect the retrieval of a threat memory in the absence of reward-seeking responses during fear conditioning. Together, these results suggest that PL is crucial to signal fear-related responses when competing with reward-seeking behavior and not when each response is signaled separately. But not all motivational conflicts are guided by learned stimuli. To test if PL is necessary in motivational conflict responses guided by innate motivations, we inactivated PL in rats where both motivations were innate (simultaneous presence of food and intense light in the center of an open field) or where one motivation was learned (step-down to a grid associated with an electric shock) but the other was innate (sweet water). We found that PL inactivation does not affect motivational conflict responses when competing motivations are both innate. Yet, if one of the two competing motivations is learned, PL inactivation decreased latency to cross during conflict trials. Thus, our results suggest that PL is necessary to execute the appropriate behavioral response (face threat to obtain reward) when animals are challenged with a motivational conflict guided by at least one previous experience but not for those guided by innate motivations.

Title: Opposing roles of the anterior and posterior ventral striatum in choice behavior guided by taste aversion memory

Authors: A. P. PEÑAS-RINCÓN, L. RAMÍREZ-LUGO, *F. SOTRES-BAYON
Inst. of Cell. Physiology, UNAM, Mexico City, Mexico

Abstract: Although much is known about brain mechanisms underlying associations with dangerous taste stimuli, very little is known about how these stored emotional associations guide choice behavior. The ventral striatum (VS) is implicated in taste aversion processing and in mediating choice between goal-directed actions. It is not clear, however, if VS, along its anterior-posterior axis, is necessary for choice behavior guided by taste preferences. To address this, we used GABA agonists (muscimol and baclofen) to perform pharmacological inactivations of anterior (aVS) and posterior (pVS) VS before retrieval of an aversive memory in choice or no-choice-based conditioned taste aversion (CTA) tasks in rats. In CTA, rats acquire aversion to a novel taste (saccharin) when followed by digestive malaise induced with lithium chloride. During standard CTA task, rats avoid a single bottle containing saccharin solution without choice (no-choice CTA). To evaluate choice behavior, we developed a choice CTA task that involves actively choosing between bottles with aversive saccharin or safe water (choice CTA). We found that aVS inactivation blocked retrieval of choice CTA, but had no effect on no-choice CTA. This suggests that aVS plays a key role in guiding choice by facilitating the use of CTA memory without being necessary for its retrieval. Notably, aVS inactivation did not affect choice behavior when guided by innate taste stimuli, highlighting its role in choice guided by learned but not unlearned stimuli. In contrast to aVS inactivation, we found that pVS inactivation facilitated retrieval of choice CTA memory without affecting retrieval of no-choice CTA memory nor choice behavior guided by innate taste. These results suggest that pVS plays an opposing role to aVS, as it is necessary to suppress the retrieval of taste aversion memory when facing a choice. Yet, like aVS, pVS is not necessary to process choice guided by innate taste stimuli. Together, these findings provide novel evidence for the role of VS in choice behavior guided by taste aversion memory by revealing opposing roles of this brain structure along its anterior-posterior axis.

Title: Basolateral amygdala, but not the orbitofrontal cortex, is necessary for motivational conflict responses guided by previous experiences

Authors: *A. HERNANDEZ-JARAMILLO, F. SOTRES-BAYON
Inst. of Cell. Physiology, UNAM, Mexico City, Mexico

Abstract: Animals foraging for food are often challenged with a conflict between opposing motivations driven by previous experiences, such as facing a cue that predicts threat to approach another cue that predicts food. Selecting the appropriate behavioral response to execute in such motivational conflict guided by biologically significant memories is critical for survival. The basolateral amygdala (BLA) has been implicated in the regulation of defensive responses to threats (fear) as well as reward-seeking signaling. The orbitofrontal cortex (OFC) has been involved in action selection based on the relative value of cues learned by positive and negative experiences. It is not clear, however, whether these structures are necessary when opposing cues compete during a motivational conflict. To address this issue, we performed pharmacological inactivations of BLA or OFC in rats trained to face a threat (crossing an electrified grid floor signaled by withe noise) to obtain a reward (press a bar to receive food signaled by light). We found that BLA inactivation (with a high but not low dose of GABA agonists muscimol and baclofen) decreased the time it takes (latency) for rats to cross the predicted threat to obtain food. This result suggests that BLA is necessary to promote fear-related responses when competing with reward-seeking behaviors. Consistent with previous studies, we found that BLA inactivation impaired the retrieval of a threat memory in the absence of available reward in fear conditioning, but did not affect the latency to obtain food in the absence of threat during no-conflict trials. These results support the predominant notion that BLA is key to execute behavioral responses triggered by cues associated with threats, but not by cues associated with rewards. Surprisingly, we found that OFC inactivation did not affect any of the motivational conflict responses including fear-related responses and reward-seeking behaviors. Together, our findings suggest that BLA, but not OFC, is necessary to promote fear-related behaviors when an animal is challenged to face potential threats to approach a reward guided by previous experiences.

Title: Habenula is necessary to promote expression of fear memory when it competes against a safety memory

Authors: *G. VELAZQUEZ-HERNANDEZ, F. SOTRES-BAYON
Inst. of Celullar Physiology, UNAM, Mexico city, Mexico

Abstract: Although the habenula has been implicated in the regulation of emotional behaviors, it is not clear *when* it is necessary to regulate defensive responses to a threat (fear). During auditory fear conditioning, animals learn the tone-shock association, which leads to the formation of a fear memory. During extinction training, animals learn that the tone no longer predicts shock, which forms a "safety memory". Thereby, it has been suggested that after extinction training, fear memory and safety memory coexist in the brain and compete for control of behavior. To evaluate the contribution of the habenula in the different phases of learned fear regulation, we performed pharmacological inactivations of the habenula at specific time points. On day 1, rats associated the presence of tones with foot shock delivery (fear learning). On day 2, rats learned to extinguish fear responses by presenting tones in the absence of foot shocks (safety learning). On day 3, rats were presented with tones alone to test for fear against safety memory retrieval. We found that habenula inactivation before fear acquisition or before extinction acquisition had no effect, indicating that this structure is not necessary for: fear learning, fear memory expression nor extinction learning. Surprisingly, however, we found that habenula inactivation before the memory retrieval test decreased fear responses, suggesting its role in regulating competing fear and safety memories. To further test the idea that habenula is necessary when fear and safety memories compete, we switched the order of fear and safety learning by using a latent inhibition protocol. Thus, on day 1, rats acquired safety learning (tones, no shocks). On day 2, rats acquired fear learning (tones paired with foot shocks). On day 3, rats were presented with tones alone to test for safety memory vs fear memory retrieval. Indeed, we found again that habenula inactivation before retrieval test of safety memory against fear memory decreased fear responses. Together our findings suggest that the habenula is necessary to promote the expression of fear memory when it competes against a safety memory.

Title: Approach/avoidance conflict training reveals distinct behavioral phenotypes for conflict resolution

Authors: *H. BRAVO-RIVERA, P. A. RUBIO-ARZOLA, A. J. CABAN-MURILLO, G. J. QUIRK
Dept. of Psychiatry, Anat. & Neurobio., Univ. of Puerto Rico Sch. of Med., San Juan, PR

Abstract: We recently introduced an approach/avoidance conflict task in which rats must choose between stepping onto a nearby platform to avoid a 2s shock predicted by a 30s tone, or pressing a lever for sucrose pellets (Bravo-Rivera et. al., GRC amygdala, 2017). Unlike our previous avoidance task where rats could obtain food between the shock-associated tones, here food was only available during a 30s light, which was co-presented with the tone. When presented with this light-tone conflict, 26% (19/70) of male rats spent all the tone on the platform and did not press for food (avoidance-preferring subgroup), 30% (21/70) engaged in excessive food-seeking showing little to no avoidance (food-preferring subgroup), and 44% (30/70) were able to accommodate both food seeking and avoidance by shifting their avoidance later in the tone (timer subgroup). Female rats showed similar percentages. We used the neural activity marker c-fos to assess activity profiles for each subgroup. The food-preferring subgroup showed decreased prefrontal c-fos density compared to the other two groups. This agrees with previous work showing a correlation between low prefrontal activity and increased reward sensitivity, impulsivity, and low anxiety levels (Rivalan et. al., 2010). Decreased PFC activity has also been correlated with decreased social interactions in rats (Hamilton et.al., 2010). Consistent with this, rats in the food-preferring subgroup showed decreased anxiety in the EPM ($F_{2,41}=7.65$, $p=0.002$) and impaired social interactions ($F_{2,40}=5.50$, $p=0.007$) relative to the other subgroups. Interestingly, the timer subgroup showed the highest PFC/Amygdala ratio of cFos density, consistent with prefrontal control of both foraging and avoidance. Next, we examined the factor of age. Developmental studies show that prefrontal pruning and myelination continues through P240 (Sturrock, R.R., 1980). Consistent with this, the food-preferring phenotype was less prevalent in older rats (5%, P180-P200, n=59) compared to younger rats (30%, P125-P140, n=70) (Chi sq= 15.77, $P<0.001$). This is consistent with a shift in older rats from ventrostriatal- to prefrontal-based decision making (Worthy et. al., 2012, Kolb et. al., 2012). Taken together, the approach of focusing on naturally occurring differences in approach/avoidance conflict, along with age and social factors, may provide insight into the circuitry of conflict resolution and its potential dysfunction in anxiety and addiction.

Title: The role of orbital/insular outputs in a rodent model of persistent avoidance

Authors: *F. J. MARTINEZ, J. E. PÉREZ-TORRES, C. I. HUERTAS-PÉREZ, M. J. SÁNCHEZ-NAVARRO, C. D. VELÁZQUEZ-DÍAZ, G. J. QUIRK
Psychiatry and Anat. & Neurobio., Univ. of Puerto Rico, Med. Sci. Campus, San Juan, PR

Abstract: Avoidance compulsions are commonly treated with exposure-with-response-prevention (ERP) therapy, in which patients are prevented from carrying out avoidant actions in response to triggers. To model excessive avoidance and ERP in rodents, we used a platform-mediated avoidance task in which rats learn to avoid a tone-signaled shock by stepping onto a nearby platform. This is followed by extinction with response prevention (Ext-RP) training, where the tone-shock association is extinguished over four days while access to the platform is blocked with a barrier (Rodriguez-Romaguera, et al., 2016). The barrier is then removed to test the transfer of extinction learning to avoidance behavior. We previously reported that pharmacological inactivation of the lateral orbitofrontal/agranular insular area (LO/AI) during the post Ext-RP test induced persistent avoidance in rats that would have otherwise not avoided (Rodriguez-Romaguera, et al., 2016). This suggests that projections of LO/AI are needed for the transfer of extinction to avoidance, but the targets of these projections are not known. To address this, we photo-inhibited LO/AI terminals in prelimbic cortex (PL), ventral striatum (VS), or basolateral amygdala (BLA) with halorhodopsin. Photo-inhibiting LO/AI-PL projections had no effect on the expression of avoidance, but induced persistent avoidance during the post-Ext-RP test ($F_{(1,14)} = 6.02$, $p= 0.03$), an effect that was maintained seven days later ($F_{(1,4)} = 13.20$, $p= 0.02$). There was no immediate effect of photo-inhibiting LO/AI projections to VS or BLA on avoidance, however seven days later, the LO/AI-BLA rats showed persistent avoidance without any additional laser exposure ($F_{(1,24)} = 6.85$, $p= 0.01$). Together, our findings suggest that activity in the projection from LO/AI to PL facilitates the execution of the appropriate avoidance decision at test, and induces plasticity in PL and BLA to maintain low levels of avoidance. Given that excessive harm-avoidant compulsions in OCD are associated with poor decision-making (Pushkarskaya et al., 2015), hypoactivity in the human homologue to rat LO/AI (vlPFC?) may promote these maladaptive behaviors.

Title: Interrogating the projections of rostral prelimbic cortex that drive active avoidance

Authors: *M. M. DIEHL[1], J. IRAVEDRA-GARCIA[1], F. N. GONZALEZ-DIAZ[1], G. J. QUIRK[2]
[1]Psychiatry, Univ. of Puerto Rico, Sch. of Med., San Juan, PR; [2]Psychiatry and Anat. & Neurobio., Univ. Puerto Rico Sch. of Med., San Juan, PR

Abstract: Active avoidance has recently garnered much interest; however, little is known about the neural circuits that drive avoidance. Using an avoidance task in which a rat can avoid a tone-signaled footshock by stepping onto a nearby platform (Bravo-Rivera, et al., 2014), we observed that pharmacological inactivation of the prelimbic prefrontal cortex (PL) delayed avoidance (Diehl et al., eLife, in press). Additionally, excitatory responses in rostral PL neurons (rPL) were correlated with platform entry. PL projections that drive avoidance remain largely unknown. Here, we assessed the role of rPL projections to ventral striatum (VS) or basolateral amygdala (BLA), two known targets of rPL (Sesack et al., 1989; Vertes, 2004), by either photoactivating with Channelrhodopsin (ChR2; 15-20Hz, 30 sec,) or photosilencing PL terminals with Halorhodopsin (Halo; 30 sec). Photoactivation of rPL-VS projections impaired the expression of avoidance (ChR2: 42.7% time on platform (n=11), eYFP-control: 77.6% (n=9), p=0.033). Photosilencing PL-BLA projections showed a trend toward impaired avoidance expression (Halo: 16% time on platform (n=5), eYFP-control: 26% (n=5), p=0.074). Moreover, photoactivation of rPL-BLA projections reinstated avoidance following extinction (ChR2: 25% time on platform (n=3), eYFP-control: 3% (n=3), p=0.005). These findings suggest that rPL projections to VS and BLA have opposing effects on avoidance and are consistent with recent cFos findings that avoidance retrieval activates PL-BLA projections but not PL-VS projections (Martinez-Rivera et al., Psychopharm., submitted). Additional experiments will determine

whether photoactivating PL-BLA or silencing PL-VS projections impair or promote platform-mediated avoidance, respectively. Together, these findings suggest that distinct rPL projections exert bidirectional control over avoidance behavior.

Title: Neural correlates of risky decision-making in rats encountering a 'predatory' threat

Authors: *E. KIM[1], H. DING[2], M.-S. KONG[1], J. J. KIM[1,3]
[1]Psychology, [2]Physiol., [3]Program in Neurosci., Univ. of Washington, Seattle, WA

Abstract: Fear alters foraging behavior in animals to decrease exposure to threats and thus increase their survival while searching for resources in their environment. Previously, we have investigated rats' foraging behavior in an ecologically-relevant setting and found that rats can discern conditional predatory (Robogator) threats and adjust their foraging strategy (Kim et al., 2016), which was abolished by amygdala lesions. Here, we investigated the neural basis for animals to discriminate the conditional threat and to switch their foraging preference by simultaneously recording single-units in the basolateral amygdala (BLA) and the prelimbic area of the medial prefrontal cortex (PL), two structures implicated in fear and decision-making processes (Mobbs and Kim, 2015). To do so, male Long-Evans rats, implanted with tetrode arrays in the BLA and PL ipsilaterally, underwent successive stages of nest habituation, foraging preference baseline, and robot testing. Tetrodes were gradually advanced towards their target structures, and neural activity was recorded as the rats exited their nest in search of food pellets placed in a large open field. During the preference baseline trials, rats were allowed to forage for chocolate and normal pellets placed equidistance from the nest but on opposite sides of the foraging arena. In general, rats exhibited preferences of choosing chocolate pellets over normal pellets. When the Robogator was placed on the opposite end of the foraging area and programmed to surge each time the animal approached chocolate (but not normal) pellet, consistent with our previous findings, all animals shifted their foraging behaviors toward normal pellets. By performing a cross-correlation analysis, we found that a subset of simultaneously recorded BLA and PL cell pairs showed increased spike synchrony prior to foraging preference shift during the robot session, where comparable proportions of the significant cell pairs

indicated BLA-leading and PL-leading cross-correlations. Moreover, a greater number of BLA cells that displayed correlated firing with PL cells responded to the robot surge while a greater number of PL cells that displayed correlated firing with BLA cells responded to the food pellets. These results suggest that BLA neurons encoding imminent threats actively interact with PL units signaling food pellets to alter foraging behavior in the face of conditional threat.

Title: The amygdala influences spatial information processing in the hippocampus in risky foraging situations

Authors: *M.-S. KONG[1], H. DING[2], E. KIM[1], J. J. KIM[1,3]
[1]Psychology, [2]Physiol., [3]Neurobio. & Behavior, Univ. of Washington, Seattle, WA

Abstract: In nature, animals seeking resources are vulnerable to predation and thus must be able to discern safe-versus-dangerous boundaries of their habitat, but how the brain integrates threat and spatial information is poorly understood. Our previous work revealed that a surging 'predator' robot induced transient remapping of hippocampal place fields near the source of threat (i.e., distal to the nest), whereas those fields adjacent to or inside of the safe area (i.e., nest) were relatively stable; amygdalar lesions prevented both fear of the robot and place cell remapping (Kim et al., 2015). More recently, we found that distinct populations of amygdala neurons transiently increased spiking as rats either advanced or fled the robot predator, which suggests that the amygdala signals the occurrence of real threats (Kim et al., 2018). To further understand these findings, we examined the functions of basal amygdala (BA) and dorsal hippocampus (dHPC) as rats exited a safe nest to procure food in a large open space before, during and after encountering the robot predator programmed to surge from distant. Male Long-Evans rats were implanted with tetrodes into the BA and the dHPC to record neural activities simultaneously. After the postoperative recovery, all rats maintained ~85% normal body weight to motivate foraging behavior during the experiment. Unit activities and local field potentials were recorded during the pre-robot (~ 10 trials of procuring the pellet without the robot predator), robot (~ 10 times of attempts to acquire the food with a presence of the robot predator), and post-robot (same as the pre-robot session) sessions. Simultaneous recordings revealed that BA neuronal activity increased while dHPC place fields became unstable as

animals advanced and fled from the predatory robot. These results suggest that fear signals from the BA influence spatial information processing in the dHPC to protect animals traversing safe and dangerous areas.

Title: The role of neonatal gonadal hormones in organizing juvenile and adult contextual fear conditioning

Authors: *L. M. COLON[1], D. G. ZULOAGA[2], A. M. POULOS[3]
[1]Psychology- Behavior Neurosci., Univ. At Albany State Univ. of New York, Albany, NY; [2]Univ. at Albany, Albany, NY; [3]Dept. of Psychology, Univ. At Albany, SUNY, Albany, NY

Abstract: Our previous research highlights a sex-dependent, developmentally divergent pattern of context fear mediated freezing. Context fear expression in male Long Evans rats increases from pre-adolescence to adulthood, while in female rats an opposite pattern of fear emerges (Colon et al., 2018). This unique developmental pattern initiated prior to puberty suggests that neonatal gonadal hormones may play a role in organizing the differentiation of neural systems underlying contextual fear conditioning. In this study, we sought to determine whether neonatal gonadal hormone exposure mitigates an organizational role in the sex-specific development of context fear conditioning by removing the presence of testicular hormones at birth in Long Evans male rats. This was accomplished by neonatal orchiectomy, and the examination of conditioning at 24 and 60 days postnatal. Our preliminary findings indicate that orchiectomy alters the expression of contextual fear compared to control subjects, suggesting that gonadal hormones have an organizational influence on the neural systems underlying contextual fear conditioning.

Title: Organization and functional recruitment of neuronal populations in rat prefrontal cortex that project to the basolateral amygdalar nuclei: A combined retrograde tracing and Fos activation study of context fear conditioning across development

Authors: *A. J. SANTARELLI[1], A. M. KHAN[2], A. M. POULOS[3]
[1]Psychology, State Univ. of New York, Univ. at Albany, Albany, NY; [2]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX; [3]Dept. of Psychology, Univ. at Albany, SUNY, Albany, NY

Abstract: A growing body of research suggests an important function for prefrontal cortical (PFC) regions in contextual-spatial mediated learning. Several of these cortical areas, including the rostral anterior cingulate (ACA), infralimbic (ILA) and prelimbic (PL) areas, undergo a protracted period of development and innervate directly the anterior and posterior portions of the basolateral amygdalar nuclei (BLAa & BLAp; respectively). These BLA afferents undergo a relatively extended period of cellular proliferation, which culminates in large-scale synaptic pruning. Recently, we proposed that the degree of PFC involvement in context fear conditioning may depend on the developmental status of ILA-BLAp and PL-BLAp projections. Here, we sought to investigate the extended anatomical development of PFC-BLA projections and their activation during contextual fear retrieval. We hypothesized that the afferent projections from certain PFC areas will exhibit a unique pattern of anatomical development in juvenile rats compared to the adult and that contextual fear conditioning in juveniles may bias the activation of these projections. We tested these predictions by combining Fluorogold (FG) tract-tracing of BLA afferents - to retrogradely label PFC neurons - with detection of Fos immunoreactivity (Fos+) induced by the retrieval of context fear memory in infant (P19), juvenile (P24, P35), and adult (P90) rats. Nissl stained coronal sections were aligned to a reference atlas extending across 1.4mm of the PFC and within proximity to the injection site. All regions and subnuclei were parcellated according to previously established definitions. We identified FG+ neurons in the PL, ILA, medial orbital (ORBm), posterior-ventral anterior olfactory nucleus (AONpv), dorsal ACA, endopiriform (EPd), tenia tecta (TTd) and agranular insular area (Aid). We then mapped the

observed FG+, Fos+, and FG+/Fos+ double-labeled neurons to a reference atlas (Swanson, 2004) through the rostrocaudal extent of these regions. Quantification of FG+ neurons across development revealed BLA afferents peaked at either P24 (ILA, ACA, AONpv) or P35 (PL, Aid) with ILA, ACA and AONpv undergoing significant pruning towards adulthood. Moreover, in P24 rats both BLA projecting, PL and ILA regions displayed increased FG+/Fos+ neurons following contextual fear retrieval. These results demonstrate that PFC-to-BLA projections in juvenile rats are quantitatively distinct from the adult and may provide vital insight into the development of fear-related neural circuitry.

Title: A neuroanatomical and functional characterization of bidirectional trans-hemispheric projections between the left and right BLA complexes in the rat

Authors: *N. ODYNOCKI, A. J. SANTARELLI, A. M. POULOS
Psychology, Univ. At Albany State Univ. of New York, Albany, NY

Abstract: The basolateral complex of the amygdala, which consists of the anterior and posterior portions of the basolateral amygdalar (BLAa, BLAp) and lateral amygdalar (LA) nuclei, is a crucial component of the neural circuitry underlying Pavlovian fear conditioning. Despite evidence in humans and rodents suggesting a left versus right BLA complex bias in the expression of fear, relatively little is known about what contributes to this asymmetrical pattern of activation. One possible source of this variation is the bidirectional trans-hemispheric projections previously identified between the left and right BLA complexes. Here, we characterize and explore the importance of this connectivity by employing double co-injections of anterograde and retrograde tracers targeting the left and right BLA as well as inactivation of these trans-hemispheric afferents during the retrieval of contextual fear memories.

Abstract: Synaptic connections are considered to be the functional elements that make up an engram, the structural representation of a memory in the brain. However, the nature of the synaptic changes that occur when a memory is formed remain poorly understood, in part because of the difficulty of visualizing a large collection of synapses in the brain before and after learning. In an effort to visualize the formation of a memory in a living organism in four dimensions (x, y, z, t) at the synaptic level, we have established a novel experimental pipeline using the larval zebrafish brain as a model for vertebrate learning. Combining FingR (Fibronectin Intrabodies Generated with mRNA display) labeling, a novel classical fear conditioning paradigm, optimized non-invasive and sub-micron-level (0.3 x 0.3 x 1.0 µm voxel size) selective plane illumination microscopy (SPIM) imaging, and a semi-automated synapse segmentation and analysis program, we monitor changes in the zebrafish pallium as a lasting fear memory is formed. After behavioral training, we found striking differences in the synaptic changes in highly circumscribed anatomical areas within the pallium, suggesting that one population of cells receives a dramatically diminished projection from sensory areas while a second region receives dramatically strengthened input.

Title: Involvement of caffeine cAMP signaling on neural activity and aggression in crayfish, Procambarus clarkii

Authors: *C. C. HORCHOS[1], R. F. WALDECK[2]
[1]The Univ. of Scranton, Scranton, PA; [2]Biology/ Neurosci. Program, Univ. of Scranton, Scranton, PA

Abstract: Caffeine is a known phosphodiesterase (PDE) inhibitor with an affinity for interacting with dopaminergic pathways in vertebrates and invertebrates (Mustard 2014). PDE inhibitors have been suspected to increase the activity of cAMP cascades producing greater exocytosis of calcium ions by blocking the breakdown of cAMP (Beaumont et. al 2001). Studies have shown that caffeine exposure also decreases action potential threshold in crayfish neuromuscular junctions (Araki et. al 2005; Chiarandini et. al 1970). Behaviorally, crayfish demonstrate a heightened submissive response in conspecific encounters through cAMP signaling on dopaminergic pathways (Momohara et. al 2014, 2016). Our study aims to observe how the physiological effects of caffeine translate behaviorally. Conspecific fights were run using adult, male, *Procambarus clarkii* to measure the aggression before and after the administration of caffeine or 3-Isobutyl-1-methylxanthine (IBMX), a sole PDE inhibitor. Losing crayfish received doses via water bath solution (10 mg/L caffeine or IBMX), while winners were submerged in vehicle. Results for IBMX and caffeine trials indicated enhanced submissive responses in losers, including a decrease in approaches (Two sample T-test; t= -2.479, p= 0.038171, = .05) and an increase in retreats as opposed to tail-flips (F-test, = 4.0205, p=0.0262, .05), when compared to vehicle in IBMX trials. In caffeine trials, control to experimental fights demonstrated a significant increase between the winner and loser mean score differences (Two sample t-test: t = -2.4522, df = 6, p-value = 0.02482). To further investigate the increase in submissive behaviors, we exposed the abdominal nerve chain for extracellular recording on nerve I of the third abdominal ganglion while dripping IBMX (15 mg/ 100 mL), caffeine (15 mg/100 mL), or vehicle (crayfish saline) solutions. When compared to vehicle, IBMX and caffeine application resulted in a mean increase of two to four events per stimulation, a three-fold rise in the magnitude of the amplitude of the peaks, and an increase in their sharpness by slope measurement. These similarities of effects could suggest that caffeine leads to synaptic enhancement through PDE inhibition which increases submission in losing crayfish.

Title: Supramammillary nucleus modulates dentate gyrus activity and hippocampus-dependent behavior

Authors: *N. NOCERA[1], A. HENNINGS[1], K. BONEFAS[4], K. VASUDEVAN[2], B. ZEMELMAN[3], M. R. DREW[3]

Abstract: The dentate gyrus (DG) is critical for memory acquisition and retrieval and modulates stress- and anxiety-related behaviors. Activity in DG is strongly modulated by novelty, but the sources of this modulation are not well understood. The Supramammillary Nucleus (SuM) of the ventromedial hypothalamus sends a pronounced projection to the DG. Previous studies demonstrate that SuM is strongly activated by contextual novelty and that lesions or inactivation of SuM impair performance in a variety of hippocampus-dependent tasks. These findings suggest that SuM may be an important modulator of DG function. However, because previous studies of SuM lacked anatomical precision, it is unknown whether these behavioral effects reflect SuM-DG interactions specifically. Here we examine the role of SuM in DG functioning by isolating and manipulating DG-specific SuM projections. We first examined novelty-evoked activity in SuM using the immediate-early gene cfos. Exposure to a novel environment or fear conditioning in a novel context evoked elevated levels of cfos expression in SuM, whereas exposure to a familiar environment did not. To confirm the role of SuM in hippocampus-dependent behavior, adeno-associated virus was used to express Gi-coupled (inhibitory) or Gs-coupled (excitatory) DREADDs in SuM. Excitation of SuM increased exploration of an open field while inhibition decreased exploration. Excitation of SuM also produced a deficit in context fear retrieval. We next explored anatomical projections of SuM to the hippocampus. Injection of AAV-GFP into

SuM confirmed strong projections of SuM along the full dorsal-ventral axis of DG, terminating within the inner molecular layer. Dorsal DG-projecting SuM cells were previously reported to be distributed more laterally than ventral DG-projecting SuM cells. To confirm this distribution, retrograde tracers (Cholera Toxin B and retrograde AAVs) were injected into dorsal and ventral DG and labeled cells in SuM were examined. Results confirm that dorsal and ventral DG receive projections from separate populations of SuM cells. To evaluate whether these projections have unique functions, retrograde AAV-Cre was injected into dorsal or ventral DG, while Cre-dependent AAVs were injected into SuM. This produced expression of excitatory or inhibitory DREADDs in cells projecting from SuM to either dorsal or ventral DG. Experiments in progress evaluate the role of DG-projecting SuM cells in spatial and emotional learning. We predict that dorsal DG-projecting SuM neurons modulate novelty-evoked learning and behavior, whereas ventral DG-projecting neurons modulate stress-dependent learning and anxiety-like behavior.

Title: Insular cortex processes aversive information and is crucial for threat learning

Authors: *E. BERRET, M. KINTSCHER, S. PALCHAUDHURI, W. TANG, O. KOCHUBEY, R. SCHNEGGENBURGER
Brain Mind Inst., Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: During threat learning, an emotionally innocuous sensory percept like a tone (the conditioned stimulus or CS), acquires emotional meaning when paired with an aversive stimulus (the unconditioned stimulus or US). The amygdala, and especially the lateral amygdala (LA) is a brain structure critical for the integration of CS (tone) and US (footshock) information in the formation of treat memories. Nevertheless, little is known about upstream CNS circuits which process aversive events and relay them to LA. We used *in-vivo* optogenetic silencing experiments with Halorhodopsin, combined with *ex-vivo* functional mapping of synapses, to investigate these questions. Optogenetic silencing of the ventroposterolateral thalamus (VPL), or of the posterior Insular cortex (pInsCx) temporally selectively at the time of footshock presentation strongly suppressed acute fear behavior, and one-day threat memory. Viral tracer experiments show that largely segregated neuronal populations in the pInsCx make output

projections with the LA, and with the central amygdala (CeA). *Ex-vivo* optogenetic mapping approaches with expression of Chronos in the pInsCx followed by slice recordings of neurons in the LA and CeA showed robust optically-evoked glutamatergic EPSCs in both amygdalar substructures. To investigate the role of each pathway in fear behavior and threat memory, we expressed Halorhodopsin bilaterally in each pInsCx, and placed optic fibers bilaterally over either the LA or the CeA. This showed that the pInsCx - LA pathway contributes to one-day threat memory but is not involved in acute fear behavior, whereas the pInsCx - CeA pathway strongly contributes to acute fear behavior, but is less relevant for one-day threat memory. Thus, the posterior Insular Cortex processes US information relevant for threat learning, and routes this information to various amygdala substructures to cause specific phases of fear behavior and threat memory.

Abstract: Fear is a central motive state that is critical for survival. The nucleus accumbens (NAc) , located in the ventral striatum, is an emotional valence center, but whether and how NAc is involved in fear have not been identified. Here, we showed that chemogenetic inhibition adenosine A2A receptor-expressing indirect pathway neurons in the core region of the NAc impaired fear learning in Pavlovian fear condition. Furthermore, we demonstrated anatomically, behaviorally and electrophysiologically that amygdala GABA-input to NAc mechanisms underlie these behaviors. Our results illustrate how defined NAc circuits regulate fear bilaterally.

Title: Cell type specific control of plasticity in the basolateral amygdala via feedforward inhibition

Authors: *E. M. GUTHMAN[1], M. MA[2], S. M. BACA[3], D. RESTREPO[4], M. M. HUNTSMAN[1]
[1]Dept. of Pharmaceut. Sci., [2]Dept. of Cell and Developmental Biology, Rocky Mountain Taste and Smell Ctr., [3]Dept. of Pharmaceut. Sciences, Dept. of Neurol., [4]Cell & Dev. Biology, Neurosci. Program, Univ. of Colorado | Anschutz Med. Campus, Aurora, CO

Abstract: The basolateral amygdala (BLA) plays a vital role in associating specific sensory stimuli with salient valence information. Excitatory principal neurons (PNs) undergo plastic changes to encode this integrated sensory-valence information; however, local BLA inhibitory interneurons (INs) gate the plasticity of the PNs via feedforward inhibition (FFI). One major source of FFI to the BLA is the lateral entorhinal cortex. Despite extensive literature implicating parvalbumin expressing (PV^+) INs in FFI in cortex and hippocampus, prior experiments in the BLA and our own work implicates somatostatin expressing (Sst^+) INs in BLA FFI. To test the hypothesis that entorhinal afferents target Sst^+ INs in the BLA to mediate FFI and gate the plasticity of PNs, we performed whole-cell electrophysiology experiments in horizontal slices of adult mice. We recorded from BLA neurons in response to stimulation of the lateral entorhinal cortex and show that these afferents synapse onto a subset of Sst^+ INs that displayed a fast spiking phenotype, PV^+ INs, and BLA PNs. However, only the fast spiking Sst^+ INs but not PV^+ INs fired action potentials in response to the stimulation. To determine the role of the different INs in FFI, we expressed the inhibitory chemogenetic protein $hM4D_i$ in Sst^+ and PV^+ INs and found that inactivation of Sst^+ but not PV^+ INs decreased FFI onto BLA PNs. Finally, we tested the role of Sst^+ and PV^+ INs in gating plasticity. To do this, we chemogenetically inactivated these cell types while attempting to induce plasticity at the entorhinal to amygdala synapse and found that inactivation of Sst^+ but not PV^+ INs allows the PNs to undergo both LTP and LTD. In the BLA, Sst^+ INs provide FFI to PNs via putative dendritic targeting inhibition in marked contrast to other brain regions, where somatic targeting PV^+ INs provide this function. Additionally, these Sst^+ INs gate the plasticity of cortical inputs to BLA PNs, consistent with the

role of dendritic inhibition across the brain in gating calcium dynamics and with BLA FFI gating plasticity.

Title: Amygdala CRF promotes fear learning with a touch of periaqueductal gray

Authors: *M. B. POMRENZE[1,2], R. MAIYA[1,2], S. M. GIOVANETTI[1,2], G. A. DILLY[1,2], A. G. GORDON[1,2], Y. SHAH[1,2], M. MARINELLI[1,2], R. O. MESSING[1,2,3]
[1]Neurosci., Univ. of Texas at Austin, Austin, TX; [2]Waggoner Ctr. for Alcohol and Addiction Res., The Univ. of Texas at Austin, Austin, TX; [3]Neurol., Dell Med. Schoo, The Univ. of Texas at Austin, Austin, TX

Abstract: Canonical models of fear circuitry involve sensory and cortical inputs to the lateral and basolateral amygdala, which activate neurons of the central nucleus of the amygdala (CeA) that target the midbrain periaqueductal gray (PAG). Recruitment of the PAG then orchestrates rapid defensive behavioral responses, such as freezing, to a fearful stimulus. Neurons in the medial subdivision of the CeA, whose activity is regulated by neurons in the lateral CeA, are thought to be the preferential population targeting the PAG to promote defensive behavior. However recent data show that lateral CeA neurons also give rise to long-range projections, some of which target the ventrolateral PAG (vlPAG) and express stress neuropeptides such as corticotropin releasing factor (CRF). Despite the existence of these projections, their contribution to fear learning is unexplored. We investigated the role of CeA CRF neurons in fear learning using *Crh*-Cre rats. We found that chemogenetic inhibition of CeA CRF neurons interferes with the acquisition, but not expression, of contextual and cued fear, similar to previous reports. Genetic knockdown of *Crh* expression in the CeA recapitulated this effect. Chemogenetic silencing of CRF neurons in the dorsal bed nucleus of the stria terminalis (BNST), a limbic structure strongly connected to the CeA, had little effect on fear acquisition. Anterograde and retrograde viral tracing confirmed a sizeable subpopulation of CeA CRF neurons that project their axons to the vlPAG. Inhibition of these axon terminals in the vlPAG using chemogenetics and targeted CNO microinjections disrupted contextual, but not cued, fear acquisition. Ongoing

experiments are employing fiber photometry to measure activity patterns of CeA CRF neurons during fear conditioning. We are also using retrograde AAV constructs to selectively record calcium dynamics and chemogenetically silence vlPAG-projecting CeA CRF neurons. These data demonstrate a dissociable role for subpopulations of CeA CRF neurons in contextual versus cued fear learning.

Title: Learning-related plasticity of dendritic inhibition in neocortical layer 1

Authors: *E. ABS[1], R. B. POORTHUIS[1], K. MUHAMMAD[1], B. PARDI[1], L. ENKE[1], I. SPIEGEL[2], J. J. LETZKUS[1]
[1]Neocortical Circuits Group, Max Planck Inst. for Brain Res., Frankfurt Am Main, Germany; [2]Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Layer 1 (L1) of sensory cortex receives top-down information from higher cortical areas, thalamic nuclei and neuromodulatory systems, which converges with bottom-up input entering in deeper cortical layers. While top-down signaling has been suggested to contribute to learning and memory expression, we know little about how this information is integrated in the apical tuft dendrites of L2/3 and L5 pyramidal cells in behaving animals. One well-studied inhibitory modulator of apical tuft dendrites are deeper layer somatostatin-positive Matinotti cells. In this study we investigate a second source for dendritic inhibition, the sparse population of L1 interneurons. Using a novel genetic marker for a subpopulation of L1 interneurons, Neuron Derived Neurotrophic Factor (NDNF) in combination with *in vitro* electrophysiology, viral tracing, optogenetics and *in vivo* 2-photon calcium imaging, we find that NDNF neurons target their output mainly within L1, connecting to distal dendrites of L2/3 and L5 pyramidal cells as well as deeper layer interneurons. These connections control the initiation of dendritic spikes in pyramidal cells through recruitment of a strong component of $Gaba_B$ receptor signalling. To address whether Ndnf positive layer 1 interneurons show learning-related plasticity, we combined *in vivo* calcium imaging with a form of cortex-dependent auditory fear learning. These

results reveal that sensory responses of Ndnf positive layer 1 interneurons are potentiated in response to learning in proportionality to the strength of the memory. In contrast, dendritic inhibition derived from somatostatin-positive Martinotti cells remains unchanged after learning, but in turn tightly controls sensory responses in Ndnf interneurons. These data indicates a differential role of these two interneuron types in dendritic inhibition. Matching these findings, results of dendritic imaging of L5 pyramidal neurons show a learning-induced increase in post-stimulus inhibition. In summary, the results indicate that, in addition to perisomatic disinhibition, memory retrieval is associated with elevated levels of a specialized form of dendritic inhibition.

Abstract: Learning and memory shape our daily life, social interactions and mental well-being. Mapping state-dependent large-scale network activity on identified neuronal circuits will be essential to understand the neurophysiological and pathophysiological basis of behaviour and memory formation. Here we follow the activity patterns of large populations of amygdala neurons across paradigms of anxiety and learned fear behaviors with the help of genetically encoded calcium indicators and a deep brain imaging miniature microscope approach in freely moving animals. We demonstrate that changes in the relative activity levels of two major, non-

overlapping populations of principal neurons in the basal nucleus of the amygdala (BA) predict switches between exploratory and anxiety-like or defensive behavioral states across different environments. Moreover, we found that the amygdala widely broadcasts internal state information via several output pathways to larger brain networks, and that sensory responses in the BA were not correlated with behavioral states. Our data indicate that the brain processes external stimuli and internal states in an orthogonal manner, which may facilitate rapid and flexible selection of appropriate, state-dependent behavioral responses.

Abstract: The field of classical conditioning highlights the role of the amygdala in learning associations between sensory stimuli and behavioral output. In parallel, the basal amygdala has long been implicated in the regulation of persistent states, such as anxiety and drive. We use deep brain calcium imaging of genetically identified neurons in the basal amygdala while mice engage in a range of self- paced behaviors. By tracking large neuronal populations across days and paradigms, we identify a hierarchy of activity patterns that emerges in the network dynamics during learning and corresponds to behavior on multiple timescales. We further describe the response of the network dynamics to perturbations along different dimensions and the interplay

between state-like representation and the processing of specific events and actions. Our findings suggest a general principle of network dynamics that could underlie the involvement of the amygdala in such different functions as sensory associative learning, action selection and emotional processing.

Title: Neuronal correlates of social interactions in amygdala circuits

Authors: *M. FUSTIÑANA, Y. BITTERMAN, A. LUTHI
Friedrich Miescher Inst. For Biomed. Res., Basel, Switzerland

Abstract: Social behaviors encompass a complex set of conducts, which are impaired in several psychiatric disorders including autism spectrum disorder (ASD) and social anxiety disorder. In humans, the amygdala has been implicated in the regulation of social interactions and ASD patients exhibit abnormal amygdala activity upon exposure to social stimuli. In rodents, the amygdala has mainly been studied in the context of fear and anxiety-like behaviors. However, the role of the amygdala during social behavior in freely-interacting rodents has not been addressed. We established a naturalistic paradigm in which two mice freely interact while recording neuronal activity. To make this complex behavior tractable, we developed a set of algorithms to automatically score active and passive behaviors, including initiated interactions, approach, avoidance and aggression. To record neuronal activity, we combined cell-type specific targeting and deep brain calcium imaging in the basal nucleus of the amygdala (BA) using a head-mounted miniature microscope. At the single cell level, our data revealed neuronal responses time-locked to social interactions. At the population level, amygdala neurons can be robustly divided into anti-correlated clusters which exhibit slow dynamics and predict the animal's active engagement in social interactions. Taken together, our results indicate that the BA is part of the brain's circuitry engaged during social interactions.

Title: Changes in limbic circuitry underlying fear related behaviors following TBI: Small and large, translational animal models

Authors: *C. D. ADAM[1], M. D. SERGISON[1,2], C. COTTONE[1], N. MAHESHWARI[1], A. ULYANOVA[1,2], H. CHEN[1,2], J. A. WOLF[1,2]

Abstract: Traumatic Brain Injury (TBI) is considered the signature injury of recent US military conflicts and has been implicated in memory deficits and anxiety disorders such as Post-Traumatic Stress Disorder (PTSD). Previous studies investigating changes in circuitry underlying these deficits suggest that TBI disrupts theta, an oscillation known to organize ensembles of neurons within and between brain regions in a behaviorally relevant manner. In order to understand how TBI disrupts theta and investigate how this disruption may lead to anxious behaviors, we subjected rats to a lateral fluid percussion injury (FPI) or sham injury, chronically implanted them with high-density silicon electrodes in basolateral amygdala (BLA) and bipolar electrodes in medial prefrontal cortex (mPFC) and ventral hippocampus (vHC), then ran them through anxiety testing consisting of plus maze (PM), open field (OF), and fear conditioning (FC). Our FC paradigm consisted of acquisition, in which rats learned to associate white noise (CS+) with a footshock, followed by 2 days of extinction, in which rats were presented with the CS+ and a novel tone (CS-) without getting footshocks, then reinstatement, in which rats were repeatedly presented the CS+ but only received a footshock with the first presentation. We found that compared to sham injured rats, FPI rats acquired fear responses (freezing) faster, extinguished fear responses to both CS+ and CS- slower, and did not consolidate extinction as well. Preliminary results have also shown FPI rats had decreased vHC-mPFC and vHC-BLA theta coherence during anxiety testing compared to sham, and BLA single-unit entrainment to vHC theta was altered between the two groups. In parallel with the above work, we have developed a method to wirelessly record from chronically implanted electrodes in pigs, and are assessing behavioral and electrophysiological changes induced by a more

translational rotational inertial TBI model in swine. In addition, we have successfully developed a FC paradigm in swine similar to the one described above for rats, and have determined that heartrate can be used as an outcome measure as it closely mirrors freezing rates in rodent FC models and is not correlated with movement. Importantly, we found that heartrate values follow typical extinction curves both within and between extinction sessions indicating that our swine FC paradigm could be a translational model of extinction therapy following PTSD. Future recordings from BLA and HC of injured pigs as they go through FC will allow us to assess how TBI induced changes in limbic circuitry may affect extinction, which is relevant to therapy for comorbid TBI/PTSD patients.

Title: Influence of nicotine exposure on the development profile of cholinergic circuits engaged in fear/threat memory

Authors: *J. A. WILKING[1], D. A. TALMAGE[2], L. W. ROLE[3]
[1]Dept. of Neurobio. & Behavior, [2]Pharmacol. Sci., [3]Neurobio. & Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Smoking during pregnancy is the most preventable risk factor associated with many adverse fetal outcomes including cognitive deficits and later increased substance abuse. Additionally, approximately 80% of smokers initiate tobacco use during adolescence. This suggests that age of nicotine exposure may play a critical role in the developing brain and the cholinergic system. The cholinergic system has been implicated in attention, learning, and memory processes. One key brain region that is highly involved in fear/threat learning is the amygdala. Part of the amygdala, the basolateral amygdala (BLA) receives abundant cholinergic innervation and is critical for establishing emotionally salient memories. Our laboratory has demonstrated that cholinergic input from the basal forebrain is critical for BLA dependent learning and memory as well as endogenous acetylcholine (ACh) increases synaptic plasticity in the BLA and this requires ACh and nicotinic acetylcholine receptors (nAChRs). Now, in order to examine the effect of chronic nicotine administration during development, pregnant C57BL/6J dams are administered 200 µg/ml nicotine plus Splenda or only Splenda in drinking water from

embryonic day 14 (E14) to postnatal day 21 (P21). Additionally, naive adolescent C57BL/6J animals (P21) are administered either 200 µg/ml nicotine plus Splenda or Splenda alone in their drinking water for 3 weeks to span most of the adolescent period as well as to correspond to length of treatment in the prenatal group. Following chronic nicotine administration animals receive paired tone and foot shock to examine freezing in this cued fear conditioning paradigm. The following day (recall), the animal receives the same tone and the freezing response is recorded to investigate nicotine and age related changes in fear response. Further, to determine cholinergic circuity modifications and developmental differences following chronic nicotine administration, changes in cFos and vesicular acetylcholine transporter (VAChT) immunohistochemistry have been measured in BLA.

Title: Contextual novelty encoded by the dorsal hippocampus regulates synaptic destabilization and memory lability in the amygdala

Authors: N. FERRARA[1], S. E. PULLINS[2], M.-S. SHIN[3], *F. J. HELMSTETTER[4]
[1]Psychology, Univ. of Wisconsin--Milwaukee, Milwaukee, WI; [2]Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [3]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [4]Deptartment of Psychology, Univ. of Wisconsin Milwaukee Dept. of Psychology, Milwaukee, WI

Abstract: During Pavlovian fear conditioning, a neutral auditory conditional stimulus (CS) is paired with an aversive unconditional stimulus (UCS). The CS acquires aversive value and can elicit a fear response during a retrieval session. Fear memory retrieval has been associated with synaptic destabilization in the amygdala, which is thought to be a primary factor allowing for modification of the original memory. The internalization of calcium impermeable AMPA receptors (CI-AMPAR) following retrieval allows for the calcium-dependent plasticity necessary to destabilize, and the protein synthesis-dependent plasticity to restabilize, amygdala synapses. Thus CI-AMPAR internalization may be critical for memory updating. Recent work from our lab shows that pre-exposure to the retrieval context is sufficient to prevent amygdala AMPAR internalization and prevent memory disruption as a result of protein synthesis inhibition (e.g., Jarome et al 2015). The dorsal hippocampus (DH) encodes information about context and shows

increased synchrony with the amygdala following auditory fear memory formation and retrieval (e.g., Narayanan et al 2007; Seidenbecher et al 2003). Additionally, strong fear memories that are resistant to disruption with protein synthesis inhibition can be made susceptible with DH lesions, suggesting DH mediated processes may contribute to memory lability and synaptic destabilization in the amygdala. The goal of these experiments was to determine how DH neural activity contributes to memory lability and synaptic destabilization in the amygdala during retrieval when contextual novelty is removed. When the training and retrieval contexts were the same, we were unable to disrupt the auditory memory with local infusions of anisomycin into the amygdala. However, DH inactivation during auditory fear conditioning was sufficient to allow for disruption of the auditory fear with protein synthesis inhibition in the amygdala after retrieval. We also found DH inactivation was associated with AMPAR internalization in amygdala synapses after retrieval regardless of contextual novelty, while removal of contextual novelty prevented AMPAR internalization, as measured by expression of AMPAR in synaptic fractions from the amygdala. Collectively, these results suggest that the DH encodes contextual information during auditory fear formation that in turn regulates retrieval-dependent memory modification. Ongoing experiments will determine whether DH activity is also necessary during retrieval when contextual novelty is removed to render the memory susceptible to disruption with protein synthesis inhibition and how this impacts AMPAR trafficking.

Abstract: Encoding and predicting aversive events is a critical function of basal ganglia and limbic circuits that support survival and emotional well-being. Maladaptive circuit changes in aversive signal processing can underlie the pathophysiology of affective disorders. The lateral habenula (LHb) has been linked to aversion and mood regulation through modulation of the dopamine and serotonin systems. We have defined the identity and function of glutamatergic (Vglut2+) control of LHb, comparing the role of inputs originating from the globus pallidus

internal segment (GPi) and lateral hypothalamus (LHA). We found that the LHb-projecting LHA neurons induced a negative bias in the probabilistic switching task and demonstrate that the aversive signals in LHb originate from glutamatergic LHA neurons and not the GABA/glutamate co-releasing GPi neurons. In addition, tracing of the presynaptic connectivity organization supported a predominant limbic input to LHA neurons, in contrast to the sensorimotor input to GPi. We further recorded the activity of Vglut2+ LHA neurons, by imaging calcium dynamics in response to appetitive versus aversive stimuli in conditioning paradigms. Vglut2+ LHA neurons displayed heterogeneous neural signals representing reward and punishment signals, including a candidate population that encoded and predicted future aversive events. We found that the LHb-projecting Vglut2+ LHA neurons signal the aversive event and rapidly acquire a prediction signal for future punishments. In summary, these findings establish the glutamatergic LHA-LHb circuit as a critical node in signaling and learning about the negative value of events.

Title: Comparisons of vlPAG cell body and midline/intralaminar thalamus terminal inhibition in positive prediction error signaling

Authors: *R. A. ZACHARIAS, S.-H. PARK, R. SUTHARD, T. PERISON, M. A. MCDANNALD
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Recent evidence has shown that the ventrolateral periaqueductal grey (vlPAG) is necessary for generating positive aversive prediction errors (+PEs), which are learning signals that function to increase future fear. It remains unknown, however, where the vlPAG sends these signals to update expectancies. The midline/intralaminar thalamus (MIT) has been implicated in fear conditioning and receives direct projections from the vlPAG, making it a likely candidate for +PE circuitry. In this study we trained male and female Long-Evans rats in a fear discrimination paradigm in which three cues were associated with different probabilities of foot shock: safety p=0.00, uncertainty p=0.38, and danger p=1.00. This task was designed such that it requires the use of +PEs to demonstrate appropriate fear, specifically for the uncertainty cue. To causally link the vlPAG-MIT pathway to +PE signaling, we bilaterally transfected the vlPAG

with halorhodopsin under control of the human synapsin promoter or with control YFP only virus. An optical ferrule was implanted over the MIT and 532 nm light was delivered precisely during the time of shock receipt on reinforced uncertainty trials, or exactly when +PEs would be generated, and on danger trials as a control. These experimental procedures allowed us to inhibit vlPAG terminals in the MIT in a temporally precise manner. Results indicated that inhibition of the vlPAG-MIT pathway did not alter fear to uncertainty, unlike cell body inhibition, suggesting another pathway or multiple pathways may carry out vlPAG +PE signaling. Ongoing experiments seek to establish if an alternate pathway, such as vlPAG-lateral hypothalamus (LH), is responsible for this signaling.

Title: Neural correlates of contextual fear expression in sign- and goal-trackers

Authors: *C. J. FITZPATRICK, J. D. MORROW
Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Pavlovian conditioned approach behavior has been previously used to identify rats that preferentially approach reward-related cues (sign-trackers; STs) or the location of the rewards that those cues predict (goal-trackers; GTs). STs are more susceptible to cue-induced "relapse," or reinstatement of cocaine self-administration, but less susceptible to context-induced reinstatement. In addition, STs are more fearful of discrete cues that predict aversive stimuli, but less fearful of contexts. This indicates that STs have a decreased capacity for contextual learning as compared to GTs, but the neural substrates underlying these behavioral differences are unknown. To test for differences in neural activity induced by contextual learning, we characterized rats as STs and GTs prior to contextual fear conditioning or a control procedure (context exposure with no shocks), followed by a contextual fear expression test twenty-four hours later. We then measured regional expression of c-Fos mRNA, a marker of neural activity, using radioactive in situ hybridization. Replicating our previous findings, GTs showed increased

contextual fear expression compared to STs during the test. Quantification of c-Fos mRNA is ongoing, but we hypothesize that GTs compared to STs will have increased expression of c-Fos mRNA in a contextual fear circuit that includes: the prefrontal cortex (prelimbic and anterior cingulate cortices), lateral septum, hypothalamus (lateral and paraventricular nuclei), thalamus (anterior and ventral posteromedial nuclei), amygdala (basolateral and central nuclei), hippocampus (dorsal and ventral), and periaqueductal gray. These findings could enhance our understanding of individual differences in contextual learning that may contribute to the development of addiction, posttraumatic stress disorder, and related neuropsychiatric disorders.

Title: Aversive learning from periaqueductal gray stimulation: Glutamatergic, endocannabinoid and vanilloid modulation

Authors: *A. P. CAROBREZ, F. BACK
Univ. Federal de Santa Catarina, Florianopolis, Brazil

Abstract: Glutamatergic stimulation of the dorsolateral periaqueductal gray matter (dlPAG) by N-Methyl-D-Aspartate (NMDA) elicited an immediate defensive response (IDR). Moreover, this experience was capable to support an olfactory fear conditioning (OFC) retrieved and expressed as defensive behavior 48h later in the presence of the olfactory stimulus (CS). Therefore, a suggestion that dlPAG-NMDA stimulation provoked IDR as well as ascending negative valence instruction, serving as unconditioned stimulus (US) facilitating aversive memory formation, was proposed. IDR can be elicited or modified by glutamatergic, endocannabinoid and vanilloid receptors systems, however, it is not clear whether dlPAG activation by these modulators also promotes learning. Considering this, we sought to investigate the interplay of these systems post dlPAG activation in both the IDR and further aversive learning. Male Wistar rats implanted with guide cannulas aimed at the dlPAG were used throughout the experiments. The OFC protocol was performed during four consecutive days divided in two stages: 1) conditioning (two days; Box A); and 2) retrieval/expression (two days; Box B). Experiment 1: twenty-four hours after being familiarized in Box A, rats received microinjections (0.2 µl) of NMDA (25-200 pmol) and

were replaced in the same box now saturated with amyl acetate odor (CS). OFC retrieval was performed in Box B (familiarization and CS-exposure). DB was scored on days 2 (Box A), 3 and 4 (Box B). Experiment 2: rats received microinjections of CB1 receptor antagonist, AM251 (50-200 pmol) or the TRPV1 agonist capsaicin (0.1-10 nmol) followed by NMDA (25 pmol) before being paired with the CS. Experiment 3: AP5, a NMDA receptor antagonist (6 nmol), DNQX, an AMPA blocker (2-4 nmol) or AIDA, an mGlu I antagonist (30 nmol) were microinjected before NMDA stimulation. Experiment 1: Rats that received NMDA 50, 100 or 200 pmol expressed higher levels of IDR than those treated with PBS or NMDA 25 pmol during CS association. However, only rats from the 50 and 100 pmol groups showed aversive learning during CS re-exposure. Experiment 2: AM251 and capsaicin potentiated learning from NMDA 25 pmol, with little influence over IDR. Experiment 3 indicated that immediate defensive responses were blocked by AP5, whereas aversive learning was blocked by DNQX or AIDA. Altogether, the results indicated that activation of dlPAG provokes IDR as well as subsequent aversive learning. IDR relies mostly on NMDA receptor activation whereas further aversive learning depends on the modulatory CB1, TRPV1, AMPA and mGlu I receptors into the dlPAG.

Title: Ventral Pallidum neurons control aversive learning

Authors: *T. MACPHERSON[1], H. MIZOGUCHI[2], A. YAMANAKA[2], T. HIKIDA[1]
[1]Lab. for Advanced Brain Functions, Osaka Univ., Osaka, Japan; [2]Res. Inst. of Envrn. Med., Nagoya Univ., Nagoya, Japan

Abstract: The ventral pallidum (VP) is a critical component of the basal ganglia neurocircuitry, and has been implicated in controlling hedonic responses to rewards. However, its possible role in controlling Pavlovian conditioning of cues associated with rewarding or aversive outcomes is unclear. Our group has previously demonstrated that nucleus accumbens (NAc) dopamine D1- or

D2-receptor-expressing neurons are known to control reward and aversive learning, respectively (Hikida et al, 2010, Neuron). While classically it was thought that only NAc D2-neurons project to the VP, recent evidence has shown that a subpopulation of D1-neurons also projects to the VP, suggesting that VP neurons may play a role in either/both types of learning (Kupchik et al, 2015, Nature Neuroscience). Here we used a Tet-Tag AAV virus system, in which designer receptors exclusively activated by designer drugs (DREADDs) were expressed in a population of VP neurons containing the peptide enkephalin, to investigate the possible role of the VP in reward and aversive learning. During acquisition of an autoshaping task, hM3Dq DREADDs were activated by administration of CNO, leading to increased activity in enkephalin-expressing VP neurons. Both CNO-treated and saline-treated (control) mice showed an equal ability to acquire the task, as indicated by an increase in Pavlovian approach behavior to a reward-associated cue over the course of 6 daily sessions. Whereas, in a passive avoidance task, administration of CNO during conditioning of an aversive foot-shock upon entering a dark chamber resulted in a decreased latency, in comparison to saline-treated controls, to enter the foot-shock-associated chamber when tested 24 hours later. These findings indicate that activity in enkephalin-expressing VP neurons disrupts aversive, but does not alter appetitive, Pavlovian conditioning. Thus, decreased activity in enkephalin-expressing VP neurons appears to be necessary for aversive learning, which supports previous evidence from our group that neurotransmission blocking in NAc D2-neurons, likely leading to disinhibition of downstream VP neurons, similarly inhibits passive avoidance learning.

Title: Direct and indirect connections from the insular cortex into the parasubthalamic nucleus in the rat

Authors: M. BARBIER, *P.-Y. J. RISOLD
Univ. Franche-Comte, Besancon, France

Abstract: The parasubthalamic nucleus (PSTN) is formed by a small cell condensation adjacent to the subthalamic nucleus (STN) in the lateral hypothalamic area (LHA). The network in which it is involved and its functions are still poorly investigated. The object of this study was to

analyze with some details the organization of its connections with the insular cortex (INS). Twelve injections of the anterograde tract tracer *Phaseolus vulgaris* leucoagglutinin (PHAL) were obtained in granular and agranular areas of the INS. Axons were traced with various densities into the PSTN from each injection sites. The INS did not provide any innervation of the STN, in contrary to projections from areas of the isocortex. Interestingly, most insular areas also innervated the capsular or lateral parts of the central nucleus of the amygdala (CEA). As the PSTN receives abundant projections from the medial part of the CEA, we performed additional experiments with injections of the retrograde tracer fluorogold (FG) into the PSTN and PHAL into the lateral CEA. PHAL axons from the capsular and lateral parts of the CEA made apparent contact on retrogradely labeled neurons in the medial CEA as well as in neighboring regions of the substantia innominata, suggesting that the INS may also influence the PSTN through this indirect route. INS, CEA are involved in responses such as neophobia and visceral pain. We then exposed rats in experimental conditions related to these responses and observed that c-Fos expression increased in the PSTN with regard to these conditions. To conclude, the PSTN is involved in a complex network with the INS and CEA. The organization of this network is reminiscent of the hyperdirect and indirect pathways connecting the isocortex with the STN. These data as well as their functional significances are actually completed by investigations in mouse models using genetic tools and the DREADD technology.

Title: Inhibition of thalamic terminals in the amygdala may facilitate extinction learning

Authors: *N. FERRARA, P. K. CULLEN, S. E. PULLINS, M. W. GRUTZA, F. J. HELMSTETTER
Psychology, Univ. of Wisconsin--Milwaukee, Milwaukee, WI

Abstract: Fear memory formation is characterized by increased excitatory synaptic strength between primary auditory areas (i.e., the auditory thalamus (MgN) and auditory cortex) and the amygdala. The strength of these connections is increased as a result of learning, and the retention of auditory fear is dependent on the maintenance of potentiated cortico- and thalamo-amygdala synapses. Extinction has been viewed as an inhibitory learning process that results in a context-specific decrease in fear responding due to increased inhibition in the amygdala. Input from the

medial prefrontal cortex is thought to be a primary factor driving elevated inhibition through strengthened connections with local interneurons. This increased inhibition is associated with several plasticity related events in the amygdala, such as maintained potentiation of cortico- and thalamo-amygdala connections and decreased phosphorylation of cAMP response element-binding protein (CREB), that may provide molecular correlates for extinction. Here we study the role of the thalamo-amygdala pathway during fear recall. We silenced input from the MgN to the amygdala using the light driven proton pump, ArchT (AAV9-CAG-ArchT-GFP). We found that MgN driven activity in the amygdala is critical during auditory fear retrieval and when silenced during retrieval, impairs fear assessed during a long-term test. This suggests activity in the thalamo-amygdala pathway is necessary to maintain fear responding at remote time points. Additionally, fear renewed in the training context, demonstrating a context-specific reduction in fear independent of thalamo-amygdala silencing. Groups that did not receive contiguous CS presentations with optogenetic inhibition during retrieval did not show reductions in fear during retrieval or test, suggesting inhibition of MgN-amygdala terminals is specifically required during memory reactivation. Phosphorylation of CREB was measured and quantified following initial retrieval, LTM test, and renewal. Groups that received MgN-LA terminal silencing during retrieval showed reduced phosphorylated CREB after retrieval and test, but not following renewal. We next measured the synaptic expression of AMPA receptors in the amygdala after MgN-amygdala inhibition and did not find differences in the expression of GluR1 or GluR2 subunits, suggesting the decrease in fear responding was not due to a loss of potentiated amygdala synapses. Together, these results suggest inhibition of MgN activity in the amygdala during recall can facilitate extinction learning.

Med., Budapest, Hungary

Abstract: Sensory information relayed by thalamic inputs to the amygdala is essential in cue-associated behaviors. However, the network elements and exact function of this thalamo-amygdala route have remained to be elucidated. We have recently shown that the majority of thalamic inputs to the amygdala is sent by calretinin-positive (CR+) cells which relay essential information in auditory fear learning.
We hereby investigated the connectivity of CR+ thalamic neurons and their spontaneous, unimodal and multimodal sensory-elicited electrophysiological firing characteristics as well as their effect on the amygdalar subnuclei. The collicular and cortical innervation of these neurons are cell type-specific and strikingly different from those of the neighboring CR- cells. In anesthetised animals, sound(CS)- and shock(US)-evoked as well as paired cue driven firing patterns were examined in CR+ and CR- auditory-related thalamic neurons. In freely behaving tetrode-implanted animals, CR+ and CR- thalamic cued responses were tested in fear conditioning and extinction. In both acute and chronic conditions, CR+ cells were more likely responsive to multimodal or associated cues and they exhibited distinct frequency tuning. Optogenetic stimulation of nucleus-specific thalamo-amygdala pathways led to different outcomes in the amygdalar circuits which underlies the presented anatomical organization and behavioral data.
According to our findings, the connectivity and firing characteristics emphasize the role of CR+ thalamic cell populations in aversive sensory processing and associative learning.

Title: Activation of nucleus reuniens is necessary for acquisition of trace fear conditioning

Authors: *Y.-J. LIN, C.-H. CHANG
Inst. of Systems Neurosci., Natl. Tsing Hua Univ., Hsinchu (city), Taiwan

Abstract: The Nucleus Reuniens (RE) of the midline thalamus is reciprocally connected to the hippocampus (HPC) and the medial prefrontal cortex (mPFC). Neuronal tracing studies suggested that there is direct projection from the HPC to mPFC, and RE may serve as a return route. In Pavlovian fear conditioning, a conditioned stimulus (CS), such as a tone, is paired with an unconditioned stimulus (US), such as a footshock. Fear conditioning is robust that animals can learn the CS-US association after a few pairings. In our study, we used two different conditioning paradigms: delay conditioning, which consisted pairings of co-terminating CSs and USs, and trace conditioning, which consisted pairings of CS and US that are separated in time by a stimulus-free trace interval. Earlier studies have suggested that the recruitment of HPC and mPFC is necessary in trace, but not delay, fear conditioning; however, the role of RE in this process remains unknown. In this study, we first used 48 male Long-Evans rats, repeated by three cohorts with 16 rats, to establish that both trace and delay fear conditioning group could achieve equivalent learning and performance. Next, we used 32 Long-Evan rats, repeated by two cohorts with 16 rats, with behavioral pharmacology approach to examine the effects of the pre-conditioning RE inactivation. We hypothesized that RE inactivation would lead to a learning deficit only in trace fear conditioning. Supporting our hypothesis, trace animals demonstrated a down-shift of fear level during retrieval test, indicating that inactivation of RE before conditioning impaired the acquisition of trace fear memory. The results pointed out that RE is recruited and played a critical role in the encoding phase of trace fear conditioning at the behavioral level. Our preliminary data suggested that inactivation of RE before memory retrieval did not interfere with the expression of learned fear in either trace or delay animals, and we are replicating this experiment. Assuming our results hold true, together our data would suggest a "learning phase" specific role of RE and only in trace, but not delayed, fear conditioning.

Title: Midline thalamic nuclei in fear renewal

Authors: *C.-W. SHIH[1], R.-J. CHIOU[2], C.-H. CHANG[1]
[1]Inst. of Systems Neurosci., Natl. Tsing Hua Univ., Hsinchu, Taiwan; [2]Anat. and Cell Biol., Taipei Med. Univ., Taipei, Taiwan

Abstract: In recent years, more and more attention has been paid to explore the pathophysiology of the anxiety disorders, like post-traumatic stress disorder (PTSD), phobia, panic disorder, and obsessive-compulsive disorder (OCD). Pavlovian fear conditioning and extinction is a widely used animal model to study the mechanisms of negative emotion control. In laboratory settings, after the rats acquire the fear response to tones with tone-footshock pairings during conditioning, fear level decreases with repeated presentation of tones alone during extinction. However, extinction does not erase the original conditioned behavior but acts as an active process to modulate learned memory, because extinguished behavior spontaneously recovers with the passage of time and renews outside the extinction context. Earlier literature suggested that context-mediated renewal requires the coordination of the medial prefrontal cortex (mPFC), the hippocampus, and the amygdala. In this study, we used cfos immunoreactivity (IR) to explore whether the midline thalamic nuclei, such as nucleus reuniens (RE) and paraventricular nucleus (PVT), were recruited during fear renewal because of their dense connections with the fear/extinction circuit. We used ABA renewal paradigm, in which the rats were conditioned (5 tone-footshock pairings) in context A, extinguished (45 tones alone) in context B for two days, and then tested (10 tones alone) in context A (DIFF, different from extinction context; n = 10) or context B (SAME, same as extinction context; n = 10). Two control groups were included for comparisons. For no-conditioning controls (NoCOND, n = 6), the animals were presented with the tones but no footshocks during “conditioning”, and for no-extinction controls (NoEXT, n = 6), the rats were placed into chambers for equivalent amount of time without tones during “extinction”. Ninety minutes after the first tone presentation during test, rats were perfused to grasp the peak of cfos expression, followed by tissue processing using standard immunohistochemical procedures to visualize the signals. Our behaviroal results suggested that fear response renewed when the tones were presented outside the extinction context (i.e., in context A). The general cfos expression level in RE was very low in all behavioral conditions (n < 5). Thus, we did not find evidence that RE was recruited during fear renewal. There has been studies pointed out that PVT is recruited in renewal of appetitive behavioral tasks, and we are currently analyzing whether the PVT is also involved in negative emotion control.

Title: Functional lateralization of lateral orbitofrontal cortex on acquisition and expression of fear extinction in rats

Authors: *Y.-H. CHANG, C.-H. CHANG
Inst. of Systems Neurosci., Natl. Tsing Hua Univ., Hsinchu, Taiwan

Abstract: Our earlier study suggested that the lateral orbitofrontal cortex (lOFC) acts to interfere expression of fear and to impair acquisition of fear extinction when it is activated bilaterally prior to fear extinction training. To investigate the mechanism underlying this effect, we tested whether the lOFC effect is mediated through the projection onto the basolateral amygdala (BLA) using functional disconnection procedure. However, unilateral activation of the lOFC-BLA pathway did not show the behavioral interference of bilateral lOFC activation in fear extinction. To rule out the possibility that the null result is because unilateral activation of the lOFC is not sufficient to induce the effect, we systemically examined unilateral lOFC activation on fear extinction learning in this study. Unilateral left or right, as well as bilateral lOFC, was activated with N-methyl-D-aspartate receptor (NMDA) before fear extinction session, while saline was infused (extinction and no-extinction) as controls. To our surprise, our preliminary data showed distinct differences between animals with left or right lOFC activation. Unilateral activation of the left lOFC, but not the right lOFC, interfered fear expression during extinction session, an effect similar to bilateral lOFC activation. Nonetheless, unilateral activation (left or right), as well as bilateral activation of the lOFC, all abolished the encoding of extinction, in that during retrieval test, all animals displayed equivalently high freezing levels comparable to no-extinction saline controls and were significantly higher than extinction saline animals. We are currently replicating this experiment. Assuming the results hold true, it will suggest a functional dissociation between the left and right lOFC on acquisition and expression of fear extinction.

Title: Activation of medial orbital frontal cortex interferes with fear extinction acquisition and fear expression in rats

Authors: *H.-T. HSIEH[1], C.-H. CHANG[2]
[1]Life Sci., Natl. Tsing Hua Univ., Hsinchu, Taiwan; [2]Inst. of Systems Neurosci., Natl. Tsing Hua Univ., Hsinchu (city), Taiwan

Abstract: The medial orbital frontal cortex (mOFC) has been studied for its role in reward-based decision-making in rodents. The similarity between its anatomical projection and that of the medial prefrontal cortex raises the question of whether the mOFC plays a role in memory extinction process. In our previous studies, we reported that activation of the lateral orbital frontal cortex (lOFC) interferes with memory extinction. Therefore, in this study, we sought out to explore the role of mOFC in extinction learning process.
We used a 3-Day Pavlovian fear conditioning and extinction protocol. On Day 1, all rats were conditioned with 5 trials of tone (CS)-footshock (US) pairings. On Day 2, half of the rats underwent extinction procedure (EXT; 45 trials of tones alone), while the other half was placed into the chambers for the equivalent amount of time without tones, serving as no-extinction controls (NoEXT). On Day 3, all rats were tested with 45 trials of tones. The mOFC was activated either immediately before the extinction (pre-extinction) on Day 2 or immediately before the test (pre-test) on Day 3 with N-methyl-D-acidic acid (NMDA) injection through pre-planted cannula or saline as controls. After histology check, a total of 57 male LE rats (31 in pre-extinction and 26 in pre-test), aged from 6 to 7 weeks, were included for final data analyses.
We found that activation of the mOFC resulted in generally low freezing levels in the early trials that developed in amplitude over time regardless of the behavioral stages of interventions (pre-extinction or pre-test) nor the presentation of tones or not (EXT and NoEXT). We also found that activation of the mOFC before extinction on Day 2 abolished the acquisition of extinction learning, for that there was no statistical difference in freezing levels between EXT and NoEXT groups when tested on Day 3, which were equivalently high compared to NoEXT saline controls. Together, these results suggested that activation of the mOFC interfered with the encoding of extinction and fear expression in general.

Title: Collateral projections from lateral orbitofrontal cortex to nucleus accumbens and basolateral amygdala

Authors: *C.-W. LAI[1], C.-H. CHANG[1,2]
[1]Inst. of Mol. Med., Natl. Tsing Hua Univ., Hsinchu, Taiwan; [2]Inst. of Systems Neuroscience, Natl. Tsing Hua Univ., Hsinchu, Taiwan

Abstract: Earlier neuronal tracing studies have shown that lateral orbitofrontal cortex (lOFC) projects to the nucleus accumbens (NAcc) and also projects to the basolateral amygdala (BLA). The lOFC to NAcc pathway and lOFC to BLA pathway each regulates different behaviors, such as compulsive drug seeking and reward-outcome encoding. However, whether the lOFC neurons modulate different downstream targets simultaneously remains unknown. In this study, we examined the connections between lOFC to NAcc and BLA, respectively, and also if there are collateral projections from the lOFC to both the NAcc and BLA. We used in vivo extracellular single unit recordings in anaesthetized rats. The stimulation electrodes were placed in the NAcc and BLA in search of antidromic or orthodromic responsive neurons in the lOFC. A total of 14 neurons were recorded from 9 rats. Among our sampled units, eight neurons projected from lOFC to NAcc with a latency of 8.34 ± 0.97 ms (range 4.49 to 12.01 ms), while five neurons projected from NAcc to lOFC with a latency 6.85 ± 2.22 (range 1.36 to 11.72 ms). We only found one neuron projected from BLA to lOFC with a latency of 26.17 ms, and failed to sample any neurons projected from the lOFC to BLA. Under our filter settings (bandpass 300-10K Hz), two of the sampled neurons (from NAcc to lOFC) have high firing rate (4.75 and 8.53 Hz) with short spike duration (0.80 to 0.78 ms), presumably are interneurons. The spontaneous firing rates of the rest 12 neurons are low (0.32 ± 0.16 Hz, range 0 to 1.8 Hz) with relative long spike duration (2.40 ± 0.25 ms, range 0.38 to 3.60 ms), suggesting the majority of these units are putative projections neurons. To confirm our methodology, we found two neurons adjacent to lOFC during our sampling but excluded from analysis because of histological misplacement, projected to the BLA. Of these two, one (in dorsal endopiriform nucleus) projected to the BLA, and the other (in lateral olfactory tract) had collateral projections to both the NAcc and BLA. Because of the low sampling rate of BLA responsive neurons in the lOFC, we will collect more neurons and further examine whether there is difference in responsive threshold of these two pathways. We will also combine tracer study to examine if there is topographic segregation of NAcc and BLA projections from lOFC.

Title: Sex differences in sucrose reinforcement in Long-Evans rats

Authors: *J. W. GRIMM, K. NORTH, M. HOPKINS, K. JIGANTI, P. JOHNSON, A. MCCOY, J. SULC, D. HOVANDER, D. MACDOUGALL, F. SAUTER
Dept of Psych and Beh Neurosci, Western Washington Univ., Bellingham, WA

Abstract: Background: There are sex differences in addiction behaviors including consumption and relapse. The present study examined sex differences in these behaviors using a rat model.
Methods: Subjects were adult male and female Long-Evans rats. Rats first self-administered 10% sucrose on a FR1 schedule of reinforcement (40 sec timeout to availability of next reinforcer) in 10 daily 2 hr sessions. Sucrose was paired with a 5 sec tone+light cue. Rats were then tested with different concentrations of sucrose (0, 3.75, 7.5 or 7.5, 15, 30%; counterbalanced) with 3 days of 10% sucrose in between each test. Rats next trained with 10% sucrose on a PR schedule for 7 days and then tested on the PR, with the different concentrations as before, with 3 days of 10% sucrose (PR) in between each test. Finally, rats trained again on a FR1 for 3 days and then had 3 extinction tests with 3 FR1 re-training sessions in between each test. Prior to each extinction test, rats were pre-treated with the dopamine D1 antagonist SCH23390 (0, 1, 10 micrograms/kg, 15 min pretreatment, IP; counterbalanced). In separate cohorts of rats, saccharin preference (2-bottle choice; 4 alternating concentrations of saccharin v. water) and sucrose preference (10% sucrose v. water) were assessed. A final study was conducted with rats responding for water on a FR1 schedule (10 days) and then PR (7 days).
Results: Females responded for more sucrose on both FR and PR schedules of reinforcement, even when not accounting for body weight. Females also responded at a higher rate in extinction. ANCOVA analysis revealed that the extinction sex difference was not accounted for by the higher rate of responding during training. The 10 microgram/kg dose of SCH23390 significantly reduced responding of both males and females. In bottle preference tests, males consumed more saccharin across a range of concentrations (0.075, 0.15, 0.3, 0.6%), but there was no sex difference when considering body weight. Males also consumed more 10% sucrose, although females consumed more when accounting for body weight. In both preference test studies, water consumption was similar between males and females. However, females responded more for water on both FR1 and PR schedules of reinforcement.
Discussion: Female Long-Evans rats are more motivated to respond for sucrose and sucrose-paired cues than males. Their increased avidity for sucrose is not explained by sweet taste preference, or a generally higher rate of operant responding (e.g. Day 10 FR1 active lever training for water for males was 17.8% of sucrose-maintained responding; 14.0% for females). These results provide a robust model for further exploring sex differences in sucrose reinforcement in rats.

Title: Serotonin modulates impulse control and motivated action

Authors: *H. B. WEINBERG-WOLF[1], N. A. FAGAN[1], O. DAL MONTE[1], S. W. C. CHANG[2,1]
[1]Psychology, [2]Neurosci., Yale Univ., New Haven, CT

Abstract: Serotonergic function is impaired in individuals suffering from disorders with seemingly opposing symptomologies - depression and impulse control disorders. We posit that depression and impulsive aggression are marked by impairments in cognitive effort but that this impairment may result in divergent effects due to individual differences. In some cases, when individuals have a family history or risk of impulsivity, an impairment in cognitive effort can manifest as impulsive action (Carver et. al, 2008). In other cases, like where individuals are at risk of depression, impaired cognitive effort can cause a drive towards inaction that is difficult to overcome, as well as low motivation and the development of clinical depression. However, no study has directly tested this hypothesis by examining how modulating central serotonin impacts impulse control and motivation under varying cognitive effort.
This study attempts to rectify this and examine the role of increasing central serotonin concentrations on impulse control and motivated action in rhesus macaques. We do this by examining performance on a saccade-based go/no-go task, allowing us to investigate not only impulse control, via typically analyzed performance on no-go trials, but also motivated action, by analyzing performance on go trials. We have previously shown that i.m. injections of the serotonin precursor l-5-hydroxytryptophan (5-HTP) effectively increases central concentrations of serotonin in CSF and modulates cognition and behavior in rhesus macaques (Weinberg-Wolf et. al 2018). We now examine how increasing 5-HTP modulates impulse control and motivated action with a repeated, within-subject, go/no-go study design.
Applying the signal detection theory, we observed that 5-HTP impacted both the sensitivity and criterion of responses. Furthermore, 5-HTP impacted both impulse control and motivated action. Critically, these effects were particularly pronounced for trials that required more cognitive effort - trials with longer delays between the onset of the go/no-go cue and the target. These results indicate that increasing central concentrations of serotonin impacts impulse control and motivation. Both of these processes are impacted by differences in cognitive effort, supporting the hypothesis that impaired serotonergic function is linked to depression and impulse control

disorders via a common impairment in cognitive effort.

Title: Effects of modafinil on impulsivity, hyperactivity and attention in prepubertal male wistar rats prenatally treated with alcohol

Authors: *D. M. GOMEZ-ORDOÑEZ[1,2], J. JUAREZ[1]
[1]INSTITUTO DE NEUROCIENCIAS, Guadalajara, Mexico; [2]Inst. de neurociencias, Univ. of Guadalajara, Guadalajara, Mexico

Abstract: It has been reported that exposure to alcohol in specific stages of prenatal development produces persistent reduction in spontaneous activity of dopamine neurons in the ventral tegmental area, which is normalized with both amphetamines and methylphenidate. Changes in the dopamine system are related with several behavioral disorders, such as the attention deficit hyperactivity disorder (ADHD), which is usually accompanied by high impulsivity. The usual pharmacologic therapy for this symptomatology includes methylphenidate and Atomoxetine. Due to the relative efficiency of these drugs, it has raised the need for the use of other drugs for alleviate that symptomatology; such is the case of modafinil that recently has been used experimentally for the treatment of symptoms of some diseases, which include ADHD, with positive results. However, there are no sufficient studies that support their efficacy. The mechanism of action of modafinil is not clear; however, it has been described that its effects on CNS and behavior are similar to those of methylphenidate; therefore, modafinil has been proposed as an alternative for ADHD treatment. Therefore, the present study sought to identify the effect of different doses of modafinil (0.0, 10, 30 and 60 mg/kg) on the reactive impulsivity in rats treated with prenatal alcohol. Animals were exposed to a “wait to go signal task” and it was observed that animals treated prenatally with sucrose (isocaloric control) show higher number of correct responses than the alcohol treated, and a dose of 30 mg/kg of modafinil reverses significantly this phenomenon during the course of the test. Animals treated prenatally with alcohol and postnatal vehicle, showed higher frequency of commissions (impulsive responses) than their sucrose controls, and the dose of 30 mg/kg, inverted this effect, i.e.,

impulsivity decreased in prenatal alcohol treated rats and it increased in control animals. This phenomenon does not occur with other doses. Additionally, the number of omissions (inattention measure) was increased significantly only in rats treated prenatally with sucrose when 30 mg/kg was administered. These results support that some symptoms of the ADHD are due to an imbalance in the dopamine mediated by other neurotransmission systems and that modafinil action contributes to the normalization of such imbalance. However, the dose-response effect of modafinil, is apparently not linear, since the low and high doses did not produce the beneficial effects of the intermediate dose.

Title: Exendin-4 dose dependently attenuates responding to reward predictive cues in rats

Authors: *K. T. WAKABAYASHI[1], A. N. BAINDUR[2], K. CHEN[2], M. FEJA[2], K. BERNOSKY-SMITH[3], C. E. BASS[2,1]
[1]Res. Inst. on Addictions, Univ. at Buffalo, SUNY, Buffalo, NY; [2]Dept. of Pharmacol. and Toxicology, Jacobs Sch. of Med. and Biomed. Sciences, Univ. at Buffalo, Buffalo, NY; [3]Dept. of Biol. and Mathematics, D'Youville Col., Buffalo, NY

Abstract: Exendin-4 (EX4) is a GLP-1 receptor (GLP-1R) agonist used to control blood sugar levels in type-2 diabetes. EX4 has been shown to induce weight loss, which can be attributed to both its peripheral and central effects, most notably in mesolimbic dopamine pathways that mediate cue-induced reward seeking. Behaviorally, GLP-1R agonists influence palatable food preference (e.g. sweet vs. fat) as well as the motivation to obtain different types of food. Recent evidence suggests that GLP-1 receptor activity can attenuate cue-induced reward seeking behaviors, including those that do not involve food. Here we have tested EX4 (0.6, 1.2, and 2.4 μg/kg i.p.) in a sophisticated rat model of incentive cue (IC) responding, in which a rat must emit a nosepoke response into a port during an intermittent audiovisual cue in order to obtain a reward (10% sucrose solution) delivered in an adjacent receptacle. Thus in this task, we interpret the

choice to enter the active nosepoke port or enter the reward cup as quantifiable elements of *response choice*, while the latency to nosepoke in response to an IC, and the latency to enter the reward cup after a reward has been delivered, are reflective of *response vigor*. Therefore, metrics centered on the motivational properties of the IC include response ratio and nosepoke latency, while metrics focused on the sucrose reward include reward cup entries and reward cup entry latencies. We found that EX4 dose-dependently attenuates responding to reward predictive cues, and increases both the latencies to respond to these cues and to enter the reward cup to consume the sucrose reward. EX4 also dose-dependently decreased the number of nosepokes compared to the number of cues presented during the session. However, the number of reward cup entries per reward earned during the session, a related reward-seeking behavior with similar locomotor demand, was not attenuated by EX4. EX4 had different effects on IC responding and nosepoke response latency at the beginning of the session versus the end, depending on the dose, so that the overarching response to 2.4 μg/kg EX4 appeared to be a delay in responding to the first IC in the session. Our findings using a free-operant task heavily reliant on ICs suggest that EX4 agonism, and by extension GLP-1 signaling can directly modulate the incentive properties of cues attributed with motivational significance.

Title: Influence of physical activity and sex on nucleus accumbens opioid mediated feeding

Authors: *J. R. LEE[1,2], M. A. TAPIA[3], V. N. WEISE[3], J. R. NELSON[3], A. M. TAMASI[3], K. R. FODOR[3], K. L. MASON[3], L. L. RIVERA[3], F. W. BOOTH[4], M. J. WILL[2]
[2]Interdisciplinary Neurosci., [3]Psychology, [4]Biomed. Sci., [1]Univ. of Missouri, Columbia, MO

Abstract: Palatability driven feeding and voluntary physical activity are both regulated via the mesolimbic reward pathway which includes the nucleus accumbens. Like other rewarding behavior, these behaviors are dependent on opioid signaling and are altered following nucleus accumbens opioid administration. In addition, physical activity and palatable diet intake both produce changes in reward related transcription factors within the nucleus accumbens. Recent studies suggest sex dependent effects on both behavioral and physiological adaptations in response to voluntary physical activity. To explore the influence of physical activity on nucleus

accumbens opioid mediated feeding, both male and female Wistar rats were provided access to a voluntary running wheel (RUN group) or no access to a wheel (SED group) and assessed for intake of 2 unique diets. After 2 weeks of RUN or SED treatment, rats were acclimated to testing chambers that contained the 2 diets presented simultaneously, a high-carbohydrate diet and a high-fat diet. After acclimation, intake of both diets were measured with various doses of a mu opioid receptor agonist (DAMGO) (0.025, 0.25 and 2.5 μg/0.25 μl/side) or opioid receptor antagonist (naltrexone) (20/.25ul/side) injected into the nucleus accumbens. Results demonstrate that all groups expressed a slight preference for the high-carbohydrate diet under control treatment. There was an effect of intra-accumbens DAMGO to increase feeding of both the high-carbohydrate and high-fat diet. This effect was greater in females compared to males. In males, the stimulatory effects of feeding were not influenced by physical activity condition for either high-carbohydrate or high-fat diet. In females, there was an interaction between dose of DAMGO and physical activity condition on intake of high-carbohydrate diet, as the there was a difference in intake between RUN and SED in only the 0.025 μg dose. Naltrexone did not alter baseline intake, but did block the increased diet intake induced by the high dose of DAMGO in all groups.

Title: Feeding elicited by mu-opioid receptor stimulation in the prefrontal cortex and nucleus accumbens: An exploration of sex differences and estradiol regulation

Authors: *B. A. BALDO[1], J. DIAZ[2], K. DUNAWAY[3], K. SADEGHIAN[1], A. AUGER[4]

Abstract: Infusion of the mu-opioid agonist DAMGO ([D-Ala2, N-Me-Phe4, Gly5-ol]-enkephalin) in the ventromedial prefrontal cortex (vmPFC) and the nucleus accumbens (Acb) induces food impulsivity and abnormally high food motivation, two features of binge eating disorder. In animal models, vmPFC or Acb mu-opioid-driven feeding has been studied primarily in males, but has received little attention in the context of sex differences. We hypothesized that

mu-opioid driven feeding could be sexually dimorphic because (1) women are more vulnerable to eating disorders, (2) in animal self-administration studies, estrogen facilitates opiate self-administration at an early post-estrogen time point, and (3) estrogen inhibits food intake (although effects on telencephalic opioid-driven feeding are not well understood). Hence, we evaluated feeding induced by mu-opioid stimulation in the vmPFC and Acb across gender and estradiol status in *ad-libitum*, chow fed rats. First, we assessed sex differences independent of estradiol by obtaining DAMGO dose-response curves in the vmPFC and Acb for ovariectomized (OVX) females without estrogen replacement and compared these effects to those seen in males. Next, we explored the effects of intra-vmPFC and intra-Acb DAMGO in OVX females given 5μg estradiol benzoate (EB) subcutaneously to evaluate acute (cell-surface receptor-mediated) and delayed (canonical genomic-mediated) effects of EB. To assess acute and delayed estrogenic effects, DAMGO-induced food intake was measured in 2-hour testing sessions both immediately post-EB administration and 24 hours post-EB. Males and females had similar DAMGO-induced dose-dependent increases in food intake; however, OVX females consumed significantly more chow when a high 2.5μg DAMGO dose was infused in the Acb. In OVX females treated with EB, both intra-vmPFC and intra-Acb DAMGO-induced feeding was inhibited 24-26 hours post-EB, but was unchanged directly after EB administration. These data suggest a slight intrinsic sex difference in intra-Acb mu-opioid sensitivity independent of the activational properties of estradiol. Additionally, our studies revealed a modulatory role of systemic EB at the delayed post-EB time-point, suggesting that genomic-mediated effects of EB exert regulatory control over telencephalic mu-opioid-responsive feeding circuits.

Title: Examining the impact of orexin A and GLP-1 receptor manipulation on feeding induced by nucleus accumbens μ-opioid receptor stimulation of the rat

Authors: *Z. PIERCE-MESSICK[1], C. DO[2], M. C. NIGRO[2], R. VACA-TRICERRI[2], W. E. PRATT[2]

Abstract: Recent work has shown that neuropeptides and peptide hormones that regulate homeostasis may additionally impact food intake by directly acting on brain regions that process

the palatable and rewarding nature of a diet. For instance, Orexin A and GLP-1 receptors are both found within the nucleus accumbens (NAcc), a brain region involved in promoting the consumption of palatable diets. Our laboratory and others have reported that stimulation of μ-opioid receptors in the NAcc with DAMGO potently increases feeding on palatable, fatty diets, but it is not known if or how this feeding effect might be impacted by orexin or GLP-1 signaling. To examine this directly, these experiments assessed the effects of stimulating or blocking NAcc Orexin A or GLP-1 receptors in rats co-treated with DAMGO. Male Sprague-Dawley rats (n = 8/group) were surgically implanted with bilateral guide cannulas targeting the NAcc. Upon recovery, they were acclimated to 2-hr daily feeding sessions during which they had free access to a sweetened fat diet and water. On subsequent drug testing days, four groups of rats received NAcc saline or DAMGO infusions (0.025 μg/side) in a cocktail with either Orexin A (0, 1.78, or 3.56 microg/side), the Orexin A antagonist SB3348670 (at 0, 0.16, or .32 μg/side), the GLP-1 agonist Exendin-4 (at 0, 0.05, or .10 μg/side), or the GLP-1 antagonist Exendin-9 (at 0, 2.5, or 5.0 μg/side). Each rat randomly received all possible combinations of their DAMGO/drug injections across 6 treatment days. Food and water intake, rearing, and ambulatory behavior were monitored throughout each session. Consistent with previous reports, stimulation of NAcc μ-opioid receptors significantly increased consumption of the high-fat diet. Although Orexin A tended to increase feeding when given on its own, co-injecting DAMGO with Orexin A transiently inhibited DAMGO-induced feeding, but had no impact on total diet eaten by the end of the 2-hr session. Blocking Orexin A receptors did not impact food intake in the presence of μ-opioid receptor stimulation. In contrast, stimulation of NAcc GLP-1 receptors inhibited DAMGO-elicited feeding, and reduced ambulatory activity. Blockade of the GLP-1 receptor resulted in a significant three-way interaction of the two drugs and time across the feeding session. Preliminary analyses suggest that GLP-1 receptor blockade did not affect feeding when given alone, but may have enhanced food intake in response to μ-opioid receptor stimulation. These studies suggest that food intake that is directed by opioid receptors in the nucleus accumbens may, in some cases, be co-modulated by peptides associated with the regulation of homeostasis and energy balance.

Title: Inactivation of the lateral habenula increases locomotion and differentially impacts feeding on palatable or pabulum diets

Authors: *H. N. CARLSON[1], B. CHRISTENSEN[2], K. COWIE[2], W. E. PRATT[2]
[1]Psychology, [2]Dept. Psychology, Wake Forest Univ., Winston Salem, NC

Abstract: Overconsumption, or eating beyond the point of homeostasis, is a key feature in the development of obesity. Although people are consuming beyond the point of homeostasis, they are not consuming constantly or indefinitely. Thus, there is likely a mechanism that acts to terminate periods of food intake at some point beyond satiation and prior to aversion, or the negative effects of extreme excess (nausea, bloating, etc.). The purpose of the present study was to assess the lateral habenula as a candidate region for such a mechanism, due to its connectivity to midbrain reward circuitry, sensitivity to metabolic signaling, and pronounced role in drug-related motivated behaviors. Two groups of male Sprague-Dawley rats were surgically implanted with bilateral guide cannula targeting the LHb. Rats were then habituated to feeding chambers, wherein locomotion and food intake were monitored throughout a two-hour session. One experimental group was tested in the presence of rat chow; the second group was instead given access to a sweetened fat diet. Across four injection days, each individual rat separately received a 0.2 µl vehicle (0.9% saline solution) and baclofen-muscimol (50ng/0.2µL of each drug dissolved in 0.9% saline) injection, first in an *ad libitum* state, and then following 22 hours of food deprivation. Additionally, on a fifth injection day, each rat received an injection of mu-opioid agonist DAMGO (0.1 µg/0.2 µl) prior to placement in the chamber. In the first experiment (N = 6), inactivation of the LHb attenuated feeding of deprived animals on a sweetened-fat diet, but had no significant impact on the feeding behavior of sated animals. Specifically, inactivation of the LHb appeared to enhance feeding early in the session when the animals were offered the sweetened-fat diet in a sated condition, but reduced feeding compared to the vehicle injections when subjects were deprived for 22 hours prior to entering the feeding chamber. Interestingly, subjects consumed less of the sweetened-fat diet following 22 hour deprivation, regardless of inactivation. In the second experiment (N = 8), inactivation did not alter feeding of the standard chow diet in deprived or sated conditions. LHb inactivation also produced a consistent increase in locomotor activity across all conditions and in both experimental groups. Furthermore, mu-opioid stimulation increased feeding on standard chow, but decreased intake of the sweetened-fat diet. Although LHb inactivation did not increase feeding as predicted, these are the first data to suggest a possible role for the LHb in directing food intake on palatable foods when rats are food restricted.

Title: Stimulation of nucleus accumbens mu-, delta-, or kappa-opioid receptors differentially affect effort-based choice in the rat

Authors: *W. E. PRATT[1], H. N. CARLSON[2], C. MURPHY[2]
[1]Dept. Psychology, Wake Forest Univ., Winston Salem, NC; [2]Dept. of Psychology, Wake Forest Univ., Winston-Salem, NC

Abstract: The nucleus accumbens (NAcc) is critical for regulating appetitive and consummatory phases of motivated behavior. Stimulation of nucleus accumbens μ- and δ-opioid receptors increases food consumption, particularly in the presence of highly palatable foods. Previous experiments in our laboratory have suggested that stimulation of NAcc μ-opioid receptors may shift the motivational state of the rat from appetitive food-seeking to an emphasis on consummatory processes. To test this formally, rats were trained to lever press for sucrose pellets on a progressive-ratio 2 (PR2) schedule, and then offered the choice to work for sugar pellets or to eat freely available rat chow following stimulation of μ-, δ-, or κ receptors of the NAcc. Male Sprague-Dawley rats (n = 12/group) were food restricted to 90% *ad libitum* weight and trained on a PR2 schedule to earn sugar pellets. Following training, food was returned, and rats were surgically implanted with bilateral guide cannulas targeting the NAcc core. Rats were then retrained on the PR-2 task, with rat chow also freely available in the operant chamber. Access to the sugar-associated lever and the food was continuous throughout each 1-hr session. Separate groups were tested following μ-opioid receptor stimulation (with 0, 0.025, and 0.25 μg DAMGO/side), δ-opioid receptor stimulation (with 0.31, 3.1 D-Pen/side), or κ-receptor stimulation (with 0.0, 0.186, and 1.86 μg/side U-50488 hydrochloride; doses were equimolar across the separate drugs). Individual rats in each drug group were tested on all doses of a single drug across three test days, and then again following 24-hr food restriction (for a total of six drug testing days). 23-hrs of food deprivation increased feeding on the available rat chow but did not reliably alter breakpoint across these experiments. Stimulation of NAcc μ-opioid receptors shifted rats' behavior away from sugar-seeking by reducing break point for the sucrose, and increased the consumption of the freely available rat chow. In contrast, stimulation of δ opioid receptors increased both feeding on the rat chow and the effort expended to earn sugar pellets; this effect appeared to be driven by increases when the animals were not food restricted during testing. Stimulation of NAcc κ receptors had no significant overall effects on food intake or lever-pressing, though there was a trend for an increased breakpoint across drug doses on days when the animals were not food-restricted. These data confirm prior reports indicating that μ- and δ-receptors of the nucleus accumbens facilitate consummatory behavior, and suggest that δ receptors may also impact appetitive motivation by impacting NAcc circuitry.

Title: Elucidating the interaction between glucocorticoids and dopamine in an animal model of individual variation in cue-motivated behaviors

Authors: *S. A. LOPEZ[1], A. VALENTA[2], P. CAMPUS[4], R. T. KENNEDY[2], S. B. FLAGEL[3]
[1]Neurosci., [2]Chem., [3]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [4]Psychiatry, Univ. of Michigan Dept. of Psychiatry, Ann Arbor, MI

Abstract: Learning to associate cues in the environment with appetitive and/or aversive stimuli allows organisms to develop a behavioral repertoire fit to obtain valuable resources or avoid danger. Cues, however, can also gain inordinate control and elicit maladaptive behaviors. For example, addicts often relapse upon exposure to cues previously associated with the drug-taking experience. Using an animal model that captures individual variation in response to reward-cues, we are able to examine the neurobiological processes that contribute to such cue-driven psychopathologies. Rats that undergo Pavlovian training, consisting of cue presentation followed by delivery of a food reward, will often develop either a sign- or goal-tracking conditioned response. For both sign-trackers (STs) and goal-trackers (GTs) the cue attains predictive value, but for STs the cue also attains incentive value. The attribution of incentive value to the cue transforms it into a "motivational magnet", rendering it attractive and desirable for STs, but not GTs. It has been shown that different brain circuits are engaged in response to the cue in STs vs. GTs, and that dopamine (DA) is necessary for incentive (i.e. sign-tracking), but not predictive (i.e. goal-tracking) learning processes. DA has long been known to interact with corticosterone (CORT), the main glucocorticoid in rodents, to mediate motivated behaviors; yet little research has been done to directly investigate the interaction between these two molecules in the context of sign- and goal-tracking behaviors. Here we assessed the relationship between peripheral and brain CORT levels and the mesocorticolimbic DA system in male and female STs and GTs. To do so, samples were obtained via tail nick (CORT) and *in vivo* microdialysis (CORT, DA) within the nucleus accumbens before and after sessions 1 and 6 of Pavlovian training. This experimental design allowed us to assess CORT/DA interactions prior to acquiring a conditioned response and following the development of sign- and goal-tracking behavior. We found that female rats tend to have greater peripheral CORT levels, but there do not appear to be sex differences in brain CORT levels. There were no apparent sex differences in brain DA levels, but STs of both sexes

show greater CORT and DA during Pavlovian conditioning relative to GTs. Ongoing studies are assessing whether differential expression of glucocorticoid receptors throughout the mesocorticolimbic system may be contributing to these results. These data contribute to our understanding of the role of glucocorticoids in DA-dependent learning processes that are relevant to cue-motivated psychopathologies.

Title: Elucidating the role of cortico-thalamic-striatal circuitry in cue-reward learning

Authors: *P. CAMPUS[1], Y. KIM[2], B. N. KUHN[3], S. A. LOPEZ[3], I. RIVERO-COVELO[1], S. M. FERGUSON[5], M. SARTER[2], S. B. FLAGEL[4,1]

Abstract: When cues in the environment are repeatedly associated with rewards, they acquire predictive value and become conditioned stimuli (CS), eliciting a conditioned response. However, such cues can also acquire incentive value, gaining the ability to trigger motivational states that can lead to dysfunctional behaviors. Individuals vary considerably in the extent to which they attribute motivational value to reward-cues. In a Pavlovian Conditioned Approach (PCA) task, in which the presentation of a lever-cue is immediately followed by the delivery of a food reward, some rats approach the lever-cue (sign-trackers, ST) while others approach the food cup (goal-trackers, GT). Importantly, while the lever-cue is a predictor for both ST and GT, it only becomes an incentive stimulus for ST. It has been previously shown that the sign-tracking response is dopamine (DA) dependent, but the goal-tracking response is not. Further, presentation of the lever-cue engages different neural circuitry in sign-trackers vs. goal-trackers. The sign-tracking response appears to be mediated primarily by subcortical mechanisms; whereas goal-tracking behavior appears to depend on “top-down” cortical engagement. We recently demonstrated that the paraventricular nucleus of the thalamus (PVT) represents a key node that integrates subcortical and cortical input differentially in ST and GT. Together, these data led us to hypothesize that in GT, the prelimbic cortex (PrL) to PVT pathway may serve to

suppress subcortical processes critical for the expression of sign-tracking. In support of this view, activation of the PrL-PVT circuit in ST, using Designer Receptors Exclusively Activated by Designer Drugs (DREADD) decreases sign-tracking behavior. In contrast, inhibition of PrL-PVT pathway in GT increases sign-tracking behavior. Here, we investigated the effects of selective manipulation of the PrL-PVT pathway on extracellular levels of DA in the NAc of ST and GT. To this end, we used a dual viral vector approach to selectively express stimulatory Gq- or inhibitory Gi/o- DREADD in PrL to PVT projecting neurons. Clozapine-N-oxide (CNO) (3 mg/kg) was administered (i.p.) to activate DREADD during Pavlovian conditioning while levels of DA and other neurotransmitters in the NAc were assessed using in vivo microdialysis. In agreement with the behavioral effects mentioned above, "turning on" the PrL-PVT pathway reduced DA in the NAc of ST while, "turning off" the PrL-PVT pathway in GT increased DA levels. Therefore, the cortico-thalamic-striatal pathway seems to be differentially "tuned" to mediate individual variation in cue-motivated behaviors.

Title: The effects of chemogenetic inhibition of a "top-down" cortico-thalamic circuit on individual variation in cue- and cocaine-induced drug-seeking behavior

Authors: *B. N. KUHN[1], P. CAMPUS[2], M. S. KLUMPNER[3], S. B. FLAGEL[4]
[1]Neurosci. Grad. Program, [2]Psychiatry, [3]Pyschiatry, [4]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Relapse remains the biggest problem in the treatment of addiction, and is often triggered by stimuli (e.g. drug paraphernalia) that have been previously associated with the drug-taking experience. Such cues become powerful motivators and gain the ability to elicit drug-seeking behaviors when attributed with incentive salience, a process that occurs via Pavlovian learning. Importantly, however, only for some individuals are such cues transformed into incentive stimuli and attain inordinate control over behavior. We are able to capture individual variation in the propensity to attribute incentive salience to reward-paired cues using an animal model. In this model, sign-trackers (STs) are rats that attribute incentive salience to a reward-

predicting cue, and approach and manipulate the cue upon its presentation; whereas goal-trackers (GTs) assign only predictive value to the cue and go to the location of reward delivery upon cue presentation. Intermediate rats (INs) vacillate between these two conditioned responses. Relative to GTs, STs are more impulsive, more motivated to take cocaine and more susceptible to cue- and cocaine-induced reinstatement. These phenotypes also engage distinct neural mechanisms in response to reward-associated cues. The paraventricular nucleus of the thalamus (PVT) has been recognized as a central node that mediates both sign- and goal-tracking behavior, but via different circuit dynamics. Data from our lab support a role for projections from the prelimbic cortex (PrL) to the PVT in differentially mediating sign- and goal-tracking behaviors. Here we investigated the role of this pathway in regulating individual differences in cue- and drug-induced drug-seeking behavior. To do so we used a dual-vector approach to selectively express inhibitory (G_i) DREADD (Designer Receptors Exclusively Activated by Designer Drugs) in the PrL-PVT pathway. Rats were characterized as STs, INs or GTs based on their behavior during a Pavlovian conditioned approach task and then underwent 2 weeks of cocaine self-administration followed by 4 weeks of abstinence and then extinction training. Prior to the tests for reinstatement, rats received either vehicle or clozapine-N-oxide (5 mg/kg) to activate the DREADD. Inhibition of the PrL-PVT pathway causes an increase in drug-induced reinstatement, independent of phenotype. In contrast, only INs show an increase in cue-induced reinstatement, such that "turning-off" this top-down circuit renders them comparable to STs. The PrL-PVT circuit, therefore, appears to inhibit drug-seeking behavior, but does so to a different degree depending on the stimulus (drug vs. cue) and phenotype (STs, GTs, INs).

Mask applied for areas involved in extinction learning (hippocampus, parahippocampus, frontal cortex

Extinction learning is laboratory model for exposure therapy. Safety learning can happen through instruction, observation, or experience. Our knowledge of combined effects of instruction and experience in extinction learning is limited. This is one of the first functional neuroimaging studies to examine combined effects of instruction with experiential learning of safety in a within subject design. We hypothesized that instruction would recruit areas involved in emotion regulation.14 healthy participants (m = 7; mean age = 20; 3T Siemens Verio) underwent two consecutive days of scanning. Habituation, conditioning, and extinction learning took place on

day 1; recall on day 2. Participants were conditioned to two stimuli paired with a loud noise (CS+). Prior to extinction learning, absence of the noise was informed for one of the two CS+ (CS+I). fMRI data were preprocessed and analyzed using typical methods (SPM12). Here, we present preliminary extinction data. A mask for the hypothesized ROIs was applied, and a one sample t-test was used to compare brain activation between CS+I and the Uninformed CS+. Extinction data showed higher activation in areas involved in contextual processing and emotion regulation (bilateral parahippocampal gyrus, right hippocampus, bilateral insula, and Brodmann's Area 9), when instruction was combined with experiential learning. Integrating instruction with exposure-based treatment may improve extinction learning by involving additional networks. This line of research will help explore potential deficits in processing of cognitive context in PTSD and GAD, with therapeutic implications.

Sch. of Med., Atlanta, GA

Abstract: Resting-state functional connectivity (rsFC) magnetic resonance imaging (MRI) represents a powerful method for illuminating brain network function. Moreover, it has a particular relevance for posttraumatic stress disorder (PTSD), where abnormalities in rsFC have recently been demonstrated. The current study is part of the PROlonGed ExpoSure and Sertraline Trial (PROGrESS; Rauch et al. *Contemporary Clinical Trials*, 2018), and examined the role that rsFC abnormalities might play in therapeutic interventions in PTSD. Methods: Sixty-one military veterans with PTSD were assigned to evidence-based treatment groups: Prolonged Exposure (PE) plus placebo, Sertraline (SERT) plus enhanced medication management, or PE/SERT. Twenty-nine veterans without PTSD were recruited as a control group. Symptom assessment and MRI scanning occurred before and after treatment. Seed-based results were thresholded at p=.001 uncorrected and then subsequently, at p<.050 (FWE) at the cluster level. Results: At baseline, seed-based analyses revealed that PTSD was associated with lower connectivity between PCC, vmPFC and other default-mode network (DMN) regions, replicating prior findings of decreased within-DMN connectivity in PTSD. In contrast, PCC and vmPFC, as well as the insula (salience-network (SN) seed), had greater connectivity with regions within dorsal-attention network (DAN) in patients, which is in line with the cross-network desegregation in PTSD. Graph-theoretic analysis showed that DMN and DAN were also characterized by decreased small-worldness in patients, further suggesting these networks' decreased integration in PTSD. When testing treatment effect, we found that patients who responded to treatment had lower baseline amygdala-PCC connectivity, supporting the importance of DMN-SN segregation in PTSD. In sum, these findings confirm and extend our knowledge of network-level abnormalities in PTSD, and importantly, propose a neural biomarker to predict successful response to treatment.

Title: Divergent astrocyte gene expression changes in post-mortem autism and PTSD cortex

Authors: *K. A. YOUNG[1,2,3], K. A. KUSTER[3,2], D. L. CORCORAN[4], D. A. CRUZ[5], D. E. WILLIAMSON[5,6]
[1]Neuropsychiatry Res. Program, CTVHCS, Temple, TX; [2]Texas A&M Col. of Med., Temple, TX; [3]Psychiatry, Baylor Scott & White, Temple, TX; [4]Duke Ctr. for Genomic and Computat. Biol., Duke, Durham, NC; [5]Psychiatry & Behavioral Sci., Duke Univ., Durham, NC; [6]Durham VA Med. Ctr., Durham, NC

Abstract: Astrocytes support neurotransmission in the cortex through a variety of functional mechanisms. While their role in reactive gliosis in response to CNS damage is widely recognized, astrocytes also form the neurovascular unit, linking neurons to the circulatory system and providing trophic support and peri-neuronal maintenance. A recent study has identified up-regulated astrocyte gene expression in cortex of autistic brains, and suggests that astrocytosis, astroglial activation, or both may be occuring (Gandal et al., 2018, PMID:29439242). Using this recently published data, we compared and contrasted post-mortem gene expression changes in autism and PTSD. Differential PTSD gene expression changes in 6 PTSD cases and 8 controls was determined in the medial orbitofrontal cortex using Illumina microarrays, quantile normalization and standard data cleaning procedures. We previously reported evidence for reductions in overall and mushroom spine density in the mOFC in these 14 cases (Young et al., 2015; PMID:26844242). Using data from purified mouse brain cells (Zhang et al., 2014 PMID:25186741), we identified a set of 119 astrocyte-specific genes with at least 16X higher expression in astrocytes compared to neurons, mature oligodendrocytes, microglia and endothelial cells. Gene set enrichment analysis (GSEA) indicated that astrocyte-specific genes were highly up-regulated in both autism and PTSD (FDR q's> 0.0001). We next identified a set of gene transcripts up-regulated in rodent models of middle coronary artery occlusion and LPS-induced astrogliosis (N=199; Zamanian et al., 2012 PMID:22553043) and a set of gene transcripts found in astrocyte endfeet making contact with blood vessels (N=49; Boulay et al.. 2017, PMID:28377822). Astrocyte endfeet genes were selectively up-regulated in PTSD (FDR q> 0.0001) compared to autism (NS), while astrogliosis genes were selectively up-regulated in autism (FDR q<0.0001) compared to PTSD (NS). Although astrogliosis has been noted in several studies of autism, the robust gene expression response observed above suggests that additional studies of classical reactive astrocyte responses may be warranted. Post-mortem studies of PTSD are very limited, and this is the first observation of astrocyte responses in PTSD brain. The lack of a strong astrogliotic signal and the presence of robust up-regulation of astrocyte neurovascular unit transcripts in PTSD suggests that trophic, neuroprotective and/or maintenance functions of astrocytes are up-regulated in PTSD orbitofrontal cortex.

Title: Increased PTSD severity reduces the discriminability of neutral compared to fearful face stimuli in a pharmacological fMRI study of working memory

Authors: *A. J. WESTPHAL[1,2,3], N. RODRIGUEZ[1,2,3], M. BALLARD[1,2,3], T. VEGA[1,2,3], A. S. KAYSER[1,2,3]
[1]Neurol., Univ. of California, San Francisco, San Francisco, CA; [2]U.S. Dept. of Veterans Affairs, Washington, DC; [3]Univ. of California, Berkeley, Berkeley, CA

Abstract: Working memory is compromised in anxiety disorders such as post-traumatic stress disorder (PTSD). This impairment is thought to result from multiple cognitive changes, including reductions in cognitive control over working memory representations and overgeneralization from fearful to neutral stimuli. We hypothesized that enhancing cortical dopamine tone through use of the COMT inhibitor tolcapone would improve mnemonic discriminability between fearful and neutral faces. In the present study, 26 participants with a range of post-traumatic stress disorder severity scores (range: 0 - 68, SD: 20.66), assessed by the CAPS PTSD scale, underwent fMRI scanning while completing an emotional working memory task after the randomized, double-blind administration of either tolcapone or placebo. The working memory task involved the presentation of three consecutive face stimuli, either all fearful or all neutral, with instructions to remember all three faces (high load condition) or only the final face (low load condition). During the intervening delay period after the cues were shown, participants indicated whether distractor stimuli were faces or scenes. Participants then rated whether the probe face stimulus, 50% of which were novel, was presented during the cue phase.
Task behavioral data specifying whether the cue period contained fearful or neutral expressions were entered into separate linear mixed models, along with drug session and CAPS and their interactions, predicting either mnemonic discriminability (d') or response bias. The model predicting d' showed an interaction between cue expression and CAPS, such that less severe PTSD severity (1 SD below mean and mean CAPS) was associated with better performance on trials with neutral expressions than with fearful expressions, while more severe PTSD (1-2 SDs above mean) was associated with non-significant d' between cue emotions. There was also a significant interaction between CAPS and administered drug, such that drug 2 did not affect d' for less severe PTSD, but did improve performance for more severe PTSD. The study currently

remains blinded. The model predicting response bias demonstrated a 3-way interaction between CAPS, cue expression, and drug session such that participants exhibited more liberal responding to fearful cues for drug 1, a finding that was exacerbated by more severe PTSD and alleviated by administration of drug 2. In contrast, participants with less severe PTSD exhibited a more conservative response tendency to neutral cues for drug 2, a result that was not shown in severe PTSD patients (2 SDs above mean CAPS). Ongoing imaging analyses will evaluate the neural correlates of these findings.

Title: Prefrontal activation during cognitive control of emotional processing in posttraumatic stress disorder is influenced by hazardous alcohol use in veterans

Authors: *G. L. FORSTER[1,2], R. SIMONS[3], J. SIMONS[3], L. BAUGH[2], V. MAGNOTTA[4]
[1]Univ. of Otago, Dunedin, New Zealand; [2]Basic Biomed. Sci., [3]Psychology, Univ. of South Dakota, Vermillion, SD; [4]Radiology, Univ. of Iowa, Iowa City, IA

Abstract: Many affective disorders including posttraumatic stress disorder (PTSD), depression, and anxiety are characterized by alterations to executive function, such as cognitive control of emotional processing. A number of prefrontal regions are implicated in such processing, including the ventrolateral (vlPFC) and dorsomedial (dmPFC) prefrontal cortices. However, there is some debate as to how these regions contribute to deficits in cognitive control of emotional processing as revealed by the emotional Stroop task. Numerous computational and neurocircuitry models predict that the Stroop effect elicited by emotional distractors would be associated with reduced prefrontal activity. This stands in contrast to a recent meta-analysis of control and clinical populations demonstrating increased activity in the vlPFC and dmPFC during negative word conditions of an emotional Stroop task. The purpose of the current study was to further examine the role of the vlPFC and dmPFC in cognitive control of emotional processing in veterans with and without current PTSD symptoms. Given that 50-85 % of individuals with PTSD exhibit hazardous alcohol use, we also sought to explore the contribution of hazardous alcohol use to prefrontal-based emotional processing. Ninety-eight male and female

right-handed veterans of Operations Enduring Freedom and Iraqi Freedom (OEF/OIF) were assessed for combat intensity, PTSD symptoms, alcohol use and alcohol dependence, and other mental and physical health indices. Participants underwent functional magnetic resonance imaging (fMRI) while performing the emotional counting Stroop task adapted for OEF/OIF veterans, with reaction time and errors recorded. A region of interest analysis was performed blind to PTSD or alcohol status and focused on changes in activity within the vlPFC and dmPFC. In line with the recent neuroimaging meta-analysis, left vlPFC and dmPFC activity increased during negative conditions across all participants. While all participants were combat-exposed, a clear Stroop effect for combat-related words was only observed for individuals with PTSD symptoms. However, greater activity of the left vlPFC and dmPFC during the combat condition was observed for participants reporting hazardous alcohol use, rather than being directly related to the presence of PTSD symptoms. Overall, findings suggest that prefrontal regions are engaged during the processing of emotional distractors. However, current results also suggest that activity of prefrontal regions during cognitive-based emotional processing in clinical populations should be interpreted in the context of the individual's alcohol use.

Title: Neuroactive steroid levels in the orbital frontal cortex of subjects with posttraumatic stress disorder and controls

Authors: *D. A. CRUZ[1], K. D. MCGAUGHEY[1], G. PARKE[1], L. J. SHAMPINE[1], J. KILTS[1], J. NAYLOR[1], C. E. MARX[1,2], D. E. WILLIAMSON[1,2]
[1]Psychiatry & Behavioral Sci., Duke Univ., Durham, NC; [2]Durham VA Med. Ctr., Durham, NC

Abstract: Neuroactive steroids mediate stress signaling pathways and have been implicated in the pathogenesis of posttraumatic stress disorder (PTSD). Measures of neuroactive steroid levels in peripheral blood and cerebrospinal fluid in subjects with PTSD show abnormal levels compared to controls. Additionally, both clinical and pre-clinical studies have shown that neuroactive steroids, particularly those that impact GABAergic neurotransmission, are decreased in PTSD with differential changes based on sex. Functional imaging studies of PTSD show hypoactivity of the ventromedial prefrontal cortex, including the medial orbital frontal cortex.

This study examines neuroactive steroid levels in the orbital frontal cortex of subjects with PTSD (n=18) and normal controls (n=40). Gray matter (80mg) was dissected from fresh-frozen medial orbital frontal cortex and the neuroactive steroids pregnenolone, pregnanolone, allopregnanolone, epiallopregnanolone, epipregnanolone, THDOC, and androsterone levels were determined by gas chromatography-mass spectrometry (GC/MS/MS) methodology with a limit of detection of 1 pg. The results identified significant interactions between sex and PTSD for pregnanolone ($F1,43 = 7.52$, $P < 0.01$) that was due to PTSD females having higher levels of pregnanolone ($F1,43 = 8.71$, $P < 0.005$) compared to control females. There was also a significant interaction between sex and PTSD for epiallopregnanolone ($F1,45 = 4.97$, $P < 0.031$) that was due to PTSD females having significantly higher levels compared to PTSD males ($F1,45 = 9.73$, $P < .003$)) but not control females ($F1,45 = 2.20$, $P < 0.145$). These data suggest that there may be sex differences in neuroactive steroids in subjects with PTSD. Future directions include expanding the number of subjects in these cohorts in order to gain better insight into sex differences in neuroactive steroid levels in subjects with PTSD. In addition, we will measure neuroactive steroids in other brain regions to determine regional distribution.

Title: Using EEG neurofeedback to decrease medial frontal theta activity in patients with PTSD

Authors: A. M. RIVAS[1], M. GRAMS[2], J. VALDEZ[2], J. A. PINEDA[2], *I.-W. SHU[1]
[1]Dept. of Psychiatry, [2]Dept. of Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: The salience network (SN), includes the limbic system, insula and anterior cingulate cortex (ACC), and is responsible for monitoring threats to the organism. The SN shares brain areas and works closely with memory systems. For example, the hippocampus, ACC and prefrontal cortex exhibit increased and synchronized neural activity during consolidation and recall of negative stimuli. These events can be assessed neurophysiologically. For example, synchronous limbic-frontal activity produces greater medial frontal theta activity during

electroencephalography (EEG). Trauma-related increases in SN activity, and its effects on memory systems, can contribute to posttraumatic stress disorder (PTSD). For example, PTSD+ subjects generally exhibit excessive recall of trauma-related memories and hypervigilance of potentially-negative stimuli. In further support of this model, PTSD+ subjects also often exhibit greater medial frontal theta activity, a marker of greater limbic-frontal activation. We hypothesize that decreasing medial frontal theta activity in patients with PTSD would lower symptoms by normalizing excessive SN activity and its effects on memory systems. To validate this, as a first step, we designed a treatment study using EEG neurofeedback to inhibit frontal theta activity in PTSD patients. More specifically, by coupling a patient's theta activity to dynamic visual targets on a digital display, EEG neurofeedback allows the patient to, in real time, decrease their theta activity by manipulating the visual targets. In this study, PTSD patients were randomized to EEG neurofeedback inhibiting medial frontal theta power or, for comparison, neurofeedback enhancing posterior alpha power. Patients received 15-30 min trainings twice a week for 6 weeks (12 trainings total). Resting EEG and clinical measures were acquired before, halfway and after treatment. Theta reduction training was associated with > 35% decrease in PTSD severity. Furthermore, clinical improvements were associated with lower resting theta power. At the single-subject level, lower theta power correlated with improved PTSD symptoms, especially in the Avoidance symptom cluster. Of note, similar neurophysiologic and clinical effects were also observed in subjects completing alpha enhancement training, suggesting that learning to modulate generators of alpha activity may also be helpful for PTSD patients. These promising early results suggest that targeting medial frontal theta activity using EEG neurofeedback may lead to novel, neuroscientically-informed treatments for PTSD in the near future.

Title: Altered maturation of emotion-regulation brain circuitry in young children with a history of Post-Traumatic Stress Disorder

Authors: *A. M. MOYETT[1], C. L. FALES[2], A. D. BARBER[2], P. DEROSSE[2], A. MALHOTRA[2], K. H. KARLSGODT[3]

Zucker Hillside Hospital, Div. of Northwell Hlth. Syst., Glen Oaks, NY; [3]Dept. of Psychiatry and Biobehavioral Sciences, Univ. of California, Los Angeles, CA

Abstract: Introduction: The experience of childhood adversity greatly increases the risk for depression and anxiety in adulthood, but the brain basis for this linkage is poorly understood. Animal studies suggest that early adversity accelerates the maturation of brain circuitry underlying emotion regulation. Likewise, human studies indicate that children who experience early adversity show emotion-regulation brain circuitry patterns that are characteristic of much older children. However these studies have most often operationalized childhood adversity as maternal deprivation or other forms of familial trauma (e.g., child abuse or neglect) likely to interfere with developing attachment systems. The current study explores the effects of trauma more generally (i.e., car accidents, natural disasters as well as familial trauma) on children's developing brains.
Methods and Materials: We examined emotion-regulation brain circuitry as a function of trauma in youth aged 9-20 (n=114) from the Philadelphia Neurodevelopmental Cohort (PNC). Three groups (PTSD, trauma-exposed controls, and no-trauma controls) underwent functional neuroimaging (fMRI) including a resting-state scan and an emotion-recognition task. Analyses examined connectivity or task activation between the right amygdala and frontal control regions.
Results: Across the age range, amygdala-prefrontal relationships were significantly different in the Post-traumatic Stress Disorder (PTSD) group relative to either control group. The youngest children in the trauma-exposed and no-trauma control groups showed a positive relationship between frontal control regions and the amygdala, a relationship that grew steadily more negative as participants aged. By contrast, the youngest PTSD group showed negative amygdala-prefrontal relationships not seen in the control groups until late adolescence. Moreover in the connectivity analyses, the prefrontal regions showing this pattern were not ventromedial, as in previous studies. Instead, when PTSD participants were compared to no-trauma controls, a right fronto-insular/orbitofrontal region (associated with salience processing and reward valuation) emerged, while when they were compared to trauma-exposed controls, two other prefrontal regions also showed this pattern (i.e., precentral/middle frontal cortex and supplementary motor area).
Discussion: These findings suggest that trauma exposure and PTSD at an early age are associated with adult-like emotion-regulation patterns in brain circuitry, providing further insight into childhood emotional resilience as well as increased risk for depression in adulthood.

Title: Chronic cannabis use effects on the extinction in post traumatic stress disorder

Authors: *B. CUCCURAZZU[1,2], D. STOUT[1,2], D. GLENN[3,2], D. ACHESON[1,2], V. B. RISBROUGH[1,2]
[1]Univ. of California San Diego, San Diego, CA; [2]Ctr. of Excellence for Stress and Mental Health, VA San Diego Healthcare Syst., San Diego, CA; [3]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Rationale: Posttraumatic stress disorder (PTSD) lifetime prevalence is estimated to be approximately 7% in USA, with high prevalence rates in victims of interpersonal violence and combat veterans. Evidences based on pharmacological and psychological interventions shows that nonresponse rates to treatments is as high as 50%, and that a high percentage of subjects use cannabis to relieve symptoms of PTSD. However, controlled studies have not been conducted to evaluate the safety or effectiveness of marijuana for PTSD. Animal studies and studies in healthy controls suggest that fear inhibition, a core deficit in PTSD, may be enhanced by cannabinoid receptor signaling. Here we tested the hypothesis that cannabis use may modulate fear inhibition processes in PSTD. To test this hypothesis we investigated the effects of moderate to high cannabis use on laboratory-based fear extinction in PTSD patients. We recruited PTSD subjects with (N=17) and without (N=11) moderate-high cannabis use (used marijuana at least 5 times/week over the previous 90 days or not a current user). On Day 1, subjects were assessed for PTSD using the CAPS for DMS-5 and cannabis use was recorded using a modified version of the CDDR. Subjects then underwent acquisition of fear learning using the fear potentiated startle task (FPS). Shortly after acquisition subjects then underwent extinction training. On Day 2, subjects returned for assessment of recall of extinction learning. Subjects were screened for acute intoxication before testing to ensure behavioral effects were not mediated by acute cannabis use effects. Results: Analyses are ongoing and will be provided at the meeting.

Title: Elevated cortisol and alpha-amylase levels in behaviorally inhibited individuals exposed to physiologic stress: Implications for enhanced associative plasticity with anxiety vulnerability

Authors: *D. R. COOK-SNYDER[1], H. LATHAM[1], J. R. MILLER[2], P. F. MARTINO[2], D. P. MILLER[1], R. J. SERVATIUS[3]
[1]Neurosci. Program, [2]Biol. Dept., Carthage Col., Kenosha, WI; [3]Syracuse VA Med. Ctr., Syracuse, NY

Abstract: A number of studies have used elevated levels of CO2 inhalation to activate physiological stress responses. While these studies reliably activate increased respiratory responding, activation of salivary stress hormones has been mixed. Our study examined stress hormone activation following exposure to 7% CO2 while controlling for stress/anxiety vulnerability. Behaviorally inhibited (BI) temperament has been identified as a key vulnerability factor for stress and anxiety disorders (e.g., Gladstone and Parker, 2005). Recently, a number of studies in both human (e.g., Allen and Miller, 2016) and non-human (e.g., Beck et. al, 2010) participants have demonstrated that organisms that are consistently inhibited across the lifespan show increased associative plasticity, especially when reinforcement of the environmental stressor is uncertain. We have hypothesized that stress vulnerable BI individuals may show enhanced stress hormone responses to environmental stressors. To test that hypothesis, we had participants perform a simple spaceship-based computer task (Sheynin et. al., 2014). Participants received 7% CO2 administration either during the first 7 min or the second 7 min of the game. A control group received air only throughout the testing. Air and CO2 were administered using a Hans Rudolph breathing apparatus. Two saliva samples from each participant were analyzed, one sample acquired 15 min prior to beginning the computer task, and a second sample taken immediately following the computer task. All samples were analyzed for alpha-amylase and cortisol levels using ELISAs. Level of BI was identified using the Adult Measure of Behavioral Inhibition (Gladstone and Parker, 2005). All participants regardless of level of BI showed increases in respiratory tidal volume immediately upon exposure to 7% CO2. Individuals who scored high in BI appeared to show increases in alpha-amylase activity shortly after exposure to 7% CO2, and increases in cortisol concentration approximately 30 min after 7% CO2 exposure. We did not see similar increases in individuals who scored low in BI. Our data indicate that, while all individuals showed physiological respiratory responses to elevated CO2, only stress vulnerable individuals appeared to show stress hormone response within our time frame. Our ongoing research examines whether sex differences may have contributed to our current

findings. Our preliminary data suggest that, given the significant consistency of enhanced associative plasticity in the human and non-human BI literature, stress hormone responding to environmental stressors may contribute to the enhanced learning that has been observed.

Abstract: Anxiety and stress disorders are prevalent diagnoses. However, the majority of individuals who experience significant aversive events do not show symptoms that endure and lead to diagnosis. The learning diathesis model suggests that individuals who are more vulnerable to these disorders show enhanced associative plasticity to environmental relationships, thus leading to symptom endurance and pathology. Numerous studies have demonstrated enhanced and persistent learning in organisms with behaviorally inhibited temperament (BI) and/or in females, two risk factors for anxiety and stress disorder. This includes rats in signaled avoidance learning (e.g., Beck, et. al, 2010) and humans in classical eyeblink conditioning (e.g., Allen, et.al., 2016). Sheynin et. al (2014) used a computer-based spaceship task to demonstrate sex and temperament differences in avoidance acquisition. However, this task is entirely cognitive, eliciting no physiological responses. We used this task to examined avoidance learning while participants breathed enhanced CO2 (7%). We tested whether stress response would alter learning acquisition and persistence in vulnerable individuals. BI was characterized using the Adult Measure of Behavioral Inhibition. Participants used a Hans Rudolph mouth piece with nose occlusion. Each session began with 15 minutes of air to allow the participant to adjust to the breathing apparatus. Avoidance training was accomplished using the spaceship task (courtesy of Sheynin and Myers). During avoidance

acquisition, participants inhaled either 7% CO2 gas (room air balance) or room air. During extinction training, participants inhaled room air. Participants receiving 7% CO2 showed rapid and consistent increases in ventilation. CO2 exposure did not appear to affect acquisition of the computer-based avoidance response, but high BI females appeared to show resistance to extinguishing the response (i.e., persistence of the response). Further, CO2 exposure appeared to significantly reduced female participant activity (i.e., a decrease in participant-controlled movement of her spaceship character and fewer shots fired). In contrast, CO2 exposure appeared to significantly increase male participant activity. Our data suggest that CO2 exposure differentially affected the performance of females and males on this task. While those performance differences did not affect acquisition of avoidance responding, it did result in a selective persistence of avoidance responding during extinction trials. We are running groups that receive air during acquisition and 7% CO2 during extinction to see if performance post-learning is similarly affected.

Title: Alterations in acoustic startle response (asr) support a two hit hypothesis of behavioral inhibition and female gender for anxiety disorders

Authors: *T. ALLEN, M. M. GARCIA
Univ. of Northern Colorado, Greeley, CO

Abstract: Behavioral inhibition (BI), a personality temperament that is a known risk factor for anxiety disorders such as PTSD, enhances eyeblink conditioning with a tone CS and an air puff US. Female gender is also known to enhance eyeblink conditioning. Prior work has demonstrated that this enhanced associative learning with BI is not due to an increased reflexive response to the US air puff. However, this finding may be due in part to exaggerated reactivity to the tone via a startle response rather than enhanced associative learning. While BI children exhibit exaggerated acoustic startle responses (ASR) under certain conditions, ASR has not been studied in BI adults. In the current work, the Adult Measure of Behavioral Inhibition (AMBI) was used to compare ASR between BI and non-inhibited individuals based on a standard cut off score. Ninety one undergraduate students (females = 59, males = 39) completed the AMBI and

underwent ASR testing with eight trials at each of three sound intensities (82/92/102 dB) presented in a pseudorandom order. Electromyogram recordings were used to quantify peak startle response amplitudes and latencies. ASR responsivity increased as a function of intensity and habituated across repeated presentations for each intensity level as would be expected. Females exhibited exaggerated ASR as compared to males while BI individuals expressed reduced ASR. However, this BI effect was observed only with females. While BI individuals and females may be more sensitive to threatening or stressful stimuli, long term activation of the hypothalamic pituitary axis (HPA) in females expressing BI may lead to a down regulation of the stress response and associated hypervigilance resulting in depressed ASR. Since BI individuals did not exhibit exaggerated ASR, enhanced eyeblink conditioning in BI individuals appears to be due to enhanced associative learning which supports a learning diathesis model of anxiety disorders.

Title: Cocaine exposure results in persisting impairment of hippocampal long-term potentiation and reduced performance in a spatial working memory task in C57BL/6J mice

Authors: *C. PRESTON[1], K. A. BROWN[2], J. J. WAGNER[3]
[1]Physiol. and Pharmacol., [3]Dept Physiol. & Pharmacol., [2]Univ. of Georgia, Athens, GA

Abstract: We investigated the effects of two different cocaine i.p. dosing schedules as well as the associated stress of vehicle (saline) injections on conditioned place preference (CPP), locomotor sensitization (LMS), long-term potentiation (LTP) in the ventral hippocampus (vH), and spatial working memory in a radial arm maze (RAM) task. CPP and LMS were established in male C57BL/6J mice using a modified conditioning protocol similar to one described by Itzhak and colleagues (2012), except that cocaine-treated mice received a double escalating-dose protocol (4,8,16,24,16,24,32,32 mg/kg; 2×4 day series). The double escalating dosing schedule produced significant CPP and LMS compared to mice that received saline vehicle. For the electrophysiology studies, a separate group of littermates were handled intermittently throughout, but not exposed to the conditioning protocol to serve as “non-behavior/naïve” controls for baseline LTP responses. Slices were prepared from the vH and fEPSPs were recorded in the CA1 region 4 weeks after the final injection day to assess persisting changes in vH function. We observed that saline conditioning results in significantly increased vH LTP (1.69 +/− 0.03) compared to behaviorally naïve mice (1.57 +/− 0.03) at this 4 week time point. A single pre-

treatment with the kappa-opioid receptor antagonist, norbinaltorphimine (norBNI; 10 mg/kg), blocks this stress-like effect associated with the conditioning protocol and results in vH LTP (1.61 +/− 0.03) that is not significantly different from the behaviorally naïve group. When norBNI is given prior to double-escalating conditioning with cocaine, we observed significantly decreased vH LTP (1.51 +/− 0.03) compared to those that received the saline vehicle ($p < .05$). Interestingly, the double-escalating/norBNI treated animals also exhibited a significant leftward shift in the stimulus-response curve of the baseline fEPSP measurements. Together, these findings are consistent with the hypothesis that a cocaine-induced enhancement of neurotransmission contributes to a partial occlusion of LTP in the vH of cocaine-exposed mice that persists 4 weeks after the final drug exposure. A separate group of norBNI/saline-treated mice showed significant improvement in a spatial working memory RAM task mice over 10 days (initial errors 1.50 +/− 0.16, final errors 0.83 +/− 0.14, $p < 0.05$) whereas norBNI/cocaine-treated mice did not show a significant improvement (initial errors 1.33 +/− 0.14, final errors 1.17 +/− 0.16). This suggests that alterations in synaptic transmission and LTP in the vH may be associated with persisting drug-induced impairments in learning and memory performance.

Title: DNMT3a in the hippocampal CA1 is critical for the acquisition of morphine self-administration in rats

Authors: *J.-J. ZHANG, F.-Z. JIANG, W. ZHENG, N. SUI
Inst. of Psychology, Chinese Acad. of Scienc, Beijing City, China

Abstract: ABSTRACT
Drug-reinforced excessive operant responding is the foundation of long-lasting addiction-like behaviors and relapse in animals. However, the unique transcriptional regulatory mechanisms responsible for the drug-specific (not natural rewards) operant behavior are not entirely clear. In this study, we established a key role for one of the *de novo* DNA methyltransferase (DNMT), DNMT3a, in the acquisition of morphine self-administration (SA) in ten weeks-old male Sprague-Dawley rats. The expression of DNMT3a in the hippocampal CA1 region but not in the

nucleus accumbens (NAc) shell was significantly up-regulated after one day and seven days morphine SA (0.3 mg/kg/infusion, n = 9-18). In contrast, saccharine SA training did not affect the expression of DNMT3a and DNMT3b (n = 6-12). DNMT inhibitor 5-aza-2-deoxycytidine (5-aza) microinjected into the CA1 region of the hippocampus significantly attenuated the acquisition of morphine SA (n = 7-12). Knockdown of DNMT3a expression impaired the ability of rats to acquire the morphine SA (n = 14-15), this manipulation also altered potential DNMT targets (*Gria2a* and *PPP1Cb*). Overall, these results suggest that DNMT3a plays an important role in the acquisition of morphine SA and may be a valid target for the treatment of morphine addiction.

Title: Remembering addictive behaviours: Effect of cocaine and nicotine conditioned context on memory formation

Authors: *M. WOLTER, E. HUFF, B. D. WINTERS, F. LERI
Univ. of Guelph, Guelph, ON, Canada

Abstract: Cocaine and nicotine enhance memory formation and thus facilitate acquisition of behaviors leading to their consumption. These behaviors, however, are also activated and maintained by environmental stimuli that have been associated with their direct effects. Hence, it is likely that cocaine- and nicotine-associated stimuli, similarly to the acute action of these drugs, can enhance memory formation. To test this hypothesis, male Sprague-Dawley rats received 5 injections of cocaine (0 and 20 mg/kg, IP) or nicotine (0 and 0.4 mg/kg, IP) in a within-subject discriminative conditioning protocol that generated a drug-conditioned context (CS+) and a vehicle-conditioned context (CS-). Post-conditioning exposure to the CS+ context in a drug-free state induced a robust conditioned locomotor response. More importantly, exposure to the CS+,

but not CS-, immediately following the sample phase of an object recognition memory task enhanced memory on a test 72 hours later. Interestingly, the magnitude of this effect was comparable to the effects of acute cocaine (5, 10 and 20 mg/kg) or nicotine (0.1, 0.2 and 0.4 mg/kg) administration. As well, the effect of post-sample exposure to the CS+, or the drugs, was lost if exposure was delayed by 6 hours. Overall, these data identify a psychological function of cocaine- and nicotine- associated stimuli that is likely to have a critical impact on the development and maintenance of addictive behaviors.

Title: Hippocampal-accumbal BDNF and extinction of morphine place preference

Authors: *M. E. LLORET[1], J. L. BARRETO-ESTRADA[2], F. J. MARTINEZ-RIVERA[2], R. N. AYALA-PAGAN[3]

Abstract: Excessive drug-seeking behaviors have been extensively associated with many molecular adaptions in the brain reward circuit. However, little is known about the impact of extinction learning in regulating the drug-induced synaptic plasticity on this circuit. We previously found that extinction of morphine-induced conditioned place preference (CPP) correlated with overexpression of Bdnf transcripts in the ventral striatum/nucleus accumbens (VS/Nac) (Martínez-Rivera et al., SFN 2016). Conversely, because the VS/NAc expresses low Bdnf levels (Allen brain atlas; Conner et al., 1997), it is possible that our results were due to changes in VS/NAc afferents such as the hippocampus, a brain region typically known by high levels of Bdnf expression (Allen brain atlas; Conner et al., 1997). Therefore, to determine possible contributions of the hippocampus, we performed western blots analysis of this brain region from rats showing 1) successful extinction, 2) extinction-failure, and 3) sham-extinction of morphine-CPP. While there were no significant differences in pro-BDNF, an increase of mature BDNF was observed in rats showing successful extinction. Together, our findings suggest that extinction learning increases hippocampal BDNF protein which could influence the

VS/Nac plasticity through its afferents. Future studies should expand protein expression to other brain areas associated to extinction of drug-seeking behaviors, such as the amygdala, and prefrontal cortex.

Title: The infralimbic prefrontal cortex is involved in the blocking effect of memory retrieval-extinction procedure on methamphetamine seeking

Authors: *Y.-Y. CHEN[1,2,3], L.-B. ZHANG[2], J. SHI[2], Y.-X. XUE[2], L. LU[2,3]

Abstract: It has been suggested that cue-exposure therapy in the clinic cannot usually prevent drug relapse when addicts return to the drug environment, which is a great hindrance to addiction treatment. In recent years, a memory retrieval-extinction procedure has been established to decrease reinstatement of cocaine, heroin and alcohol seeking, and to reduce cue-induced drug craving in heroin and nicotine addicts. The aim of the current study was to investigate the effect of memory retrieval-extinction procedure on methamphetamine relapse in rats and the underlying mechanisms. Firstly, rats that had learned methamphetamine self-administration were divided into three groups: no retrieval + extinction, retrieval +1h delay + extinction, and retrieval + 6h delay + extinction. We found that exposing rats to the retrieval manipulation 1h before every extinction session decreased the spontaneous recovery, renewal and methamphetamine-priming-induced reinstatement of methamphetamine seeking, although it had no effect on the extinction of methamphetamine seeking. Exposing rats to the retrieval manipulation 1h after every extinction session can also prevent the priming-induced reinstatement of methamphetamine seeking. In order to explore the brain mechanisms underlying the behavioral effects, we trained rats for methamphetamine self-administration and removed their brains 90 minutes after conditioned stimulus (CS) retrieval or no retrieval for detection of Fos and NeuN in

both prelimbic (PrL) and infralimbic (IL) prefrontal cortex, a brain area implicated in drug seeking. We observed significant activation of neurons in both PrL and IL after CS retrieval compared with the no retrieval group. Moreover, chemogenetic inactivation of IL but not PrL before CS retrieval blocked the effect of retrieval-extinction procedure on methamphetamine seeking. More specifically, selective inactivation of glutamatergic but not GABAergic IL neurons also blocked the effect of retrieval-extinction procedure on methamphetamine seeking. Taken together, these data suggest that glutamatergic neurons in the IL may contribute to the blocking effect of memory retrieval-extinction procedure on methamphetamine seeking in rats.

Title: Methamphetamine associated memories independently go through reconsolidation, rendering the disruptive effects of memantine on drug-paired memories to be selective

Authors: *M. HANNA, A. OSBOURNE, T. TADROS, M. JESKE, T. UNDERWOOD
Vanguard Univ., Costa Mesa, CA

Abstract: A major contributing factor to drug relapse is exposure to environmental stimuli that have been previously associated with drug administration. Exposure to such cues evokes memories of the effects of the drug and induces drug-seeking behavior. Drug associated memories go through a process of consolidation, wherein unstable memories are placed into a permanent state. When these memories are later triggered they go through reconsolidation, in which a memory becomes temporarily unstable and liable to disruption before becoming stable once again. Using the conditioned place preference (CPP) paradigm, previous research from our lab has shown that multiple injections of the NMDA receptor antagonist memantine immediately after brief exposure to a methamphetamine-paired compartment attenuated preference for the drug-associated compartment. In this study we aimed to determine the specificity of memantine in interfering with the reconsolidation of multiple drug-associated memories. We found that administration of memantine (10mg/kg) after exposure to one methamphetamine-associated compartment disrupted drug-seeking behavior for that particular compartment, but did not disrupt drug-seeking behavior for a second methamphetamine-associated compartment. Additionally, we found that exposure to a single modality, an olfactory cue, of a drug-associated memory that involved multiple modalities was sufficient to render a memory liable to

interference. Moreover, rats injected with memantine did not reinstate drug-seeking behavior when tested more than a week later, suggesting that the disrupting effects of memantine on drug-associated memories are long term.

Title: Escalating voluntary oral methamphetamine impairs hippocampal-dependent spatial memory and reduces synaptic stabilization through GSK3β signaling in females but not males

Authors: *N. MEMOS[1,2], J. A. AVILA[1,2], T. ANDRZEJEWSKI[1], F. TAVERNIER[1], O. SIDDIQUE[1], V. LUINE[1], P. A. SERRANO[1,2]

Abstract: Methamphetamine (MA) is an addictive psychostimulant producing neurodegenerative processes that impair cognition. Reports indicate that females are more susceptible to the detrimental health effects and cognitive deficits associated with MA abuse. Females are also more susceptible to drug craving, relapse, and more rapidly escalate their MA abuse. We investigated the underlying mechanisms that may contribute to the increased susceptibility associated with drug abuse in female populations using a mouse model of voluntary oral MA administration (VOMA). Our VOMA paradigm involves 10d of escalating MA doses and presentations starting with one presentation/day at 0.25 mg/kg/bait over days 1-3; 4 presentations/day at 0.25 mg/kg/bait over days 4-6; 16 presentations/day at 0.25 mg/kg/bait over days 7-8; and 16 presentations/day at 0.5 mg/kg/bait over days 9-10. On days 11-28 mice receive 1mg/kg/bait for 16 presentations/day, occurring every 15 min over 4h. Our results show that the consumption rates of MA between sexes were not different. Males consumed an average total of 156 mg/kg bw/28d (7.34 mg/kg/day over last 18d). Females consumed an average total of 181 mg/kg bw/28d (8.88 mg/kg/day over last 18d). Mice were assessed for spatial working memory performance on the radial-8 arm maze two weeks into MA abstinence, followed by hippocampal tissue dissection and preparation for western blot analyses. Our results show that MA-female mice display a significant deficit in working memory performance compared to MA-male mice. Previous work from our lab has identified MA-induced spatial memory deficits

corresponding to altered AMPA receptor expression at synaptic membranes. Accordingly, we analyzed the expression of various markers within the signaling pathways associated with AMPA receptor endocytosis. Our results show that D1, Estrogen Receptor α, phospho-AKT, and phospho-GSK3β are all reduced in MA-female compared to MA-male mice. Reduced expression of these markers is known to increase GSK3β activation, promoting AMPA receptor endocytosis and the destabilization of the post-synaptic density via PSD95 phosphorylation. These results suggest that VOMA induces GSK3β activity in female mice that results in decreased proliferative signaling in the hippocampus and provides a molecular framework for female-specific susceptibility to psychostimulant-induced behavioral deficits. Current work is examining the balance of neuroprotective and neurodegenerative molecular signaling in the context of this model. Future work will determine the time course and shifts in neurodegenerative and neuroprotective signaling resulting from MA and other drugs of abuse.

Title: Activity changes and Perineuronal nets characterization around cerebellar Golgi cells in cocaine-induce preference memory

Authors: *J. GUARQUE-CHABRERA[1,2], I. GIL-MIRAVET[2], A. SANCHEZ-HERNANDEZ[2], M. MIQUEL[3]
[1]Área de Psicobiología, Univ. Jaume I, Castellon de la plana, Spain; [2]Área de Psicobiología, Univ. Jaume I, Castellon, Spain; [3]Área de Psicobiología, Univeritat Jaume I, Castellon, Spain

Abstract: Human studies in drug addicts show that the prefrontal cortex and cerebellum might work in a competitive manner during reward tasks. Also, prefrontal impairment is accompanied by cerebellar hyperactivation. Hence, it seems that the cerebellum would acquire a higher functional relevance when the prefrontal function is compromised by disease or chronic drug use. Perineuronal nets (PNNs) are cartilage-like structures of extracellular matrix molecules (hyaluronan and hyaluronan synthases, chondroitin sulfate proteoglycans, tenascins, and link proteins) that enwrap in a net-like manner the cell-body and proximal dendrites of special subsets of neurons. PNNs stabilize their incoming connections and restrict plasticity, consequently, they have been proposed as a candidate mechanism for learning and memory storage. Indeed, PNNs

are considered to contribute to the maintenance of drug-induced conditioned memories after prolonged drug abuse. In the cerebellum, PNNs surround both inhibitory and excitatory neurons in the DCN but only inhibitory Golgi cells in the cerebellar cortex. Previous studies from the lab showed that either the deactivation of the infralimbic cortex (IL) or a lesion in the dorsal cerebellum promote preference towards cocaine-associated cues and regulates the expression of PNNs in the distal structure. Therefore, both areas seem to be part of a functional and structural network which would work on restraining goal-directed behavior when drug-cue associations are acquired.
The present research aimed to assess activity changes around Golgi PNNs in the dorsal cerebellum after an infralimbic deactivation in animals trained to acquire cocaine-induced preference conditioning. We used vGluT1, vGluT2, VGAT, and calretinin expression to estimate changes in neural activity. Also, we used synapsin I and PSD-95 to assess active synaptic contacts. Moreover, we phenotyped Golgi cells expressing PNNs using WFA, mGluR2, GlyT2, and neurogranin to determine whether there is a special population of Golgi cells that express PNNs. Our results showed that the IL deactivation increased selectively vGlut2-but not vGlut1-mediated activity around cerebellar Golgi cells' PNNs in the dorsal cerebellum. Neither VGAT nor calretinin activity seemed to be mediated by the IL deactivation. In this manner, the IL impairment would increase cerebellar activity throughout vGlut2 activity. These findings suggest that the IL has the capacity to regulate activity in the dorsal cerebellar cortex.

Abstract: Drug addiction is a chronic relapsing disorder characterized by compulsive drug use. While significant resources have been dedicated to reveal neurobehavioral factors that promote drug relapse, this strategy has yet produced an effective treatment against relapse. Here we employed a different strategy by examining factors that suppress - rather than promote - relapse. Adapting Pavlovian procedures to suppress operant drug response, we determined the anti-relapse action of environmental cues signaling drug omission (*un*availability) in rats. Under conditions linked to compulsive drug use and heightened relapse risk, omission cues suppressed all three major modes of relapse-promotion (drug-predictive cues, stress, and drug exposure) across two major classes of abused drugs (cocaine and alcohol), thus establishing the translational relevance of the present approach. This relapse-suppression is, in part, driven by a functional unit of omission cue-reactive neurons (neural ensemble) in the infralimbic cortex comprised of distinct cellular phenotypes. Further studies of such anti-relapse neural ensembles, as well as ensemble-specific brain processes, may improve addiction medicine through functional characterization of druggable targets for relapse prevention.

Title: Extended access to methamphetamine self-administration-induced greater propensity for relapse in male Long Evans rats is predicted by neuroadaptations in the dentate gyrus

Authors: J. TSENG[1], M. J. FANNON[2], M. J. TERRANOVA[1], D. PUROHIT[1], L. W. QUACH[1], K. K. KHARIDA[1], R. OLIVER[2], C. D. MANDYAM[1,2], *Y. TAKASHIMA[1]

Abstract: The present study examined gender differences in methamphetamine (Meth; 0.05 mg/kg, i.v.) self-administration in adult Long Evans male and female rats during distinct phases of Meth addiction. Our findings demonstrate that females responded more than males during self-administration in an extended access paradigm. However, males and females demonstrated escalation in Meth intake with significant differences in latency to escalate. Following protracted abstinence, females show reduced spontaneous reinstatement during extinction, and have greater latency to extinguish compared with males. After extinction, females demonstrated lower context-driven reinstatement compared to males. Our findings demonstrate that Meth-addicted phenotype can be modeled in rats based on gender differences in preferred levels of Meth intake and a propensity for relapse in withdrawal. Moreover, using whole-cell patch-clamp recordings, intrinsic excitability of dentate gyrus (DG) granule cell neurons (GCNs) were recorded in acute brain slices from Meth naïve (controls) and Meth experienced male and female rats. Reinstatement of Meth seeking reduced spiking capability in GCNs compared to controls in males, an effect that was not evident in females, demonstrating distinct functional neuroadaptations in males and females GCNs. In male rats that reinstated Meth seeking, these altered electrophysiological properties of GCNs were associated with enhanced expression of plasticity-related proteins including GluN2A, CaMKII, and PSD95 and reduced expression of pGluN2B and GABAA subunits in the DG. In females, reduced reinstatement of Meth seeking correlated with reduced expression of pGluN2A and enhanced expression of pCaMKII. The alterations in functional properties of GCNs and plasticity related proteins in the DG paralleled with no significant changes in structure of microglial cells in the DG and mossy fiber projections in the DG. Taken together, our results demonstrate that enhanced reinstatement of Meth seeking results in alterations in intrinsic spiking in the GCNs and concomitant increases in expression of GluNs and decreases in GABAA subunits that may contribute to the altered synaptic connectivity-neuronal circuitry-and activity in the hippocampus, and enhance propensity for relapse in male rats. The present results highlight the importance of including sex as biological variables in exploring individual differences in Meth addiction-like behavior.

Title: The effect of nonmuscle myosin II inhibition on polydrug memories and reconsolidation

Authors: *M. HAFENBREIDEL[1], S. B. BRIGGS[1], E. J. YOUNG[1], G. RUMBAUGH[2], C. A. MILLER[1]
[1]Neuroscience; Mol. Med., [2]Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Substance use disorder (SUD) is maintained by long-lasting drug-cue memories, which can promote relapse. Persistent drug-associated memories are maintained, at least in part, by learning-induced, actin-dependent changes to the structure and stabilization of dendritic spines. We previously reported that depolymerizing actin with the nonmuscle myosin II inhibitor Blebbistatin (Blebb) disrupts methamphetamine (METH)- and amphetamine-associated memories. This disruption is immediate, retrieval-independent, specific to the basolateral amygdala (BLA), and selective, as Blebb does not have an immediate effect on fear-, food-, cocaine (COC)-, or morphine-associated memories. However, it was unclear if Blebb treatment would disrupt memories of other amphetamine class drugs. Thus, we first examined if Blebb could disrupt mephedrone (bath salts)-associated memories, as well as those associated with nicotine (NIC), as that had yet to be established. Using the CPP paradigm, we found that Blebb failed to disrupt NIC- or mephedrone-associated memories during the first test. However, similar to our findings with COC, reconsolidation of both drug memories was disrupted. To further examine this possibility, we are currently determining Blebb's ability to disrupt reconsolidation of a contextual COC-associated memory in the self-administration paradigm. Moreover, many individuals abuse multiple drugs (e.g., METH and NIC), but it was unknown if Blebb could disrupt polydrug memories, or if the inclusion of another substance would render Blebb no longer able to disrupt METH-associated memories. We found that NIC/METH- or morphine/METH-associated memories were rendered susceptible to Blebb disruption. Finally, we determined the effect of Blebb on drug/fear memories to assess dual memories composed of positive and negative valence. Interestingly, we found that METH or COC administration before fear conditioning resulted in attenuate freezing during a subsequent retention test. However, this affect was reversed in Blebb-treated mice given METH, but not COC. These results demonstrate that the inclusion of fear conditioning with METH administration did not render the fear memory susceptible to Blebb disruption, but did reinforce previous findings that Blebb treatment is selective for METH-associated memories. Substances are rarely used in isolation, and the recent resurgence of METH use in combination with other substances like opioids, indicates an important need to determine the mechanisms underlying polydrug memories for the development of novel therapeutics, in addition to developing further application of Blebb's therapeutic potential.

Title: Cue-elicited approach is associated with sensitivity to D1- and D2-like receptor agonists

Authors: *J. A. TRIPI, P. J. MEYER
Psychology, Univ. at Buffalo Dept. of Psychology, Buffalo, NY

Abstract: There are substantial individual differences in the ability of reward-associated stimuli ("cues") to elicit approach and control motivated behavior. For example, we have shown that rats trained in a Pavlovian conditioned approach paradigm approach either the cue itself ("sign-tracking") or the reward delivery location ("goal-tracking"). Others have shown that learning to sign-track, but not learning to goal-track, is dependent on dopamine neurotransmission (Flagel et al. 2011), and that "sign-tracker" rats (STs), compared to "goal-trackers" (GTs), have differences in D1-like and D2-like dopamine receptors before and after conditioning (Flagel et al. 2007). Furthermore, we have shown that sign-trackers emit more cocaine-induced ultrasonic vocalizations (USVs) than goal-trackers, but do not differ in cocaine-induced locomotion (Tripi et al., 2017). The objective of this study was to determine whether sensitivity to dopamine receptor stimulation is associated with sign- and goal-tracking. To test this, we measured locomotor sensitivity to the D1- and D2-like receptor agonists quinpirole (0, 0.1, 0.3, 1 mg/kg; *s.c.*) and SKF-82958 (0, 0.1, 1mg/kg *i.p.*) in STs, GTs, and intermediate rats (n=48 total). We also measured cocaine-induced (10 mg/kg, *i.p.)* USVs and locomotion in these same animals. Results indicated that STs were more sensitive to SKF-82958-induced locomotion at the 1 mg/kg dose ($p < 0.01$), but not to quinpirole. However, when sensitivity to both agonists were considered together, rats that were highly sensitive to both quinpirole and SKF-82958 (as determined by median splits) sign-tracked more and goal-tracked less than rats that were sensitive to only one or neither agonist ($ps < 0.05$). Finally, while quinpirole sensitivity was positively associated with cocaine-induced locomotion, sensitivity to either agonist was unrelated to cocaine-induced USVs. These data suggest that D1- and D2-like receptors promote sign- and goal-tracking in an additive fashion. In contrast, cocaine-induced USVs, while strongly associated with sign-tracking, are not related to sensitivity to the agonists used in this study.

Title: mRNA expression of immediate early genes in the rat hippocampus during compulsive methamphetamine self-administration in the presence of punishment

Authors: *S. JAYANTHI[1], J. A. HERNANDEZ[2], L. CONTU[2], M. T. MCCOY[2], B. LADENHEIM[2], M. JOB[2], J. L. CADET[3]
[1]Mol. Neuropsychiatry Br., NIDA-IRP, Baltimore, MD; [2]Natl. Inst. on Drug Abuse, Baltimore, MD; [3]Mol. Neuropsychiat Br., NIH, Baltimore, MD

Abstract: Methamphetamine (METH) addiction is a serious problem with 24.7 million abusers worldwide. METH addicts experience complex psychological symptoms that are accompanied by cycles of abstinence and relapses. Maintenance of METH addiction may depend on epigenetic and transcriptional adaptations in various brain regions including the hippocampus that plays integral roles in memory formation. Nevertheless, because investigations of drug-induced neuroadaptations have focused on the nucleus accumbens, very little is known about the consequences of METH intake in the hippocampus. As a first step towards to elucidate potential involvement of the hippocampus in METH self-administration, we have quantified the mRNA expression of immediate -early genes (IEGs) in that structure. To mimic METH addiction, we used a rat model of METH self-administration (SA) wherein animals were initially divided in three groups: control (CT), saline yoked-shock (YS), and METH groups. Rats were trained to self-administer METH or saline during three 3-h sessions/day with a 30 min off interval between sessions for a total of 21 days. METH-trained rats escalated their intake of the drug during self-administration. Thereafter, lever presses for METH were punished by mild foot-shocks for 8 days (0.18-0.36 mA). The shocks led to the segregation of the METH-trained animals into two phenotypes: one METH group continued to compulsively press the lever for METH (shock-resistant, SR), whereas the other group progressively decreased their intake (shock-sensitive, SS) because of the footshocks. Groups of saline SA rats were also yoked to the METH groups so that they received footshocks at the same time as METH SA rats received shocks. Rats were euthanized 2 hours after the last METH plus shock session and quantitative PCR was used to measure mRNA in the rat hippocampus. We found that, in comparison to control and sensitive rats, resistant rats exhibited increased mRNA expression of members of *fos* (*c-Fos, fosB,* and *Fra2*), *jun* (*JunB*), *egr* family (*Egr1* and *Egr2*) and (*Nr4a1* and *Nr4a3*) families of IEGs as

compared to control and SS rats. Altered mRNA expression in the hippocampus suggests their involvement in memory mechanisms that may, in part, be responsible for the neuroadaptive changes that mediate some aspects of repeated relapses. Title: Escalating voluntary oral methamphetamine administration induces resilience in male mice through GSK3beta signaling

Authors: *A. ASLAN[1], J. A. AVILA[1,2], T. ANDREJEWSKI[1], F. TAVERNIER[1], A. TANG[1], P. A. SERRANO[1,2]
[1]Dept. of Psychology, Hunter College, City Univ. of New York, New York, NY; [2]Psychology, The Grad. Ctr. of the City Univ. of New York, New York, NY

Abstract: Methamphetamine (MA) is a neurotoxic psychostimulant of abuse that produces neurodegenerative processes that impair cognition. We previously characterized a novel voluntary oral methamphetamine administration (VOMA) model that produced neurotoxic effects in the hippocampi of male mice and learning and memory deficits on the radial arm maze (Avila et. al, 2018). Subsequently, we aimed to characterize the higher limits of voluntary consumption through an escalating dose model of VOMA (E-VOMA). We hypothesized initial restriction to MA access would offer neuroprotection to chronic administration of the drug. Our previous work revealed that male mice on static dose VOMA (S-VOMA), who received 1 mg/kg/bait for 16 presentations/day over 28d, consumed 5.23 mg/kg bw/day, with an average total of 146 mg/kg bw. Male mice that received 10d of E-VOMA started with one presentation/day at 0.25 mg/kg/bait over days 1-3; 4 presentations/day at 0.25 mg/kg/bait over days 4-6; 16 presentations/day at 0.25 mg/kg/bait over days 7-8; and 16 presentations/day at 0.5 mg/kg/bait over days 9-10. On days 11-28 these mice received 1mg/kg/bait for 16 presentations/day. E-VOMA male mice consumed 7.34 mg/kg/day over days 11-28, with an average total of 156 mg/kg bw. Despite a shift in consumption rates, total MA consumed was not

statistically different between groups. Two weeks into MA abstinence, spatial memory assessments on the RAM revealed a significant working memory deficit for male mice on S-VOMA. However, E-VOMA did not produce a working memory deficit in male mice. Western blot analyses of hippocampi collected following radial arm maze assessments revealed that S-VOMA produces a lasting neuroinflammatory response via COX-2 and GFAP, a result not present in E-VOMA mice. Furthermore, GSK3β-phosphorylation was increased in E-VOMA mice, suggesting increases in proliferative and pro-plasticity signaling. The inactivation of GSK3β via ser9 phosphorylation is essential to the expression of pro-growth activity and the inhibition of pro-apoptotic signaling involving COX-2 and GFAP. Finally, D1 receptor and Estrogen Receptor α expression are both increased in E-VOMA mice, revealing the upstream mechanisms underlying E-VOMA induced neuroprotection via GSK3β phosphorylation. Our data have revealed a role for gradual escalation of psychostimulant exposure in priming neuroprotective pathways in the brain. Current work is examining AMPA receptor trafficking and stabilization regulated by GSK3β signaling in the context of different VOMA models.

Title: HDAC3 regulation of cocaine-induced plasticity and cocaine-associated learning in nucleus accumbens cell subtypes

Authors: *R. R. CAMPBELL[1], E. A. KRAMAR[2], A. J. LOPEZ[2], D. P. MATHEOS[2], T. J. HEMSTEDT[2], M. A. WOOD[2]
[2]Neurobio. and Behavior, [1]Univ. of California, Irvine, Irvine, CA

Abstract: Cocaine exposure alters molecular and cellular mechanisms within the nucleus accumbens (NAc) that leads to the formation of context-drug associations that are critical for drug-seeking. Although the activity of the two major cell subtypes within the NAc, cells expressing dopamine D1- (D1R) vs D2-receptors (D2R), exert opposing effects on cocaine-related behaviors, the molecular mechanisms underlying these differences are unclear. Prior work from our lab demonstrates that the histone deacetylase HDAC3 within total NAc regulates cocaine-induced enhancements in gene expression and cocaine-associated memory formation. Additionally, we have shown that deletion of HDAC3 within the NAc increases gene expression

of the transcription factor Nr4a2 following the acquisition of cocaine-associated memory. NR4A2 is essential for dopaminergic neuronal differentiation and survival during development, and necessary for long-term memory in the adult brain. Although there is evidence to suggest that Nr4a2 is differentially regulated following exposure to chronic cocaine, how it may act to promote drug-seeking behaviors in these cell types remains unknown. Here, we have examined HDAC3-regulation of Nr4a2 expression within D1R- vs D2R-containing cells of the NAc following cocaine-conditioning. In addition, we have investigated the role of HDAC3 within D1R vs D2R containing cells in cocaine-induced synaptic plasticity. Lastly, we have examined the role of HDAC3 role within D1- and D2-containing cells of the NAc in cocaine-associated memory formation. Together, these results elucidate a mechanism by which HDAC3 may be regulating key downstream target genes, like Nr4a2, during cocaine exposure that leads to persistent changes in neuronal function and ultimately behavior.

Col. of Physicians and Surgeons, New York, NY

Abstract: Epigenetic mechanisms lead to persistent changes at the cellular level that can ultimately result in long-lasting behavioral adaptations. Nucleosome remodeling is a major epigenetic mechanism that has not been well explored with regards to drug-associated memories. Nucleosome remodeling is carried out by multi-subunit complexes that interact with DNA or

chromatin structure and possess an ATP-dependent enzyme to disrupt nucleosome-DNA contacts and ultimately regulate gene transcription. Calcium RESponsive Transactivator (CREST) is a transcriptional activator that interacts with enzymes involved in both histone acetylation and nucleosome remodeling. In these experiments, we investigated the effects of knocking down CREST in the nucleus accumbens (NAc) core on drug-associated memory and synaptic plasticity. To examine the role of CREST in the NAc core, C57BL/6J mice or Long Evans rats received infusions of either Morpholino or small interfering RNAs (siRNA) targeted against CREST. Conditioned place preference (CPP) was used to study cue-elicited context preference. Knocking down CREST in the NAc core resulted in impaired cocaine-associated CPP memory and deficits in theta-induced long-term potentiation (LTP) in the NAc core. Further, similar to the CPP findings, using a self-administration paradigm, we found that CREST knockdown in the NAc core of rats had no effect on instrumental responding for cocaine itself on a first-order schedule, but did significantly attenuate responding on a second-order chain schedule, in which responding has a weaker association with cocaine. Together, these results suggest that CREST in the NAc core is required for cocaine-associated memories as well as synaptic plasticity.

Title: Place-conditioning phenotype predicts methamphetamine self-administration behavior in male, but not in female, C57BL/6J mice

Authors: *C. N. BROWN, A. PAGE, E. K. FULTZ, J. SHAHIN, A. F. HEALY, T. E. KIPPIN, K. K. SZUMLINSKI
UCSB Psychological and Brain Sci., Santa Barbara, CA

Abstract: Understanding the genetic, molecular and cellular mechanisms underpinning individual variance in drug-taking behavior and addiction vulnerability requires the development of validated, high throughput screens that are amenable to the study of large numbers of animals. To this end, our laboratory demonstrated previously that the direction and magnitude of methamphetamine (MA)-induced place-conditioning predicts the propensity to acquire oral MA self-administration, as well as the efficacy of MA to serve as a reinforcer in male C57BL/6J mice. To date, it is not known whether or not behavior manifested under simple MA-induced

place-conditioning procedures predicts subsequent MA self-administration in female mice. To examine this issue, adult female C57BL/6J mice were underwent a 4-day MA conditioning procedure in which they were injected with saline and confined to one compartment of a 2-compartment apparatus in the mornings. Approximately 4-5 hours later, the mice received an injection of 2 mg/kg MA and were confined to the opposite compartment. Then mice were tested for the expression of place-conditioning in a drug-free state. Then mice were trained to nose-poke for delivery of a 20 mg/L MA solution under FR1 to FR5 schedules of reinforcement, followed by dose-response testing (5-160 mg/L MA). As observed in males, the majority of females tested to date (57%) exhibited a conditioned place-preference (> 100 sec in the MA- versus saline-paired compartment), while 33% of the mice were MA-ambivalent and a minority (16%) exhibited a conditioned place-aversion (greater than 100 sec in the saline- vs. MA-paired compartment). However, unlike males, the place-conditioning phenotype did not relate to MA-reinforced nose-poking behavior or MA intake at any point during training or dose-response testing in female subjects. While only one MA-conditioning dose has been assayed to date, these data indicate that sex does not majorly shift the proportion of C57BL/6J mice that perceive MA's interoceptive effects as positive, neutral or aversive. However, a sex difference exists in the predictive relation between the motivational valence of MA and subsequent drug-taking behavior, with females exhibiting MA-taking behavior and reinforcement, despite their initial perception of this stimulant's interoceptive effects as neutral or aversive. Future studies seek to understand the role for ovarian hormones in regulating the motivational valence of MA in females as it relates to subsequent drug-taking behavior and relapse-related behaviors.

Title: Binge-drinking history augments the positive subjective effects of methamphetamine in both male and female C57BL/6J mice

Authors: *C. L. JIMENEZ CHAVEZ, E. K. FULTZ, K. R. SERN, K. K. SZUMLINSKI
Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: A high degree of co-morbidity exists between methamphetamine (MA) addiction and alcohol use disorders and sequential alcohol-MA mixing increases risk for coabuse. As little preclinical work has focused on the biobehavioral interactions between MA and alcohol within the context of animal models of drug reward, we tested the effects of a prior history of binge-drinking (14 days of 2h-access to 5, 10, 20 and 40% alcohol) upon the perception of MA's subjective effects as either appetitive or aversive using place-conditioning procedures in C57BL/6J mice. As female mice tend to binge-drink more alcohol than males and female rodents tend to be more sensitive than males to the psychomotor-activating properties of MA, we compared the dose-response functions for MA-induced place-conditioning (4 pairings of 0.25, 0.5, 1, 2, or 4 mg/kg IP) between male and female mice. As expected, female mice binge-drank more alcohol than males over the course of the 14-day drinking period and exhibited higher levels of MA-induced locomotion during the conditioning sessions. Interestingly, despite these sex differences, no sex difference was apparent in the shift upwards in the dose-response function for MA-induced place-conditioning produced by a prior history of binge-drinking. Further, no sex difference was apparent in the potentiation of locomotor sensitization elicited by the mid-range MA doses observed in binge-drinking animals. These data extend prior observations from males that a binge-drinking history heightens the positive subjective effects of MA to females and argue that sex does not contribute majorly to this alcohol-MA interaction. If relevant to humans, these data argue that both males and females with a prior binge-drinking history are similarly vulnerable to MA abuse and it remains to be determined whether or not the neural substrates underpinning this increased vulnerability reflect common or sex-specific adaptations in reward-related brain regions.

Title: ERK activation within the medial prefrontal cortex regulates the positive motivational valence of methamphetamine in mice

Authors: *E. K. FULTZ[1], K. K. SZUMLINSKI[2]
[1]Dept. of Psychological & Brain Sci., Univ. of California - Santa Barbara, Santa Barbara, CA; [2]Univ. California-Santa Barbara, Santa Barbara, CA

Abstract: While illicit methamphetamine (MA) abuse remains a significant public health concern, the neurobiological mechanisms driving MA addiction remain largely unexplored. Prior unpublished data from our laboratory suggested a positive correlation between conditioned place-preference (CPP) scores in C57BL/6J mice and increased pERK:ERK expression within the medial (mPFC), where high methamphetamine place-preferring mice predicted increased ERK activity. A follow-up experiment sought to elucidate the role of mPFC ERK in the positive motivational valence of MA. For this, adult, male C57BL/6J mice were surgically implanted with bilateral guide cannulae aimed over the mPFC. Following recovery, mice underwent place-conditioning procedures (4 pairings of 2 mg/kg) and the presence of a CPP was verified in a drug-free state. Then, mice were examined for changes in CPP magnitude in a series of additional tests, immediately prior to which animals were infused with different doses of the MEK inhibitor U0126 (0, 1, 10 and 100nM) into the mPFC. Mice were infused with one U0126 dose per day, with the order of dosing counterbalanced across days. To control for the effects of repeated microinjections upon the magnitude of a CPP, a group of control mice received only saline microinjections. Microinjections of saline vehicle into the mPFC did change place-preference scores, even with repeated testing. In contrast, U0126 dose-dependently reduced the magnitude of the CPP, with the highest U0126 doses blocking the conditioned response. This effect was observed despite no U0126-induced change in locomotor activity during testing. These results provide novel evidence that ERK activity within the mPFC is key in regulating the positive subjective effects of MA, and implicate ERK hyperactivity within mPFC as a pathological state driving enhanced sensitivity to MA reward.

Title: Role of basolateral amygdala in context-induced the reinstatement of alcohol seeking after punishment-imposed abstinence

Authors: *T. S. YOKOYAMA[1], J. MOREIRA[2], R. A. MAEDA[2], P. PALOMBO[2], C. R. ZANIBONI[2], P. C. BIANCHI[3], R. M. LEÃO[4], F. C. CRUZ[2]
[1]Pharmacol., Univ. Federal of São Paulo, Suzano, Brazil; [2]Pharmacol., Univ. Federal of São Paulo, São Paulo, Brazil; [3]UNESP - State Univ. of São Paulo, Araraquara, Brazil; [4]Univ. Federal of Bahia, Salvador, Brazil

Abstract: Introduction: Alcohol addiction is a chronic relapsing brain disease. About 80% of patients relapse to alcohol use during the treatment. The main risk factor to relapse in human addiction is exposure to environmental cues that were previously associated with alcohol use. The basolateral amygdala (BLA) has been involved in cue-induced relapse to drug seeking. However, the role of this subregion in context-induced alcohol seeking is not completely understood. **Objective:** We investigated whether context-induced reinstatement of alcohol seeking after punishment-imposed abstinence, would be mediated by activation the basolateral amygdala. **Material and methods:** We trained male Long-Evans rats to self-administration ethanol in context A and extinguished the lever pressing under a punishment protocol in a distinct context B. In the extinction phase, for one group, alcohol-reinforced response was punished by adding quinine in the alcohol solution; two other groups either received a solution of quinine without alcohol or water. On the test day, context-induced reinstatement of alcohol seeking was tested by placing rats back in the drug-paired context (A). We also determined the effect of context-induced alcohol seeking on Fos expression in BLA. **Results:** In context B, animals that received alcohol+quinine were more resistant to suppression of alcohol-taking behavior than the quinine or water group (average of active lever presses in the 7 first extinction session: alcohol+quinine 125±20; quinine 94±26; water 90±9).
However, the reinstatement of alcohol self-administration induced by contextual cues was not different among the groups (lever pressing in context A or B respectively: alcohol+quinine 35±11 and 22±7; quinine 34±3 and 11±2; water 33±6 and 28±7).
Moreover, context-induced reinstatement of alcohol seeking after punishment-imposed abstinence was associated with increased Fos expression in BLA (Fos expression on context A or B respectively: alcohol+quinine 97±6 and 20±2; quinine 82±1 and 57±4; water 63±9 and 30±2).
Conclusion: Our results suggest that our procedure can be used as model to study context-induced relapse to alcohol seeking after alcohol-taking to have been suppressed by adverse consequences. We also found that activation of the BLA is correlated with context-induced alcohol seeking after punishment-imposed abstinence.

Title: biperiden reduces drug reward effects

Authors: *P. PALOMBO[1], R. A. MAEDA[1], S. A. ENGI[1], P. C. BIANCHI[2], C. ZANIBONI[1], T. YOKOYAMA[1], P. C. J. D. SANTOS[1], J. C. F. GALDUROZ[3], F. C. CRUZ[1]

Abstract: Recent studies suggest that nicotinic and muscarinic cholinergic receptor mediate dopamine release in the mesolimbic system and can alter the drug's reinforcing value. It was demonstrated that systemic treatment with the biperiden, a muscarinic cholinergic (*M1)* antagonist receptor blocked the expression of cocaine conditioned place preference (CPP) in mice. Here, we examine the effect of systemic biperidene injection (1, 5 and 10mg / kg ip) on alcohol conditioned place preference. The CPP procedure consisted of the following phases: habituation, conditioning and testing. It was used a three-chamber 'unbiased' apparatus. During the habituation, each male Swiss mouse was placed in the neutral compartment with the guillotine doors removed to allow access to the entire apparatus for 15 min for 3 days. On day 3, mice were placed in the apparatus the time spent in each compartment was recorded. For conditioning, mice were randomly paired to alcohol or saline administration. Conditioning was performed using a protocol consisting of 8 injections of 2.0 mg/kg i.p. of alcohol or saline over 8 alternate and consecutive days. The test was conducted 24 h after the last conditioning session. Thirty minutes before the test mice were grouped in 4 groups and were injected with biperiden at the doses of 1 or 5 or 10 mg/kg and were placed in the neutral compartment with the guillotine doors removed to allow access to the entire apparatus. The time spent in each compartment was recorded for 15 min. Biperiden 10 mg/kg blocked the alcohol CPP expression (Saline: pretest - 35.20% ± 0.02; test - 59.61 ± 0.04; Bip 1mg/Kg: pretest - 34.55% ± 0.03; test - 48.71% ± 0.14; Bip 5 mg/Kg: pretest - 35.17% ± 0.02; test - 50.51% ± 0.03; Bip 10 mg/Kg: pretest - 33.18% ± 0.03; test: 45.28% ± 0.02; $p<0.05$). Our results add to growing evidence that biperiden might be a promising drug for drug addiction treatment.

Title: The influence of ventral striatum direct pathway on alcohol context-induced reinstatemet: Functional and molecular findings

Authors: *C. R. ZANIBONI, III, J. MOREIRA, P. PALOMBO, T. YOKOYAMA, R. MAEDA, F. C. CRUZ
Pharmacol., Univ. Federal De São Paulo - UNIFESP, Sao Paulo, Brazil

Abstract: Alcohol addiction is a world health problem and is associated with a higher rate of relapse during the treatment. Learned associations play a significant role in addiction. The nucleus accumbens direct and indirect pathway have been implicated in learning associations between contextual cue and drug reward effects. However, the precise mechanisms that underlie these functions remain unclear. Here, we studied the role of projections to substantia nigra reticulate (SNr) from nucleus accumbens (NAc) in context-induced relapse to alcohol-seeking. For this propose, male Long-Evans rats were trained to self-administrate ethanol in context A and extinguished lever pressing in a distinct context B. On the test day, the context-induced reinstatement of ethanol seeking was tested in the ethanol context (A). First, we measured the neuronal activity marker Fos in the SNr. Next, we used an anatomical asymmetrical disconnection procedure to demonstrate the role of the projections from NAc to SNr (direct pathway) in context-induced relapse to alcohol seeking. In this procedure, rats were ipsilateral cannulated into NAc and SNr and, 10 minutes before the test, received microinjections of saline or $CoCl_2$ on SNr and SCH23390 (D1 antagonist) on NAc to block this pathway (Experiment 2). Context-induced reinstatement of alcohol seeking was associated with decreased Fos expression in SNr neurons (Fos expression on context Homecage, B and A respectively Mean±SEM: 8.14±3.32; 7.33±2,0; 15.36±3.67). Further, Injections of D(1)-family receptor antagonist SCH 23390 into NAc and $CoCl_2$ into SNr decreased context-induced reinstatement (Mean±SEM - Active bar press SCH23390/CoCl 2: 0.6667 ± 0.3333 x Active bar press Saline: 44.00 ± 9.866; $p \leq 0,05$). Our results suggest the involvement of nucleus accumbens direct pathway in context-induced reinstatement of alcohol seeking behavior

Title: Neurons in the nidopallium caudolaterale (NCL) and entopallium (ENTO) of pigeons (Columba livia) convey category information in a discrimination task between Picasso and Monet paintings

Authors: *C. ANDERSON, R. S. PARRA, M. COLOMBO
Univ. of Otago, Dunedin, New Zealand

Abstract: In 1995, Watanabe and colleagues demonstrated that pigeons could successfully discriminate between Picasso and Monet paintings, and even generalise this discrimination to other cubist and impressionist paintings. To add to the behavioural findings of Watanabe et al. (1995), we recorded neural activity via single-unit electrophysiology while pigeons performed a similar task to that of Watanabe et al. (1995). The avian nidopallium caudolaterale (NCL) is generally considered to be an analogue of primate pre-frontal cortex (PFC). Both PFC and NCL have been implicated in categorisation behaviour (i.e. Kirsch et al., 2009; Freedman et al., 2001). The avian entopallium (ENTO) is a higher-order visual area that is thought to be similar to striate cortex in primates, and is also involved in categorical processing in birds based on lesion studies (see Watanabe 1991; 1996). We recorded from the NCL and ENTO of four birds during a Picasso/Monet painting discrimination task similar to that of Watanabe et al. (1995). Half the birds were trained with Monet paintings as the S+, and the other half were trained with Picasso paintings as the S+. Pigeons were required to peck the S+ stimulus in order to receive a food reward, but refrain from pecking the S- stimulus, which was never rewarded. We found that for both NCL and ENTO, cells in the left hemisphere appeared to carry category-relevant information, as there was a significant difference in activity from baseline inter-trial interval activity for both S+ and S- stimuli. There was also a significant difference between activity to the S+ and the S- minus stimuli, with more activity occurring when the S+ stimulus was presented than when the S- stimulus appeared. Furthermore, we found that reward-related activity was present in the NCL, but not in ENTO. In NCL, activity during the reward period also deviated from baseline levels, and was also significantly different between S+ and S- trials.

Title: A 4-Hz oscillation in the prefrontal cortex and in the accumbens nucleus characterizes prosocial but not food rewards in rats

Authors: *F. ROCHA-ALMEIDA, A. CONDE-MORO, J. DELGADO-GARCÍA, A. GRUART
Div. of Neurosciences, Univ. Pablo De Olavide, Seville, Spain

Abstract: As a basic physiological need, food is a natural reward used in many experimental procedures with rodents to study learning processes or decision-making abilities. On the other hand, social interactions also play an important role in the good development of these species and it could be used as a positive reinforcement. The main goal in this study was to determine rat's preferences and to study the local field potentials (LFPs) in selected cortical and subcortical brain structures when presented with these two types of reinforcements: food or social interactions. For this aim, we used two modified and adjacent Skinner boxes divided into two equal-size compartments separated by a guillotine door. One of these Skinner boxes had two available levers: one lever that, when pressed, provided access to food pellets, with a 1:1 fixed ratio schedule; and another lever that, when pressed, allowed 10 s of visual and partial physical contact with another rat located in the adjacent box. To increase the needs for social interactions, selected rats were fed *ad libitum* and were placed in social isolation for one month. Rats were implanted with recording electrodes in the medial prefrontal cortex (mPFc), the accumbens septi (NAc) nucleus, the mediodorsal thalamic (MD) nucleus and the hippocampal CA1 area (CA1). It is well known that all these brain areas are related to motivational circuit loops, including reward-related phenomena, appetitive, and decision-making processes in rodents. Our results showed a preference for the food reward in all rats, but the social isolation helped to increase the number of lever presses to obtain a social interaction. The analysis of recorded LFPs showed the presence of different peaks in the spectral power in the delta range (1.5 - 4 Hz) of frequencies, for the two rewards. The dominant spectral power during eating (~3 Hz) seems to be lower than the one present (~ 4 Hz) during social interactions. These slow oscillations are particularly present in the mPFc and in the NAc. In addition, the spectral power in the theta band was significantly higher when interacting with the other rat than when eating. The hippocampal CA1 area presented a dominant 8-Hz rhythm when the animal was moving during the social interaction, but decreased during eating, because of its immobility. The MD nucleus presented two dominant peaks at 3-4 Hz and ~ 8 Hz reflecting mPFc and hippocampal activities. In conclusion, both the mPFc and NAc seem to be directly involved in decision making responses and their LFPs present specific dominant frequencies for social versus food rewards.

Title: Establishing a role for ACC in the modulation of directionally selective neurons in DMS in rats performing a stop-change task

Authors: *A. T. BROCKETT[1,2], S. S. TENNYSON[1,2], F. GAYE[1], M. R. ROESCH[1,2]
[1]Psychology, [2]Program in Neurosci. and Cognitive Sci., Univ. of Maryland, Col. Park, College Park, MD

Abstract: Cognitive control, or the ability to flexibly adjust behavior in accordance with internally maintained goals, while simultaneously suppressing more automatic responses that distract from this goal, is an essential component of cognition and is often diminished in patients with schizophrenia and depression (Kollings et al., 2016; Shenhav et al., 2016). The neuroimaging literature has suggested that deficits in cognitive control correspond to diminished or abnormal activity in the anterior cingulate cortex (ACC) (Dalley and Robbins, 2017). Utilizing a stop-change task in rats, recent data suggests that ACC is important for detecting conflict between two competing inputs, showing higher firing rates on STOP trials, that are positively correlated with behavioral accuracy and movement speed (Bryden et al., 2018). These early findings are some of the first to suggest that ACC detects response competition in rodents. However, it remains unclear what the downstream consequences of successful conflict detection are. Previous research suggests that the dorsal medial striatum contains neurons that are directionally selective during performance of the stop-change task (Bryden et al., 2012). To examine whether putative 'conflict' signals in ACC are important for regulating overall behavior we infused ibotenic acid unilaterally to lesion neurons and passing fibers in ACC, while simultaneously recordings from downstream neurons in the DMS as rats performed a stop-change task. We predicted that unilateral lesions will disrupt performance on STOP trials only when the STOP signal is presented on the side of the rat that is contralateral to the lesion. These data are important for establishing the physiological and behavioral relevance of the apparent 'conflict' signals generated in ACC.

Title: Punishment history modulates medial prefrontal cortex responses to ambiguous stimuli

Authors: *F. LUCANTONIO, A. J. CHANG, J. Y. COHEN
Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Making optimal decisions in the face of ambiguous information is fundamental to adaptive behavior. These decisions are influenced by context: prior exposure to punishments in an environment biases decisions about ambiguous outcomes toward avoidance and away from approach. The medial prefrontal cortex (mPFC) is involved in context-based decision making, but how its neurons regulate behavioral responses to ambiguous stimuli is unclear. To address this question, we trained head-restrained mice on a Pavlovian discrimination task in which one odor predicted sucrose (an appetitive sweet solution), while a different odor predicted denatonium (an aversive bitter solution). Mice showed anticipatory licking responses after sampling the positive, sucrose-predicting cue and withheld licking after sampling the negative, denatonium-predicting cue. Mice were assigned to two groups, one in which they were also exposed to an odor that predicted an unavoidable air puff delivered to their face, the other in which they were exposed to an odor that predicted no outcome. After learning, we measured behavioral responses to ambiguous stimuli by exposing mice to mixtures of varying proportions of sweet- and bitter-predicting odors, without reinforcement. Licking rates for odor mixtures scaled with the proportion of the mixture that was the sweet-predicting odor, indicating that mice responded to parametrically varying ambiguous stimuli with smoothly varying behavioral responses. Mice exposed to air puffs responded to ambiguous odor mixtures with fewer licks during the anticipatory period, consistent with a negative bias to the ambiguous stimuli. During the task, we recorded action potentials extracellularly from mPFC. Firing rates in mPFC neurons in mice exposed to air puffs were enhanced selectively during ambiguous mixture trials, compared to neurons in mice not exposed to air puffs. Given the enhanced firing rate in neurons of mice exposed to air puffs, we next asked whether manipulation of mPFC activity would

modify behavioral responses to ambiguous stimuli. We expressed channelrhodopsin-2 in pyramidal neurons in mPFC and excited them during ambiguous mixture trials. Mice showed decreased licking responses during these trials, mimicking the effects observed in mice exposed to air puffs. These results demonstrate that exposure to negative events can bias decisions under ambiguity by altering the activity of mPFC neurons.

Title: Ventromedial thalamic projection neurons to prelimbic cortex in cost-benefit decision-making

Authors: *B. SIEVERITZ, M. GARCIA-MUNOZ, G. W. ARBUTHNOTT
Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: Ventromedial thalamic projection neurons target and drive prelimbic corticostriatal neurons (Arbuthnott et al., Neurosci 38:1, 1990; Collins et al., Neuron, 2018) that are involved in cost-benefit decision-making. Cost-benefit decision-making provides animals with a choice between a high cost/high reward and low cost/low reward option. Optogenetic inhibition of prelimbic corticostriatal neurons increases the choice of rats for the high cost/high reward option, while optogenetic stimulation increases the choice for the low cost/low reward option (Friedman et al., Cell 161:6, 2015). Ventromedial thalamic nucleus has also been implied in predicting choice behaviour (Tanaka, J Neurosci 27:44, 2007) and as such ventromedial thalamic input to prelimbic cortex may play a crucial role in cost-benefit decision-making. The aim of the presented study was to determine, if ventromedial thalamic projection neurons to prelimbic cortex are involved in cost-benefit decision-making.
We trained five week old male Sprague-Dawley rats on a benefit-benefit, cost-cost, and cost-benefit decision-making task. These tasks offer animals a choice between i- a high and low reward option, ii- a high and low cost option, and iii- a high reward/high cost and low reward/low cost option. The concentration of the low reward, diluted sweetened condensed milk, was adjusted for each animal so that animals chose the low reward/low cost option in roughly 50% of the trials on the cost-benefit decision-making task. As soon as animals acquired the task, either a virus expressing archaerhodopsin (AAV5-CAG-ArchT-GFP) or a control virus not expressing archaerhodopsin (AAV5-CAG-GFP) was injected into ventromedial thalamic nucleus (interaural zero AP +7.0, ML -1.2, bregma DV -6.6). An LED fiber probe was implanted into prelimbic cortex (bregma AP +3.72, ML -0.1, DV -3.6). After two weeks the virus was

expressed in ventromedial thalamic axon terminals in prelimbic cortex and the performance of animals on all three tasks was tested under two conditions; with and without administering optogenetic inhibition to ventromedial thalamic axon terminals in prelimbic cortex. The choice behaviour of animals was compared between conditions. Early results suggest that on the cost-benefit decision-making task optogenetic inhibition increases the preference of animals for the high cost/high reward as compared to the low cost/low reward option by about 15%; from choosing the high cost/high reward option in about 60% of the trials to choosing it in about 75% of the trials. The preference of animals remained unchanged on the other two tasks.

Title: Characterizing empathy-driven prosocial behavior in rats

Authors: *J. HERNANDEZ-LALLEMENT[1], V. GAZZOLA[2], C. KEYSERS[2]
[1]Netherlands Inst. For Neurosci., Amsterdam, Netherlands; [2]Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: Showing what is commonly referred to as prosocial behaviors is appreciated and rewarded in human society, whereas anti-social actions often lead to isolation and reclusion. While neuroimaging can explore vicarious activations using correlational approaches, it cannot influence neuronal activity (hence limiting insights into causality), and have a limited spatial resolution. Here, we present a rodent model of empathy-driven prosocial behavior, suited for cutting-edge neuroscientific manipulations, which scrutinizes the response to other's distress in the form of prosocial (help) or anti-social behaviors (aggression). In this task, rats first developed a preference for a higher value option in a binary choice situation. In a second phase, choosing that option led to a punishment to an adjacent conspecific. Accordingly, if other’s distress carries a negative value for some individuals (prosocial) but not for others (instrumental aggressors), the first group should switch preference while the second should stick with the higher value option while accepting the collateral damage to others. Importantly, animals had experienced the shock delivered to the partner in a prior self-experience session. We found that a subset of animals switched their previously acquired preference upon association with a shock to a conspecific, hence behaving pro-socially. Interestingly, the time delay between self-experience and prosocial task was crucial: animals that underwent self-experience shortly before the prosocial task behave

more prosocially than rats that experienced the shock at an earlier period. Moreover, while all animals perceived the conspecific's reaction to the shock, only a subset of animals behave prosocially, raising potential distinctions between prosocial and indifferent/antisocial individuals (i.e., hurting others to obtain food). Hence, this behavioral paradigm provides means to scrutinize both pro- and anti-social behaviors. Indeed, while the *first group* allows examining how the perception of other's distress promotes pro-social behavior, the *second group* enables exploring what predisposes some individuals to disregard the distress of others.

Title: Plasticity in the ventromedial prefrontal cortex underlies the therapeutic effects of fear extinction

Authors: *D. PAREDES[1], E. A. FUCICH[1], D. A. MORILAK[2]
[1]Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX; [2]Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Current treatments for stress-related psychiatric disorders such as depression and posttraumatic stress disorder (PTSD) are inadequate. Behavioral therapies can be effective in the treatment of these disorders. However, little is understood about the neurobiological mechanisms underlying behavioral interventions. We have previously shown that fear extinction (i.e. learning that an innocuous cue previously associated with a fearful stimulus no longer predicts that stimulus) can be used to model the effects of exposure therapy on cognitive flexibility that have been compromised in chronically stressed rats. In addition, using Gi-DREADDs, and Gq-DREADDs, we have observed that activity of glutamatergic neurons in the ventral medial

prefrontal cortex (vmPFC) during extinction is necessary and sufficient for the therapeutic effects of extinction learning on cognitive flexibility and coping behavior. Thus, in these experiments we set out to test the hypothesis that fear extinction restores stress-induced hypo-responsivity in the mPFC. We found that CUS reduced mPFC responsivity, assessed by measuring afferent-evoked field potentials in the mPFC, and this reduction was reversed by extinction treatment. Additionally, we investigated whether the expression of glutamate receptors in the mPFC is altered by chronic stress and extinction. Preliminary results suggest that GluA1 expression is decreased in stressed animals, and fear extinction following chronic stress normalizes the expression of GluA1 back to control levels. Thus, plasticity in the vmPFC underlies the long-lasting beneficial effects of fear extinction on cognitive flexibility.

Abstract: Introduction
We aim to investigate the effect, efficacy, and reproducibility of focused ultrasound

neuromodulation (FUN) using resting-state fMRI (rs-fMRI) in *Macaca mulatta*. We compare stimulation targeted at two frontal regions, supplementary motor areas (SMA) and frontal polar cortex (FPC).

Methods

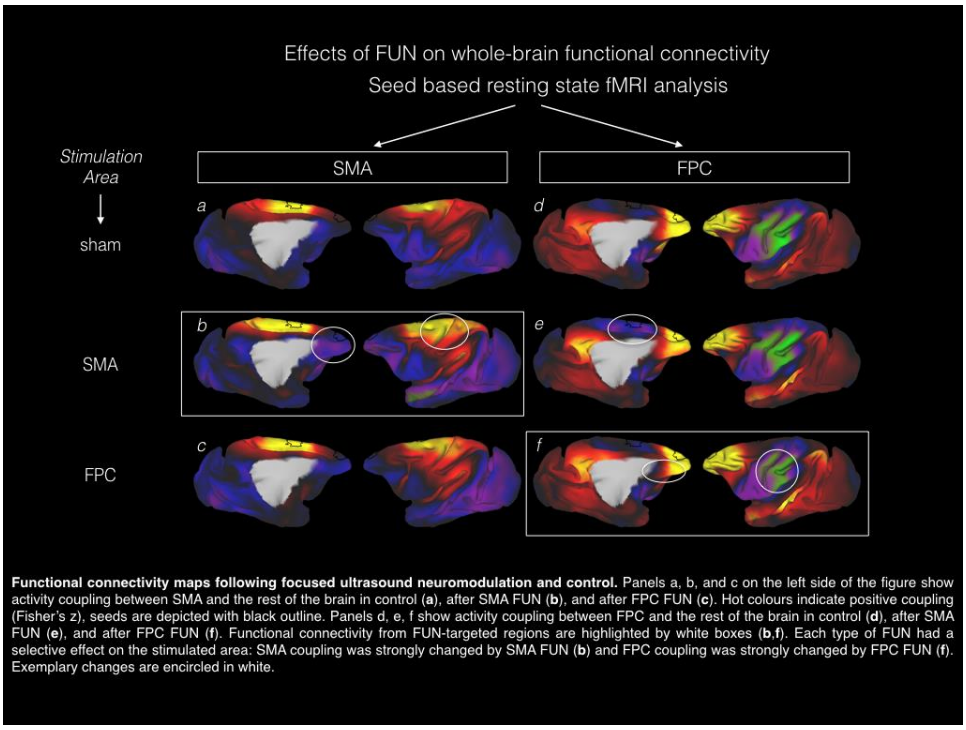
A single-element ultrasound (US) transducer, focused at ~5cm, was used to stimulate either SMA or FPC or used in a sham procedure in 3 macaque monkeys. We delivered US waves at 250 kHz in 100ms bursts for 40 seconds, targeted based on each animal's individual anatomy by neuronavigation. We subsequently acquired rs-fMRI data for up to 90 minutes at 3T under isoflurane anaesthesia.

Results

We investigated the off-line effects of FUN targeted at SMA and FPC by quantifying changes in functional connectivity between these areas and the rest of the brain. First, we found that FUN induced signal changes in the cerebral spinal fluid leading to widespread synchronisation in this compartment, suggesting that it sometimes exerted an extensive vascular effect. Importantly, however, in the grey matter FUN induced region-specific changes in coupling with the stimulated area. Namely, FUN applied to SMA transiently and reversibly changed its coupling with the sensorimotor system and prefrontal cortex. Consistently, FUN targeted at FPC changed coupling with prefrontal and cingulate regions. FUN increased coupling between the stimulated area and areas normally closely connected with it while, at the same time, decreasing coupling between the stimulated area and areas normally less closely connected with it. These effects were replicated in a set of control animals (n=3), and across repeated sessions (n=4) in a single individual.

Conclusion

FUN leads to a sharpening of the stimulated region's connectivity profile in a non-invasive and reversible manner with high efficacy, spatial resolution, and reproducibility.



Functional connectivity maps following focused ultrasound neuromodulation and control. Panels a, b, and c on the left side of the figure show activity coupling between SMA and the rest of the brain in control (**a**), after SMA FUN (**b**), and after FPC FUN (**c**). Hot colours indicate positive coupling (Fisher's z), seeds are depicted with black outline. Panels d, e, f show activity coupling between FPC and the rest of the brain in control (**d**), after SMA FUN (**e**), and after FPC FUN (**f**). Functional connectivity from FUN-targeted regions are highlighted by white boxes (**b**,**f**). Each type of FUN had a selective effect on the stimulated area: SMA coupling was strongly changed by SMA FUN (**b**) and FPC coupling was strongly changed by FPC FUN (**f**). Exemplary changes are encircled in white.

Title: The role of the secondary motor cortex in feedback integration to guide decision-making

Authors: *D. C. SCHREINER[1], C. M. GREMEL[1,2]
[1]Psychology, [2]Neurosciences Grad. Program, Univ. of California San Diego, La Jolla, CA

Abstract: While much research has focused on motivational control of decision-making (e.g. do I want the outcome), less understood is how decision-making integrates and responds to ongoing feedback (e.g. was my action successful). Feedback can also include ongoing, internal representations of progress such as confidence or action plans. The neural mechanisms responsible for integrating feedback in goal-directed decision-making are unclear. We adapted a self-initiated, self-paced, and un-cued lever press task in mice to assess feedback during decision-making. Mice are trained to hold down a lever for at least a given duration to earn a food reward across days (i.e. >400ms to >800ms to >1600ms). Mice modify their lever press duration based on whether or not they successfully met the target on the previous press. If mice fail to reach the target they increase the duration of their next press, whereas if they meet the target they decrease the duration of their next press (on average). When we manipulated reward probability we found internal feedback (confidence) resulted in a subsequent change in next lever press duration similar to external food delivery cues. Secondary motor cortex (M2) has been implicated in associative integration for behavioral selection. Preliminary evidence suggests that acute chemogenetic inhibition of M2 impairs task performance and decreases the feedback-induced change in subsequent lever press duration. Optogenetic inhibition of M2 projection neurons across the duration of lever presses similarly decreased feedback-induced changes in press duration. Interestingly, inhibition during only the first 400ms of a lever press increased the subsequent change in lever press duration and increased task performance. We used fiber photometry to record calcium activity in M2 projection neurons. Preliminary evidence shows preparatory calcium activity in M2 prior to action initiation followed by suppression of calcium activity during early action performance, with the magnitude of calcium activity suppression increasing with longer press durations. Our results provide evidence for M2 as a key locus in utilizing internally and externally generated evidence (e.g. feedback) to modulate ongoing goal-directed action contingencies during decision-making.

Title: Neural dynamics underlying decision making in a dynamic environment

Authors: A. PIET[1], *A. EL HADY[2], C. BRODY[2]
[1]Neurosci., Princeton Univ., Princeton, NJ; [2]Princeton Neurosci. Inst., Princeton, NJ

Abstract: How are choices made within constantly-changing noisy environments? The gradual accumulation of noisy evidence is considered to be a fundamental component of decision making, but has usually been studied in stationary environments. We trained rats on an auditory decision-making task in a changing environment (Piet 2018). Crucially, in a dynamic environment, subjects must discount old evidence that may no longer be informative about the current state of the environment. Using high-throughput behavioral training and quantitative modeling, we find that rats can optimally discount evidence in a dynamic environment. The optimal timescale for evidence discounting is a function of both the environmental variability, and the reliability of the noisy evidence. The reliability of the noisy evidence in turn depends on both the noisy stimulus, and the subject's sensory noise. When accounting for sensory noise, the find that rats accumulate and discount evidence on the optimal timescale. Additionally, we demonstrate that individual rats rapidly adjust their discounting timescales in response to changes in the environmental variability. Due to the dynamic nature of each trial, subjects change their mind often during each trial allowing experimental measurement of changes of mind within one trial. Further, these changes of mind are driven by internal estimates of accumulated evidence. Our behavioral task thus facilitates the investigation of neural mechanisms underlying evidence integration and discounting, as well as changes of mind. Previous studies of rat decision making have identified a cortical structure, the Frontal Orienting Fields (FOF) as a potential substrate for upcoming choice memory (Erlich 2011, Erlich 2015, Hanks 2015, Piet 2017). We recorded spike trains from FOF neurons, and analyzed their dynamics and their relationship to the dynamic evidence.

Title: Neural representation of a Bayesian belief in the macaque prefrontal cortex during reinforcement learning

Authors: *R. BARTOLO, R. C. SAUNDERS, A. R. MITZ, B. B. AVERBECK
NIMH/NIH, Bethesda, MD

Abstract: In a noisy environment, learning requires organisms to keep track of choices and their associated outcomes across successive decisions to form beliefs about value in the world. This allows them to predict future outcomes and to update their belief after each outcome. The

primate prefrontal cortex (PFC) integrates information carried by reward circuits, in addition to its role in working memory. The present study explores the PFC computations related to updating current beliefs in multifaceted reward environments. We conducted high-channel count single-unit recordings in two male macaques (N=3225 neurons), while they executed a two-armed bandit reversal learning task, responding with a saccade towards the chosen target. Through trial and error, animals associated either screen locations or images with a reward. In each block of 80 trials, one of two images (WHAT blocks) or one of two locations, at which the images randomly appeared (WHERE blocks), had a higher reward probability with respect to the other. The block type was randomized and not cued, so the animals had to form a belief about whether WHAT or WHERE determined the reward during each block. The reward contingencies were reversed near the middle of each block at a randomly defined trial within a fixed interval (trials 30-50), requiring the animals to reverse their choice preference. Critically, the monkeys were highly familiar with the fact that there were two possible block types and that a reversal would occur within each block. Behavioral analyses showed that they used this prior knowledge to guide reversals in their choice preference. Detailed knowledge of the task structure also allowed us to fit a Bayesian model to the monkeys' choice data, from which we estimated posterior distributions over block type and the reversal trial for each block of trials. Next, we looked for associations between the Bayesian posterior estimates and activity of prefrontal cortex neurons. We found persistent encoding of posterior estimates of the block type, as well as encoding of posterior probability that a reversal occurred. We also found strong encoding of saccade direction, regardless of the block type. This contrasted with relatively weak encoding of the stimulus identity of the chosen option. Overall these results suggest that prefrontal neurons encode oculomotor decisions associated with Bayesian subjective values and highlight the role of the PFC in representing a belief about the current state of the world.

Title: Spatial attention and value encoding in the dorsolateral prefrontal cortex

Authors: *Y. XIE, W. ZHANG, T. YANG
Inst. of Neurosci., Shanghai City, China

Abstract: Both spatial attention and reward value have been shown to modulate neuronal activities in the dorsolateral prefrontal cortex (DLPFC) during decision making. However, their

interaction is unknown. Here we developed a behavioral paradigm that allowed us to tease apart the two factors. Two monkeys were first trained to learn the associations between five shapes and their respective rewards, which were 0, 1, 2, 4, 8 drops of juice. After the monkeys learned the stimulus-reward association, we then trained them to perform a visual detection task. The monkeys were required to fixate at a center point when two shapes were presented on both the left and the right sides of the fixation point. After a random period, the luminance of one of the shapes changed (go cue), and the monkeys had to report this change by saccading to a target 6 degrees above the fixation point within 400 ms after the go-cue onset. A square frame was presented for 400 ms at 200ms before the shapes as the attention cue. For 85% of the trials (valid), the go cue appeared on the opposite side of the frame. For the other 15% of trials (invalid), the go cue appeared on the same side of the frame. If the monkeys correctly detected the visual change, a reward was delivered at the end of the trial. The reward was randomly chosen between the associated rewards of the two shapes presented in the trial. The accuracy and the reaction time measurements indicated that the monkeys performed the task and assigned their attention appropriately.
We then recorded single unit activity in the DLPFC. Divided by their spatial preferences, 27.2% of the DLPFC neurons' activities were higher when monkeys attended to the contralateral location and 21.1% of the neurons' activities were higher when monkeys attended to ipsilateral location. Divided by their value preferences, 39.8% of the neurons preferred higher value while 16.5% preferred lower value. The neurons that were spatially selective and preferred higher value signaled only the value of their preferred location. The neurons that preferred lower value signaled the average value of the two stimuli. The neurons that showed no significant spatial preference but value preference also encoded the average value. Our results suggest that spatial attention and reward value are encoded differently by different groups of DLPFC neurons.

Title: Developing a task for examining the contribution of reward and cost to decision-making

Authors: S. TANIMOTO[1], *M. KONDO[1,3], K. MORITA[2], M. MATSUZAKI[1]
[1]Grad. Sch. of Med., [2]Grad. Sch. of Educ., The Univ. of Tokyo, Tokyo, Japan; [3]JSPS Reserch Fellow, Tokyo, Japan

Abstract: Animals choose something and act appropriately in their daily life. Since all sorts of actions need energy and cost, animals have to compute the reward expected from individual

actions and the cost to act before they decide which action should be chosen. One of the inevitable and simple costs is the physical cost accompanying muscle contractions. To address how the relationship between the reward expectancy and the physical cost affects the decision-making, we developed a simple behavioral task in which mice chose whether to pull the lever or not in response to two different tones. Two different tone cues were respectively assigned to two different probabilities of water delivery (reward probabilities) after a successful lever pull. No reward was delivered when the lever was not successfully pulled. If the mouse learns that the cost value to pull the lever with its right forelimb is higher than the expected value of the reward associated with a tone cue, the mouse will not pull the lever in response to this cue. As expected, after two-week training sessions, the probability to pull the lever stayed approximately 100% when the tone cue assigned to a high reward probability was presented, while it decreased to 0-30% when the other tone cue with a low reward probability was presented. However, the probability to pull the lever did not necessarily depend on the absolute value of the reward probability because the mice pulled the lever frequently in response to a tone cue with a relatively low reward probability if the other cue was assigned to a much lower reward probability. These results suggest that the mice used the relative value of the tone cue rather than the absolute value for decision-making in the lever-pull action. In order to clarify how the value of each cue and the cost value are computed in the mouse brain, we are trying to fit the changes in the mouse behaviors during learning of the task to reinforcement learning scheme. This task will help us understand the neural mechanisms underlying the computation of the reward expectancy and the physical cost.

Title: Risk-dependent choice following the lesion of medial prefrontal cortex in the rat

Authors: *Y.-H. YANG[1], C.-Y. CHUANG[2], S.-F. CHEN[3], R.-M. LIAO[4]
[1]Inst. of Neurosci., Taipei, Taiwan; [2]Inst. of Neurosci., [3]Inst. of Neurosci.,Department of Psychology, [4]Inst. of Neuroscience,Department of Psychology, Res. Ctr. for Mind, Brain and Learning, Natl. Cheng-Chi Univ., Taipei, Taiwan

Abstract: Despite a growing body of research showing the cortico-striatal systems involved in the decision making under risk, how the subareas of prefrontal cortex modulate in the risk-based decision making remains unclear. This study used a T-maze task of risk dependent choice which the rat was required to assess a certain level of risk through choosing either a small and certain

reward arm or a large but uncertain reward one. The choice of latter option was given with a probability (*p*) of 0.5, 0.25, or 0.125 correspondingly given by 2, 4, or 8 sweet pellets in three different reward ratios, whereas the choice of former one was always ended by 1 pellet given for certain (in $p = 1$). This risk choice task was then run with the expected value in equal for binary choice options. The rats first received ibotenate lesion in the medial prefrontal cortex (mPFC) and followed by post-lesion behavioral examination. The rats were randomly assigned to six groups; each received either lesion or sham lesion and tested under a specific reward ratio. A risk-dependent choice pattern appeared in the rats with sham lesion control over a 7-day test. They chose more large/risky than small/certain reward when $p = 0.5$ to obtain 2 pellets, and it shifted to a risk-averse style when larger reward given in lower *p*. The mPFC lesion did not significantly disrupt the acquisition of aforementioned risk-dependent choice. Neither the gross motor action nor the discrimination capability was impaired by the present mPFC lesion. These results, together with our lesion data of orbitofrontal cortex (OFC), suggest that the mPFC and OFC might be dissociated in the acquisition of risk-dependent choice.

Title: A two alternative forced choice paradigm using homecage training to reduce training time in an Air-Track floating platform

Authors: *A. NASR[1], M. NASHAAT[2], S. DOMINIAK[2], R. SACHDEV[2], M. LARKUM[2]
[2]Biol., [1]Humboldt Univ. of Berlin, Berlin, Germany

Abstract: Training of head fixed mice to perform complex behaviors is a time-sink, almost a full time job in itself. Not only do highly expert neuroscientists spend a lot of time training mice to perform tasks, but often it is not clear that the head fixed behavior is natural. Optimally, animals should perform a task that is not too deviant from normal behavior and it should be possible to use available techniques for recording from the brain, many of which could involve head-fixation (2-photon imaging, whole-cell patch recordings, etc.). Here, we try to make it easier to use the floatingplatform method, the Air-Track system (Nashaat et al., 2016, J. Neurophys), in a two-alternative forced-choice paradigm by training mice in their home cages, without head fixation, and we examine whether the behavior is natural. We trained mice (n=10) in a Y-maze in which the animals choose between the two alternative lanes on the basis of sound and light cues. Rodents typically take several weeks to learn two-alternative type tasks while head-fixed (Burgess et al., 2017, Cell Reports). However, the advantage of the Air-Track system is that it

can be easily adapted to a freely-moving homecage version in which animals can learn in an automated (unsupervised) environment. This reduces the time investment of the researcher significantly. Here, we present data showing that when pre-trained in the homecage version using the AirTrack apparatus in the Y-maze configuration, animals retain the knowledge of the task in the head-fixed condition. After habituation to head-fixation on the floating platform, and in the Air-track, animals rapidly reach the >80-90% performance, that they had in the homecage within 1-2 days. Furthermore, while the sequence of behaviors emitted by the animal when performing the task freely in the home cage and when head fixed in the Air-Track were similar, the speed of movement was slower when animals were head-fixed. Both the homecage and Air-Track environments can be easily manufactured for <$1000 and all the CAD diagrams and control software are publicly available. We conclude that by combining AirTrack with homecage pre-training, it is not only possible to reduce the researcher supervised time spent per experiment but also to train mice in more complex tasks which would normally not be possible due to time constraints.

Title: The role of frontal eye fields in mixed-strategy decision-making

Authors: *S. XIE, M. C. DORRIS
Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai City, China

Abstract: The primate prefrontal lobes are implicated in the abstract computation required for complex cognitive behaviors such as decision-making. The transformation from such abstract computation into premotor commands necessary for enacting choice remains unclear. The Frontal Eye Fields (FEF) may be important in this process because it receives diverse prefrontal inputs and sends premotor commands to the brainstem Superior Colliculus (SC). Here, we examined the role of the FEF during strategic saccadic decision-making. We trained monkeys to perform a saccadic version of the mixed-strategy game Matching Pennies. On each trial, monkeys directed a saccade to one of two targets, one of which was placed in an FEF neuron response field. A computer opponent dynamically exploited monkeys' choice pattern, hence monkeys approached the Nash Equilibrium strategy of choosing stochastically. FEF activity

became increasingly predictive of upcoming choices as the deadline for saccade approached. To test causality, we applied sub-threshold microstimulation to the FEF in an effort to enhance FEF activity for a particular vector but at a level unable to directly trigger saccades. Indeed, microstimulation biased choice, but unexpectedly, away from the stimulation vector rather than towards it. To examine possible reasons for this counterintuitive result we performed a number of control microstimulation experiments. Extending microstimulation throughout the decision and motor epochs further exacerbated the biasing effect.
To determine whether this biasing-away effect was confined only to strategic decisions, we designed a perceptual guided decision task. As much as possible we kept the parameters the same but, instead of volitional choices, monkeys were trained to saccade towards the brighter of two targets. Notably, sub-threshold FEF microstimulation also shifted monkeys' psychometric curves away from the stimulation site during perceptual decision-making.
Our neuronal recording and microstimulation results demonstrate that FEF plays an active role in mixed-strategy saccade decision-making. However, the mechanism underlying the biasing-away effect of microstimulation still needs more empirical evidence. Some possibilities include: a) FEF plays a monitory role and provides negative feedback signals for the decision process, b) microstimulation activates inhibitory circuits with greater efficacy, c) microstimulation recruits additional cortical areas and/or the indirect FEF◊Basal Ganglia◊SC inhibitory pathway. Ultimately, optogenetic tools may be required to isolate the role of the direct FEF◊SC excitatory pathway.

Title: Identification of differential gene expression profile in rats showing risk-averse and risk-seeking preferences in rat gambling task

Authors: *M. GWAK[1], S. JUNG[2], W. KIM[1], M. KU[1], Y.-J. CHUNG[2], J.-H. KIM[1]
[1]Dept. of Physiol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]The Catholic Univ. of Korea Col. of Med., Seoul, Korea, Republic of

Abstract: Measuring expected risk is important for making rational decisions, and maladaptive decision making may underlie various psychiatric disorders. However, genetic and neural correlates involved in this process are still largely unknown. Rodent version of the gambling task (rGT) has been developed to measure decision-making in rodent by adopting the same principle of Iowa Gambling Task in humans. In the present study, we examined using next-generation

sequencing (NGS) whether there are differences in gene expression profiles in the brain when rats make different choices toward risk in rGT. Rats were trained in a touch screen chamber to learn the relationships between 4 different light signals on the window of the screen and accompanied reward outcomes or punishments set up with different magnitudes and probabilities. Once they show a stabilized pattern of preference upon free choice, rats were classified into risk-averse or risk-seeking group. Besides, an additional group of rats were raised in home cage without any exposure to rGT training. After classification in rGT, rats were decapitated, the prefrontal cortex (PFC) and the nucleus accumbens (NAc) were dissected out from their brains, and NGS was performed with total RNA extracted. We found that there were significant differences in 7,875 genes (fold change>1.5, $p<0.05$) up or down-regulated in rGT compared to control rats, regardless of their brain regions or risk preferences. When comparing risk-averse group to risk-seeking group regardless of their brain regions, 21 genes were found to be significantly different. Interestingly, however, when looking at each brain region separately, 68 genes were identified as significantly different in the PFC, while no genes identified in the NAcc, between risk-averse and risk-seeking groups. These results suggest that differential gene expression profile appearing in the PFC may importantly contribute to the preference toward risk choice in rGT.

Abstract: In the current study, we captured the cerebral blood volume (CBV) variations from the supplementary eye field (SEF), a dorso-medial frontal cortex area active during eye movements tasks in non-human primate using functional ultrasound (fUS) [1]. We recorded SEF region in the context of cognitive tasks when a primate is awake and freely behaving without the need for any statistical averaging.

Functional data were acquired with 2 trained captive-born macaques (Maccaca Mulatta) performing baseline (rest phase), fixation, pro-saccade and anti-saccade trials in a blocked design of 60 seconds each (~ 20 trials/task) for a total of 85 different acquisitions (Fig 1.a). Eye position of primate was monitored at 1 kHz with an eyetracker camera which enabled live control of behavioral paradigm and delivery of liquid reward based on success or failure of visual task. Variation of CBV was measured using a linear ultrasound probe (15 MHz, 110x100 µm² of spatial resolution, FOV 14×10 mm^2) inserted in an electrophysiology recording chamber and driven by an ultrafast ultrasound research scanner. Filtered ultrasound images (11 steered ultrasound plane-waves fired at 5500 Hz) revealed both brain activity (~0.35Hz) and pulsatility (~3.5Hz) (Fig 1.b). A spatio-temporal movie of CBV in SEF (Fig 1.c) was then reconstructed (temporal sliding window of 250ms, increment 20ms). For all the sessions, peak amplitude of the CBV signal increased in the SEF on average by 31.3 ± 15.2 % over baseline in large ROI and up to 84.8 ± 38.7 % in 1-pixel ROI. Only a single pixel was thus sufficient to detect a significant modulation of CBV signal (Fig 1.e). Moreover, even in a single pixel ROI, only the first single trial of each block was needed to increase and detect CBV above 2 standard deviation from baseline after just 2.0 ± 0.5 s (Fig 1.d).

Our study demonstrates the capacity and the interests of using fUS to map cortical brain areas in awake non-human primates at a single trial level.

Figure 1: The high sensitivity to CBV changes of fUS (functional Ultrasound) Imaging give access to single trial detection of Supplementary Eye Field (SEF) activation during visual tasks

Title: Time to decide: How decision time affects choices

Authors: *J. MARTIN, D. KVITSIANI
Dandrite, Aarhus C, Denmark

Abstract: One of the functions of the brain is to integrate environmental information with internal states to produce behavior. In probabilistic environments optimal decision-making is guided by past experiences such as rewards, a process that is marvelously captured by reinforcement learning (RL) models. In this project, we investigate how elapsed time prior to the choice affects the decision process. To this end, we established a dynamic matching task in mice similar to the task performed in monkeys by Lau et al. (2005). Briefly, after correct trial initiation, the animal can choose freely between two ports, where water rewards are delivered independently and probabilistically on a concurrent variable rate schedule. In addition to reward probabilities, however, we systematically manipulate the wait durations during trial initiation. According to Herrnstein's matching law animals assign their choices relative to the experienced reward ratio. We find that this sensitivity is different for distinct wait delays with a seemingly higher sensitivity on longer trials. Moreover, animals tend to switch more often between options upon short wait delays independent of the preceding reward experience. Regression analysis reveals that this is due to an increased influence of past choices while the impact of past rewards remains similar. This suggests that animals use different choice strategies depending on the elapsed waiting time by integrating previous experiences to different degrees. We are currently in the process of testing various models ranging from Win-Stay-Lose-Shift to RL models and a mixture of these to understand the mechanisms that may contribute to the observed behavior. Furthermore, in order to reveal the neural representation of task relevant variables we are simultaneously recording in the medial prefrontal cortex (mPFC). Because previous work by Kvitsiani et al. (2013) showed that Parvalbumin (PV) interneurons in the mPFC encode elapsed time, we focus our analysis on optogenetically identified PV cells enabling us to dissect their potential function in the underlying circuit.

Title: Neural population analysis of reward expectation and choice trace in mouse medial prefrontal cortex

Authors: *D. KVITSIANI[1], J. LOPEZ[2], J. MARTIN[1]
[1]Mol. Biol. and Genet., [2]Chem., Aarhus Univ. / DANDRITE, Aarhus C, Denmark

Abstract: Reinforcement learning (RL) models have been successfully used to explain animal choices and activity of selected neurons in decision making tasks. In the RL framework, the reward expectation and the choice trace are key variables that dictate the probability of the upcoming choice. However it is not entirely clear how a neural population as opposed to single neurons encodes those variables. To address this question we set up a free-choice task in mice while recording neurons from the medial Prefrontal Cortex (mPFC). In this task, the animals were asked to choose between two side ports that delivered water rewards probabilistically. These probabilities changed in a blockwise manner without providing any cues for the transitions. Thus, the animals had to rely on their internal estimate of reward income to adjust their choices, which they quickly accomplished. The performance of the animals was best captured by an improved-version of RL model that allowed us to map the extracted learning rates of the reward expectation and choice traces to the neural representations using the mean of multivariate LASSO regressions. Despite diverse representations across individual neurons, we found that the information about choices and reward expectation was best captured by population activity. To further validate the experimentally observed neural representations, we built a recurrent neural network (RNN) that recapitulated some of the key aspects of biologically observed neural dynamics. Our results suggest that task relevant- information is distributed in neural population.

Title: ACC inactivation impairs performance monitoring in mice

Authors: *R. F. OLIVEIRA[1], I. O. R. VAZ[1], T. AKAM[2], R. M. COSTA[3]
[1]Champalimaud Ctr. for the Unknown, Lisbon, Portugal; [2]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [3]Neurosci., Columbia Univ., New York, NY

Abstract: When a musician performs a difficult piece, actions have to be performed with striking accuracy. Previous work has shown that after a self-paced action sequence has been rehearsed, the trial-to-trial variability in performance decreases (precision increases). Furthermore, if the action is complex the modulation of behavior and neural variability is contingent to the relevance of each dimension (e.g. speed, duration) to the task. However, it is unclear whether animals can monitor and report their performance on a particular trial before the outcome is presented or not. To assess this we trained mice to execute a sequence of 4 or 5 lever presses to obtain a cached reinforcement. After training, animals had to wait for 8 seconds before the outcome was received, and could choose whether to wait to know the outcome or abort the trial and start again. Mice aborted more trials after incorrect than correct sequences. This leads to a U curve distribution of aborted trials with its lowest point centered around the target lengths (4 and 5). Logistic regression analysis showed that the probability of aborting the current trial depends on the recent history of aborted trials and current trial performance. We think the former reflects slowly changing task engagement, and the latter a fast performance monitoring process. Optogenetic inactivation of Anterior Cingulate Cortex impairs performance monitoring leaving effort/cost as the main fast variable determining the decision to abort or not the current trial. This translates in a shift of the U curve and a lower fraction of long sequence trials aborted when the ACC is inactivated. These results show that mice learn to perform sequences of movements within narrow constraints and that they are capable of monitoring their own accuracy in executing actions. Moreover, the data shows that variables with different time dynamics are involved in assessing action performance.

Abstract: The brain continually exhibits a wide array of self-generated activity related to internal state transitions and body movements. During behavior, this “internal backdrop” affects the processing of task-relevant stimuli and may have substantial consequences for decision-making. To understand the joint effects of internal backdrop and task-imposed variables on neural activity, we trained GCaMP6f-transgenic mice on a delayed two-alternative forced choice paradigm and measured neural activity across the entire dorsal cortex using a tandem lens macroscope. Concurrently, we monitored changes in internal backdrop through various self-generated parameters including pupil diameter, breathing, whisking and body motion. To attribute neural activity in specific cortical areas to internal or task-imposed variables, we used a multivariate linear regression model. The model accurately predicted changes in neural activity throughout the cortex, confirming expected areas as involved with different sensory or motor events. Surprisingly, the model revealed that internal backdrop dominated neural activity across the entire dorsal cortex and dwarfed task-related variables like sensory stimuli. Model-based reconstruction of imaging data also showed that many features that are found in a trial average are best explained by the internal backdrop. To assess whether this was true for individual neurons, we used two-photon microscopy and recorded activity over many neurons in frontal cortex. The same linear model revealed that internal backdrop had an even stronger impact on individual neuron recordings. In particular, we found that model variables that were based on animal movements were highly predictive for both meso-scale population activity as well as for single-cell data. By accounting for multiple dimensions of internal backdrop we were also able to uncover obscured signatures of truly task-related computations and identify cortical areas and individual neurons that were most likely to reflect sensory processing or decision making. Detailed quantification of movements and internal state therefore captures a fundamental

dimension of neural activity and enables previously inaccessible insights into task-related computations.

Title: A modified evidence accumulation task to probe the decision time/evidence strength relationship in rats

Authors: *D. GUPTA[1], C. KOPEC[1], C. BRODY[1,2]
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Gradual accumulation of evidence is a core cognitive process which has been shown to be involved in a wide range of decisions. In recent years, the study of evidence accumulation for perceptual decision making has been extended to rodents which has enabled a greater access to experimental methods for measurement and perturbation of underlying neural activity. However, currently most rodent tasks assay subject's decisions after a fixed duration of stimulus presentation, prohibiting the subject from responding as soon as it has made its decision. This obscures the time that was required to reach the decision, a behavioral measurement that is highly informative for mapping neural activity to the gradual decision process. To this end, we modify our existing evidence accumulation task in rats, the Poisson clicks task (Brunton et al., 2013), in order to measure decision times.
The classic Poisson clicks task involves presenting the rat subject with two simultaneous streams of randomly-timed discrete pulses of evidence (clicks), one from a speaker to their left and the other to their right, for a fixed duration. The subject must maintain fixation throughout the entire stimulus, and subsequently orient towards the side which played the greater number of clicks. The discrimination difficulty is controlled on each trial by varying the ratio of the generative Poisson rates of the two click streams.
Here we modified the Poisson clicks task by requiring the subject to sample the stimulus only until a minimum amount of evidence is reached (|total clicks left - total clicks right| > threshold), with no limit to how much longer they can choose to sample the stimulus, before they select a side response.
We find that in this new task, subjects' stimulus sampling times scale with trial difficulty, even

when considering trials in which they did not complete the experimenter-required sample time. This finding can be accounted for by a bounded evidence accumulation mechanism, similar to previous work in humans and non-human primates using reaction-time versions of accumulation of evidence tasks. We will quantitatively compare this model with alternative behavioral strategies using trial-by-trial model fitting.

Title: Neural mechanisms of recurrent neural networks with interneurons and dendrites performing context-dependent decision making

Authors: J.-A. LI[1], *G.-Y. R. YANG[2], X.-J. WANG[3]
[1]Univ. of Sci. & Technol. of China, Hefei, China; [2]Zuckerman Inst., Columbia Univ., New York, NY; [3]New York Univ., New York, NY

Abstract: Recurrent neural network (RNN) training has been a useful tool for studying neural computation mechanisms crucial for cognition and behavior. However, most existing RNN models do not take into account the many different cell types in the brain, and ignore the subcellular information processing within neurons. RNN models that did take into account distinct cell types only focused on distinguishing excitatory and inhibitory neurons (Dale's principle). Here, we trained RNNs with excitatory neurons and three types of inhibitory neurons to mimic multi-compartmental pyramidal cells and parvalbumin (PV)-expressing, somatostatin (SST)-expressing and vasoactive intestinal peptide (VIP)-expressing interneurons in the real cortical circuits (Fig. 1a). The broad connectivity pattern across all populations was specified based on experimental findings, while the detailed connection weights are trained with stochastic gradient descent. We studied the neural mechanisms of such networks performing a generalized version of a context-dependent decision-making task (the Mante task) (Fig. 1b). Our results showed that after training, dendrites of excitatory neurons became selective for sensory inputs. Meanwhile, inhibitory neurons developed selectivity for contextual control signals (Fig. 1c), allowing them to inhibit and disinhibit dendrites of excitatory neurons to perform the task. We also found that when there are more dendrites for pyramidal neurons, the networks prefer to gate sensory inputs on dendrites rather than on somas of excitatory neurons (Fig. 1d). These results indicate that the interaction between inhibitory neurons and multi-compartmental excitatory

neurons can support flexible context-dependent cognitive functions by inhibition, disinhibition and gating. This study can provide a basis for studying computational mechanisms of multi-cell-type RNNs and shed light on how function is related to broad connectivity in those networks.

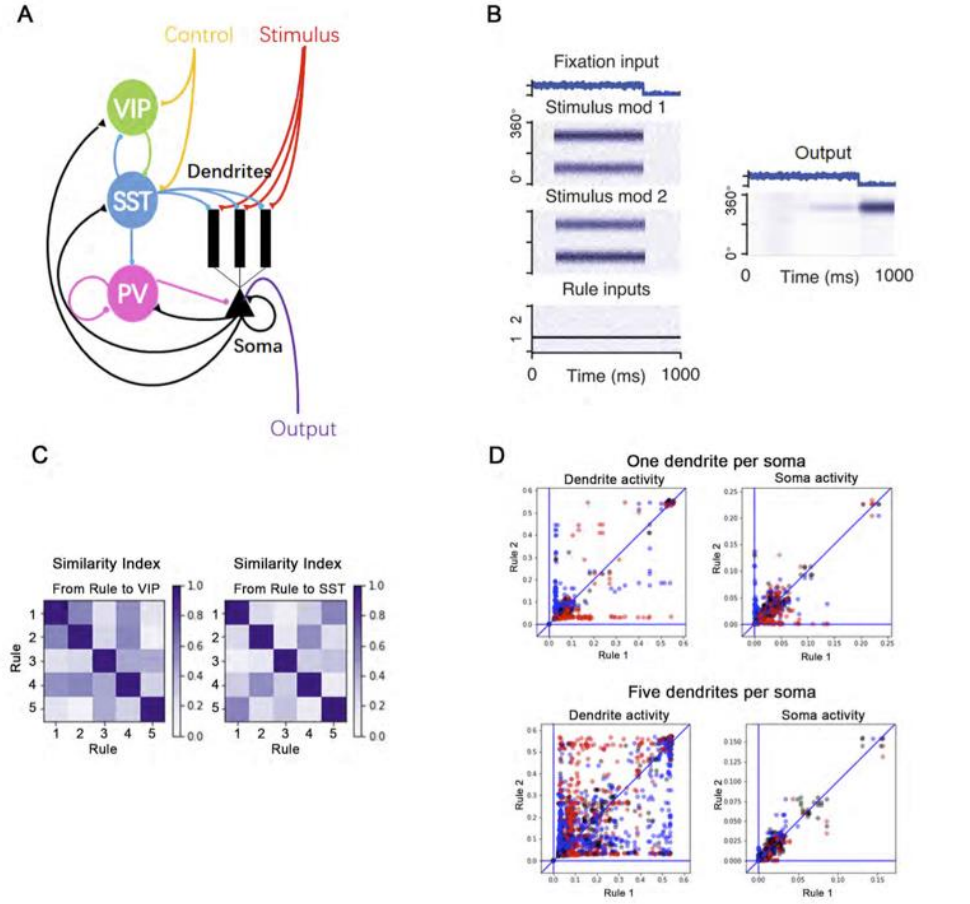

Fig. 1. (A) The circuit model. The recurrent neural network models contain multi-compartmental pyramidal neurons (dendrites and somas) and three types of interneurons, VIP, SST and PV. The control signal (the rule) targets on VIP and SST and the stimulus signal goes to dendrites. The connectivity and proportion were set mimicking microcircuits in the real cortical circuits. (B) The Mante task. In the task, there are inputs encoding a fixation signal, stimuli from two modalities (rings of units), and a rule signal indicating which modality should be focused on. The networks were required to ignore signals from the irrelevant modality and to respond to the stronger stimulus in the correct modality. The original Mante task was generalized to five modalities for our networks. (C) The similarity matrix of connections from five rules to VIP (left) and SST (right). Off-diagonal elements were close to zero, indicating interneuron population developed segregation according to rules. (D) The variance of activity of dendrites and somas under different contexts when there is one dendrite per soma or five dendrites per soma. Comparisons for all dendrites or somas under all pairs of contexts are shown. Each dot is the variance of the activity of one unit (dendrite or soma) given one pair of rules. The dot is colored red if it received stronger connections from one rule, blue if received stronger from the other and black if received equal from both. When there are more dendrites, somas are less selective for contexts, indicating the networks prefer to gate sensory inputs on dendrites rather than on somas.

Title: Dorsomedial frontal and anterior cingulate cortex support cognitive reasoning about errors in a hierarchical decision making task

Authors: *M. SARAFYAZD, JR[1], M. JAZAYERI[2]
[1]Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: Monitoring performance and reasoning about errors is central to mental computation that supports intelligent behavior. Previous work has established that action outcome monitoring relies on signals in the dorsomedial frontal (DMFC) and anterior cingulate cortex (ACC). However, real-world actions may result from a hierarchy of decisions (What are the task rules? What is the best course of action? What should I do next?) making the source of errors ambiguous. To characterize the neural circuits and mechanisms that resolve this ambiguity, we trained monkeys to perform a hierarchical decision task. Within each trial, animals had to perform a time interval bisection task and report their choice by making a pro- or anti-saccade eye movements. Across blocks of trials, task rules that specify correct response contingencies (i.e., prosaccade for “Short” and antisaccade for “Long”) switched covertly motivating animals to accumulate information about errors within single trials to infer rule switches across trials. Animal’s behavior and fitted computational models indicate that following an error trial, animals relied on their degree of uncertainty about the time interval to infer whether or not the error was caused by an incorrect choice of rule.
To investigate the underlying neural mechanisms, we recorded from DMFC and ACC and focused on activity in the intertrial intervals when the animal had to evaluate errors. Both areas had a representation of timing error after individual trials that varied with expected accuracy. ACC activity was additionally modulated by cumulative errors across trials providing a substrate for reasoning about errors due to rule switches. Electrical microstimulation of ACC provided evidence that ACC was causally involved in animal’s decision about rules. Finally, given the different timescales of error representation in DMFC (single trials) and ACC (across trials), we

hypothesized that ACC might rely directly or indirectly on DMFC to compute switch evidence. We tested this possibility by applying electrical microstimulation in DMFC while recording in ACC. Results indicated that DMFC stimulation increased spiking activity in ACC in the hierarchical decision task but not in control task where errors were not ambiguous (i.e., externally cued rule). Overall, our results demonstrate how DMFC and ACC support cognitive reasoning about errors in nonhuman primates.

Title: Dorsal prefrontal cortex tracks projected outcomes in a dynamic competitive game

Authors: *J. M. PEARSON[1], S. IQBAL[1], C. DRUCKER[1], J.-F. GARIEPY[2], M. L. PLATT[3]
[1]Duke Inst. for Brain Sci., [2]Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC; [3]CCN, Univ. of Pennsylvania, Philadelphia, PA

Abstract: The ecological niches occupied by most organisms, including humans, are both dynamic and uncertain, requiring that actions be taken in real time. However, most studies of dynamic decision-making to date have explored either repeated trials of the same task under slow changes or interactions between agents from a restricted action space. These limitations may severely constrain our understanding of the neural mechanisms that mediate strategic interactions. To address this gap, we examine data from repeated trials of a real-time strategic interaction with continuous freedom of movement. We trained monkeys to play a game in which the goal of one (the "shooter") was to move a colored dot (the "puck") from the left to right side of a computer monitor using joystick input. The goal of the second monkey (the "goalie") was to block the dot by moving a vertical line along the right-hand side of the screen to intercept it. Thus, each player controlled an avatar with at least one continuous degree of freedom, in principle allowing for dynamic coupling between the two. We analyzed these data by modeling the trajectory of each player as the output of a linear control model applied to a latent goal state. This goal represented an onscreen position toward which each player directed his avatar at each moment. These goal positions followed a Markov dynamics governed by a "kinetic energy" that favored smooth trajectories and a "potential energy" that depended on the current state of each

player. This characterization allowed us to directly look for correspondences between goals and neural activity. We recorded 353 single units from the lateral and medial dorsal prefrontal cortex of three rhesus macaques (137 DMPFC; 216 DLPFC) during 130 sessions in which the recorded monkey played as the shooter. We found that in 58% of DMPFC cells (79/137) and 43% of DLPFC cells (92/216) spiking activity was modulated following shooter wins. In fact, this signal often began to emerge even before trial end, at the moment the outcome of the trial became apparent. In addition, we used LFADS (Pandarinath et al.) to infer latent factors that drove firing rates across units and sessions. These latent factors were correlated with variables that tracked progress through the trial and variables related to variability across trials. In particular, multiple latent factors were correlated with the momentary entropy of the shooter's strategy, suggesting an instantaneous measure of decision complexity. Taken together, these findings suggest that single neurons in dorsal PFC not only encode evaluative signals necessary to update behavioral policies, they do so online as the prospects of winning dynamically evolve.

Abstract: The ability to adjust one’s behavioral strategy in complex and variable environments in the absence of instruction is at the core of higher cognition. One proposal is that such behavioral flexibility is enabled by a targeted exploration of a set of working hypotheses, or beliefs, about an environment’s governing rules. However, little is known about how an animal’s beliefs about its environment are represented in neural circuits. Our initial efforts to probe the neural basis of the representation of beliefs about the environment’s rules — an internal model of the environment — focused on settings that induce dramatic changes in these beliefs. The detection of corresponding changes in population dynamics allowed us to pinpoint the anterior cingulate cortex in the rodent as a likely region involved in the encoding of these beliefs. Over the past few years, we have developed techniques to monitor and manipulate neural activity using wireless headstages in freely behaving animals in a way that does not impair behavioral

flexibility. We will discuss our results from experiments that take advantage of behavioral tasks where animals flexibly explore different hypotheses about their environment. These experiments have permitted us to focus on the neural mechanisms of encoding internal models, how they are updated through experience, and used to direct behavior.

Abstract: The ability to adjust one's behavioral strategy in complex and variable environments in the absence of instruction is at the core of higher cognition. Recent work has posed that the brain makes the potentially unwieldy problem of mapping the multitude of uncertain situations onto behavioral choices tractable by first re-evaluating the set of learned strategies before deciding to construct new ones (Donoso et al., 2014). Functional imaging studies in humans supported this theoretical framework and suggested that anterior cingulate cortex (ACC), driven by internal estimates of the need to question the reliability of the ongoing one, plays a role in switching to alternative learned strategies (O'Reilly et al., 2013). These findings dovetailed with the body of findings in humans (e.g. Behrens et al., 2007), primates (e.g. Blanchard et al., 2014) and rodents (Karlsson et al., 2012) implicating ACC in keeping track of alternative learned strategies, and in learning higher order statistics about the environment that can inform internal estimates of reliability. However, whether ACC plays an active role in strategy switching, or merely monitors behavioral performance remains unclear. Over the past few years, we have developed molecular tools that permit robust circuit dissection in rodents (Tervo et al., 2016; Brown et al., 2018). We will discuss our findings from perturbation experiments these tools enabled geared to elucidate the precise role ACC plays in strategy arbitration.

Title: Reward-predictive persistent membrane potential dynamics in prefrontal cortex

Authors: *E. KIM[1], B. A. BARI[2], J. Y. COHEN[3]
[1]Johns Hopkins Sch. of Med., Rockville, MD; [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: The prefrontal cortex (PFC) has a crucial role in integrating and transforming internal and external information into complex cognitive behavior. Persistent activity, in which task-relevant information is held "online" after its disappearance from the environment, is thought to be a key mechanism underlying these processes. Although previous studies using extracellular recordings showed diverse patterns of persistent activities, the underlying mechanisms that generate and maintain these persistent activities remain largely unknown.
Therefore, to understand the neural mechanism underlying persistent activity in PFC, we measured the subthreshold membrane potential (Vm) in layer 5 pyramidal neurons using in vivo whole-cell recordings combined with optogenetically-induced perturbations in head-restrained, behaving mice. In addition, by using a GFP-expressing plasmid, we reconstructed a subset of neurons to identify their morphologies and the depth of the recordings.
Thirsty mice were trained to perform a behavioral task in which different odor cues predicted the delivery of water reward following different delays. Vm and action potentials (AP) that were measured during the task revealed three distinct reward-predicting persistent activities in layer 5 pyramidal neurons: 1) sustained Vm depolarization and increased AP firing during the delay between stimulus and predicted reward; 2) sustained Vm hyperpolarization and cessation of AP firing during the delay; and 3) Vm depolarization and increased AP firing after reward delivery. Recording depth estimates showed that the first types of responses were located predominantly in upper layer 5 where cortico-striatal and cortico-cortical neurons are found, whereas the second

type was located predominantly in lower layer 5 where pyramidal track neurons are found, indicating that different types of persistent activity may reach different postsynaptic targets. To understand the mechanisms responsible for these differences, we recorded from pyramidal neurons in these two sublayers in anesthetized mice and found different intrinsic membrane properties. Next, to test whether intrinsic mechanisms lead to persistent changes, we perturbed Vm during the delay period and found that Vm immediately returned to unperturbed levels. This indicates that persistent membrane potential dynamics are stable states that are robust to perturbation. Thus reward-predictive persistent firing rates changes are due to stable changes in Vm, carried by different subtypes of neurons, that may send different information to distinct downstream targets.

Title: Strategy selection based on trial feedback in a rule-based categorization task

Authors: *M.-Y. PARK[1], D. A. CROWE[2], M. V. CHAFEE[1,3]
[1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Biol., Augsburg Univ., Minneapolis, MN; [3]Brain Sci. Ctr., VA Med. Ctr., Minneapolis, MN

Abstract: In uncertain and changing environments, trial-and-error feedback is important to make decisions to optimize reward. To test how feedback affects categorical decision making we trained two monkeys to perform a rule-selection categorization task. Two circular stimuli were presented in sequence that differed in position and size. In blocks of trials, monkeys were rewarded for determining the relationship of the second stimulus to the first, either with respect to size (‘larger than’, or ‘smaller than’) or to position (‘left’, or ‘right). Under the size categorization rule, monkeys made a saccade to the second stimulus if it was larger than the first (‘Go’ trial), or withheld the saccade if it was smaller (‘NoGo’ trial). Under the spatial categorization rule, the 'Go' versus 'NoGo' decision was based on the relative positions of the two targets. The categorization rule was not explicitly instructed. Rather, monkeys inferred the correct rule in each block using trial-and-error feedback. Contrary to our expectation that monkeys would form two discrete rules and apply them to categorize the relevant stimulus dimensions independently, we found that monkeys generated compound categories based on combinations of size and spatial relationships (‘smaller left’, ‘larger left’, ‘smaller right’, and

‘larger right’). Two such compound categories were 'congruent' in the sense that they required the same response regardless of the rule in force (‘larger left’ and ‘smaller right’). The other two compound categories were 'incongruent' in the sense that monkeys had to switch from a 'Go' to 'NoGo' response strategy to those categories when the rule changed. We found that performance on congruent compound categories was high (≥80%) and remained high when the rule switched, reflecting the constant response strategy required for the two rules in these cases. Conversely, performance on incongruent compound categories dropped after a rule switch to ~40% and showed strong learning effects - monkeys reached asymptotic performance (~80%) in 30-40 incongruent trials. Trial feedback on incongruent trials was informative about the rule switch, whereas trial feedback on congruent trials was not. We hypothesized therefore that trial feedback was differentially processed on congruent and incongruent trials. We computed success probability as a function of trial feedback on the preceding trial, and found this differed according to whether the preceding trial was congruent or incongruent (chi-square 40.12, d.f. = 3, $p < 0.001$). The animals were more likely to perform correctly after a rule switch following an error on an incongruent trial in comparison to an error on a congruent trial.

Abstract: Neurons encoding spatial information have been detected in the hippocampal CA fields and dentate gyrus of a number of animals including rodents, bats, as well as both human and non-human primates. However, a clear representation of self-position encoded in the firing rates of pyramidal neurons in primate hippocampus, that is, so called canonical place cells, remain elusive during active navigation. A combination of hardware and experimental design challenges in the case of the non-human primate, and surgical contraindication in the case of human epilepsy patients, has made investigation of place encoding in the primate hippocampus difficult thus far. In recent years, the common marmoset (*Callithrix jacchus*) has emerged as a

powerful model for primate neurophysiology. The marmoset hippocampus exhibits a great degree of similarity to other old-world primates both in gene expression and structural organization, but whose in-vivo electrophysiological dynamics have never been characterized. We sought to characterize those dynamics in the context of free navigation in several spatial environments consistent with previous studies of rodents, and specifically characterize spatial tuning of hippocampal neurons during unrestrained, high velocity locomotion. To this end, we implanted chronic microwire arrays into marmoset hippocampus using a structural-MRI guided surgical procedure. Neurons recorded in marmoset hippocampus during high velocity track exploration displayed significant encoding of information about the marmoset's current position within the track. Furthermore, these neurons exhibit statistically significant coherence with the phase of the underlying local field potential in a frequency band similar to the theta band in rodents. However, we did not observe a very high amplitude and temporally consistent theta oscillation during locomotion of the implanted marmosets.

Abstract: A large corpus of literature has shown that the hippocampus plays an important role in representing the surrounding environment during free navigation. Studies in rodents and bats have demonstrated the existence of spatially-tuned place cells that fire preferentially when the individual occupies a particular region of space - "place field." - Whether primate hippocampus achieves a similar spatial representation during active navigation, however, remains an open question. Primates rely heavily on their vision in particular to explore their surroundings, and the visual sensory information they acquire is known to contribute to spatial representations in the medial temporal lobe. The reliance on visual exploration suggests that there may be spatial

encoding mechanisms that are not exclusively related to physical occupation of space, a pattern consistent with data observed during both human and non-human primate neurophysiology studies. A more thorough characterization of the electrophysiological dynamics of the primate hippocampus at the single neuron level is required, particularly in the context of concurrent visual and physical exploration of a naturalistic environment. Here we demonstrate a novel paradigm developed to investigate how primates represent space while navigating a 3-dimensional environment either alone or with conspecifics. We record the activity of single units in the hippocampus of freely-moving marmosets while simultaneously tracking spatial location and head direction of all monkeys in the environment. We will present behavioral and neural data in this paradigm related to fundamental questions of how primates represent and explore physical and social space in hippocampus.

Title: Cross-modal representation of individual identity in marmoset hippocampus neurons

Authors: *C. T. MILLER[1], G. CAUWENBERGHS[2], H. COURELLIS[3]
[1]Cortical Systems and Behavior Lab., [2]Dept. of Bioengineering, [3]Bioengineering, UCSD, La Jolla, CA

Abstract: The convergence of multi-modal sensory information in the hippocampus facilitates the internal representation of a complex external world. A human, for example, integrates information acquired from an individual across multiple sensory modalities, such as the sight of their face or the sound of their voice, to establish a cohesive representation of that individual's identity, a process supported by mechanisms in hippocampus. Here we sought to interrogate whether neurons in the hippocampus of an awake marmoset monkeys (Callithrix jacchus) exhibited mechanisms for individual identity representation. Like humans, this primate species routinely uses both visual and acoustic social signals to mediate their conspecific social interactions. We presented subjects with concurrent visual and auditory signals - faces and vocalizations - collected from their family members and unrelated animals in the colony. We hypothesized that single units in the marmoset hippocampus would be differentially responsive to these sensory signals when presented separately and presented concurrently. We further

hypothesized that a sub-population of neurons would be sensitive to the congruence of these signals for representing the individual identity of the monkey. We implanted chronic multi-electrode arrays into marmoset hippocampus using a structural-MRI guided surgical procedure. Marmosets were head-fixed before a digital display and a speaker to present both auditory and visual stimuli. Task structure involved a brief fixation after which either a vocalization, face, or combined audiovisual stimulus were presented. Audiovisual stimuli were further sub-divided into matched and mismatched stimulus identity. We found hippocampal single units to be significantly differentially responsive to audiovisual combinations of sensory stimulation. Furthermore, we identified a population of neurons sensitive to the congruence of identity between auditory and visual stimuli. These initial analyses suggest that neurons in marmoset hippocampus contribute to a cross-modal representation of individual identity.

Title: Encoding of spatial variables in retrosplenial cortex during landmark dependent navigation

Authors: *L. FISCHER[1], R. MOJICA[2], E. H. S. TOLOZA[1], D. BARNAGIAN[1], M. T. HARNETT[1]
[1]MIT, Cambridge, MA; [2]Univ. of Puerto Rico at Mayagüez, Cambridge, MA

Abstract: Retrosplenial cortex is an associative cortex that has been found to be critical for spatial navigation and route planning. Monosynaptically restricted anatomical tracing using rabies virus show that it receives direct inputs from primary visual, secondary motor and anterior cingulate cortices, as well as multiple thalamic nuclei. Direct connectivity of RSC with hippocampal regions, however, is limited. This suggests a role in integrating visual and motor feedback during navigation. To test the hypothesis that RSC is critical for using visual landmark information to guide navigation, we developed a spatial task for head-fixed mice in virtual reality that requires the integration of visual inputs and motor feedback during a path integration period to locate a reward zone along a linear corridor. Animals are required to learn different distances to hidden reward locations associated with different visual landmarks. We find that inactivation of RSC reduces task performance only when both components, landmark utilization and motor feedback, are required for task completion. A purely visually guided version of the task was not affected by inactivation. 2-photon population imaging in layers 2/3 and layer 5 of GCaMP6f-labeled neurons shows highly specific encoding of landmarks and path integration periods. However, the majority of these neurons are inactive, or are attenuated, in amplitude and

robustness, when a movie of the same environment is passively replayed to the animal. Population analysis shows similar subpopulations of neurons are being active during path integration, regardless of the distance required to travel to the reward, while landmarks are encoded by less overlapping subsets of neurons. To gain a better understanding of the computations carried out by RSC, we imaged axonal boutons originating in V1. Unexpectedly, we found that V1 boutons also show complex receptive fields responding to during landmarks and path integration periods. Together these results show that RSC is important for landmark-dependent navigation and that its populations encode both integration of visual features that provide spatial information and execution of navigation to a goal location. However, V1 provides more sophisticated inputs than previously thought and the specific contributions of RSC and V1 during landmark-dependent navigation remain to be established.

Title: Somato-dendritic encoding of head-direction in mouse retrosplenial cortex

Authors: *J. VOIGTS[1], M. T. HARNETT[2]
[1]Brain and Cog. Sci., [2]MIT, Cambridge, MA

Abstract: Efficient navigation requires the context-dependent integration of a multitude of signals. A familiar landmark on an animal's right side, for instance, has a different meaning depending on whether the animal is facing north or south. Retrosplenial cortex (RSC) has been proposed to serve a central role in solving such computations by translating between egocentric and allocentric representations of the environment. Neurons in RSC integrate multiple navigational variables, including egocentric visual information and position relative to landmarks, allocentric location within an environment, and heading. These mixed representations in RSC neurons, in which individual inputs can change the impact of other inputs, form a convenient model system for studying associative neuronal computations. Dendrites, which endow individual cells with complex nonlinear processing capability, may play an important part in these computations. Here, we examine the subcellular computations underlying the encoding

of heading direction in RSC using calcium imaging in mice exploring a physical 2-dimensional environment. We developed an experimental approach that permits mice to freely rotate their heads in the azimuthal plane with negligible inertia and friction during conventional 2-photon imaging. We used this system to perform GCaMP imaging at somas and dendrites of pyramidal neurons in retrosplenial cortex. We found that distal apical dendritic tuft segments in RSC neurons encode heading, but only partially predict a cell's head direction or spatial tuning. Our findings indicate that individual RSC neurons receive a variety of tuned inputs in their apical dendrites, that are nonlinearly modulated by other inputs before influencing somatic output. Our results provide insight into the role of dendritic computations in head-direction encoding in RSC and will provide a starting point for studying more general associative dendritic computations.

Title: Simultaneous encoding of head angle, episodic distance, and position by hippocampal activity in a virtual water maze

Authors: *J. J. MOORE[1,2,3,4], M. R. MEHTA[1,2,3,4,5]
[1]W. M. Keck Ctr. for Neurophysics, Los Angeles, CA; [2]Integrative Ctr. for Learning and Memory, [3]Brain Res. Inst., [4]Dept. of Physics and Astronomy, [5]Departments of Neurology, Neurobio., UCLA, Los Angeles, CA

Abstract: The Morris Water Maze is a widely used behavioral test of hippocampus dependent spatial learning, memory and navigation. Yet the neural basis of this behavior is not well characterized, owing to the difficulty of performing single unit recordings in this task and the limited number of trials in a session. To overcome these limitations we have developed a virtual water maze task[1] with only visual cues defining position, in which rats can run more than 100 trials per session[2]. This allows us to perform robust statistical analyses of the contribution of different parameters to neural firing and how these firing properties relate to behavioral performance. Here we focus on three parameters: head angle, episodic distance, and allocentric position.Well trained rats follow fairly stereotyped paths in this task, and so tuning in one domain may generate false selectivity in another due to partial collinearity between parameters.

Hence, we developed a generalized linear model with added regularization to estimate the simultaneous contributions of head angle, episodic distance, and allocentric position to the firing of >1000 hippocampal pyramidal cells. The regularization term also allows robust estimates using small amounts of data, so tuning changes can be tracked within a single session.From this experimental and statistical-model based approach we report five findings:
1. Despite good task performance, we observed very little allocentric spatial selectivity.
2. A substantial proportion of cells were modulated by episodic distance, and the distribution of peak locations was biased towards the beginning of trials.
3. Many cells were modulated by head angle, and the population of these cells was biased towards the quadrant containing the hidden reward zone.
4. Across sessions, the percentage of neurons that were tuned to any of these parameters was positively correlated with behavioral performance.
5. Both behavioral performance and the activation of neurons increased with experience within a single session.
Thus, even though there is little hippocampal allocentric spatial selectivity during this task, other navigationally relevant parameters are encoded by the hippocampus, and the degree of this tuning is correlated with behavior. These experience based changes may be driven by similar mechanisms of synaptic plasticity demonstrated in studies on linear tracks[3-5], thus linking behavioral learning with hippocampal activity and cellular mechanisms of plasticity.

Title: Multisensory mechanisms of hippocampal slow oscillations

Authors: *K. SAFARYAN[1], M. R. MEHTA[1,2,3,4]
[1]Departments of Physics and Astronomy, Neurology, Neurobio., UCLA, Los Angeles, CA; [2]W. M. Keck Ctr. for Neurophysics, Los Angeles, CA; [3]Integrative Ctr. for Learning and Memory, Los Angeles, CA; [4]Brain Res. Inst., Los Angeles, CA

Abstract: The hippocampal theta oscillations differ across species and experimental conditions. Specifically, the hippocampal 8 Hz theta rhythm (Buzsaki & Vanderwolf, 1983) is readily seen in rodents during spatial exploration. Several mechanisms of the theta rhythm have been

suggested including the medial septal (Winson, 1978) as well as multiple generators within (Kocsis et al., 1999) and outside (Moore et al., 2013) of the hippocampal system. However, the 8 Hz theta rhythm is not seen in the healthy bats' or primates' hippocampus. Instead, infrequent bouts of low frequency oscillations are observed. In addition, the nature of the theta rhythm in humans is debated. These differences could arise due to various reasons such as differences in task demands, behavioral state or sensory cues. Thus, the sensory and behavioral mechanisms governing hippocampal slow oscillations remain to be fully understood.
We hypothesized that one of the reasons for these differences is the nature of multisensory cues available under different conditions (Ravassard et al. 2013). To test this hypothesis, we compared the nature of the hippocampal theta oscillations on the same electrodes when rats run on a linear track either in the real world (RW) or in virtual reality (VR). The main differences between the two environments are in the nature of linear acceleration and multisensory cues except visual cues. We found that the power of theta oscillations is comparable between RW and VR, and the speed-dependent increase in theta power is also similar. This suggests that the differences in multisensory or vestibular cues are not critical for the speed-dependence of theta amplitude. However, the speed-dependence of theta frequency in VR is shown to be abolished in some studies (Ravassard et al. 2013; Bourboulou et al., 2018), but preserved in others (Fuhrmann et al., 2014). We found that these differences arise due to differences in analytical methods used to detect the theta rhythm. We developed a robust method which showed that speed dependent increase in theta frequency is indeed abolished in VR, but the same method shows reliable increase in theta frequency in the RW.
Finally, we found that electrodes that were well localized within the hippocampus showed an additional oscillation at about 4Hz in VR. The amplitude of this oscillation also increased with the running speed but its frequency remained unchanged. This 4Hz oscillation was not seen in the RW. As a result, the activity of hippocampal single units was strongly influenced by both the 4 Hz and the 8 Hz rhythms in VR. These results show that the nature of multisensory cues have a profound influence on the amplitude and frequency of hippocampal slow oscillations.

Title: Medial precentral cortex transforms spatial and directional information into planned action

Authors: *D. A. NITZ[1], J. M. OLSON[2], J. LI[3]
[1]Univ. of California San Diego, La Jolla, CA; [2]MIT, Boston, MA; [3]Stanford Univ., Palo Alto, CA

Abstract: Fluid navigation requires constant updating of motor plans as obstacles and goals change across space. In order for the brain to achieve this, the neural substrate must receive spatial and sensory information and have motor targets as outputs. Based on its anatomical connectivity, medial precentral cortex (MPC), a frontal association cortex of the rat, is a prime candidate for this role (Reep et al., Neurosci. Lett., 1984). There exists extensive reciprocal connectivity between MPC, posterior parietal cortex (PPC), and retrosplenial cortex (RSP), and large populations of PPC and RSP neurons have spiking activity that maps animals' positions within the space of complex routes as well as those that correlate with turning behaviors (Nitz, Neuron, 2006; Alexander and Nitz, Nat. Neurosci, 2015). Smaller populations provide signals as to head orientation relative to the environment. Completing the hypothesized sensory to motor pathway, MPC projects to primary motor cortex as well as along the corticospinal tract to the spinal cord (Donoghue and Wise, J. Comp. Neurol., 1982). Anatomically, the MPC subregion of prefrontal cortex is ideally suited for transformation of knowledge of current position into a plan for specific motor actions. We conducted electrophysiological recordings of individual neurons in medial precentral cortex of rats while they navigated a complex multi-route maze. As hypothesized and supported by previous recordings in the area, we report activity that encodes current actions (left/right turns) in MPC as well as activity encoding upcoming actions. These representations of actions are robust across environmental factors, including the direction of travel, spatial location, and position within the route being traversed. They are even robust to whether the action is at a choice point or if only one possibility exists. To then test the hypothesis that transformation into action occurs in the MPC circuitry, we investigated evidence of spatial and other contextual information being represented in the region. Individual neurons and the population as a whole reliably discriminate environmental position, direction, route position, and either choice vs forced turns. These results support a model in which spatial and contextual information is transformed to egocentric frames of reference for the purpose of fluid, efficient navigation.

Title: Visual cues alone are insufficient to generate robust grid cells and head-direction cells in the medial entorhinal cortex

Authors: *Z. M. AGHAJAN[1,2,3,4,5], A. L. KEES[8,2,3,4,6], P. VARANASI[2,3,4,6], S. SANDHU[2,3,4,6], M. R. MEHTA[2,3,4,5,7]

Abstract: The medial entorhinal cortex (mEC) is thought to play a crucial role in allocentric navigation—a task that is heavily influenced by visual cues, e.g. in the water maze task. Navigation requires information about spatial position and direction. The activity of mEC neurons exhibit spatial and directional selectivity, in the form of grid and head-direction cells' firing patterns respectively. The mEC projects to the downstream area CA1 (*1*), and dorsal CA1 neurons show spatial and direction selectivity, hypothesized to be generated from the mEC spatially selective grid cells (*2*, *3*) and mEC head-direction cells. To test these hypotheses, we measured rats' mEC responses in a purely visual virtual reality (VR), and compared it with their responses in a visually identical real-world (RW). The task design was such that the VR session was performed in between two RW sessions, thus allowing us to examine the activity of the same cell across these conditions.

Consistent with our prior findings, the activity of grid cells was severely disrupted in VR. These neurons showed intact spatial modulation in RW, but despite similar levels of firing rates across all sessions, their spatial modulation was abolished in VR. Thus, visual cues alone are insufficient to generate mEC grid pattern. This finding could also explain the loss of spatial selectivity in CA1 place cells in VR, as predicted by previous models (*2*, *3*).

Direction selectivity of neurons in VR manifested two surprising findings. First, there was a small but significant fraction of cells with directional selectivity with respect to the VR visual cues (but not to the animals' head-direction in the RW reference frame). Second, in contrast to our findings in CA1—where direction selectivity was intact in VR and even comparable to that in the RW—here, direction selectivity was diminished for the majority of head-direction cells. This shows that visual cues alone are sufficient to generate direction selectivity in a small fraction of mEC neurons while other mEC cells require multisensory cues to generate spatial and directional tuning. Further, this suggests that while CA1 spatial selectivity may be inherited from mEC, it is possible for CA1 directional selectivity to arise by some other mechanisms—independent of mEC inputs—such as the inputs from LEC (*4*).

Title: Place versus places: Spatially-specific activity in subiculum encodes structural similarities among interconnected paths

Authors: *A. B. JOHNSON[1], J. M. OLSON[1,3], E. L. TAO[4], X. WANG[4], L. CHANG[4], A. C. PHUTISATAYAKUL[4], D. A. NITZ[2]
[1]Cognitive Sci., Univ. of California San Diego, LA Jolla, CA; [2]Univ. of California San Diego, La Jolla, CA; [3]MIT, Cambridge, MA; [4]UCSD, La Jolla, CA

Abstract: To reveal potentially novel functions of subiculum (SUB) in spatial cognition, we studied and compared activity of CA1 neurons, SUB neurons, and posterior parietal cortex (PPC) neurons while animals navigated a maze having 6 distinct, but interconnected paths. Four of the paths partially overlap and lead the animal to a reward location. The remaining two are non-overlapping and bring the animal back to the rewarded paths' shared starting location. The rewarded paths have the same lengths but dissociate through differing sequences of three 90 degree left/right turns. The return paths have the same lengths, flank either side of the environment, and are made of two 90 degree turns. This path network structure results in reward paths and return paths that vary in spatial separation, direction of travel, and required action sequences. However, among the four reward paths and return paths, there exist multiple non-overlapping locations that are spatially 'analogous' in sharing combinations of the animal's direction of travel, proportion of distance through a path, current action, and/or axis of travel. We observe here that PPC neurons' activity patterns are most closely related to progression through a route and/or current action. CA1 neurons typically exhibited one place-specific firing field. The spatial distribution of the multiple-field exhibiting CA1 neurons was seemingly random. This data is consistent with prior conceptions of PPC and CA1 generating complementary representations of the rat's location in route and environmental spaces, respectively. In stark contrast, SUB neurons often exhibited multiple fields and the spatial distribution of these fields was mostly non-random. For the majority of individual SUB neurons,

spatially-specific firing fields were distributed across analogous locations of 2 or more paths. This tendency and its contrast to CA1 and PPC neuron populations was quantified through correlation of individual neuron positional rate vectors and through correlation matrices examining ensemble correlations between all pairs of path network locations. A decision-tree analysis applied to all 6 positional rate vectors of each neuron was implemented to determine which spatial and directional variables were key to generating similar firing across analogous path locations.
These data indicate that a unique role for SUB in spatial cognition lies in extracting and encoding structural features of a path network. Furthermore, the findings highlight the importance of SUB as a potential region able to extract, compare, and respond to similarities between otherwise distinct experiences.

Title: Simultaneous representations for virtual and real spaces in the rat hippocampus

Authors: *C. PURANDARE[1,2,3,4], K. CHOUDHARY[5,2,3,4], M. R. MEHTA[6,2,3,4]
[1]Bioengineering, Univ. of California Los Angeles, Los Angeles, CA; [2]W. M. Keck Ctr. for Neurophysics, [3]Integrative Ctr. for Learning and Memory, [4]Brain Res. Inst., [5]Physics and Astronomy, UCLA, Los Angeles, CA; [6]Departments of: Physics & Astronomy, Neurology, Neurobio., Univ. of California at Los Angeles (UCLA), Los Angeles, CA

Abstract: During unconstrained real world (RW) exploration, rodent hippocampal activity shows robust spatial selectivity, which is hypothesized to be governed by distal visual and locomotion cues, along with contributions from other sensory-motor cues. To dissect the contributions of these different variables on hippocampal spatial selectivity, we have recently developed a virtual reality apparatus. Here, the rat runs on a spherical treadmill that floated freely on an acoustically quiet air cushion, to receive liquid rewards through a tube in front of the rat. Our VR system employs a hinged harness that gently body-fixes the rats but allows for head movements around body. The harness, reward tube and VR chassis constitute a novel,

constrained real world (c-RW) where the rat's legs and head can move freely but his body does not. Movement of his legs cause a rotation of the spherical treadmill that induces a change in the virtual scene, i.e. virtual movement, without any significant change in the rat's position in the c-RW position. In previous studies we found that during random foraging in our VR, spatial selectivity is markedly reduced while directional modulation was comparable to RW [1, 2]. Here, we investigated the selectivity in c-RW while the rat performed two dimensional navigational tasks in the VR space. We find that a substantial number of neurons showed selectivity to the rat's head angle in the c-RW environment, in the absence of task demands in the c-RW frame and in the absence of active navigation driven changes in c-RW position (owing to body restriction). Our results suggest that hippocampal neurons can simultaneously maintain representations of real and virtual environments and have important implications for the growing use of virtual reality for scientific, and commercial uses.

Abstract: Persistent neural activity is thought to be a neural substrate for mediating working memory during behavior, as it can establish a representation of a stimulus that persists after the

stimulus is extinguished. Recent *in vivo* work in rodents during slow-wave sleep [1] has shown a close link between persistent activity in layer III neurons of the medial entorhinal cortex (MECIII) and the up-down state (UDS) oscillations in the afferent neocortex, where neurons show a ubiquitous pattern of synchronized transitions between active periods of tonic firing (UP states) and periods of quiescence (DOWN states). Interestingly, while the membrane potential of neurons in MECIII show both persistent activity [1] and inactivity [2] in response to cortical dynamics, this persistence is absent in neighboring lateral entorhinal cortex (LECII) neurons. While several models have been proposed to explain neocortical UDS [3, 4] and *in vitro* MEC persistent activity [5] separately, the link between the two has been left unexplored. Here, we present a model, based on a bi-stable attractor, to understand the mechanisms underlying cortico-entorhinal coupled dynamics during UDS. The MECIII is modeled as a bi-stable network of excitatory and inhibitory neurons, and this network is coupled to an oscillatory two-state neocortical network. The MECIII network takes the periodic input from the neocortex and responds such that a state change is induced only when the input exceeds a prescribed threshold. These results reveal a possible biophysical mechanism behind the experimentally observed persistent activity in membrane potential *in vivo* and suggest a potential contribution of this coupled behavior to cortico-entorhinal-hippocampal interaction, which is thought to be involved in working memory, the learning of long behavioral sequences during behavior, and memory consolidation during sleep. Title: Rule-based fragmentation of environmental space yields trajectory-specific encoding in posterior parietal cortex, but not hippocampus

Authors: *L. E. SHELLEY[1], D. A. NITZ[2]
[1]UCSD, La Jolla, CA; [2]Univ. of California San Diego, La Jolla, CA

Abstract: The current study examined environmental subspace representations using a task-defined, behavioral rule to demarcate the division of a room into two subspaces, rather than by a

concrete feature or visible dividing line. Rats traversed a T-shaped track placed in one of four locations. The task was structured into blocks of five trials at each position. Rats were trained to turn left when the track was placed in one half of the room, and to turn right when placed in the other half.
Behavioral results indicate that rats can learn such logical fragmentation, as evidenced by high accuracy during probe trials in which the track was placed in novel locations. Furthermore, while performance at all track positions was well above chance, accuracy was poorer for track locations near the fragment boundary.
Neurons in both the hippocampus (HPC) and posterior parietal cortex (PPC) were recorded during task performance. Spatial firing patterns in both regions followed track, not room, position at each of the four positions, an effect that was expected for posterior PPC neurons, but was unexpected for HPC. Furthermore, PPC ensembles, but not HPC ensembles, were prospective in discriminating L- versus R-going trajectories past the halfway point along the stem.
The first trial of any block demanded that the animal apply the fragmentation rule while performance on trials 2-5 could be derived from the success/failure outcome of the first. Therefore, we also examined whether trial number within each block was a variable that could differentiate PPC and HPC firing patterns. Firing patterns in both areas differentiated trial 1 from subsequent trials maximally at early stages in each run, an effect that was stronger and persisted past the halfway point of the stem for HPC ensembles.
The findings indicate that rats are capable of learning a rule-based spatial division of the environment and that task performance is associated with unexpected spatial firing properties of HPC and PPC neurons. PPC neurons exhibited prospective encoding of choice behavior. HPC did not and, further, exhibited spatial firing activity tied to the track's frame of reference. We interpret the trial number impact on HPC firing patterns as reflecting the heightened spatial awareness needed to perform the task when the track is moved to a new location.

Abstract: Hippocampal CA1 cells have known to exhibit allocentric spatial selectivity [1], which has been extensively studied over years. Several different theories have been hypothesized to explain the origin of this selectivity. These include cognitive mapping, largely based on visual landmarks, or path integration, which relies on internal variables, such as orientation and steps taken. Our lab recently proposed that hippocampal activity patterns can be explained by combinations of multisensory cues in the environment. This is supported by the observation that hippocampal activity and the nature of spatial selectivity are quite different in Virtual Reality (VR), even when the visual and locomotion cues are comparable to Real World (RW) [2]. Atop the spatial selectivity, we also showed the presence of directional selectivity in CA1 cells during random foraging [3] in RW and VR, which were found to be comparable in these environments. In fact, individual visual cues exerted a causal effect on the directional response of the entire hippocampal ensemble. We found that the directional preference of the cells rotated with the distal cues, and their tuning widths changed with the width of the visual cues. In this work, we investigate the contribution of mulitsensory cues to the directional selectivity in CA1 cells using novel experimental manipulations and analytical methods.

The experimental paradigms used in this work involved rats random foraging on an open platform in 2D environments, with combinations of distal and proximal visual cues, without any reward association to these cues. Manipulations of multisensory cues in these setups included changing position, orientation and size of the distal visual cues, and suspending a similarly sized and shaped proximal visual cue above the platform. For analyzing the data, we make use of generalized linear model (GLM) [3], which provides an estimate of the independent contributions of rat's position, direction, speed etc., on single unit responses.

By employing these techniques, we are able to dissociate the spatial and directional tuning of each cell. We find the directional tuning of the cells to be dependent on experimental conditions used, and follow the visual cue's position, while responding differently to distal and proximal cues. We also find that in the RW setups rich in distal visual cues, the contribution of spatial selectivity to the activity of hippocampal cells is significantly greater than that of directional selectivity.

Title: A statistical model based approach to decipher the mechanisms governing spatial and directional tuning of hippocampal neurons

Authors: *M. SHAHI[1,2,3,4], S. DHINGRA[1,2,3,4], R. SANDLER[1], R. RIOS[1,2,3,4], C. VUONG[1], L. ACHARYA[5], M. R. MEHTA[6,2,3,4]

Abstract: Hippocampal CA1 cells show allocentric spatial selectivity [1], which has been extensively investigated. In addition, our lab recently showed the presence of robust directional selectivity in CA1 cells during random foraging in real world (RW) and virtual reality (VR) [2]. The direction selectivity was found to be comparable in both the worlds, even though vestibular cues were substantially reduced in the latter. Alongside, we recently reported that rodent hippocampal neurons can show directional tuning to the maze center in virtual reality (Dhingra et al. SfN 2017, Shahi et al. SfN 2017). These results indicate that hippocampal neurons contain information about multiple behaviorally relevant variables, such as spatial position, head direction, speed, etc., and are differentially influenced by multisensory cues in the maze. These variables often co-vary, which makes it difficult to disentangle their contribution to neural responses. To address these challenges, we measured neural responses under a variety of conditions and developed a statistical model based approach. The experimental setups used in this work involved random foraging on an open platform in 2D environments, in RW and VR, with specific combinations of proximal and distal visual cues, without any reward association to these cues. These manipulations included changing the position, orientation and size of the distal visual cues, and suspending a similarly sized and shaped proximal visual cue above the platform, which alters the spatial relationship of the visual cue without altering rat's behavior (Sandler et al. SfN 2016). To decipher the spiking activity of cells we further developed the generalized linear model (GLM) framework we recently employed [2]. To cross validate our findings, we

applied GLM to synthetic data that consisted of spike trains generated using behavioral data and inhomogeneous rate-modulated Poisson processes. By employing these techniques, we can dissociate the mechanisms governing different types of spatial and directional responses in hippocampal CA1 neurons. Our GLM framework provides an estimate of the relative influence of these variables on the spiking activity of individual cells. This method allows us to identify the nature of the directional selectivity of these cells in the presence of other tuning parameters, and under various multisensory conditions. These results provide novel insights about the mechanisms governing place cells, and have important implications for theories of hippocampal function.

Title: Mixed selectivity in the rodent medial temporal lobe and related regions

Authors: *C. MIKKELSEN[1], M. W. HOWARD[2]
[2]Dept. of Psychological and Brain Sci., [1]Boston Univ., Boston, MA

Abstract: Previous work has established that the macaque prefrontal cortex utilizes a mixed selective coding strategy (Rigotti, et al., 2013). Mixed selectivity is notable in that it requires many cells to respond to conjunctive pairings of different variables. Although previous work has argued that conjunctive coding develops in the rodent hippocampus and related regions (e.g., Komorowski, et al., 2009) and is important for learning associations, to our knowledge there has not thus far been a quantitative and systematic study of mixed selectivity in the rodent MTL. We used existing rodent data from the same contextual association task to ask whether mixed selectivity is observed in the rodent MTL, including studies of the hippocampus (McKenzie, 2014), lateral entorhinal cortex, medial entorhinal cortex and perirhinal cortex (Keene et al., 2016). In addition, we also analyzed datasets from the rodent orbitofrontal cortex (Farovik et al. 2015) and a previously unpublished dataset from the medial prefrontal cortex. The recordings encompass a total of approximately 2,000 single units. Although there are perhaps some subtle

differences across regions in the emphasis placed on variables for spatial/contextual and object information, the most notable result is that all regions showed robust mixed selectivity. This suggests that performance in the contextual association task makes use of a widespread network of interacting brain regions that use the same form of coding.

Title: Grid cell dysfunction in the medial entorhinal cortex correlates with path integration deficits in an amyloid mouse model of Alzheimer's disease

Authors: *J. YING[1], A. KEINATH[2], M. P. BRANDON[2]
[1]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada; [2]Psychiatry, McGill Univ. Douglas Hosp. Res. Ctr., Montreal, QC, Canada

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease popularly characterized by the presence of beta-amyloid (AB) plaques at the cellular level. Human patients typically show spatial memory impairments in the form of disorientation and difficulty navigating familiar environments. One potential circuit-level mechanistic explanation for these symptoms is that the onset of AB plaques causes a disruption of spatial coding in the brain's navigation system that consists of grid cells, head-direction cells, and border cells in the medial entorhinal cortex (MEC). In support of this view, previous in-vivo electrophysiological recordings in the Tg2576 mouse model of AD have confirmed that place cell degradation correlates with increased plaque load in the hippocampus. Here, we employed in-vivo electrophysiological recordings in the MEC of the freely behaving transgenic J20 mouse model of AD, which expresses an onset of beta-amyloid (AB) plaques in the hippocampus at five months of age. We demonstrate that grid cells are disrupted in aged J20 animals (months 5-7), evidenced by substantially fewer neurons that exceed our significance threshold for a metric designed to capture the spatial periodicity of grid cells. Even grid-like cells in J20 mice exhibit irregularity in the location of firing field. Network-level impairments of non-classified cells in the MEC are detectable in young J20 animals (months 2-4), preceding the formation of plaques. To corroborate our physiological findings, we aimed to better characterize the nature of spatial memory impairment seen in AD and to propose a function for the MEC in navigation and memory. J20 mice were tested in a path integration food-foraging task in darkness where they must integrate self-motion cues such as heading direction and movement speed to continuously update their perceived location in space. Without allocentric visual cues, this task provides an opportunity to characterize the classic navigational deficits seen in AD patients as well as the role of specific MEC cell types in navigation. Our data show that aged J20 mice demonstrate impaired path integration behaviour which correlates to the observed physiological dysfunction. Overall, our results suggest that grid cells in the MEC are important targets for future therapies to restore spatial cognitive function in human AD patients.

Title: Spatial correlates of the retrosplenial cortex during free exploration

Authors: *L. C. CARSTENSEN, A. S. ALEXANDER, J. R. HINMAN, M. E. HASSELMO
Boston Univ., Boston, MA

Abstract: The retrosplenial cortex (RSC) is an association area that is highly interconnected with sensory and motor processing regions as well as structures including the hippocampal formation (HPC), entorhinal cortices (EC), and anterothalamic nuclei (ATN) that are known to represent an animal's position or heading direction with respect to the external environment. Given this anatomy, it is perhaps no surprise that neural ensembles of the RSC encode numerous variables relevant to spatial navigation, including: position within a well-known route, position or heading within a global and/or local environment, and the current or upcoming actions of the animal. Investigations of the HPC, EC, and ATN have often focused on spatial responses observed while the animal freely explores an open arena. In contrast, RSC spatial representations have, with a few exceptions, been primarily examined in linear environments while the animal performs track running tasks. Given that RSC serves as both an input and output hub for the broader neural spatial circuitry, it is important to register RSC spatial responses in the two-dimensional (2D) environment with respect to place cells, grid cells, and head-direction cells of the HPC, EC, and ATN. In the current work, we sought to further characterize RSC spatial representations during free exploration. To do so, we performed in vivo electrophysiological recordings while rats explored familiar and novel arenas that had varying shapes or visual cue configurations. Consistent with previous work, we observed both allocentric and egocentric spatial representations within the region during open field exploration. We report that individual RSC neurons can exhibit complex 2D spatial correlates that are reliable across sessions and can anchor to either local or distal cues. RSC neurons also exhibited linear and non-linear speed related firing as well as other self-motion correlates. Finally, a sub-population of RSC neurons exhibited activity that was tuned to the egocentric relationship of the animal with respect to environmental boundaries. Collectively, these results identify multiple features of RSC spatial mapping in 2D environments that may have interesting implications for the formation or anchoring of spatial correlates in regions reciprocally connected with the RSC.

Title: Hippocampal representations of rooms with multiple entryways

Authors: *A. T. KEINATH[1], A. NIETO-POSADAS[2], M. P. BRANDON[3]
[1]Psychiatry, McGill Univ., Verdun, QC, Canada; [3]Psychiatry, [2]McGill Univ., Montreal, QC, Canada

Abstract: Outside of the laboratory, environments are often defined by multiple entryways; yet little is known about how multiple entryways might shape hippocampal map. Previous work examining the hippocampal representations of rodents in multiroom environments has demonstrated that rooms with similar spatial geometry and entryway directions elicit similar hippocampal maps (Spiers et al., 2013). Map similarity is minimized when these rooms are disambiguated by unique entryway directions (Grieves et al., 2016), suggesting that entryway direction may be an especially important determinant of the hippocampal representation of an environment. Here, we tested whether and how multiple entryways affect the hippocampal map within a given room. To do so, we simultaneously recorded calcium transient activity of large populations of place cells in CA1 as mice repeatedly explored a multiroom environment. In this environment, each room shared the same square spatial geometry, internal cues, and a common entryway direction, but was disambiguated by an additional unique entryway direction which was offset either 90°, 180°, or 270° from common entryway. We found that entryway direction modulated the hippocampal map both within and across rooms at the population level. Within each room, common-entrance maps and unique-entrance maps were similar; however, map similarity was lowest for the 180°-offset room. Across rooms, unique-entrance maps exhibited less repetition than common-entrance maps. Unique-entrance maps did not rotate relative to common-entrance maps, indicating that entryway direction modulated map identity but not map orientation. Together, these results demonstrate that entryway direction modulates hippocampal map identity within a room on an entrance-by-entrance basis.

Title: Schema accommodation in hippocampal memory ensembles

Authors: *S. J. LEVY[1], M. E. HASSELMO[2], H. EICHENBAUM[3]
[1]Grad. Program in Neurosci., [2]Psychological and Brain Sci., [3]Boston Univ., Boston, MA

Abstract: Hippocampal cells are known to remap their firing rates and global responses to immediate changes in task demands (Wood et al., 2000, Smith et al., 2006) and to changes in the environment (Wills et al. 2005, Leutgeb et al., 2005). This results in population codes related by graded similarity for distinct experiences. Gradual changes in the representation, or "drift," have also been observed, which don't affect the day-to-day precision of navigation (Rubin et al., 2015). The study presented here tests how new information that conflicts with a pre-existing spatial memory influences that existing spatial memory in the same population of neurons. The theory of accommodation of schema, also studied as retroactive interference, predicts that an existing representation should be noticeably altered by the integration of new, conflicting information. We studied this process by training mice to perform two different rules on a plus maze, "go East" and "turn right," on separate, consecutive days. We recorded the activity of the same population of cells in dorsal CA1 with calcium imaging, and show how both individual cells and the population code for one rule are altered by learning a second rule. We then compare the stability of population representations in conditions where information is learned in the same environment against learning in different environments. These results advance our understanding of memory maintenance and formation in the presence of interference.

Title: Investigation of the head-direction network activity in the Anterodorsal Thalamic Nucleus using miniaturized microscopes in freely behaving mice

Authors: *Z. AJABI[1], M. P. BRANDON[2]
[1]Integrated Program in Neurosci., [2]Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: Head direction (HD) cells are the most abundant spatially tuned neurons in the brain. HD cells are found in a series of regions starting in the brainstem and extending through the hypothalamus, thalamus, and up into the cortex areas that govern navigation and spatial memory. One area of interest is the Anterodorsal Thalamic nucleus (ADN), which contains a high concentration of HD cells (~60%) and is directly downstream of the circuitry believed to initially generate the HD signal, between the dorsal tegmental nuclei and the lateral mammillary bodies. One major obstacle to obtaining data from this region, especially in mice, is its small size (a spherical nuclei with a 0.3mm diameter). Thus, previously reported data has rarely shown recordings of more than 10 HD cells simultaneously. Here, we show calcium imaging of more than 50 HD cells at once and during behaviour. We use a miniaturized microscope built following the guidelines of the Miniscope project at UCLA (miniscope.org). To reach the ADN, we implanted a 0.5mm-diameter GRIN relay lenses, in mice that were injected, beforehand, with a non-specific adeno-associated virus (AAV) to express GCaMP6f, in the target region, which reduced damage to the brain tissue to its minimum and recordings were stable over the course of at least two months. Calcium transients allowed us to identify HD cells by means of polar plots and a correlation measure between fluorescence changes and the stimulus signal that was recreated by fitting a Gaussian curve centered at the angle to which the mean resultant length of the said polar plot points. Our recordings also show a stable preferred firing direction of HD cells for more than two months. Interestingly, our data shows a possible clustering of the HD cells with regards to their preferred firing directions and a potential topographical representation of the animal's head direction in the ADN. This preliminary finding needs to be further investigated. This technique also allowed us to analyze the HD cells' activity from a network perspective. Using dimensionality reduction methods, we were able to track the evolution of the HD system's state space during free exploration, in an open field. Preliminary results suggest a major impact of self-motion in maintaining a high level of activity in the HD network. Whereas, periods of immobility were generally characterized by a low network activity. Calcium imaging of substantial populations of HD cells may thus provide a way to further understand the dynamics of the HD system and can possibly be used to test the validity of the classic theory that defines the HD system as a ring attractor network.

Title: Coding of what and when in lateral entorhinal cortex and hippocampus during a delayed matching task

Authors: *J. H. BLADON, M. HOWARD, W. NING, L. WERNECK
Psychology, Boston Univ., Boston, MA

Abstract: Episodic Memory involves the integration of events into the spatial and temporal context within which they occurred. The Lateral Entorhinal Cortex (LEC) is a central node in the episodic memory network and is thought to provide the majority of object or event related information entering the hippocampus. The LEC is hypothesized to buffer object and event information so that it may be properly integrated into a spatiotemporal context within the hippocampus (HPC). Recent finding have suggested that the LEC may be a source of temporal information feeding into the hippocampus (Tsao, 2017; Meister & Buffalo, 2017; Tsao & Moser, 2017). We employed simultaneous LEC and HPC (CA1) tetrode recordings during a memory task known to generate time cells in the hippocampus. Units in both the LEC and HPC exhibited object specific responses during object presentation and during the delay. We will characterize the similarities and differences in temporal and object coding between these two structures.

Title: Investigating the role of medial septal cell types in generating the hippocampal code for time

Authors: *H. YONG[1], M. P. BRANDON[2]
[1]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada; [2]Psychiatry, McGill University, Douglas Hosp. Res. Ctr., Montreal, QC, Canada

Abstract: Recent work has shown that hippocampal neurons code for the time spent in the delay period of a delayed spatial alternation task. These 'time cells' have been shown to require input from the medial septum, as muscimol inactivation of the medial septum disrupted the activity of time cells and impaired memory performance. However, the exact role of the medial septum in time cell function remains unclear as muscimol-induced inactivation of the medial septum persisted for the entire duration of the behavior task. It remains possible that time cells may require information computed outside of a delay zone by other brain regions that rely on the medial septum. Moreover, inactivation of the medial septum with muscimol silences the activity of every septal neuronal population, thus it is unknown which cell population within the medial septum supports time cell activity. We therefore pursued an optogenetic strategy to selectively silence genetically-defined cell populations within the medial septum only when animals were running on the treadmill in the delayed spatial alternation task. We show that inhibition of GABAergic neurons not only led to reduction in theta amplitude recorded from CA1 region of the hippocampus, but also had heterogeneous effects on time cell activities. Moreover, there was significant reduction in mean and peak firing rates of time cells when GABAergic neurons were inhibited. Moreover, we tested the role of cholinergic neurons in the medial septum by using ChAT::Cre transgenic mice. In this approach, we injected Cre-dependent viral vector to induce expression of Archaerhodopsin in septal cholinergic neurons. These animals were trained to run reliably on the motorized treadmill and to alternate between the left and the right arms of the maze for water reward. They were required to run for 10 seconds on the treadmill between each alternation trial. Activity of time cells was recorded from CA1 region of the hippocampus with tetrodes while septal cholinergic neurons were selectively silenced with a green laser (520nm) when animals ran on the treadmill. We are currently analyzing the extent by which time cells and behavioral performance are disrupted during optogenetic silencing of septal cholinergic neurons. Next, we plan to assess the role of glutamatergic neurons in the medial septum. Together, this data will reveal how each septal population is involved in time cell function in the hippocampus, which will in turn help us shed light on the underlying mechanisms that code for time in the hippocampus.

Title: Retrosplenial and entorhinal cortical representation during visually-based triangulation

Authors: *A. S. ALEXANDER, M. E. HASSELMO
Boston Univ., Boston, MA

Abstract: Visual information can define the boundaries or spatial structure of the observable environment, and thus can anchor or orient map-based spatial representations observed in the anterothalamic nuclei, medial entorhinal cortex (MEC), and hippocampus. The retrosplenial cortex (RSC) is an association area that is reciprocally connected to visual processing regions and the aforementioned structures. Critically, visual information is initially processed in egocentric coordinates as the relationship between the positions of visual landmarks and the animal itself. Thus, in order for this information to be incorporated into allocentric spatial representations a translation between egocentric and allocentric coordinate systems must occur. RSC may be important for reference frame transformations required to integrate visual landmark information with externally-referenced head-direction or grid cell representations observed in MEC. To explore the neural mechanisms underlying such a process we recorded the activity of neurons in the MEC and RSC while animals performed a novel visually-guided triangulation paradigm. On each trial, rats were required to determine the relative relationships among multiple visual cues to navigate to a hidden zone in the two-dimensional plane that when entered would trigger reward delivery to a random part of a large open field. Visual cue positions and the corresponding reward zone shifted across trial blocks with the goal of forcing rats to repeatedly compute relationships between their current location, distal visual cues, and discrete allocentric locations. Animals quickly learned the task and were able to rapidly triangulate to hidden zones using a variety of behavioral strategies. We observed complex activity correlates across spatial reference frames in both MEC and RSC, including responses anchored to visual cues or to single or multiple hidden zones. In some cases, hidden zone locations appeared to distort allocentric spatial representations in the two regions. Together these results begin to elucidate features of MEC and RSC activity that could be critical for goal-directed navigation or anchoring spatial representations to visual cues.

Title: Comparison of the compression of time and space in dorsal CA1

Authors: *D. J. SHEEHAN, M. W. HOWARD
Boston Univ. Ctr. For Memory and Brain, Boston, MA

Abstract: The hippocampus contains neurons that robustly code for temporal and spatial relationships between events. It has been shown that hippocampal time cells, which code for temporal relationships, have firing fields that expand in size and decrease in number with the passage of time (e.g., Salz, et al., 2016). The increase in time field size and decrease in number of time fields is consistent with decrease in the accuracy of temporal coding for events that recede into the past. It is thus far not known whether place cells, which code for spatial relationships, exhibit the same form of compression. Whereas time cells code for time since a reference event, because a typical place cell experiment includes many possible landmarks, it is not immediately obvious what spatial relationship a particular place cells represents. Past work has demonstrated that CA1 cells with spatially tuned firing fields can fire in relationship to a movable landmark (Gothard, et al. 1996, 2001). In this study rats with microdrives targeting dorsal CA1 were shaped to run along a linear track paired with a movable start box, coupled with variable lighting conditions. Previous findings indicate that place cells that respond along paths from the movable start box encode distance from the start box, enabling one to establish a zero along the distance axis. The firing characteristics of principal cells of the dorsal CA1 region are investigated with respect to the movable start box. We compare the width of place fields and the number of place fields as a function of distance from the start box. This enables a direct comparison between the form of compression for time and space in the hippocampus.

Title: Disentangling the role of medial septal cell types in grid cell generation

Authors: *J. ROBINSON[1], M. P. BRANDON[2]
[1]McGill Univ., Verdun, QC, Canada; [2]Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: The medial entorhinal cortex (MEC) is a high-level cortical region critical for spatial navigation and episodic memory processing. The MEC contains a specialized circuit of spatially tuned neurons including grid cells, which preferentially fire at distinct locations that form a repeating hexagonal pattern. This spatial periodicity is known to be dependent on input from the medial septum (MS), a basal forebrain structure densely connected to the MEC. The MS contains three distinct cell types that project directly to the MEC; GABAergic, glutamatergic and cholinergic neurons. While it is known that a complete inactivation of all cell types in the MS disrupts the spatial firing patterns of grid cells, the role that each cell types plays in the generation of grid cells remains unknown. Here, we aim to resolve the role that MS GABAergic and glutamatergic populations play in the grid cell signal. To achieve this, we used an optogenetic approach to selectively silence each cell type in the MS while simultaneously recording the activity of MEC grid cells in an open field environment. We used VGAT-Cre and VGLUT2-Cre transgenic mouse-lines, which selectively express cre recombinase in the GABAergic and glutamatergic neurons in the septum, respectively. A cre-dependent viral vector (AAV-Flex-ArchT-GFP) was injected into the MS for optogenetic silencing, a fiber optic was placed just above the MS for light delivery, and a four-tetrode microdrive was implanted into the MEC for local field potential and grid cell recordings. Our data shows that optogenetic inactivation of septal GABAergic cells cause a 70-80% reduction in theta power, similar to that observed during pharmacological inactivation of the entire MS. In contrast, silencing glutamatergic neurons did not affect theta power or frequency. We are currently analyzing the effect that these manipulations have on grid cells. Together these experiments will reveal the role of GABAergic and glutamatergic MS populations in generation of the grid cell spatial firing pattern.

Title: Speed coding by entorhinal cortex speed cells differs across behaviorally relevant time scales and is independent of cholinergic modulation

Authors: *H. DANNENBERG[1], C. KELLEY[1], C. MONAGHAN[2], M. E. HASSELMO[1]
[1]Boston Univ., Boston, MA; [2]McLean Hosp., Belmont, MA

Abstract: Running speed can be coded by the firing rate of a dedicated subpopulation of neurons in the entorhinal cortex which have been called speed cells. This speed code is used in various computational models for path integration. In these models firing rate is considered to be linearly tuned by running speed, and speed tuning curves are assumed to predict spiking at every moment in time. However, many speed cells have saturating exponential tuning curves, and it has currently not been tested if the speed code is linear and accurate at short time scales. We first tested this assumption on data obtained from open field recordings in rats by applying a novel filtering approach differentiating between speed codes at short time scales in the range of a few seconds, presumably relevant for path integration, and long time scales in the range of seconds to minutes, presumably reflecting modulation of brain activity by different behavioral activity states. By analyzing the speed code at different time scales, we demonstrate many cells show a strong linear correlation with running speed across multiple time scales, but slopes of speed tuning curves tend to increase with longer time scales. Modelling demonstrates an increase in speed tuning curve steepness at longer time scales results in an overall saturating exponential speed tuning curve. We further show integration of spiking rates over short time scales has a negative impact on the overall speed score, which cannot be explained by the influence of Poisson noise alone. Moreover, speed coding by spiking rate is most efficient when spiking rate is integrated over many seconds. We validate these results on a mouse data set and further show that optogenetic inhibition of cholinergic neurons in the medial septum/diagonal band of Broca (MSDB) does not affect coding of running speed by firing rate during open field exploration of a familiar environment. These results are relevant for models of path integration and for our

understanding of how behavioral activity states modulate firing rates and information processing in the entorhinal cortex.

Title: Remapping in ventral hippocampus during a context fear teleportation task

Authors: *R. R. ROZESKE, L. RUNTZ, M. P. BRANDON
Douglas Hosp. Res. Ctr., McGill Univ., Montreal, QC, Canada

Abstract: An organism's survival depends upon whether it can discriminate between safe and threatening contexts. The ventral hippocampus (VH) is thought to encode contexts via specialized place cells whose firing is tuned to specific locations within a context, which as a population form a spatial map. Although the VH is necessary for the formation of context fear memories, the defined neuronal circuits and place cell populations that encode threatening and safe contexts have not been thoroughly characterized. To assess the neuronal population activity and potential pathway specificity during context fear discrimination we used a novel fear conditioning paradigm in combination with fiber photometry and miniature microendoscope (UCLA miniscope) calcium imaging. Mice underwent differential context fear conditioning using a large cylindrical LED screen that permitted rapid teleportation between visual contexts. Visual Context A was associated with electric shock delivery, whereas Visual Context B was remained neutral. In the first set of experiments, GCaMP6f was expressed in ventral CA1 and optic fibers were implanted locally to record global fluorescence using fiber photometry during transitions between contexts A and B. Fluorescence was also quantified in vCA1 projection regions during context transitions to determine whether specific vCA1 projection were implicated in context discrimination. A second set of experiments visualized cellular fluorescence following expression of GCaMP6f in vCA1 using miniscope recording, permitting

examination of place cell activity during context transitions. Population level analysis of place cell activity during context discrimination will be presented. Together this study will elucidate how the VH preferentially controls the transmission of context information necessary for context fear discrimination.

Title: Neuronal representation of environmental boundaries in egocentric coordinates

Authors: *J. R. HINMAN[1], G. W. CHAPMAN, IV[2], M. E. HASSELMO[2]
[1]Ctr. for Systems Neurosci., [2]Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: Animals must navigate through the complex spatial environments they inhabit. The sensory information about such environments and the physical movements that comprise navigation are often represented in an egocentric reference frame, one that is centered on the agent. Yet the hippocampus, entorhinal cortex and associated structures store spatial representations in an allocentric or world-centered reference frame involving place, grid, head direction and boundary coding cells. The dorsomedial striatum (DMS) is important for egocentric navigational response strategies. We implanted rats with up to 16 tetrodes targeting the medial portion of the striatum and recorded multiple single units while they foraged in a large open field. A novel spatial cell type was identified that represents the boundaries of the environment in an egocentric reference frame that we have termed egocentric boundary cells (EBCs). Approximately 18% of cells were identified as EBCs, which spike when an environmental boundary occupies a specific orientation and distance relative to the animal. We conducted recordings following a series of different environmental manipulations, including rotating the open field relative to the testing room, changing the size of the environment and changing the visual appearance of the boundaries and found that EBCs maintain the same preferred boundary orientation and distance relative to the animal across each manipulation. Next, we assessed whether EBCs remap across environments, as is observed for the allocentric spatial map in the hippocampal formation. EBCs did not remap across different familiar environments or in a completely novel environment, but rather maintained a stable egocentric

representation of boundaries relative to the animal. In addition to EBCs, head direction cells similar to those in the hippocampal formation were present in DMS, as were cells coding running speed and other self-motion signals similar to those observed in posterior parietal cortex. In a subset of recordings hippocampal theta oscillations were simultaneously recorded in order to assess whether the egocentric spatial representation in DMS maintains a specific theta phase relationship. Some EBCs were found to be significantly phase locked to hippocampal theta oscillations, while others showed no preference for the theta phase at which they fired. Overall, the DMS contains navigation related cells including EBCs, head direction cells and self-motion coding cells that may be part of a network responsible for tranforming and implementing allocentric translation vectors that could be generated by the hippocampal formation.

Title: Tracking the ontogeny of trajectory-dependent neuronal activity in the hippocampus

Authors: *N. R. KINSKY, W. MAU, D. W. SULLIVAN, H. B. EICHENBAUM, M. E. HASSELMO
Boston Univ., Boston, MA

Abstract: Many neurons in the hippocampus encode information beyond the well-established place code. For example, trajectory dependent or “splitter” cells modulate their firing activity in the same location of a T-maze based on the rodent’s past location and/or future trajectory. Despite a number of studies demonstrating the robustness of trajectory dependent activity in over-trained rodents, little is known about the origin of these cells. Does the emergence of splitter cells correlate with learning of a task? Given their importance for task performance, are splitter cells more likely to remain active in subsequent sessions? Do they reliably retain trajectory dependent firing in subsequent sessions, or do they remap at the same rate as place cells? Here, we utilized *in vivo* calcium imaging using a miniscope to reliably track neurons across days and investigate the ontogeny of splitter cells while mice performed a continuous spatial alternation task. We found that the proportion of the active cells exhibiting trajectory dependent behavior correlated with accuracy on the alternation task, suggesting that splitter cells were important for proper task performance. Furthermore, splitter cells were significantly more likely than other cells to be active on subsequent sessions, indicating that behaviorally relevant

cell phenotypes might exhibit greater stability than other cells. Finally, trajectory dependent activity emerged rapidly and decayed slowly, indicating that once trajectory dependent activity emerged a cell was slow to change/remap. Thus, our results fill in gaps in existing literature about the emergence of trajectory-dependent firing and hint that cell phenotype might influence the stability of neurons over subsequent hours to days.

Title: Encoding of contextual fear memory in the hippocampal-amygdala pathway

Authors: *J.-H. CHO, W. KIM
Univ. of California, Riverside, CA

Abstract: In contextual fear conditioning, experimental subjects learn to associate a neutral context with an aversive stimulus and display fear responses to a context that predicts danger. Although the hippocampal-amygdala pathway has been implicated in the retrieval of contextual fear memory, the mechanism by which fear memory is encoded in this circuit has not been investigated. Here, we show that activity in the ventral CA1 (vCA1) hippocampal projections to the basal amygdala (BA), paired with aversive stimuli, is both necessary and sufficient to generate conditioned fear memory. Contextual fear conditioning induced selective strengthening of the vCA1-BA engram cell pathway, which was prevented under anisomycin-induced retrograde amnesia. Moreover, BA engram cells preferentially received monosynaptic inputs from vCA1 engram cells, whose activity was required for contextual fear learning. Our study suggests that strengthening of the vCA1-BA engram cell pathway plays pivotal roles in adaptive fear to a relevant context.

Abstract: Memory resides in engram cells distributed across the brain. However, the site-specific substrate within these engram cells that underlies memory storage remains theoretical, even though it is generally accepted that synaptic plasticity encodes memories at the synapse. Here, we developed the dual-eGRASP technique to examine synapses between engram cells to identify the specific neuronal site for memory storage. In this study, we found an increased number and size of spines on CA1 engram cells receiving input from CA3 engram cells. In contextual fear conditioning, this enhanced connectivity between engram cells encoded memory strength. We also revealed that CA3 engram to CA1 engram projections showed strong occlusion of long-term potentiation based on increased release probability and enhanced postsynaptic responses. These results suggest that structural and functional enhancements of the connectivity between engram cells across two directly connected brain regions are the synaptic correlate of memory.

Title: Distinct activated neuronal ensembles differentially modulate contextual fear memory discrimination

Authors: *X. SUN[1], M. BERNSTEIN[1], M. MENG[1], L. YAO[2], A. T. SÖRENSEN[3], X. ZHANG[2], Y. LIN[1]

Abstract: Memories are hypothesized to be encoded in sparse neuronal ensembles in which enduring molecular and synaptic changes occur. Activity-dependent genes, whose expression is induced in neurons activated during learning, are believed to underlie the plasticity that converts transient experience into long-lasting memory. As a result, the activation of these genes have been used to tag active neuronal ensembles, with the assumption that these ensembles are largely overlapping and functionally similar. Here we report that there exist functionally distinct active neuronal ensembles, defined by different activity-dependent pathways. Based on the Robust Activity Marking (RAM) system that we recently developed, we constructed two activity-dependent reporters, RAM2 and RAM3, which are activated by two different activity-dependent transcriptional pathways. Using these reporters, we identified two functionally distinct active neuronal ensembles in the mouse dentate gyrus (DG) during contextual fear conditioning (CFC). These two ensembles underwent distinct experience-dependent modifications, and differentially modulated the balance of contextual fear memory discrimination and generalization. Using electrophysiological recording and chemogenetic behavioral manipulation, we found that the $RAM2^+$ ensemble neurons recruited stronger local inhibitory inputs and are required for context discrimination. On the other hand, the $RAM3^+$ ensemble neurons received stronger excitatory inputs from the upstream entorhinal cortex (EC) and promote context generalization. Taken together, our findings demonstrated for the first time the functional heterogeneity of active neuronal ensembles, and that encoded memories can be decomposed into discrete neuronal ensembles defined by different activity-dependent transcriptional pathways.

Title: Prefrontal circuit dynamics associated with context-dependent fear discrimination learning

Authors: *J. MAYER[1], J. PASTORE[1], T. W. BAILEY[2], J. SPEIGEL, III[2], E. KORZUS[1]
[1]Psychology, Univ. of California Riverside, Riverside, CA; [2]Neurosci., Univ. of California Riverside, Riverside, CA

Abstract: Recent studies have revealed molecular and synaptic mechanisms of information storage and it has been postulated that neural representation activated during memory encoding is preferentially recruited during memory retrieval. How specific neuronal representations are recruited to form and maintain memories is unknown. Present studies aim at identifying the neural representation of contextual fear memories and assess circuit dynamics underlying disambiguating safety and danger. Fear behavior is regulated by the medial prefrontal cortex (mPFC) via fear excitation and inhibition, respectively, which may be due to differential connectivity with amygdala. Current research investigates how the PFC is able to act through multiple pathways to exert both excitatory and inhibitory influences on fear responses under the central hypothesis that accuracy of fear memory is attained via extinction of fear responses to non-reinforced stimuli. Alterations of prefrontal network activity during fear modulation associated with context-dependent fear discrimination learning is evaluated via real time network activity assessment using miniaturized head-mounted microscopes followed by computational analysis of large-scale neuronal activity patterns. Head-mounted miniaturized microscopes are capable of measuring calcium transients reflecting neuronal activity from more than thousands neurons in a freely behaving mouse. To evaluate large-scale circuit dynamics associated with fear discrimination learning, the calcium sensitive fluorescent protein GCaMP6f is expressed in the prelimbic subdivision (PL) of the mPFC followed by assessment of real-time prefrontal network changes in response to dangerous and safe context stimuli across the behavioral testing. The functional relationship between fear and context is evaluated using computational analysis of large-scale neuronal activity patterns using chronically head-mounted microscopes. These head-mounted microscopes allow visualization of calcium transients associated with neuronal activity providing insights into emergent circuit dynamics in response to dangerous or safe contextual stimuli within relevant brain regions during different phases of fear discrimination learning to uncover the neural mechanisms underlying the ability to distinguish between danger

and safety. Understanding how fear memories are encoded and kept resistant to confusion is clinically relevant as fear memory overgeneralization is a hallmark of phobias, PTSD and generalized anxiety disorder.

Abstract: For efficient and correct information processing in cerebral cortex, neural circuit dynamics must be spatially and temporally regulated with great precision. Medial prefrontal cortex (mPFC) of rodents has been shown important for various types of learning and memory, including fear memory, and related to various psychiatric diseases. However, it has been challenging to understand the computational mechanism in the mPFC, of which major problems are the complexity and heterogeneity of the prefrontal networks. While recent studies based on electrical or optical recording in the mPFC demonstrated that neuronal responses are heterogeneous and dynamically modulated throughout the learning process, it still remains unclear how population of neurons in this region enables the information processing, depending on learning states. Little is known especially about the mechanism underlying fear memory. Here we investigate this by chronic two-photon Ca^{2+} imaging from populations of neurons in mouse mPFC *in vivo*, which allows us to 1) record activities simultaneously from large number of neurons at the single cell resolution with high temporal resolution, and 2) investigate changes of neuronal responses depending on the learning states. We focus on the change in population responses of mPFC neurons for the fear memory by developing a new device to perform and test Pavlovian fear conditioning under the microscope. While many of the previous imaging studies for the mPFC relied on the invasive method, our system can minimize such damage by

introducing a microprism-based observation method.
Currently, we investigate population coding underlying memory recall as well as extinction.

Title: Balance of prefrontal division-mediated excitation and inhibition drives context-dependent fear discrimination learning

Authors: *T. W. BAILEY[1], J. SPEIGEL, III[2], J. MAYER[4], J. PASTORE[3], E. KORZUS[2]
[1]Neurosci., [2]Psychology, [3]Univ. of California Riverside, Riverside, CA; [4]Psychology, Univ. of California Riverside, Riverside, CA

Abstract: Failure to discriminate between aversive and harmless stimuli due to the similarity of external cues that were present during trauma in humans can lead to the intrusive recollection of aversive memories. Overgeneralized fear evoked by trauma reminders is typical of anxiety disorders, including posttraumatic stress disorder (PTSD), and is believed to be triggered by cues resembling the traumatic experience despite a currently secure environment. Our long-term goal is to characterize the mechanisms of fear memory accuracy versus generality and how these mechanisms translate into the control of neural circuits, behavior, and mental disorders. The central hypothesis of this project, based on our preliminary data and a large body of previous work, is that fear memory accuracy is attained via a medial prefrontal cortex (mPFC)-dependent mechanism involving the reduction of fear responses to harmless non-reinforced stimuli. Fear behavior is differentially regulated by the prelimbic (PL) and infralimbic (IL) regions of the mPFC via fear excitation and inhibition, respectively, which may be due to differential connectivity with the amygdala. Current research investigates how the mPFC is able to act through multiple pathways to exert both excitatory and inhibitory influences on fear responses under the central hypothesis that the accuracy of fear memory is attained via the extinction of fear responses to non-reinforced stimuli. A coactivator of transcription and histone acetyltransferase, cAMP response element binding protein (CREB)-binding protein (CBP) is required for long-term memory consolidation. The expression of the selective inhibitor of long-term memory consolidation CBPΔHAT in PL neurons results in severe deficits in fear

discrimination learning but not in fear conditioning. In addition, independent manipulations targeted specifically to the IL suggests that IL neurons may be also directly involved in coding new memories associated with in fear discrimination learning. In addition, real-time evaluation of neural ensembles of contextual memories with opposite valence in mPFC using head-mounted miniaturized microscopes shows alterations of context-dependent memory representations within the mPFC during fear discrimination learning, These findings provide strong support for our hypothesis that fear discrimination learning is a result of balancing the PL-mediated excitation and IL-mediated inhibition of fear responses. The impaired fear discrimination learning caused by maladaptations in the prefrontal cortex/amygdala circuits are likely to be relevant to neuropsychiatric disorders such as PTSD.

Title: The specific role of GABAergic interneurons in fear extinction

Authors: *X. ZHANG, Y. ZHOU, W. LI
Shanghai Jiao Tong Univ., Shanghai City, China

Abstract: Neural circuits and synaptic mechanisms involved in fear memory acquisition have been studied for several decades. However, fear extinction seems to play crucial part in the treatment of some stress disorders. Previous studies have found that the interneurons in BLA region (basolateral amygdala) play key roles in fear extinction. Nevertheless, mechanism of fear extinction has not been involved in the relationship between the function of interneurons and behavior performance. Our team successfully construct ArcCreERT2, cFosCreERT2, GAD67CreERT2 transgenic mice, which can be crossbreed with R26RSTOP-floxed-tdTomato mice to mark various types of neural circuits stimulated by fear acquisition and extinction. Furthermore, we construct interneuron-specific adenovirus associated virus (AAV) combined with DREADDs to specifically regulate interneurons fired during memory extinction. With the help of these transgenic mice, DREADDs and in-vivo calcium imaging, our data provide direct evidence of the interneurons in fear extinction.

Title: Anatomical, molecular, and experience dependent organization of a ventral hippocampal circuit

Authors: K. CLAUSING, *V. S. TURNER, M. KHEIRBEK
Psychiatry, Univ. of California, San Francisco, CA

Abstract: The ventral hippocampus (vHPC) has been implicated in encoding a diverse array of information and modulating a number of behaviors including anxiety-related behavior, reward seeking and fear learning. These multiple functions have been attributed to the routing of information from the vHPC to a number of distinct downstream targets, including the prefrontal cortex (PFC), nucleus accumbens (NAc), lateral hypothalamus (LH), and basal amygdala (BA). For example, projections to the medial PFC and LH have been implicated in anxiety-related behavior, projections to the NAc in reward seeking, and projections to the BA in context fear learning. However, there remain gaps in our knowledge related to 1) the long-range circuit organization of the vHPC with respect to its inputs and outputs 2) the molecular profile of cells defined by their targets and 3) the differential recruitment of vCA1 cell-types by behavioral experiences. In this study, we used viral and transcriptional approaches to define the wiring and molecular organization of the vHPC circuit. Using a rabies-based viral approach to trace the relationship between input and output of the vHPC, we determined whether vHPC neurons projecting to the mPFC, NAc, LH, or BA have similar or distinct presynaptic inputs. Next, we profiled vHPC projection neurons using viral translating ribosome affinity purification to determine whether vCA1 projection neurons are molecularly distinct. Finally, we performed activity-dependent capture of vCA1 transcripts to determine the profile of neurons recruited by distinct experiences. By transcriptionally profiling cells captured by Fos activation (as a proxy for neural activity) we determined whether exposure to innately rewarding or aversive stimuli, or the encoding or retrieval of a fear memory recruit molecularly distinct populations of vCA1 neurons. These studies will provide an anatomical and molecular blueprint for the extended vHPC circuit and insight into the pathways and cell-types recruited by distinct experiences.

Title: Dynamic and stable coding of emotional stimuli in the ventral hippocampus

Authors: *J. BIANE[1], F. STEFANINI[3], T. KRAUSZ[4], M. A. S. LADOW[4], N. I. WOODS[2], S. P. BODDU[5], A. FAN[5], D. L. APODACA[5], M. KHEIRBEK[6]

Abstract: Mood and anxiety circuits are widely distributed, comprised of interconnected networks at the local and brain-wide level. Within some areas, stimuli with orthogonal emotional valence are encoded by distinct subsets of neurons. In the ventral hippocampus (vHPC), a crucial node for anxiety-related behavior, cells with distinct projection streams have been reported to differentially encode anxiety-provoking environments, reward locations, and control aspects of fear learning. However, how the vHPC represents and learns about salient stimuli in the environment remains unclear. Here, we use functional calcium imaging to ask whether vCA1 neurons 1) have mixed selectivity for stimuli with differing valence, 2) have stable representations to emotionally relevant stimuli over time, and 3) encode associations between conditioned and unconditioned stimuli. Mice were injected with a virus encoding the calcium indicator GCaMP6f into vHPC and a GRIN lens was implanted above vCA1 for optical access. In our first series of experiments, we used freely moving microendoscopy to test whether single vCA1 neurons harbor 1) distinct representations to distinct stimuli, 2) representations to a particular valence class of stimuli, or 3) mixed selectivity to multiple stimuli regardless of valence. Activity in vCA1 was recorded during serial exposure to positive (sucrose, female interaction, appetitive odor) or negative (shock, open arms of elevated plus maze (EPM), aversive odor) stimuli. The following day, stimuli were presented again to assess the stability of neural representations. Within vCA1, a fraction of cells could be classified as either sucrose or shock responsive, with a small proportion selective for both. Interestingly, percentages of sucrose and shock responsive neurons did not differ between closed arm and open arm preferring neurons in the EPM. To assess whether these neural representations of task features in vCA1 change during associative learning, a separate cohort of mice underwent tone-sucrose trace

conditioning while performing 2-photon imaging of vCA1. In a fraction of vCA1 neurons, the representation of sucrose reward was maintained across learning. Conversely, the representation of the predictive tone cue was dynamically transformed, with tone-responsive neurons emerging over the course of training. Current efforts are aimed at understanding how these encoding dynamics differ along the dorsoventral axis of CA1 and among different projection streams from vCA1 to cortical and subcortical targets. Collectively, these experiments elucidate mechanisms by which innately salient stimuli are represented and learned within the vHPC.

Title: Population level coding of olfactory information in the dentate gyrus

Authors: N. I. WOODS[1], F. STEFANINI[2], *M. KHEIRBEK[1]
[1]Univ. of California, San Francisco, San Francisco, CA; [2]Columbia Univ., New York, NY

Abstract: A central goal of neuroscience is to understand how stimuli are encoded within ensembles of neurons, and how these representations are modified by learning. The hippocampus (HPC) has a well-documented function in encoding spatial information, however, it also encodes non-spatial information crucial for memory formation. Granule cells (GCs) in the dentate gyrus (DG) receive input from the lateral entorhinal cortex (LEC), which is known to process olfactory information. Here, we used *in vivo* 2-photon calcium imaging and behavior to determine the mechanisms by which DG GCs represent odor information and how learning alters these representations. We developed a fear conditioning task where mice discriminate between three odorants, two similar (methyl butyrate (CS+) and ethyl butyrate(CS-)) and one distinct (isoamyl acetate (CS-)). Silencing LEC input to the DG with tetanus toxin impairs encoding of the CS+ and behavioral discrimination between the similar odors. Population activity in DG GCs was imaged in a baseline pre-conditioning session and a day after conditioning. In both sessions, a subset of DG GCs show odor-selectivity, responding to individual or pairs of odors, or to odor offset. Analysis of the population code in DG GCs showed high similarity in the ensembles of neurons representing repeated presentations of the same odor, while distinct ensembles of

neurons encode each odor. Using machine learning, we were able to predict odor identity from DG GC activity with very high accuracy (>80%) for the three odor identities. Moreover, decoding accuracy was just as high among similar odors as distinct odor pairs, consistent with the theory that the DG takes overlapping, similar inputs and converts them into highly dissociable patterns of activity. To determine how neural representations change with learning, we trained our decoder with neural data from the preconditioning session and tested on the data after conditioning. This revealed accurate decoding of the CS- odors, suggesting stability in the ensembles, but not the CS+ odor, indicating that the representation in the DG changed with associative learning. This was supported by examining the similarity of recruited ensembles, which were more similar across sessions for CS- than the CS+ odor. Finally, examining fear discrimination scores revealed a correlation between decoding accuracy and fear discrimination, with the best odor discriminators at a behavioral level exhibiting the highest odor decoding accuracy. These results demonstrate that odor identity is strongly encoded in an LEC to GC circuit and the changes imposed by associative learning are reflected in selective changes in the population code.

Title: Critical dynamics and short-term memory in neuronal networks

Authors: *T. L. RIBEIRO[1], M. J. BERRY, II[2], D. PLENZ[3]
[1]Section on Critical Brain Dynamics LSN/NIMH, NIH, Bethesda, MD; [2]Princeton Univ., Princeton, NJ; [3]Sect Critical Brain Dynamics, Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: The property of short-term memory in neuronal circuits of the brain has been a subject of study for a long time, with different approaches being proposed as possible explanations for this important feature. For instance, previous models have shown temporal coding when slow neuronal properties are incorporated, such as paired-pulse facilitation (PPF) and slow inhibitory postsynaptic potentials (IPSPs) (Buonomano et al., 1995) or distant-dependent synaptic delays (Wyss et al., 2002). In the context of recovering information about stimulus intensity, another study demonstrated that getting closer to criticality improves short-term memory (White et al., 2004). Furthermore, echo state networks (Jaeger & Haas, 2004), which could potentially be implemented by neuronal circuits, not only are well known for their extended memory capacity

but are also optimized at the edge of chaos (Legenstein & Maass, 2007; Busing et al., 2010). In the present work, we expand on the ideas linking criticality and short-term memory by simulating a simple network composed of cellular automaton units randomly connected (Larremore et al., 2014). The weights of these connections (20% of which are negative, representing inhibitory synapses) are controlled in order to tune the network to the critical point. We then proceed to present, in random order, two possible stimuli to this network. Both stimuli have the same intensity, and each is directed to a small, non-overlapping, subpopulation of the network. Finally, by applying a machine learning algorithm -- Support Vector Machine (SVM; Bishop, 2006) --, we aim to detect which stimulus was presented as function of time after the stimulus is turned off. The decoding takes part on the so-called reservoir, which are the units in the network that were not directly stimulated. We show that the decoder accuracy is maximized at the critical point during and, most importantly, after the stimulus presentation, indicating information about the stimulus is preserved in the network for a longer period of time at criticality.

Title: Neural activity in rat medial prefrontal cortex is predictive of memory performance in an odor span task

Authors: *E. DE FALCO[1], L. AN[2], A. ROEBUCK[3], C. C. LAPISH[1], J. G. HOWLAND[3]
[1]Psychology, IUPUI, Indianapolis, IN; [2]Univ. of Saskatchewan, Saskatoon, SK, Canada; [3]Physiol., Univ. Saskatchewan, Saskatoon, SK, Canada

Abstract: Medial prefrontal cortex (mPFC) is known to play a fundamental role in working memory, attention regulation, and behavioral inhibition. However, the neural computations that underlie these are poorly understood. Here we recorded the activity of neurons in the mPFC in awake, behaving rats performing an odor span task (OST). This task is designed to assess working memory capacity in rodents (Dudchenko et al., 2000) and is impaired following mPFC inactivation (Davies et al., 2013). Neural activity was assessed via principle component analysis

to identify how firing changed throughout a trial of the task. Neural populations were observed that encoded distinct task epochs. We found that the transitions between task epochs is accompanied by abrupt remapping of neural activity patterns in mPFC and that the temporal characteristics of remapping are predictive of span. Furthermore, increases in interneuron activity were only observed at the termination of the delay thus indicating that local processing in inhibitory networks was a unique (and possibly key) feature to initiate foraging. During foraging, neural activity patterns associated with the approach to a familiar odor were weak. However, robust changes in neural activity were observed upon approach to a novel odor. Collectively these data indicate that mPFC plays a critical role initiating new action plans (e.g. foraging, digging) and changes in neural activity patterns reflect this process.

Title: A dynamic neural mechanism for encoding spatial targets and behavioral contexts in rat perirhinal cortex

Authors: *T. OHNUKI, Y. SAKURAI, J. HIROKAWA
Grad. Sch. of Brain Sci., Doshisha Univ., Kyotanabe Kyoto, Japan

Abstract: Perirhinal cortex (PRC) has long been implicated in cue-target association for object memory. This region receives sensory inputs from various cortical areas of almost all modalities, contextual information from prefrontal cortex and reward-related signals from ventral tegmental area and amygdala. Integration of such diverse information would enable PRC to create abstract representations of objects. A fundamental and unsolved question in information processing of PRC is whether and how the same objects in behaviorally different conditions are encoded while distinguishing the contextual information. Here we show that PRC neurons systematically switch their responses to spatial targets between different contexts. We trained rats in a two-alternative spatial choice task with unimodal visual and olfactory stimuli as cues and recorded multiunit activities from the PRC during the task performance. In each trial of the task, either a visual or an olfactory cue was presented, and the rats chose the left or right port based on a cue-target

association rule. Choices to the correct port were immediately rewarded by a drop of water. We analyzed neural activities during the two contexts: cue-presentation and reward. Individual neurons responded to the spatial target in combination with or without the context. A subset of those neurons dramatically reversed their preferential firings for the target between the contexts. This unexpected property of the neurons indicates that individual PRC neurons not only integrate information about objects, space and behavioral contexts but also distinguish behavioral contexts. A population analysis reliably decoded the spatial targets and the contexts with the presence of those neurons. Our results suggest a mechanism that enables PRC to keep track of target information across behaviorally different contexts.

Title: Gone or misplaced?: Investigation of memory engrams across development

Authors: *S. POWER, C. ORTEGA, L. MARKS, J. O'LEARY, T. RYAN
Sch. of Biochem. and Immunol., TBSI, Dublin, Ireland

Abstract: Infantile amnesia, the developmental loss of memories formed in early childhood (prior to 2-4 years), affects 100 % of humans. Although behavioural neuroscience has already demonstrated that rodents display infantile amnesia, little is known about the basic neurobiology of the phenomenon. This project aims to probe the question of how memories are stored in the brain throughout development, by integrating recently developed engram labelling technology with various rodent models of infantile amnesia.
Infant mice (P17) were trained using contextual fear conditioning (CFC), where recall was tested 1 day, 1 week and 3 weeks after training. As demonstrated in previous studies, P17 mice exhibit forgetting as early as one week after training, while P56 mice show continuous memory retention. Crucially, we tested whether optogenetic stimulation of ChR2-EYFP expressing engram neurons in the DG, labelled during encoding of a fear memory in infancy, is sufficient for recall of that fear memory in adulthood. FosTRAP (Fostm1.1(cre/ERT2)Luo) mice were crossed with Ai32(RCL-ChR2(H134R)/EYFP) to produce an Ai32-FosTRAP line that allows for permanent labelling of engram cells, and compound transgenic mice were trained using CFC at P17. After behavioural demonstration of forgetting, the delivery of blue light to the DG activated ChR2-EYFP expressing neurons (neurons labelled during encoding of the fear memory) and

resulted in freezing behaviour. These data demonstrate that memory engrams retain information following infantile amnesia, and that when these cells are reactivated by blue light in a context different from the original one used for the conditioning, these animals display freezing behaviour, giving evidence of fear memory recall.
To determine whether the engram cells activated at the time of encoding are also active during recall, we quantified the number of *c-fos* positive cells overlapping with ChR2-EYFP positive cells as a measure of engram reactivation We characterized engram cell activity during recall trials at developmental stages prior to, and after, forgetting in infant mice. We also assayed the effect of optogenetically activated infant DG engrams on downstream engram reactivation in the hippocampus and amygdala of adult mice, giving insights into the nature and extent of the apparent retrieval failure.
This experimental framework will allow for the potential retrieval of seemingly lost-memories from early childhood, as well as a deeper understanding of how long-term memories are stored as an enduring and stable biological change.

Title: Epigenetic regulation of neuronal ensemble activity to enhance spatial learning and memory

Authors: *X. LIN, L. CHEN, Y. ZHANG, Y. WU, M. A. WOOD, X. XU
Univ. of California Irvine, Irvine, CA

Abstract: Histone modifications may allow for modulating transcription required for long-term memory processes. Previous studies have shown that histone deacetylases (HDACs) including HDAC3 are highly expressed in the brain, and HDAC3 is a powerful negative regulator of memory formation. However, it is largely unknown how epigenetic mechanisms regulate neuronal ensemble activity required for memory processing. Thus in conjunction with pharmacological inhibition of HDAC3, we use in vivo calcium imaging of neuronal ensemble activity to study neural mechanisms underlying epigenetic modulation of object location memory (OLM) based spatial learning and memory. We specifically test the hypothesis that pharmacological inhibition of HDAC3 via a selective HDAC3 inhibitor (RGFP966) enables stronger neuronal ensemble activity in hippocampal CA1 to enhance spatial learning and

memory in behaving mice. We use head-mounted, miniaturize microscopes, and the animals move around with them very well. This imaging approach enables us to simultaneously examine a large number of the same neurons across different environments and behavioral contexts. Stereotaxic injection of AAV-Camk2a-GCaMP6 was used to selectively express GCaMP6 in CA1 excitatory neurons in wildtype C57 mice (3-5 months old) for simultaneous in vivo calcium imaging of hippocampal CA1 neuronal populations in behaving mice. A subthreshold OLM training design was used to test if RGFP966 enhances OLM encoding compared with the control treatment. The ensemble neural activation strength associated with object exploration was measured by *in vivo* miniscope-based calcium imaging across baseline exploration, OLM training and testing sessions. Both control and RGFP966 treated mice showed an increase in neural activation strength in hippocampal neural ensemble activity during OLM training and testing sessions compared with baseline open-field exploration. Overall the RGFP966 mice exhibited higher neural activation strength associated with the moved object than the unmoved object during the testing session; this association of object/place and neural activation strength did not occur for the vehicle treated mice. Consistent with differential neural ensemble activation, the RGFP966 treated mice showed enhanced memory performance as reflected by the object discrimination index measurements in the testing session. Control mice did not show significant memory with the subthreshold OLM training (3 min). Together, OLM-based spatial learning and memory is enhanced by inhibition of HDAC3, and differential object/place neuronal ensemble activity in CA1 appears to underlie this behavioral memory outcome.

Title: Multiplexed encoding of sensory and reinforcement cues in the cholinergic basal forebrain supports associative learning and cortical plasticity

Authors: *B. ROBERT[1,2], W. GUO[2], D. B. POLLEY[1]
[1]Harvard Med. Sch., Boston, MA; [2]Eaton Peabody Lab., Massachusetts Eye and Ear Infirmary, Boston, MA

Abstract: The rodent basal forebrain is studded with dense clusters of cholinergic neurons. Artificial stimulation of these areas can produce striking plasticity in sensory cortex, but an

organizing schema for understanding the natural activators of cholinergic basal forebrain units has proven elusive due to the technical difficulty of recording from genetically defined cell types across this distributed deep brain network in behaving animals. Here, we describe an optogenetic antidromic phototagging approach to isolate single cholinergic units in Nucleus Basalis (NB) that project to the auditory cortex (ACx) and characterize their response properties and learning-related plasticity in awake, head-fixed mice.
We found that phototagged cholinergic NB --> ACx units (ChACx) and neighboring non-cholinergic NB units (NChACx) had robust, short-latency responses to meaningless, unconditioned auditory stimuli such as tones or noise bursts. ChACx and NChACx units also showed robust responses to unpleasant stimuli, such as air puffs directed at the face. Because NB unit spike trains multiplex neutral sensory stimuli and unconditioned behavioral reinforcers, we reasoned that they could play a critical role in linking conditioned stimuli with temporally delayed (i.e., distal) reinforcement cues. We tested this by pairing pure tone stimuli (CS+) followed by air puffs (US) 5s later and confirmed behavioral evidence of associative trace learning. We observed a rapid tone-specific plasticity in the frequency receptive fields of ACx units and ChACx units, but not NChACx units. Paired recordings from ACx and NB over the course of conditioning revealed a strong increase in gamma band coherence that parallels a selective potentiation of spike-evoked L2/3 local network activity from ChACx units during the initial CS and US pairings.
These findings identify a new role for cholinergic units in the caudolateral extreme of the basal forebrain (Nucleus Basalis) in driving cortical plasticity that supports learned associations between sensory conditioned stimuli and distal, temporally delayed reinforcement cues. Our ongoing studies utilize deep-brain imaging methods to identify regional differences among cholinergic basal forebrain neurons to sensory stimuli, behavioral reinforcement valence, and the encoding of sensory and reinforcement error signals. By discerning underlying rules for activating these distributed deep brain neuromodulatory neurons, we hope to develop new approaches to efficiently transform neocortical sensory representations.

Title: Locus coeruleus activity in a classical conditioning task

Authors: *M. OMRANI, G. S. ASTON-JONES
Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: Locus coeruleus (LC) is a small brainstem nucleus (~3,000 neurons in rats & ~30,000 in humans) and is the nearly exclusive source of norepinephrine (NE) to neocortex. Many previous studies have proposed a role for LC in learning. To further explore this idea, we implanted micro-array wires in LC and recorded unit activity in waking rats during a classical conditioning paradigm. During the paradigm, in each block (400 trials) the rats received a tone (5100Hz, 75 db, 300ms) alone (neutral stimuli (NS) in an unconditioned block) or a similar tone followed by air puff to the face (300ms puff, 300ms tone-puff interval; conditioned stimuli (CS) in a conditioned block), while the rat was hanging in a sling. LC neurons exhibit two modes of firing activity: phasic and tonic (Aston-Jones & Cohen, Ann rev Neurosci. 2005). In a sensory driven decision task, sensory stimuli that are relevant to the task (targets) evoke phasic responses in LC as opposed to similar stimuli with no task relevance (distractors). Both NS and CS tones evoked phasic LC activity in our paradigm. We were interested to know whether phasic LC responses differ for similar tones in different contexts. The NS does not have a predictive value, but through conditioning the animal learns that the CS predicts the occurrence of the aversive air puff. Therefore, we initially expected an enhanced phasic response to the CS tone as opposed to the NS tone. To our surprise, phasic responses were smaller in the conditioned block (i.e., for CSs) as compared to the unconditioned block (i.e., for NSs). On the other hand, tonic LC activity (the activity in between tones) was significantly larger in the conditioned blocks, consistent with a role for increased NE release in learning the CS-US association. Next we tested whether changing the task contingency multiple times within a set of blocks changed LC tonic activity accordingly. In this task, during every 80 trials a tone was presented either alone or with a puff. We investigated how LC tonic activity changed through the block and across blocks in relation to tone contingencies. We found that for every switch in task contingency (whether from conditioned to unconditioned or vice versa), tonic LC activity first increased and then gradually decreased to a baseline level during the 80 trials of the block. The increase in tonic LC activity induced by switches were significantly larger in transitions from unconditioned to conditioned blocks. These results are consistent with the idea that the increased tonic activity at the contingency switches may facilitate learning the new tone contingency and the predictive value of the tone.

Title: Deep reinforcement R-learning actor-critic model can explain mouse foraging behavior

Authors: *S. SHUVAEV, S. STAROSTA, A. KEPECS, A. KOULAKOV
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Behavioral choices can be performed either simultaneously or sequentially. For sequential choices, the decision is often about whether to exploit a current option or to search for a better one. Examples of such behaviors arise in many situations including foraging, employment (whether to accept a job/candidate or seek a better one), mate selection, and economic decisions. In the case of foraging behaviors, an animal's decision is whether to continue to exploit a dwindling food resource or to leave the current source in search of a better one. The average-case optimal choice strategy in this setting is described by the Marginal Value Theorem (MVT), which suggests that the animal should abandon a dwindling resource if the rate of reward falls below the average expected rate for the environment. We designed a foraging task for mice that enables us to infer the trial-to-trial choice strategy. Mice were allowed to run back and forth between two reward ports that provided water upon entry. Re-entry into the same port decreased the amount of water; switching to the other port reset water to the full amount. This behavior allows exploring the dynamics of switch-stay choices as resources are dwindling in an experimentally controlled setting. To interpret the choice patterns, we designed a reinforcement learning algorithm called deep R-learning in actor-critic model. R-learning is the reinforcement learning method that allows optimizing the average rate of reward by similarly weighting both near- and far-term rewards. As a consequence, R-learning can replicate the average behavior described by MVT. We use a deep neural network to infer R-values (the discounted sum of expected rewards), estimated average reward in the environment, likelihood to stay, and likelihood to switch based on the sequence of rewards and choices. The algorithm develops a switch/stay policy, which maximizes a difference between current and average reward. To train the neural network, we use the simulated reward data matching the experimental setup. We show that the behavioral patterns obtained with our model using the simulated data match the statistics of observed mouse behavior. We suggest that, in foraging tasks, mice compare current and average rewards to make a switch/stay decision in a way that can be explained by R-learning reinforcement learning algorithms.

Title: Dopaminergic and cholinergic modulation of NMDA-mediated behavior

Authors: *I. M. WHITE[1], E. A. COLLINS[2], W. WHITE[1]
[1]Psychology, [2]Neurosci. Program, Psychology Dept., Morehead State Univ., Morehead, KY

Abstract: NMDA antagonists impair wide range of behaviors, simple to complex. Reversal of NMDA-induced impairment varies depending on drugs tested and behavioral measures. Nevertheless, the precise mechanism of drug action on behavior is not well understood. In the present study, we systematically examined behavioral effects following administration of different classes of drugs, including NMDA antagonists (MK801 and PCP), cholinergic antagonists (scopolamine and mechamylamine) or agonist (nicotine), and dopamine agonists (amphetamine and cocaine) and antagonists (SCH23390 and eticlopride). We also examined drug effects on reversal or additive effects of drug combination on behavior. Wistar rats received one or combination of drugs and their performance in learning tasks and open-field activity were measured. Consistent with previous findings, NMDA antagonists, scopolamine, and dopamine agonists produced behavioral excitation, which was blocked reliably by dopamine antagonists. However, drug effects on learning tasks differed: low doses of MK801, scopolamine, SCH23390, or eticlopride impaired learning, whereas low doses of amphetamine or mechamylamine had no effects. Combination of MK801+SCH23390 reversed MK801-induced deficits, but not by other drug combinations, suggesting that D1 antagonist reversed behavioral impairment induced by NMDA antagonist. On the other hand, scopolamine+SCH23390 combination produced severe learning deficits, while other combinations produced minimal changes. Reversal or additive effects of drug combination on learning suggest that behavioral changes mediated by NMDA receptors reflect altering different neural mechanisms. Further study is warranted.

Title: Glutamatergic and GABAergic sources of synaptic input to septohippocampal cholinergic projections

Authors: *M. R. GIELOW[1], R. L. STORNETTA[2], L. ZABORSZKY[3]
[1]Rutgers Univ., Newark, NJ; [2]Pharmacol., Univ. of Virginia, Charlottesville, VA; [3]Rutgers The State Univ. of New Jersey, Newark, NJ

Abstract: Acetylcholine is a neuromodulator (neurotransmitter) critical to normal function of hippocampal and entorhinal cortical circuits. Control of medial temporal cholinergic efflux is achieved by cholinergic cell bodies located in the medial septum and diagonal bands (VDB and HDB) of the basal forebrain. We previously showed that, depending on projection target, different populations of cholinergic basal forebrain cells enjoy different inputs (Chavez & Zaborszky 2017; Gielow & Zaborszky 2017). The location of cells supplying excitatory and inhibitory inputs onto cholinergic neurons specifically projecting to the hippocampus remains unknown, and defies estimation based on retrograde tracing from the anterior basal forebrain itself, as a given nucleus in the basal forebrain contains multiple different populations of cholinergic cells projecting to disparate corners of the brain. Monosynaptic retrograde replication-deficient rabies vectors delivered to cholinergic terminals in hippocampus, coupled with cre-dependent helper virus transfection in choline acetyltransferase-positive cells of the rat basal forebrain presently allows us to map the whole brain atlas of GFP-tagged inputs to the hippocampal cholinergic projection in particular, verifying exact location of cells subsequently via same-section thionin nissl stain. We additionally employ fluorescent in situ hybridization of glutamatergic and GABAergic markers in the same tissue and map the resulting double-labeling of inputs. This DNA-tagged connectome of the cholinergic septohippocampal system enables novel and testable hypotheses regarding monosynaptic control of cholinergic tone in the hippocampus, and together with previous studies, allows a glimpse of the actors able to control local vs global cholinergic activity.

Title: Contribution of the basal forebrain to fine-tuned cortical states during a visual discrimination task in rats

Authors: *P. GOMBKOTO, P. VARSANYI, L. ZABORSZKY
Rutgers The State Univ. of New Jersey, Newark, NJ

Abstract: The basal forebrain (BF) contains a diverse population of neurons, including cholinergic and non-cholinergic corticopetal cells that play a crucial role in the regulation of cortical synchronization and desynchronization of different cortical regions. The basal forebrain's activity, through its projection patterns, provides a key functional involvement in cortical activation, attention, and memory. Cortical activity is defined through an interaction of external stimuli with spontaneous patterns that are produced endogenously. Spontaneous cortical population activity in an awake animal does not simply switch between discrete synchronized and desynchronized states but forms a continuum of states characterized by fluctuation depth of oscillations that correlate at least partially to ongoing behaviors (Harris and Thiele, 2011). We hypostatized that the BF, via its projection patterns, participates in the coordination of distinct cortical areas based on behavioral demands.We examined cortical state changes in V2, VO/VL, and from multiple locations of the BF simultaneously in freely moving awake rats. We determined the beginning of up-phases in V2 and VO/VL separately, and we distinguished the up-down states for global (phase locked) and local state changes. These time points were used as cross trigger sources for observing modulation of cellular activity within these cortical regions and in the BF.During cross triggered local cortical states, Cholinergic and noncholinergic cells of the BF, showed either agonist modulations, antagonist modulations, or their activity ignored the cortical state change. On the other hand, during task related activity of the animals, the LFPs from BF and both cortical regions were in highly active desynchronized state. The energy content of continuous wavelet transformation between 45-100Hz of LFPs fluctuated along the frequency domain. We introduced Topic Model Analyses (LDA) on the clustered Principal Component Analysis of the data that reflect combination of gamma band compartments in order to define "micro" cortical state changes which selectively correlated with the BF activity. We localized those cells from the BF which were involved in the modulation of local changes in the cortex. Our study suggests that the BF may contribute to changes of local synchronized states. This in turn, can represent a 'power save' mode of the local cortical region that is independent from specific states in other cortical regions. In contrast, during tasks, the BF neuronal activity participates in the fine-tuned pattern of micro gamma band changes of cortical regions and synchronize distinct cortical areas to the behavioral demands.

Title: Striatal activity during early acquisition and later habit formation of an auditory operant task

Authors: *C. M. CHAVEZ[1], D. NOOFOORY[1], K. BIESZCZAD[2], L. ZABORSZKY[1]
[1]Ctr. for Mol. and Behavioral Neurosci., Rutgers, The State Univ. of New Jersey, Newark, NJ; [2]Psychology, Rutgers, The State Univ. of New Jersey, Piscataway, NJ

Abstract: The basal forebrain cholinergic (BFC) projection system plays a critical role in learning and memory processes including the induction of experience-dependent neural plasticity in the cerebral cortex. Monosynaptic viral tracing of cholinergic projection cells, including those that target the primary auditory cortex (A1), revealed that the BFC receives a large proportion of its input from the striatum (Chavez & Zaborszky, 2017; Gielow & Zaborszky, 2017). While the role of the striatum in learning, habit formation, and memory has been well established, it has not been considered in relation to the BFC-A1 circuit. The proposed function of striatal projection cell activity during learning and later habit formation vary depending on their affiliation with the direct or indirect pathway as well as their localization within the striatum (Macpherson et al., 2014; Natsubori et al., 2017). We hypothesize that striatal cells that specifically project to the BFC-A1 circuit exert their influence differentially during early vs. late stages of auditory task performance. Using monosynaptic viral tracing with EnvA g-deleted rabies virus coding for channelrhodopsin (ChR2) in ChAT::Cre rats, we restricted ChR2 expression to cholinergic projection neurons that target A1 and their specific input cells within the striatum. This technique enabled selective optogenetic control over the striatal-BFC-A1 circuit allowing us to identify and determine striatal cell activity during an auditory-based behavioral task dependent on A1 plasticity (Elias et al., 2015; Bieszczad & Weinberger 2010). We recorded from the striatum and the basal forebrain throughout daily behavioral training sessions using a 64-channel 8-shank silicone optrode. Striatal inputs to A1-projecting BFC neurons were identified by brief optical stimulation following each training session. The behavioral training consisted of an operant task where a pure tone stimulus (S+) signaled the availability to bar-press for a water reward for water deprived rats. Preliminary data provide evidence for a diverse range of S+ tone driven activity in the striatum and BF that suggests a changing profile of characteristic responses expressed early or late in training. These findings may show that the striatum dynamically alters its inputs to the auditory projecting BFC neurons as behavioral performance improves in auditory tasks.

Title: Lateral hypothalamic area projection neurons contribute to an innate freezing response

Authors: *J. HAZEN[1], M. WIGESTRAND[1], I. AASEBØ[1], A. TULLY[1], T. DINH[2], M. LEPPERØD[2], T. HAFTING[2], M. FYHN[1]

Abstract: Rodents display innate defensive responses to a range of visual stimuli mimicking the hunting behavior of aerial predators. In the looming assay, an expanding dark circle simulates overhead attack. In response, rodents make an informed choice about the appropriate response. If shelter is available, they rapidly flee. If no shelter exists, animals engage in extended freezing. For each type of response (freezing/escape), much of the circuitry linking visual perception areas to integrative/affective areas to motor output areas has been roughly outlined. Importantly, how pro-freezing signals reach output areas remains unresolved. The medial hypothalamus is well known for its role in innate defensive responses, while the lateral hypothalamic area (LHA) is viewed as chiefly responsible for arousal and feeding. However, electrical stimulation of the LHA elicits defensive behaviors. Based on this, we hypothesized the LHA may play an important role in innate defensive behaviours. Using optogenetic excitation, we show that activation of anterior LHA induces avoidance/escape behavior, while activation of posterior LHA induces freezing. Furthermore, posterior LHA neurons project to the periaqueductal gray (PAG) motor output area and optogenetic stimulation of LHA terminals in PAG induces freezing. Interestingly, we observe that chemogenetic silencing of the LHA does not block conditioned freezing but does significantly impair looming induced freezing. Based on these observations, we hypothesize that LHA plays an important role in transmitting looming induced pro-freezing signals to the PAG motor output area. To further elucidate the neural network and computations in the LHA underlying looming induced freezing, we are performing calcium imaging on behaving rats.

Title: Social memory processing and plasticity in hippocampus CA2

Authors: *A. CHRISTENSEN[1,2], T. STÖBER[4,3], S. K. NOSSEN[2], M. FYHN[2], T. HAFTING-FYHN[1,2]
[1]Inst. of Basic Med. Sci., [2]Dept. of Biosci., [3]Dept. of Informatics, Univ. of Oslo, Oslo, Norway; [4]Simula Res. Lab., Oslo, Norway

Abstract: Emerging evidence suggests that CA2 plays an essential role in social memory as blocking activity in CA2 neurons impairs social memory in mice without affecting other hippocampus-dependent memory tasks. A striking feature of CA2 is its seemingly low levels of plasticity, both in terms of resistance to undergo LTP by stimulation of input from CA3, as well as high calcium buffering capacity and dense expression of perineuronal nets (PNNs). Plasticity in CA2 may be facilitated however by removal of the PNNs or application of neuromodulatory agents suggesting that a salient cue, such as a social encounter, may cause learning of important events. The CA2 is uniquely positioned for integrating social information into complex representations. Through direct projections, CA2 receives sub-cortical inputs from vasopressinergic neurons in the paraventricular nucleus, stored associative, contextual information from DG and CA3 as well as online sensory information from layer II of the entorhinal cortex. Indeed, local stimulation of vasopressin terminals in CA2 is shown to increase social memory in mice, indicating that heightened plasticity induced by the modulatory effects of vasopressin helps to strengthen social memories. Here, we first test if heightened plasticity of CA2 neurons is enough to elicit a similar effect on social memory. For this, we selectively delete the ACAN gene from CA2 neurons to permanently remove PNNs in CA2 of adult mice, which is shown to cause potentiation of excitatory signal transmission in vitro. We have then tested social memory in mice with and without PNNs in CA2.
In contrast to the stable spatial representations of the CA3 and CA1, place fields of CA2 neurons are unstable over time. In fact, they have been shown to change their location of firing (global remapping) in response to a social stimulation. We hypothesize that the the social encounter causes vasopressin release from paraventricular nucleus into the CA2 which facilitate plasticity necessary for global remapping to occur. Using guide cannulas to infuse vasopressin in CA2 of

rats, we examine the effect of modulatory neurotransmitter vasopressin on spatial representations in CA2 and on social memory.

Title: A CRISPR-Cas9 platform for genetic perturbation of brain extracellular matrix regulators in-vivo

Authors: *S. GRØDEM, G. SANDVIK, K. LENSJØ, J. HAZEN, T. HAFTING, M. FYHN
Univ. of Oslo, Oslo, Norway

Abstract: Perineuronal nets (PNNs) are lattice-like extracellular matrix structures surrounding the soma and apical dendrites of a subset of inhibitory neurons in the mammalian cortex. These specialized structures are posited to be critical regulatory elements of synaptic plasticity through structural control and stabilization of synaptic connections. The development of PNNs in the juvenile brain coincides with the maturation of Parvalbumin-positive (PV+) inhibitory neurons and the closure of critical phase plasticity, and it was recently demonstrated that the nets are required for long-term memory in the visual cortex.
While the structural components of the PNNs are well characterized, the principal regulators of the nets remain obscure. Several candidate proteases from the ADAMTS and MMP families have been implicated in attenuation of the nets, but their expression is heterogenous and they also act on other ECM components outside the nets, making it difficult to determine which protease is specifically concerned with regulating the PNNs. In order to identify and characterize the function of the genes regulating the PNNs in various cell-types and brain regions in-vivo we are developing a CRISPR-Cas9 gene perturbation platform for both gain and loss of function control of candidate genes. This involves AAV delivered single- or multiplex-targeted CRISPRko, transcriptional activation using dCas9-HSF, and transcriptional inhibition using dCas9-KRAB.
Furthering our understanding of PNN regulation could not only provide a more physiological route for studying the function of the PNNs, but also reveal promising therapeutic targets.

Title: Layer specific characterization of local projections within the medial entorhinal cortex

Authors: *M. L. FU[1], I. ZUTSHI[1], S. LIU[1], J. K. LEUTGEB[1], B. K. LIM[1], S. LEUTGEB[1,2]
[1]Neurobio. Sec. and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UCSD, San Diego, CA; [2]Kavli Inst. for Brain and Mind, La Jolla, CA

Abstract: The superficial layers (LII and LIII) of the medial entorhinal cortex (mEC) are the primary source of excitation to the hippocampus and the hippocampus, in turn, projects back to the deep layers (LV and LVI) of the mEC. The loop through hippocampus is closed by extensive projections from the deep to the superficial mEC layers, but there are also shorter recurrent loops that consist of local projections within and between mEC cell layers. These local connections become particularly relevant based on the observation that mEC cells have unique functional properties corresponding to combinations of grid, head direction, border, speed, and other context-dependent spatial tuning. Moreover, the spatial scale of some of these functional cell types, such as grid and head direction cells, increases in modular steps along the dorso-ventral axis of the mEC (Giocomo et al., 2014; Stensola et al., 2012), suggesting some degree of topographical organization within the mEC. Several studies have previously examined local projections between layers (Beed et al., 2010; Sürmeli et al., 2015) and within LII (Couey et al., 2013; Fuchs et al., 2016; Winterer et al., 2017) using patch recordings from multiple cells, but this method is only feasible in sampling cells in proximity to each other and does not capture the topographical organization of projections within the mEC. In our study, we took advantage of a wide range of layer specific mouse lines, corresponding to the two major excitatory cell types in layer II - pyramidal (LIIP) and stellate (LIIS) cells, and to cells in LIII, LVa and LVI, and utilized cell type specific anterograde and retrograde viral tracing strategies to dissect and quantify local projections between the mEC layers. Surprisingly, neurons from both LVa and LVI only weakly projected to the superficial layers of the mEC, suggesting that LVb neurons act as the primary source of projections from the deep to superficial layers. By performing retrograde tracing of inputs to sub-populations of LIIP cells at various depths along the mEC, we

found that projections originate predominantly from LII and LIII cells at the same dorso-ventral level, which is consistent with a modular organization. We are currently performing similar experiments to determine the organization of local projections to LIIS and LIII cells. We propose that a comprehensive characterization of deep to superficial layer projections, as well as of recurrent superficial layer projections, will provide a foundation for identifying circuit computations that give rise to the diverse functional cell types in the mEC.

Title: Coordination of theta and slow oscillations across medial septum, hippocampus, olfactory bulb and prefrontal cortex

Authors: *S. SRIKANTH[1], J. K. LEUTGEB[2], S. LEUTGEB[3]
[1]Div. of Biol. Sciences, Section of Neurobio., [2]Ctr. for Neural Circuits and Behavior, Neurobiol Section, Div. of Biol Sci., UCSD, La Jolla, CA; [3]Neurobio. Section, Univ. of California San Diego, La Jolla, CA

Abstract: It has been proposed that communication between the sensory cortices and the hippocampus during memory acquisition and retrieval is coordinated by oscillations (Buzsáki, 1996). Furthermore, hippocampal oscillations are thought to be synchronized by subcortical inputs from the medial septal area (MSA). To investigate whether MSA may coordinate oscillations across a larger cortical network, we recorded local field potentials (LFPs) across brain regions with prominent oscillations in the theta range. These regions not only include the hippocampus and prefrontal cortex, but also the olfactory bulb (OB) where oscillations in the theta band (3-12 Hz) closely follow the respiratory frequency (Rojas-Líbano et al., 2014). In particular, the respiration rhythm and the dorsal and ventral hippocampal theta rhythms are coherent during odor learning and discrimination tasks (Macrides et al., 1982; Kay, 2005). The olfactory respiration rhythm may thus couple to theta band rhythms in the limbic-cortical network and contribute to sensory processing. To begin to understand the mechanisms for theta coupling, we simultaneously recorded LFP signals from the OB, MSA, dorsal hippocampus (dHpC), ventral hippocampus (vHpC), and medial prefrontal cortex (mPFC). We compared these

signals between different periods when mice were running on a figure 8 maze, actively sniffing a neutral odor presented at an odor port, or sleeping in the home cage following behavior. As expected, we found that the oscillations in the MSA and dHpC were coordinated in the theta range (7-9 Hz) throughout all the phases of behavior (odor sniffing, running and sleep). However, septal oscillations were coherent with the vHpC only during sleep and odor presentation, but not during running. During sleep, the OB and mPFC oscillations were highly coherent to each other and to the other three regions in the 3-5 Hz range, but this coherence shifted to higher frequencies (5-7 Hz) during odor presentation. Oscillations are thus differentially coordinated between these regions during each behavioral epoch, such that task-dependent functional subnetworks emerge, which can each use frequencies in the theta range for coupling.

Title: Effects of manipulating theta frequency on medial entorhinal cells

Authors: *C. R. QUIRK, N. DEVICO MARCIANO, J. K. LEUTGEB, S. LEUTGEB
Neurobio. Sec. and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC San Diego, La Jolla, CA

Abstract: Computational models for generating medial entorhinal cortex (mEC) grid cells all require a running speed signal in the form of either an oscillatory or firing rate signal. Theta oscillations are prominent in the hippocampus and in mEC and increase in frequency and amplitude with faster running speeds. It has therefore been hypothesized that theta oscillations could be the speed signal to grid cells. Previous work has demonstrated that inactivating the medial septum results in a substantial reduction of theta power and disrupts the spatial periodicity of grid cells while border, head direction, and place cells are retained. However, it remains unclear whether disrupted grid patterns selectively emerge from effects on theta oscillations or, more generally, from the decreased excitation after septal inactivation. To specifically examine the influence of theta oscillation frequencies on grid cell generation, we took advantage of the role of medial septal parvalbumin-expressing GABAergic (PV) cells in generating theta oscillations and selectively expressed channelrhodopsin (ChR2) in PV cells in

the medial septum. We established that rhythmic stimulation of PV cells in the medial septum could be used to reliably control the frequency of theta oscillations in freely moving mice within the endogenous theta frequency range (e.g., 8 Hz) as well as outside the normal range (e.g., 10 and 12 Hz). We then recorded mEC cells in an open field and found that shifting theta to frequencies of 8 Hz, 10 Hz, and 12 Hz had no effect on the average firing rate of principal cells but significantly lowered the firing rate of interneurons relative to their baseline firing rates. We also found that pacing theta at 8 Hz and at 10 Hz reduced the spatial precision of mEC cells. These findings are consistent with the notion that theta oscillations are essential for spatial processing in the medial entorhinal cortex but they do not reveal a direct relation between theta frequency and spatial scaling.

Title: Modulation of CA1 and CA3 hippocampal cell oscillation frequencies by optogenetically paced theta oscillations from the medial septal area

Authors: *I. ZUTSHI[1], M. P. BRANDON[2], M. L. FU[1], S. LIU[1], J. K. LEUTGEB[1], S. LEUTGEB[1,3]
[1]Neurobio. Sec. and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC San Diego, La Jolla, CA; [2]Douglas Hosp. Res. Centre, Dept. of Psychiatry, McGill Univ., Montreal, QC, Canada; [3]UC San Diego, Kavli Inst. for Brain and Mind, La Jolla, CA

Abstract: Oscillations in the brain organize the temporal firing of neurons, facilitating information flow and supporting cognitive functions. The 6- to 9-Hz theta band is one such local field potential (LFP) oscillation that coordinates the rhythmic firing of hippocampal neurons. GABAergic neurons in the medial septal area (MSA) act as pacemaker neurons that control the frequency of theta oscillations by projecting to local interneurons in the hippocampus. While these projections from the MSA to hippocampal GABAergic cells terminate in all the sub-regions of the hippocampus, interneurons in the CA3 and DG are more densely targeted compared to CA1 (Freund and Antal, 1988). A recent study further described a distinct sub-

population of highly rhythmic parvalbumin (PV+) cells that extensively project to basket cells and axo-axonic cells in CA3 but bypass CA1 (Joshi et al., 2017). These anatomical projections are consistent with the observation that CA3 pyramidal cells are more tightly phase locked and phase precess to a lesser extent than CA1 pyramidal cells (Mizuseki et al., 2012). Furthermore, on controlling the frequency of LFP oscillations using optogenetic activation of PV neurons in the MSA, we recently demonstrated that the cellular oscillation frequency of CA1 neurons remained broadly distributed and that interneurons in the CA1 pyramidal cell layer oscillated faster than the stimulation frequency (Zutshi et al., 2018). Based on these physiological studies and the anatomical projections, we hypothesized that CA1 principal cells and interneurons in the CA1 cell layer are not directly controlled by septal PV neurons but rather by local feedback loops within CA1. To allow for the observed control of the LFP at the frequency of the septal pacemaker, we tested whether interneurons and principal cells that target the CA1 dendritic region, such as CA3 pyramidal cells, are more directly controlled by the septal pacemaker. Consistent with this hypothesis, we found interneurons outside of the CA1 cell layer that were phase locked to the septal stimulation frequency and we are currently testing whether optogenetic pacing of theta oscillations more directly controls the oscillation frequency of CA3 pyramidal cells and interneurons. Together, the variety of responses of CA1 and CA3 pyramidal cells and interneurons can be combined to generate a model to describe how local hippocampal circuits can generate oscillations that are directly paced by the medial septum while simultaneously generating accelerated cellular oscillation frequencies.

Title: Distinct and complementary roles of medial entorhinal cortex and dentate gyrus inputs for hippocampal CA3 phase precession

Authors: *S. AHMADI[1], M. SABARIEGO[1], T. SASAKI[1], C. LEIBOLD[2,3], S. LEUTGEB[1,4], J. K. LEUTGEB[1]
[1]Neurobiol. Section and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UCSD, La Jolla, CA; [2]Univ. of Munich, Planegg-Martinsried, Germany; [3]Bernstein Ctr. for Computat. Neurosci. and Dept. Biol. II, Ludwig-Maximilians-Universität München, Munich, Germany; [4]Kavli Inst. for Brain and Mind, UC San Diego, La Jolla, CA

Abstract: The temporal order of events is a defining characteristic of episodic memory which critically depends on the hippocampus (HPC). Theta phase precession (PP) organizes the order of place cell spikes in relation to behavior and can be thought of as consisting of "prospective and true-field" portions (Sanders et al., 2015). How the inputs, intrinsic cellular and network properties combine in HPC to compute current location and future choices on an ensemble level is not well understood. To understand the network mechanisms supporting PP in HPC CA3, we trained rats to perform a HPC-dependent task and disrupted the primary theta-modulated inputs of HPC, either the medial entorhinal cortex (MEC) or the dentate gyrus (DG), by selective lesions. We then recorded single unit activity (n = 101, 158, 84, and 68 for MEC^{CTRL}, MEC^{LESION}, DG^{CTRL}, and DG^{LESION}) in the CA3 area. Lesions of the MEC or the DG resulted in significant reductions in the fraction of phase precessing cells in CA3 (DG: C 67%, L 40%, p = 0.001; MEC: C, 59%, L 35%, p = 0.0001; Fisher's exact) and the average slopes (DG: C = -0.33, L = -0.02, $p < 0.05$; MEC: C = -0.29, L = -0.07, $p < 0.05$; Mann-Whitney; units cyc/field). Despite the reduction after loss of either input, the effects were nonetheless qualitatively different. In control animals, the onset phase of spikes showed a preference for late theta (DG: $\Phi_0^C = 243°$, MEC: $\Phi_0^C = 236°$). This preference diminished and shifted to earlier phases only when the DG, but not MEC, input was disrupted (DG: $\Phi_0^L = 202°$, w.r.t. C $p < 0.001$; MEC: $\Phi_0^L = 237°$, w.r.t. C p = 0.84; non-parametric test for equal circular median). The offset phase of PP was unaffected by the manipulations (DG $\Phi_f^C = 144°$, $\Phi_f^L = 132°$; MEC $\Phi_f^C = 133°$, $\Phi_f^L = 135°$; $p > 0.05$). These observations suggested that the DG is responsible for the prospective portion of CA3 place field firing while the MEC input controls the precise temporal code and the true-field representation. A computational model is proposed, consisting of two multiplicatively combining oscillatory inputs modulated by both theta and the local gamma inputs. The interaction of the inputs generates a suprathreshold total drive onto CA3 cells, providing short windows during which the CA3 cells emit spikes by a Poisson process. The intact model reproduced PP similar to that of the experimental data. A degraded MEC input reduced overall PP and increased the "burst weight" of firing. In contrast, a degraded DG input reduced the onset phase and PP, analogous to the effects observed in animals with DG lesions. Taken together, these observations support the notion that PP is supported at the network level and provide insight into the mechanisms by which these effects are produced.

Title: Dentate dependent-CA3 network pattern separation can occur in the absence of neurogenesis

Authors: *A.-L. SCHLENNER[1], V. C. PIATTI[1,2], L. A. EWELL[1], Y. AN[1], O. HON[1], H. A. CAMERON[3], S. LEUTGEB[1,4], J. K. LEUTGEB[1]

Abstract: In the dentate gyrus (DG) neurons are born and integrated into the DG network throughout the lifespan, which implies that a proportion of dentate granule cells is immature. The increased excitability of immature cells has been proposed to sparsify dentate network activity such that adult dentate neurogenesis is essential for supporting network discrimination of novel or overlapping network patterns. To determine how immature granule cells in the DG influence network processes of pattern separation in the downstream CA3, we recorded CA3 single unit activity in rats with and without neurogenesis. We used a task where dentate network activity was shown to be necessary for CA3 principal neurons to discriminate between novel sensory cues (McHugh et al., 2007). In this paradigm, rats were allowed to explore a novel environment over four 10-minute sessions. The walls of the environment were switched in each session from black (A) to white (B) in an A-B-B-A order. The experiment was repeated across multiple days. CA3 pyramidal cells were recorded in the transgenic GFAP-TK rat strain in which adult neurogenesis can be completely ablated by daily administration of the drug Valganciclovir. By performing doublecortin and bromodeoxyuridine immunohistochemistry, we confirmed that neurogenesis was ablated (99 ± 0.5%) in GFAP-TK^{+} rats (n = 6) 6-8 weeks after continuous drug administration compared to GFAP-TK^{-} control animals (n = 8). In animals with confirmed ablation of dentate neurogenesis in comparison to controls we did not observe significant differences in the degree of CA3 network discrimination for novel sensory cues, a dentate-dependent computation, or the pattern separation of the same cues once familiar. Although we observed a decrease in firing rate with increasing familiarity of the environment in control rats,

the firing rates stayed the same across days in animals without neurogenesis. This resulted in a significantly lower firing rate in control animals already on the second, more familiar day ($p=0.0011$, Kolmogorov-Smirnov test). The difference in CA3 network firing rate between GFAP-TK^{+} rats and GFAP-TK^{-} controls was not accompanied by a significant difference in field size, number of fields per cell or spatial information. Our results suggest that adult born neurons modulate the excitability of the downstream CA3 network, but are not critical for dentate-dependent CA3 network pattern separation.

Title: Hippocampal sequential firing during delay intervals is not required for working memory performance

Authors: *M. SABARIEGO, D. T. ZIMMERMAN, A. SCHONWALD, V. ALLURI, N. GONZALEZ, B. L. BOUBLIL, J. K. LEUTGEB, S. LEUTGEB

Abstract: The hippocampus is critical for remembering the flow of events in distinct experiences and, in doing so, bridges temporal gaps between discontinuous events (MacDonald et al., 2011). In order to temporally organize experiences, it has been suggested that hippocampal neural activity patterns represent sequential time points in support of episodic memory (Robinson et al., 2017). This type of sequential cell firing has been observed in both CA1 and CA3, although in tasks with no episodic memory demand and hence during tasks that are not dependent on hippocampus (Salz et al., 2016; Wood et al., 2000). Therefore, the functional significance of discrete serial firing patterns observed during delay periods in behavior remains unclear. We used a spatial working memory (WM) task in which animals needed to alternate between left and right sides of a figure-8 maze on a trial-by-trial basis to receive a reward. On each trial the rat had to remember the last episode and turn in the opposite direction compared to the previous trial. We manipulated the WM load by introducing delays of various lengths (10s and 60s) between trials. Recordings of hippocampal CA1 and CA3 single units and local field

potentials were performed to investigate the neuronal firing patterns that characterize WM processing throughout delay periods. In CA1 and CA3, WM maintenance was not accompanied by an unbroken chain of persistent delay activity. In addition, the order of sequential firing was not maintained across repetitions of equivalent trials so that right versus left trials could not be distinguished by analyzing neural activity at precise temporal intervals. Together with performance levels that were consistently above chance in all delay conditions, sequential hippocampal delay activity was therefore not associated with accurate WM-guided behavior. Rather, differential trial dependent activity re-emerged right before the animals turned to retrieve the next reward and persisted until the entrance to the delay site. Thus, during the delay, trial-related information could be maintained as a pattern of synaptic weights, analogous to long-term memory. Our results are consistent with the interpretation that temporally organized sequences between encoding and response preparation are not necessary, at least in the hippocampus, for the continuity of the mental representation during WM performance.

Title: Genetically targeted expression of APP to the hippocampal CA3 subpopulation of principal neurons leads to neuronal network dysfunction and memory impairment

Authors: *S. VIANA DA SILVA[1], M. G. HABERL[1], K. GAUR[1], M. L. FU[1], J. K. LEUTGEB[1], E. H. KOO[2], S. LEUTGEB[1,3]

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by a striking loss of episodic memory. We developed transgenic mice that express human amyloid precursor protein (APP) selectively in CA3 pyramidal cells as models to investigate how amyloid beta (AB) peptide induced synaptic toxicity leads to hippocampal circuit and memory dysfunction during early phases of AD. CA3-APP mice have normal basal synaptic transmission but impaired synaptic plasticity at Schaffer collateral synapses from 2 months of age. To test for

hippocampal memory deficits, we performed a spatial alternation task on a figure-8 maze with either no delay or brief delays (i.e., 2 s or 10 s) at the beginning of the center arm. Introducing a delay period is known to make the task hippocampus-dependent, in contrast to the continuous version. Aged CA3-APP mice (16-19 months) show deficits in hippocampus-dependent memory while younger mice (4-6 months) display only a transient deficit during the initial days of testing, reaching control levels after 5 days of behavioral testing. To understand changes in network function that may underlie the behavioral phenotypes, we recorded local field potentials (LFP) and single units before, during, and after the mice performed the spatial alternation task. Despite the limited expression of APP, we found extensively altered hippocampal physiology. In LFP recordings performed in the CA1 region of aged CA3-APP mice we observed a decrease in the frequency of theta and gamma oscillations in transgenic mice both in the return and central arms. Younger CA3-APP mice also show a decrease in theta (6-12Hz) and gamma frequencies (40-120Hz), but less pronounced when compared with the aged CA3-APP. No difference in the velocity modulation of these oscillations was found between genotypes. We further identify a transient peak in the LFP at the Beta range (15-30Hz) in the central arm, close to the point where the mice need to turn right or left. No statistical difference was found in the amplitude of this peak between genotypes. Additionally, we are currently investigating spatial and temporal firing patterns of hippocampal CA1 neurons in order to complete our understanding of whether AB-induced synaptic impairment alters interneurons and principal cell's activity and their modulation by the different oscillations in the LFP. Overall, our data indicate that local synaptic plasticity deficits may lead to network dysfunction, and the results strengthen the idea that memory in AD could be improved by restoring brain oscillations. Title: Optogenetic expression of situation-specific behavior to a cue composing multiple memory traces

Authors: *C. A. COELHO, A. RASHID, S. JOSSELYN, P. FRANKLAND
The Hosp. for Sick Children (Sickkids), Toronto, ON, Canada

Abstract: A number of studies have employed viral and transgenic approaches to 'tag' neuronal populations expressing c-fos (a proxy for activation) during encoding, and later optogenetically manipulate these neurons to artificially induce recall in the absence of reminder cues. In most of these studies, freezing behavior was used as the readout of memory. Here we ask whether similar engram reactivation can drive active, situational-specific behaviors for stimuli that have different meanings in different contexts. To do this we used a discriminative context-odor pair associates paradigm in which mice learn that in one context (A), digging in a peppermint-scented (odor 1), but not carvone-scented (odor 2), bedding is reinforced. Concurrently, these mice learn in a second context (B) that digging in carvone-scented (odor 2) but not peppermint-scented (odor 1), bedding is reinforced. Following training, mice underwent unrewarded memory probes in either context A or B, where they were presented with odor 1 and odor 2, and we assessed where mice dug for food. In order to tag neurons during the learning experience, we first infected wild type mice under doxycycline (dox) food diet with an AAV(DJ)-RAM-ChR2-EYFP virus in the dentate gyrus (DG). After recovery, mice were trained as above. Once mice reached asymptotic performance, DOX was removed in order to tag a single learning session (either in context A or in context B, counter-balanced). After two more intermixed sessions, mice underwent two unrewarded probe sessions (10 trials each) in the novel context C. Remarkably, opto-stimulation in the neutral context biased animals toward situation specific responding (i.e., responding as if they were in context A when context A tagged neurons were reactivated, or responding as if they were in context B when context B tagged neurons were reactivated). This result suggests that engram stimulation is not only able to drive complex memory-specific behaviors, but also circumstance-specific.

Title: Relaxing the rules of memory allocation in the lateral amygdala attenuates fear memory strength and specificity

Authors: *A. J. RASHID[1], C. YAN[2], J. YU[3], P. W. FRANKLAND[4], S. A. JOSSELYN[5]

Abstract: Increasing neuronal excitability in a small, random population of principal neurons in the lateral amygdala (LA) via overexpression of CREB drives allocation to a fear memory engram and enhances memory strength in mice. A similar effect can be induced by increasing neuronal excitability via expression of ChR2 in a population of LA neurons and brief activation of these neurons with blue light just prior to auditory fear conditioning. This increase in excitability is accompanied by concomitant inhibition of surrounding principal neurons, likely through activation of parvalbumin-positive interneurons, suggesting a form of feedforward inhibition from more-excitable to less-excitable principal neurons that may serve to constrain the overall size of an LA engram. To investigate the rules of allocation, we virally co-expressed CREB and tetanus toxin light chain (TetTx) in a random subset of principal LA neurons (~20%) to prevent neurotransmission from neurons with increased excitability without interfering with their ability to receive input. Compared to the enhanced fear memory in mice microinjected with CREB alone, mice microinjected with CREB+TetTx showed control levels of memory. A similar lack of memory enhancement was observed in mice microinjected with ChR2+TetTx compared to mice microinjected with ChR2 alone. Since neurons expressing TetTx could not provide output to contribute to the behavioral response (freezing), this suggested that control levels of freezing in mice microinjected with CREB+TetTx (or ChR2+TetTx) was mediated by non-infected neurons in the LA. This was supported by examining the overall size of the engram after fear conditioning using nuclear mRNA levels of the neuronal activity marker Arc. The Arc+ engram was larger in mice microinjected with CREB+TetTx as there was an increase in Arc expression in non-infected neurons. To further examine the behavioral consequences of disrupting the rules of neuronal allocation in the LA, we also examined memory specificity. Mice were fear conditioned such that a 2.8 kHz tone (CS+) was paired with foot-shock. Generalization was assessed by measuring freezing both to the CS+ tone and to a novel, distinct tone (7.5 kHz, CS-). While mice microinjected with vectors expressing CREB, GFP or TetTx alone showed high discrimination between CS+ and CS-, mice microinjected with CREB+TetTx displayed increased freezing to CS-. Collectively, our findings suggest that, within the LA, local interactions between excitatory and inhibitory neurons help establish the rules of neuronal allocation to a fear memory engram and that this mechanism plays a key role in regulating memory strength and memory specificity.

Title: Active myelination is required for spatial learning and memory consolidation

Authors: *P. E. STEADMAN[1], M. AHMED[2], F. XIA[2], A. J. MOCLE[2], S. A. JOSSELYN[3], P. W. FRANKLAND[4]

Abstract: The mechanisms for memory encoding and consolidation have focused on neuronal and synaptic modifications. Recent discoveries have shown oligodendrocyte precursor cells (OPCs) are highly responsive to experience and may represent another form of plasticity in the adult brain. Research over the last decade converges on the idea that experience-dependent myelination represents an important aspect of functional plasticity underlying behaviour. However, the relevance of white matter plasticity in learning and memory remains to be explored. In this study, we ask how acquisition and consolidation of a spatial memory influence oligodendrogenesis in distinct neural circuits, and whether adaptive myelination is needed for learning and consolidation in the adult brain. We find that acquisition and consolidation of a memory for a spatial task induces oligodendrogenesis in functionally-relevant regions of the brain. Furthermore, active myelination is required for learning and consolidation of a spatial memory. These findings suggest that adaptive myelination is an important facet of neuroplasticity supporting learning and memory beyond the neuron.

Title: Maturation of hippocampal perineuronal nets underlies the ontogeny of memory specificity

Authors: *A. I. RAMSARAN[1], B.-R. A. YEUNG[1], M. AHMED[1], S. A. JOSSELYN[2], P. W. FRANKLAND[3]
[1]The Hosp. for Sick Children, Toronto, ON, Canada; [2]Neurosci. & Mental Hlth., [3]PGCRL - NMH 5th floor, Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Compared to memories in adults, memories in infants and young children are more prone to forgetting over time (i.e., infantile amnesia; IA) and expressed less specifically (i.e., infantile generalization; IG). While biological mechanisms have been identified for IA, the neurobiology of IG remains unknown. We hypothesized that the maturation of perineuronal nets (PNNs), late-developing extracellular matrix structures known to inhibit juvenile plasticity in sensory systems, may regulate memory specificity across development. To test this, we first performed contextual fear conditioning (CFC) in mice from infancy (P16) through adulthood (P60). Fear memory was generalized in mice tested before P21 whereas fear expression was specific in mice tested after P24, indicating that IG drastically decreases during the fourth postnatal week. To examine whether this shift in memory expression was related to PNN development, we next characterized the distribution of PNNs in the dorsal hippocampus. Consistent with previous reports, we found that PNNs in the adult hippocampus varied in density, laminar organization, and co-localization with inhibitory and excitatory cell populations across subfields. Across development, we found that PNNs in CA1 rapidly accumulated around parvalbumin interneurons between P20 and P24, which tracked the behavioral transition from memory generalization to specificity. These experiments suggested that the maturation of PNNs in the hippocampus may regulate the switch from memory generalization to specificity during the fourth postnatal week. Accordingly, we predicted that disrupting PNNs in adult mice would reinstate juvenile-like memory generalization. To this end, we performed intracranial injections of chondroitinase ABC (ChABC) to digest PNNs in CA1 of adult mice. Local injections of ChABC drastically reduced the density of PNNs in CA1 3- and 7-days post-injection, but PNNs regenerated in CA1 to control levels by 14-days after surgery. In line with these results, we

observed fear memory generalization in adult mice that received injections of ChABC into CA1 3- and 7-days prior to CFC (i.e., when PNNs were reduced in CA1), but not 14-days prior to CFC (i.e., after PNNs regenerated in CA1). Thus, PNNs in CA1 were necessary for adult-like memory specificity and reducing PNNs in CA1 was sufficient to reinstate juvenile-like memory generalization in adult mice. Our findings support a role for PNNs in the development of the hippocampal memory system, and we demonstrate for the first time that the maturation of PNNs in the hippocampus underlies the switch from memory generalization to memory specificity.

Title: A two colour system for *in vivo* calcium imaging of engram populations

Authors: *A. D. JACOB[1,3], C. YAN[3], A. I. RAMSARAN[3,1], I. FELTS ALMOG[2], J. POON[2], P. W. FRANKLAND[3,1], S. A. JOSSELYN[3,1]
[1]Psychology, [2]Electrical and Computer Engin., Univ. of Toronto, Toronto, ON, Canada; [3]Neurosci. and Mental Hlth., The Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Understanding the contributions of neuronal populations to memory encoding and retrieval remains an important question in neuroscience. Previous work has identified a subpopulation of cells - termed the engram - whose activity is both necessary and sufficient for memory recall. To date, most investigations of the engram have used immediate early genes (IEGs) as a marker of this cell population. However, these IEG-based approaches do not provide information concerning the temporal dynamics of the engram population during mnemonic tasks. Miniaturized fluorescence microscopes offer the possibility of examining these dynamics by allowing for the simultaneous recording of activity from hundreds of neurons stably across days. While promising, current iterations of this technology only allow for imaging in a singe channel. As a result, identification and analysis of sparse neuronal subpopulations like the engram remains difficult using current calcium imaging techniques.
To address this issue, we developed a novel two-channel calcium imaging system based on our previously published compact head-mounted endoscope (CHEndoscope). This system allows for

imaging of dynamic activity in genetically defined neuronal populations in vivo during unrestrained behaviour. The system utilizes a green calcium reporter and a red fluorophore whose expression is activity dependent. Using red/green overlap, it is possible to distinguish between activity patterns in a relevant subpopulation compared with the overall population. We describe the construction and use of this system, as well as its potential application in analysing activity of an engram population or other genetically-defined subpopulation.

Title: Modeling the impact of neurogenesis on memory formation and stability

Authors: *L. M. TRAN[1,2], S. A. JOSSELYN[1,3], B. A. RICHARDS[4], P. W. FRANKLAND[1,3]
[1]Neurosciences & Mental Hlth., The Hosp. for Sick Children, Toronto, ON, Canada; [2]Physiol., [3]Psychology, Univ. of Toronto, Toronto, ON, Canada; [4]Biol. Sci., Univ. of Toronto Scarborough, Scarborough, ON, Canada

Abstract: In neural networks, the stability of stored information may be compromised by a) changing the neural architecture (e.g., adult neurogenesis) and b) adding new memories. Furthermore, these processes may also effect the ability to learn new memories. We tested these ideas in a three layer feedforward neural network. In this network the input, middle and output layers represent the entorhinal cortex, DG and CA3 regions, respectively, with neurogenesis occuring only in the DG layer. We generated input patterns, drawn from two partially overlapping distributions, A and B. The network was trained to recognize A and B input patterns and produce one of two discrete output patterns. The networks ability to generalize was assessed by presenting novel input patterns that were either drawn from the A and B distributions, and measuring accuracy of the output pattern produced. Following training, we either a) added new neurons to the middle layer, or b) trained the network on two new distributions C and D. Both a) new neuron addition and b) new learning impaired AB categorization, consistent with previous modeling and experimental data. Moreover, increasing plasticity, excitability and input and output connectivity of the new neurons exacerbated these categorization impairments. Next, we studied the impact of neurogenesis on subsequent learning. In this experiment, we trained the

network on AB and then added new neurons, as above. We then retrained the network on a) new distributions C and D, or b) a reversal condition where expected outputs of A and B are flipped (A'B'). The addition of new neurons enhanced reversal learning as well as new learning (albeit to a lesser extent). We found that with neuron addition, the degree to which networks forgot AB was correlated with enhancements and overall performance in reversal learning (A'B'), but not with new learning (CD), and not in the absence of neurogenesis. Next, we explored the consequences of varying both the rate of neuronal addition and the rate of neuron replacement relative to number of new neurons added (i.e. rate of turnover) on these observed effects. The network learned reversal categories best when turnover is zero (full addition). However, as the turnover ratio increased to one (balanced addition/loss) and beyond (net loss), the reversal enhancement decreased while the neurogenesis-mediated forgetting significantly increased. By exploring how new neurons impact stored memories and new memory storage, and the differential impact of various parameters governing these processes, our results begin to help us understand how adult neurogenesis in the hippocampus influences cognition.

Neurobio. Lab., The Campbell Family Brain Res. Institute, The Ctr. for Addiction & Mental Hlth. (CAMH), Toronto, ON, Canada

Abstract: *Ptchd1* is a gene located on chromosome Xp22.11, where genomic deletions or loss-of-function coding mutations has been reported in autism spectrum disorder (ASD) patients[1-5]. In order to determine the significance of *Ptchd1* mutations for ASD, *Ptchd1* knockout mice have been generated through excision of exon 2 (*Ptchd1*$^{\Delta exon2}$)[6-8]. Various autistic-like behavioral phenotypes - hyperactivity, learning deficits, motor coordination abnormalities - are characterized in the *Ptchd1*$^{\Delta exon2}$ mice, but no alterations in social behaviors have been identified, which is one of key features of ASD[9-10]. Here, we note that Ptchd1 frameshifting/prematurely truncating mutations are identified within exon 3 in patients, but not in exon 2, probably leading to PDZ-containing C-terminal truncation for both Ptchd1_a and Ptchd1_c transcript isoforms. In an attempt to recapitulate more clinically relevant *Ptchd1*-related ASD traits, we generated an alternative *Ptchd1* knockout mouse model where frameshifting/truncating mutations are introduced to the exon 3 using CRISPR/Cas9 technology (*Ptchd1*^{exon3} mice). As a result, male hemizygous from two *Ptchd1*^{exon3} lines (*Ptchd1*^{G387Ifs*29}: *Ptchd1*^{exon3} line1; *Ptchd1*^{G387Vfs*2}: *Ptchd1*^{exon3} line2) exhibit previously reported ASD-related behavioral phenotypes including hyperactivity, decreased learning, and motor deficits. In contrast with the *Ptchd1*$^{\Delta exon2}$ mice, however, our both *Ptchd1*^{exon3} line1 and *Ptchd1*^{exon3} line2 show striking deficits in social behaviors as well as repetitive behavior. Additionally, application of unsupervised data-driven analysis of human speech[11] reveals that *Ptchd1*^{exon3} mice produce significantly altered ultrasonic vocalizations (USVs) (i.e., spectro-temporal features of individual syllables and diversity of syllable repertoire). Unexpectedly, using both gene expression microarray and RT-PCR, our analysis of mRNA from the *Ptchd1*$^{\Delta exon2}$ mice reveals a modest elevation in overall *Ptchd1* transcriptional levels. Consistent with excision of exon 2, this appears to be due to loss of the *Ptchd1_a* transcript (exons 1 to 3, encoding and 888 amino acid open reading frame), but homeostatic activation of *Ptchd1_c* (exons 1 and 3, encoding open reading frames up to 542 amino acids long), suggesting that compensatory upregulation of *Ptchd1_c* in the *Ptchd1*$^{\Delta exon2}$ mice rescues social deficits.
Collectively, our results suggest that mutations on the exon 3 site of *Ptchd1* and resultant impairment of *Ptchd1_c* transcript are related with autistic-like social deficits and repetitive behaviors, providing more clinically relevant behavioral phenotypes compared to previously reported *Ptchd1* mouse models.

Title: Role of sleep spindles in consolidation of competing memories

Authors: *O. C. GONZALEZ[1], G. P. KRISHNAN[2], M. V. BAZHENOV[2]

Abstract: Previously encoded memories can be damaged by encoding of new memories, especially when they are relevant to the new data and hence can be disrupted by new training. Sleep can prevent the damage by replaying recent memories along with the old relevant memories. Though multiple evidences point to the role of sleep in memory consolidation, exact mechanisms remain to be understood. In this new study, we explored the role of stage 2 (N2) sleep spindles in protecting against memory degradation in response to encoding new memories. We used previously developed computational model of the thalamocortical network which exhibits transitions between awake, stage 2 (N2), and stage 3 (N3) sleep by modeling changes in neuromodulator concentrations. The model was able of generating characteristic sleep spindles in N2 and slow oscillations in N3. Spike-time dependent plasticity (STDP) was implemented on excitatory connections between cortical neurons to model synaptic weight changes associated with training and memory consolidation. When N3 sleep was presented alone, consolidation resulted in replay and improved performance for the newly encoded strong memory, while performance for the weak old memory was reduced. In contrast, a presence of N2 prior to N3 sleep resulted in improved consolidation of both strongly and weakly encoded memories. This difference arose from the local and asymmetric changes in synaptic weights, through local memory replay in N2. The local changes in synaptic weights were then further amplified during following N3 sleep. Together, this study provides evidence for the role of N2 sleep spindles in protecting pre-existing weak memories from undergoing degradation and interference in response to newly encoded memories.

Title: Reactivation in network motifs during NREM and REM sleep in thalamocortical model

Authors: *G. P. KRISHNAN[1], R. RAMYAA[3], M. V. BAZHENOV[2]
[1]Univ. of California San Diego, LA Jolla, CA; [2]Dept. of Med., Univ. of California San Diego, La Jolla, CA; [3]New Mexico Tech., Socorro, NM

Abstract: Reactivation or replay of the memory traces during sleep is critical for memory consolidation. However, very little is known about the neural mechanisms that result in memory replay during sleep. Empirical studies have shown that memories are represented in a distributed fashion widely across the brain. Thus, memory reactivation during sleep requires precise large-scale interaction and coordination of activity in the distributed neuronal ensembles. In this study, we examined how reactivation occurs in various network motifs during NREM and REM sleep in a biophysical thalamocortical network model. Each node in the network motif consisted of the biophysically realistic pyramidal neurons and interneurons with high probability of recurrent AMPA, NMDA and GABA connections within a node and sparse connections between nodes mediated by AMPA and NMDA synapses. Changes in the level of neuromodulators were modeled to obtain NREM and REM like states in the computational model. We examined network motifs (sizes 3, 4 and 5) which have previously observed in high frequency structural and functional imaging studies during awake. During NREM sleep, motifs which are cyclic were reactivated at higher frequency compared to REM sleep. We developed a simplified probabilistic neuron model which could be analytically analyzed within a framework of Markovian dynamics that explains the differences in reactivation during NREM and REM sleep. Our results suggest a differential role of NREM and REM sleep in shaping long-range interaction in cortical networks that is specific to the type of the network motifs.

Title: Continuous learning in a multi-layer network with rewarded spike-timing-dependent plasticity

Authors: *M. V. BAZHENOV[1], R. GOLDEN[2], E. DELANOIS[1], P. SANDA[3]
[1]Dept. of Med., [2]Neurosciences, Univ. of California San Diego, La Jolla, CA; [3]Inst. of Computer Science, Czech Acad. of Sci., Prague, Czech Republic

Abstract: Neural networks with multiple plastic layers equipped with rewarded spike-timing-dependent plasticity (R-STDP) and homeostatic regulation mechanisms are capable of learning advanced foraging tasks which have a pattern discrimination component as a sub-goal. However, if the networks are subsequently trained on a second foraging task which has different reward contingencies, memory of the first task will be overwritten - a phenomenon called “catastrophic forgetting” - and relearning must occur. In other words, these networks do not have flexible reward revaluation. In contrast, human and animal brains are fully capable of new learning without erasing old knowledge. We now believe this is accomplished by replaying both new and old knowledge during periods of off-line processing such as sleep. Here we used our previously developed computer model of reinforcement learning [Skorheim at al. PLoS One 2014; Sanda et al. PLoS Comp Bio 2017] to explore the idea that simulated replay can help preserve memories for multiple tasks. The network utilized reward modulated and non-reward modulated STDP and implemented multiple mechanisms for homeostatic regulation of synaptic efficacy. A basic convolution driven by unsupervised STDP occurred between input and hidden layers to learn input features. The network allowed for decorrelated subsets of middle-to-output layer synapses to develop for each task. Memory replay ensured that the output layer neurons maintained functional synaptic traces for tasks that had not been experienced in the recent past. The study predicts a critical set of properties for spiking neuronal networks with STDP that can continuously learn to solve complex foraging tasks without catastrophic forgetting.

Title: Surround inhibition and memory replay support sequential encoding of multiple stimulus-response associations without catastrophic forgetting

Authors: *R. GOLDEN, G. P. KRISHNAN, M. BAZHENOV
Med., Univ. of California San Diego, La Jolla, CA

Abstract: Stimulus-response associations are learned through a neurobiological implementation of reinforcement learning (RL) which uses dopamine (DA) signaling to represent reward-prediction errors (RPEs). While computational models of dopamine-mediated reinforcement learning have previously been implemented in spiking neural networks using a reward-modulated spike-timing-dependent plasticity (R-STDP) rule, these models have some major pitfalls. For example, if trained on a second task, these models will generally undergo catastrophic forgetting (i.e. they overwrite the stimulus-response associations they had learned for the first task). In this new study, we tested whether memory replay during stage 3 (N3) sleep can allow the model to overcome catastrophic forgetting. To do so, we used our computational model of a thalamocortical network which exhibits transitions through awake and N3 sleep by modeling changes in neuromodulator concentrations and can generate Up and Down states during slow oscillations in N3. Additionally, we implemented the R-STDP rule as a model of neurobiologically plausible RL. We found that memory replay is sufficient to overcome catastrophic forgetting only if the input patterns for the stimuli have low mutual information. As the mutual information between the input patterns increased, a broader radius of inhibition to implement surround inhibition was needed to ensure that the initial encodings are decorrelated enough to circumvent catastrophic forgetting. This study provides evidence for the crucial roles of surround inhibition and memory replay during the encoding and consolidation phases of continuous learning.

Title: Cellular resting-state network activity depends on previous experience of a mouse

Authors: *K. A. TOROPOVA[1,2], D. SUKHININ[2], E. KONOVALOVA[3], A. NATROVA[1], A. IVANOVA[1], D. IVASHKIN[1], O. IVASHKINA[1,2], K. ANOKHIN[1,2,3]

Abstract: The brain activity in a resting state is often interpreted in terms of background replay of neural networks of prior experience. Here we show that past traumatic experience can shape the resting-state neuronal networks of a mouse. The c-Fos activity of sensory and motor cortices, hippocampus, parahippocampal cortex, amygdala, basal nuclei, associative and sensory thalamic nuclei, hypothalamic nuclei and midbrain was investigated in mice that underwent post-traumatic stress disorder (PTSD) inducing footshock stress 7 days earlier and naive (non-stressed) mice. PTSD induction strongly affected subsequent resting-state brain activity: mice with prior traumatic experience had significantly more c-Fos+ cells in cingulate, retrosplenial, parietal associative and entorhinal cortices, basolateral and lateral amygdala, paraventricular thalamic nucleus and periaqueductal gray. We used graph theory approach to reconstruct resting-state network connectivity of naive and PTSD mice and compared experimentally identified networks with model networks: random, scale free and small world. In both groups of mice, the clustering was at the random network level. These clusters had weak interactions with each other: global efficiency of experimental networks was at the same level as of a random network. At the same time, PTSD network was less clustered and the clusters were divided by longer routes than in naive mice. PTSD induction caused global changes in the resting-state network structure, which affected all studied brain areas. While naive mice had most of the connections between the cortical areas, in PTSD mice the majority of connections were subcortical. PTSD induction eliminated almost all functional connections present in naive mice; the only cluster to survive was the closely connected cluster of visual and auditory cortical areas. Furthermore, while cingulate and retrosplenial cortices were the main network hubs in naive mice, functional connectivity between those areas was lost in PTSD mice, and paraventricular thalamic nucleus

became a hub. Conversely, while functional connections of amygdala were almost absent in naive mice, in PTSD mice there was a substantial number of connections between amygdala, cortical associative areas and striatum. Our data suggest that experience of stressful event can change both resting-state spontaneous activity and resting-state functional connectivity patterns in the mouse brain long after the traumatic episode. We hypothesize that these changes reflect a replay of neuronal assemblies involved in the states of past subjective experience. We plan to test this hypothesis by using TRAP technique.

Title: Application of TRAP strategy to investigate engram dynamics: Genetical tagging and *in vivo* calcium imaging of cognitively indexed neurons

Authors: *A. GRUZDEVA[1,2], O. IVASHKINA[1,2], K. TOROPOVA[1,2], K. ANOKHIN[1,2,3]
[1]NBICS-Center, NRC Kurchatov Inst., Moscow, Russian Federation; [2]Ctr. for Neural and Cognitive Sci., Lomonosov Moscow State Univ., Moscow, Russian Federation; [3]Lab. for Neurobio. of Memory, Inst. of Normal Physiol., Moscow, Russian Federation

Abstract: Numerous evidence suggest that memory engram is not static, however, not much is known about cellular mechanisms of engram reorganization over time. In this study we describe a novel application of targeted recombination in active populations (TRAP) strategy to investigate short-term and long-term engram dynamic at the cellular level. TRAP strategy uses a tamoxifen-inducible Cre-recombinase system under control of immediate-early genes promotors and allows to compare neuronal populations which were activated in two episodes of activity spaced for at least 72 h. To study long-term changes in cellular engram over time Fos-Cre-tdTomato mice were trained in contextual fear conditioning. Tamoxifen was injected 24 h before retrieval of the recent memory (3 days) to tag activated neurons with tdTomato. 30 days later we performed a remote memory retrieval and used double immunostaining for endogenous c-Fos and tdTomato to compare neuronal populations which were active during retrieval of recent and remote memory. To investigate short-term engram changes we developed a variation of TRAP

strategy based on double immunostaining for endogenous c-Fos and Cre-recombinase expressed under c-fos promotor. Tamoxifen was injected to Fos-Cre mice 24 h before the contextual fear conditioning, and immunostaining for c-Fos and Cre was performed at different time points after training. We show that the total number of Cre-positive neurons was maximal at 3-8 h and decreased by 16 h after the training. Thus, this strategy allows to compare neurons that were activated in two cognitive episodes spaced for 3-8 h. Next we employed Fos-Cre-GCaMP transgenic mouse strain to image calcium activity in cognitively indexed neurons. To this end we used TRAP strategy to introduce GCaMP3 sensor into engram neurons of conditioned fear to auditory stimulus. Tamoxifen was injected 24 h before the training, so that the neurons that expressed c-fos during fear conditioning also expressed the GCaMP3. The total number of GCaMP3 positive neurons reached maximum 72 h after the tamoxifen injection and remained stable for at least two months. We performed two-photon calcium imaging of TRAPed neurons in the mouse parietal cortex during presentation of the conditioned sound (CS) and found neurons which responded during CS and neurons which responded between CS. Additionally, the use of Fos-Cre-GCaMP mice reveal calcium dynamic in dendritic spines of TRAPed neurons. Thus, in vivo calcium imaging in the brain of conditioned Fos-Cre-GCaMP mice allows to investigate dynamic of calcium activity in the engram neurons.

Title: Epigenetic regulation of the circadian gene Per1 contributes to age-related impairments in long-term memory

Abstract: Aging is accompanied by impairments in both long-term memory and circadian rhythmicity. Although it is clear that memory is affected by circadian cycling, it is unknown whether age-related disruption of the circadian clock causes impaired hippocampal memory or whether these biological processes simply share a common mechanism that is altered with age. Here, we tested whether dysregulation of a key epigenetic mechanism, histone deacetylase 3 (HDAC3) in the aging hippocampus might contribute to impairments in long-term memory formation. HDAC3 typically represses gene expression by removing acetyl groups from histone tails and has previously been shown to be a key negative regulator of long-term memory formation. Here, we hypothesized that dysregulation of HDAC3 activity in the aging brain contributes to an unusually repressive chromatin structure that limits synaptic plasticity and memory formation. To test this, we disrupted HDAC3 in the dorsal hippocampus of 18-month-old mice with two different manipulations: focal genetic deletion with HDAC3$^{flox/flox}$mice and activity-specific disruption with a dominant-negative point mutant virus (AAV-HDAC3(Y298H)). We found that deletion or disruption of HDAC3 ameliorated age-related impairments in both long-term memory and synaptic plasticity. To identify the mechanism through which HDAC3 deletion ameliorates age-related memory impairments, we ran RNA sequencing on hippocampal tissue from young mice, aging mice, and aging mice with focal HDAC3 deletion in the dorsal hippocampus. We identified a subset of genes, including the circadian gene Period1 (*Per1*), that is restricted in the aging hippocampus by HDAC3. Using siRNA-mediated knockdown of PER1 protein, we show that hippocampal PER1 is critical for long-term memory formation in young mice. Finally, to determine whether overexpression of *Per1* is sufficient to ameliorate age-related memory impairments, we locally upregulated *Per1* in the dorsal hippocampus using two methods: lentivirus-mediated overexpression of wildtype *Per1* (pLVX-Per1) or transcriptional activation of *Per1* using the CRISPR/dCas9 SAM system. Both methods demonstrate that overexpression of *Per1* in the dorsal hippocampus can ameliorate age-related impairments in long-term memory formation. Together, our data suggest that HDAC3-mediated repression of *Per1* contributes to age-related impairments in long-term memory formation. More broadly, this age-related disruption of *Per1* might connect age-related impairments in both long-term memory and circadian rhythmicity, depending on the structure.

Title: Cilostazol, a phosphodiesterase 3 inhibitor, maintains and improves memory function in aged mice

Authors: *S. YANAI[1], T. ARASAKI[2], S. ENDO[2]
[2]Aging Neurosci. Res. Team, [1]Tokyo Metropolitan Inst. of Gerontology, Tokyo, Japan

Abstract: The cAMP pathway mediates a variety of physiological functions including learning and memory. Intracellular concentration of cAMP is achieved by the balance between its synthesis by adenylate cyclase and hydrolysis by phosphodiesterases (PDEs). Therefore, inhibitors of PDEs, which elevate intracellular concentration of cAMP, are promising targets for the development of cognitive enhancement drugs by upregulating cAMP functions such as the activation of PKA-CREB pathway. Among several PDE inhibitors, we have been focused on cilostazol, a PDE3 selective inhibitor, as potential therapeutic intervention for age-related cognitive impairment in human. In the present study, we examined the effect of cilostazol administration on age-related memory impairment in the standard mice model of aging, C57BL/6J mice. To examine whether long-term cilostazol administration maintain cognitive function in aged mice, cilostazol (0, 0.3%, or 1.5%) had been administered by mixing it in the feed starting from 13 months of age, when their cognitive function starts to decline. At 23 months of age, the mice were subjected to the behavioral battery of tests. The 1.5% cilostazol-administered mice performed significantly better in the object recognition task and the Morris water maze task compared to the non-cilostazol-administered control mice, suggesting that long-term cilostazol administration maintain the hippocampus-dependent memory in aged mice. Separate groups of mice were administered cilostazol starting from 22 months of age, when they show major impairment in cognitive functions. After relatively short-term administration period for 1 month, the behavioral battery of tests were conducted at 23 months of age. Consistent with long-term administration, performance of the 1.5% cilostazol-administered mice in two hippocampus-dependent memory tasks were significantly better than that of the non-cilostazol-administered control mice. These results suggest that cilostazol can improve the age-related memory impairments. Regardless of the administration period (10 or 1 months), no apparent influences of cilostazol were observed in the open field test, suggesting that cilostazol have no significant effects on locomotor activity and anxiety. Based on these findings that cilostazol is effective for the prevention and treatment of age-related memory impairment, a clinical trial is now underway in Japan to treat mild cognitive impairment. Because the safety evaluation of cilostazol is well established, cilostazol is a potentially promising target for the maintenance and treatment of cognitive impairment in the aging human population.

Title: DEK loss is associated with cellular, molecular, and clinical features of dementia

Authors: *A. GREENE[1], N. J. BALMER[2], V. GHISAYS[3], L. PRIVETTE VINNEDGE[4], M. B. SOLOMON[2]
[2]Dept. of Psychiatry and Behavioral Neurosci., [3]Exptl. Psychology, [4]Div. of Oncology, Cancer and Blood Dis. Inst., [1]Univ. of Cincinnati, Cincinnati, OH

Abstract: DEK, a chromatin-remodeling phosphoprotein, is well-known to have a role in cancer and autoimmune diseases; however, we have accumulated compelling data suggesting that DEK deficiency is linked with cognitive dysfunction. Our laboratory was the first to characterize the neuroanatomical distribution of DEK in the male and female murine brain, where it is prominently expressed in cognitive-relevant brain regions including the prefrontal cortex, amygdala, and hippocampus. Behavioral consequences of DEK loss in female knockout mice include impaired object recognition relative to wild-type mice, which was not due to increased anxiety-like behavior or deficits in locomotion. In addition, we have determined that cortical DEK protein expression decreases with dementia severity (Clinical Dementia Rating >2.0) in elderly women, but not men. This is notable because DEK is an estrogen receptor-α target gene, and these findings suggest a sex-specific functional role for DEK in learning and memory, and perhaps dementia. Further, a Topp-Gene analysis identified Alzheimer's disease (AD) and age-related cognitive decline as candidate DEK loss-associated diseases.
In an effort to elucidate how DEK loss may contribute to AD-related pathology or cognitive dysfunction, we employed *in vitro* and *in vivo* methodology. We report that DEK loss in neuronal cell lines (HT22; immortalized mouse hippocampal cells or differentiated SH-SY-5Y cells) induces cellular and molecular signatures of dementia or cognitive dysfunction including: DNA damage (phosphorylated-p53), apoptosis (cleaved caspase 8), decreased β-catenin levels, and increased tau accumulation. Further, female DEK KO mice exhibit decreased hippocampal MAP-2 protein expression compared with wild-type mice, indicative of decreased dendritic

density. This observed decrease in hippocampal MAP-2 expression may partly explain our previously observed cognitive impairment in female DEK KO mice. Together, these data suggest a critical role for DEK in cellular and behavioral markers of learning and memory.
We are currently exploring the role of DEK in other cellular and behavioral features of learning and memory (e.g., spatial and social) and in males to determine if these cognitive effects are limited to females.

Title: Surveying the epigenetic landscape of Arc-mediated age-related cognitive decline

Authors: *C. MYRUM, B. R. FLETCHER, S. DE, K. G. BECKER, P. R. RAPP
Natl. Inst. of Health: NIA, Baltimore, MD

Abstract: Pinpointing the molecular basis of age-related cognitive decline is critical for early detection, treatment, and slowing age-related memory loss. The protein Arc (activity-regulated cytoskeleton-associated protein) has been dubbed the "master regulator" of memory-related synaptic plasticity, and several aspects of Arc regulation are altered in aged rats with cognitive impairment. In the current study, we examined whether altered epigenetic control (a hallmark of aging) is coupled with cognitive outcome. Utilizing a well-characterized rat model of neurocognitive aging, young and aged animals' spatial memory capacities were assessed in a water maze. Aged rats were then classified as either unimpaired (AU) or impaired (AI) relative to young (Y). The hippocampal CA3 subfield—a key site of altered plasticity in age-related memory impairment—was then microdissected and processed for analysis. We surveyed three key epigenetic mechanisms of Arc gene regulation: (A) DNA methylation examined by bisulfite conversion and analyzed using a next-generation sequencing (NGS) MiSeq platform; (B) histone modification analyzed via chromatin immunoprecipitation (ChIP) followed by RT-qPCR; and (C) nucleosome positioning assessed via micrococcal nuclease digestion followed by Ion Torrent NGS. Bisulfite experiments identified seven bases that were differentially methylated between Y, AU, and AI rats (p's < 0.05). One particularly noteworthy base was significantly elevated in AI rats compared to Y and AU under basal conditions (p's < 0.05), but became significantly

demethylated (and thus non-significant compared to Y and AU) following exploratory behavior ($p < 0.05$). This active demethylation may represent an unsuccessful compensatory mechanism to enhance Arc expression following exploratory behavior. ChIP experiments revealed two histone markers for active transcription (H3K9AcS10p and H3K9Ac) and one repressive marker (H3K9me2) that were more enriched in AI animals than in Y or AU animals (p's < 0.05), while Y vs AU comparisons showed no difference ($p > 0.05$). Available results from nucleosome positioning experiments suggest that Arc nucleosome occupancy and fuzziness are strikingly stable between Y, AU, and AI rats. Together these data identify important neuroepigenetic signatures that distinguish impaired and successful cognitive aging, and represent novel, potential drug targets for treating age-related memory decline.

[1]Human Developement, [2]Human Develop., Cornell Univ., Ithaca, NY; [3]Cornell Unibersity, Ithaca, NY

Abstract: The ability to update one's mental schemas in order respond flexibly and adaptably - i.e. cognitive flexibility - is crucial to navigating a dynamic environment. Proactive interference (PI) is a phenomenon wherein prior memory impedes the formation of new memories for similar information, biasing behavior toward no-longer-relevant schemas. Thus, overcoming PI is an important aspect of cognitive flexibility. PI is exacerbated during aging, and in turn contributes to age-related deficits in cognitive flexibility. In young animals and young adult humans, resolution of PI has been found to rely on neuromodulatory activity via Acetylcholine (ACh), and ACh levels are known to decline in aging, however it has yet to be demonstrated whether these age-related changes in ACh directly contribute to age-related increase in PI. Here, we first compared PI resolution in middle-aged (13 months, n = 8) and old (23 months, n= 11) male Long Evans rats, finding that old animals were more inefficient in resolving PI when compared to the middle-aged animals. Furthermore we performed cholinergic deafferentation, with the immunotoxin 192-IgG saporin (SAP; 0.2 µl of 0.3 µg/µl dissolved in sterile phosphate buffered

sale in each of four locations targeting bilateral anterior and posterior basal forebrain), in our older rats (N= 5 SAP and N=6 Sham) which had no effect on the floor performance of older rats. This suggests that the inability to resolve PI seen in the aged rats may be due to already-depleted levels of ACh. We are currently collecting local field potential data in the prelimbic and posterior parietal cortices in behaving older and younger rats and will combine this with central administration of muscarinic cholinergic pharmacology to continue to examine age-related changes in the cortical dynamics that support cognitive flexibility. Based on prior findings in our laboratory examining similar attentional flexibility, we predict the young animals will demonstrate increased beta band LFP activity in the posterior parietal cortex, and potentially increased beta coherence between prefrontal and posterior parietal cortices, related to successful resolution of PI. We expect such activity to be mitigated by cholinergic antagonists and in the older animals.

Title: The dissociation of normal aging from Alzheimer's disease in mouse models of tauopathy and amyloidosis

Authors: *I. MORGANSTERN[1], D. HE[1], R. ZENOWICH[1], L. THIEDE[1], D. HAVAS[1], A. AMBESI[2], M. BANSAL[2], T. HANANIA[1]

Abstract: Aging is the leading risk factor for the chronic diseases that account for the bulk of morbidity, mortality, and health costs. Although there's been a tremendous progress in understanding the underlying molecular processes important in the aging cascade, much remains unknown specifically with regard to the relationship of normal aging to more advanced pathological states such as Alzheimer's disease (AD). In order to better understand this critical relationship and provide more robust pre-clinical models for drug development, the goal of the current study was two-fold; 1) to identify the prominent behavioral features related to standard aging in C57BL/6 mice using both standard and computational analyses; 2) to examine the behavioral similarities and distinctions of normal aging from that of two mouse models of AD, namely rTg4510 (Tauopathy) and APP/PS1 (Amyloidosis). The test battery consisted of commonly used metrics for motor function (Open Field, Rotarod), depression (Forced Swim, Tail Suspension), anxiety (Marble Burying) as well as cognition (Y-maze, Fear Conditioning, Odor Habituation). Additionally, more complex behavioral patterns profiled using proprietary

platforms such as SmartCube®, combined with computational analyses were utilized in order to identify an age-related behavioral signature. We tested three age-groups of wild type C57/BL6 mice, young (7-10 weeks), middle-age (16-20 weeks) and old-age (39-43 weeks) and AD mutant lines, rTg4510 and APP/PS1, at similar ages. The behavioral findings demonstrate age and line-dependent similarities and distinctions from normal aging mice. While behaviors related to motor function and depression were distinct in both AD lines compared to aging mice; behaviors related to cognition and anxiety demonstrated some similarity with that of normal aging. Using SmartCube® technology we identified distinct behavioral features that are directly-related to aging and progressed over time. Comparison of these age-related features to that of the two AD lines (rTg4510 and APP/PS1) demonstrated a clear relationship between aging and AD as well as pointed to several unique features that are specific to AD. In summary, we demonstrate here the common and distinct features of aging and AD phenotypes using both standard and algorithm-based behavioral tests. More importantly, we are able to dissociate aging-specific behavioral features from mutant lines of Tauopathy and Amyloidosis and identify, more precisely, AD-specific features using advanced and un-biased computer vision systems. Such an approach would be extremely valuable when assessing novel potential therapeutic approaches for AD and aging.

Title: Paramylon improves age-dependent impairment of spatial memory of the senescence-accelerated mouse prone 8

Authors: K. YASUDA[1], M. OGURA[2], S. TANIGUCHI[2], A. NAKASHIMA[1], *S. KENGO[1,3], K. ITO[2]
[1]Euglena Co.,Ltd., Yokohama-shi, Japan; [2]Univ. Tokyo, Kasama, Japan; [3]RIKEN Cluster for Science, Technol. and Innovation Hub, Yokohama-shi, Japan

Abstract: *Euglena gracilis*, a single celled microalga, is used as natural sources to obtain a whole variety of compounds, such as vitamins, minerals, amino acids, and unsaturated fatty acids. Euglena cells also accumulate β-1,3-glucan (paramylon), a Euglena-specific novel polysaccharide. Recent studies revealed that paramylon improves not only intestinal regulation or immune function but also antioxidant activity which is involved in the learning and memory. However, the effects of Euglena and the extract of Euglena on cognitive function are poorly

understood. Here, we aim to evaluate the potency of Euglena and paramylon on age-related decline of learning and memory in the senescence-accelerated mouse prone-8 (SAMP8) which exhibits age-dependent cognitive deficit at around 6 months old. We used 6-month-old SAMP8 fed 2% Euglena or paramylon for 5 weeks and adopted Morris water maze test and Y-maze spontaneous alternation test for the assessment of spatial learning and short-term memory, respectively. On day 4 of the learning phase in Morris Water maze test, paramylon-supplemented SAMP8 required significantly shorter escape latency compared to control and euglena-supplemented group although there was no difference between the Euglena-supplemented group and the control group. In contrast, we could not find any significant differences among the groups in the probe test. The swimming velocity of paramylon-supplemented SAMP8 was comparable with other groups. Y-maze spontaneous alternation task showed no significant differences in alteration behavior rate among the groups. These data suggest that 2% paramylon treatment attenuates the age-related spatial learning deficits, while it does not influence on memory consolidation or acquisition of short-term memory in SAMP8. Although the underlying mechanism of paramylon on the hippocampus are yet unclear, paramylon has potentiality for therapeutic application on cognitive decline.

Title: The effects of chronic curcumin treatment in a non-human primate model of aging

Authors: ***A. UPRETY**[1], M. MEDALLA[1], B. G. BOWLEY[1], P. L. SHULTZ[1], S. M. CALDERAZZO[1], E. J. SHOBIN[2], D. L. ROSENE[1], M. B. MOSS[1], T. L. MOORE[1]

Abstract: Studies of both humans and non-human primates have demonstrated that aging is typically characterized by a decline in cognition specifically in the domains of executive function and memory starting as early as midlife. While the underlying cause of age-related cognitive

decline is unclear, there is significant evidence for age-related pathology in the white matter associated with an increase in age-related inflammation. Nutraceuticals that are rich in polyphenols, have received considerable attention as possible treatments to slow or potentially mitigate age-related cognitive decline by virtue of their anti-inflammatory and antioxidant effects. Of these, curcumin (CUR), has been shown to produce significant anti-inflammatory and antioxidative effects in humans and rodents. Accordingly, using the rhesus monkey well-established model of normal aging, we assessed for the first time the efficacy of dietary supplementation of CUR as an intervention to reduce the effects of aging on cognitive function and markers of inflammation. Daily oral doses (500mg) of CUR or a vehicle control were given to 17 monkeys over an 18-month period during which they completed tasks of visual recognition memory spatial working memory, and reversal learning. To date, we have demonstrated that CUR treated monkeys evidenced enhanced performance on spatial working memory and reversal tasks compared with monkeys that received vehicle control. No differences were seen between groups on recognition memory or object discrimination tasks. In addition, we have preliminary data demonstrating that CUR treatment significantly alters the morphology and antigen presentation of microglia, the resident macrophages and mediators of inflammation in the brain. Specifically, there is a reduction in LN3+ expression in the frontal white matter and corpus callosum of CUR treated monkeys. Additionally, compared to vehicle controls, microglia in the cingulate cortex (BA 25) of CUR subjects had longer distal processes with increased branching characteristic of a 'surveying' state morphology, typically associated with a reduced inflammatory state. Together these findings are consistent with the anti-inflammatory properties of CUR and its potential for reducing age-related cognitive decline in normal aging monkeys.

Title: Age dependent effect of testosterone on the spatial memory in the male rat

Authors: *G. JIMENEZ RUBIO, H. A. MARTINEZ BECERRIL, M. S. MARQUEZ BALTAZAR, J. J. HERRERA PEREZ, L. A. MARTINEZ MOTA
Inst. Nacional de Psiquiatria Ramon de La Fuen, Ciudad de Mexico, Mexico

Abstract: Old people present substantial declines in spatial memory, it has been proposed that gonadal or stress-related hormones may contribute to these changes in cognition. The aim of our

study was to identify in male rats the role of testosterone (T) in age-related differences in the performance of spatial memory. Young (3 months old) and aged (21 months old) Wistar rats were assigned to one of three independent groups: intact, orchidectomized or orchidectomized treated with T (pellets with 9 mg of T propionate). Spatial memory was evaluated using the Barnes maze, this test elicits low levels of stress respect to other paradigms. The phases of acquisition and retention of spatial memory were evaluated. The open field test was carried out in the animals in order to investigate whether changes in general motor function could interfere with the performance in the Barnes maze. It was found that, compared with young, the aged intact animals took more time to find goal, made more mistakes and did not improve the performance in the Barnes maze across the acquisition period. Orchidectomized young animals did not improve their performance across the acquisition phase in comparison to intact young animals, which increased the search in the goal sector and decreased the number of errors in comparison with the first day. Additionally, hormonal suppression in young animals deteriorated spatial memory in the retention phase, but the long term T treatment prevented this deficit by means of increasing the search for goal sector and reducing the number of errors in the test. Conversely, neither the orchidectomy nor T treatment modified the spatial memory of aged rats in the acquisition or retention phases. On the other hand, the ambulatory activity was significantly reduced in aged animals, independently of their hormonal condition, however the increased travelled distance and the error numbers of aged rats in the maze suggested that their poor performance is associated with a cognitive damage. In conclusion, declination in T levels could partially explain the age-related deficits in the learning and spatial memory of males rats

Title: Aging impairs the flexible use of environment-specific representations in humans

Authors: *M. R. FORLOINES[1], L. HEJTMÁNEK[1,2], D. L. OCHOA[1], B. A. OBER[1], A. D. EKSTROM[3]

Abstract: Remembering a spatial environment entails encoding its details and discriminating it from other spatial environments. Recent work from our lab suggests that participants show a small behavioral cost when pointing to landmarks in a new environment after learning a first environment, an index of "remapping" (Kyle et al. 2015). Participants' multivariate hippocampal codes, measured with fMRI, show less correlation in different environments than same environments, providing a potential neural measure of remapping. Older adults often show difficulty differentiating similar experiences during memory recall, or memory rigidity. The extent to which rigidity applies to navigation in humans is unknown. In rodents, older rats showed consistency in their neural representations of learned environments within session, but when placed in a new space, their representation corresponded equally with the original and to the subsequent space. This result suggests that older rats are similar to young rats initially, but their neural representations vary in a second environment, whereas neural codes in young rats showed differentiation between environments (Barnes et al. 1997). Determining the nature of remapping deficits in elderly humans is important due to increased difficulty navigating in aging. To address this, participants (young: 18-25, elderly: 65-90) encoded layouts of virtual cities, and subsequently recalled store locations within each city. Participants learned multiple cities with slight variations; stores varied in their placement or their identity, which allowed for an analysis of interference effects across similar cities, and the ability to create new representations through remapping, in other words, using a different representation for a new city versus reverting to an old one. Initial results showed that older adults took longer and made more errors than their younger counterparts overall. We found evidence that older adults showed impairments in remapping. Specifically, the small sample tested so far perseverated when switching to a different environment compared to younger adults, demonstrating remapping impairments. These findings thus suggest that studying remapping may be a means of better understanding navigation-related impairments that accompany aging.

Title: Comparative analysis of mouse resources for systems genetics of normal cognitive aging

Authors: A. OUELLETTE[1], S. NEUNER[2], G. CHURCHILL[1], *C. C. KACZOROWSKI[1]
[1]Genomics, The Jackson Lab., Bar Harbor, ME; [2]Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Classical inbred mouse strains, such as the C57BL/6J, have played an important role in defining physiological changes associated with normal cognitive aging. However, given the limited genetic variation in inbred models, results from these studies may not generalize to other mouse strains - let alone human populations. Using the BXD genetic reference panel, we have shown that that increasing genetic variation in aging models significantly enhances translatability of mouse data at the genome, transcriptome, and phenome level of analyses [1,2]. Since the BXDs vary to a lesser degree in genetic complexity than the highly admixed Collaborative Cross (CC) population [3,4], we tested the hypothesis that using the Collaborative Cross (CC) population would enhance the phenotypic variation of cognitive traits. To do this, we analyzed the performance of CC lines on the Y-maze working memory task (% Spontaneous Alternation, %SA), acquisition of contextual fear (CFA), and contextual fear memory (CFM), and compared the results to those previously collected on age-matched BXD strains. Although we predicted the CC panel would exhibit wider variation in cognitive performance than the BXDs, comparative analysis of working memory (range; BXD= 30%-75%, CC=38%-70%), CFA (range; BXD= -2.43-19.43, CC= 1.12-10.16), and CFM (range; BXD=1-82%, CC=9-48%) did not support this hypothesis, as BXD strains showed a wider variation for CFA and CFM. Heritability (h^2) for %SA was comparable in the CCs (BXD h^2=0.27, CC h^2=0.24), whereas h^2 for CFA and CFM was higher in the BXDs (CFA; BXD h^2= 0.65, CC h^2= 0.20, CFM; BXD h^2=0.75, CC h^2=0.32). As heritability reflects the within-strain (technical/environmental) variance compared to the between-strain (genetic) variance, these results may suggest that cognitive performance across the CC panel is more sensitive to these external factors than the BXD panel, and thus, there may be a greater impact of genetic variants on phenotypic variance within the BXD panel. It is possible that observed differences in phenotypic range and heritability may have resulted from differences in housing conditions, diet, microbiome and other unknown factors. Lastly, it is also important to note that we analyzed fewer CC strains (n = 9) on CFM than BXD strains (n = 21), which may affect both h^2 calculations and the phenotypic range. Ongoing work aims to evaluate cognitive performance on a larger number of CC strains to facilitate more robust comparisons, so that future experiments can select the population most appropriate for studies of cognitive aging.

Title: Sexually dimorphic effects of dietary vitamin D supplementation on cognition in aging rats

Authors: L. D. BREWER, J. R. THIBAULT, J. C. GANT, K. C. CHEN, K. L. ANDERSON, H. N. FRAZIER, A. O. GHOWERI, J. B. HOFFMAN, S. D. KRANER, P. W. LANDFIELD, O. THIBAULT, E. M. BLALOCK, *N. M. PORTER
Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY

Abstract: Increasing evidence suggests that vitamin D plays a role in maintaining cognitive function and that vitamin D deficiency may accelerate age-related cognitive decline. In our previous study using aging male rats (Latimer et al., 2014), we attempted to model the range of human serum vitamin D levels, from deficient to sufficient, to test whether vitamin D could preserve or improve cognitive function with aging. For 5–6 months, mid-aged F344 rats were fed diets containing low, medium (standard amount), or high (100, 1,000, or 10,000 IU/kg diet, respectively) vitamin D3 (VitD3, cholecalciferol). The Morris water maze (MWM) was used to test hippocampal-dependent learning and memory. Rats on high VitD3 achieved the highest blood levels (in the optimal range for humans) and significantly outperformed low and medium groups on MWM reversal, a particularly challenging task that detects more subtle changes in memory.
Here, we attempted to replicate those findings and determine whether VitD3 effects were sex-dependent. Beginning at 12 months of age, 20 male and 20 female F344 rats were fed an AIN-93 diet containing either standard (1000 IU/kg diet) or higher VitD3 (10,000 IU/kg). Following 6 months of treatment, rats were trained in the MWM to assess effects on learning and memory. Rats were trained for 3 days and the probe trial performed on day 4 to assess memory for platform location. The probe test indicated that higher VitD3 significantly reduced path length and latency ($P = 0.01$) to the digital platform in females but not males. On day 5, we switched the location of the platform and performed one day of reversal training. No performance differences were detected according to sex or diet. On day 8 and three days after reversal training, we

conducted the reversal probe test. Results indicated that higher dietary VitD3 improved performance in males but not females by significantly reducing path length and latency to the digital platform ($P<0.05$). Upon completion of behavioral analyses, we examined the cecal contents of these animals to determine whether dietary VitD3 affects the gut microbiome - brain axis and possibly influence behavior. A Shannon Diversity Index of the gut microbiome indicated a significant treatment effect of higher dietary VitD3 in females ($P = 0.01$). Together, these MWM results not only replicate our previous study in aging male rats but also indicate that vitamin D may have sexually dimorphic effects on specific cognitive pathways involved in memory formation. Further, our studies provide further support that serum vitamin D levels considered in the optimal range for humans may improve the likelihood of successful brain aging.

Title: A multiple memory systems approach to understanding cognitive aging: Not all aging is equal

Authors: *R. S. GARDNER[1], P. E. GOLD[2], D. L. KOROL[2]
[2]Biol. Dept., [1]Syracuse Univ., Syracuse, NY

Abstract: Extensive evidence across species and contexts highlights an age-associated decline in hippocampus-sensitive learning and memory with relatively little consideration of effects of aging on other memory systems. These experiments compared the effects of aging in male rats on learning and memory in distinct tasks that require participation of hippocampal or striatal memory systems. Relative to young adult (3-mo-old) Fischer-344 rats, 2-yr-old rats were impaired on a set of hippocampus-sensitive tasks, including a place maze and a double object displacement recognition task. However, old rats showed no impairment and sometimes

enhancement on striatum-sensitive tasks, including a response maze and a double object replacement recognition task. Additionally, when trained on a dual-solution task that can be solved with either place (hippocampal) or response (striatal) strategies, young rats predominantly expressed a place solution and old rats a response solution. In young rodents, these memory systems sometimes competitively interact; for example, disruption of one structure can lead to enhancement of learning on a task dependent on the other. Thus, we examined whether interference across systems contributes to learning and memory in old rats and to age-related learning impairments. Using young and old rats, we inactivated either the hippocampus or striatum with central lidocaine (2%) infusions prior to response or place training, respectively. As seen in young animals, inactivation of the striatum prior to training enhanced hippocampus-dependent place learning in old rats. Thus, learning disabilities in some cognitive domains in old rats may result in part from exaggerated interference or competition across memory systems and not strictly from deterioration of the canonical neural system. These findings suggest that interventions to down-regulate striatal processing may effectively improve hippocampus-dependent learning across the life span and highlight the utility of a multiple memory systems approach for understanding cognitive aging.

George Mason Univ., Fairfax, VA

Abstract: Alzheimer’s Disease (AD) is the most common form of dementia and the 5th leading cause of death in the United States. Antioxidant-rich diets have been shown in previous studies to reduce the toxicity of amyloid (Aβ). White button mushrooms (WBMs) are an antioxidant and are shown to mimic nerve growth factors (NGFs), which are neuroprotective and prevent cognitive decline. WBMs constitute 90% of the mushrooms eaten in the US. One of the

symptoms of AD is disrupted circadian rhythms. We are examining effect of WBMs on spatial memory, circadian rhythms, and nesting.
J20/hAPP transgenic mice and wildtype (C57BL/6J) mice from Jackson Laboratories were fed a 10% WBM feed triweekly to yield a 5% total diet of WBMs. Behavioral tests were conducted at 3.5 months and will be retested at 8 months of age. Tests include: Morris Water maze (MWM), circadian rhythm (CR), and nesting. Preliminary MWM data has shown that mice at 3.5 months on the WBM diet spent significantly more time in the target quadrant during probe trials on days 2 ($p=0.045$) and day 4 ($p=0.032$) of the test, indicating mice on WBMs have greater spatial ability. Testing at 8 months will determine whether long term consumption of WBMs has a positive effect on behavior and on amyloid levels in hAPP and wildtype mice.

Title: Increasing hippocampal neurogenesis rejuvenates learning strategies and memory throughout life

Authors: *G. BERDUGO-VEGA[1], A. LOPEZ-FERNANDEZ[1], B. ARTEGIANI[3], A. GARTHE[4], G. KEMPERMANN[1], F. CALEGARI[2]
[2]Calegari Lab., [1]Ctr. for Regenerative Therapies - TU Dresden, Dresden, Germany; [3]Hubrecht Institute, Developmental Biol. and Stem Cell Res., Utrecht, Netherlands; [4]German Ctr. for Neurodegenerative Dis. (DZNE), Dresden, Germany

Abstract: Age-related cognitive decline particularly affects hippocampal function, being contextual learning, allocentric navigation and episodic memory severely compromised in old people.
Adult hippocampal neurogenesis is a prime form of plasticity that allows the flexible contextualization of information and also decreases with age. In this work, we asked if rescuing the natural decline in neurogenesis in old age or throughout life would compensate the many effects of ageing on hippocampal function in rodents.
Thus, we further explored a method described by our group to genetically and cell-intrinsically

increase the proliferation of hippocampal neural stem cells (NSC; Artegiani et al., 2011). Acute NSC expansion in old mice (16 months old) successfully increased the number of integrated adult-born neurons in the hippocampus and rejuvenated its function by reverting the age-related switch from allocentric to egocentric navigational strategies. Furthermore, chronic expansion of NSC throughout life delayed the age-related decrease in neurogenesis and preserved contextual learning strategies and episodic memory by a change in hippocampal versus striatal neuronal activity.
In summary, our study demonstrates that critical aspects of hippocampal cognitive impairment can be reversed in old age or compensated throughout life by extrinsically exploiting endogenous brain reserves.

Title: The effects of learning and aging on functional characteristics of layer v pyramidal neurons of the lateral entorhinal cortex

Authors: *K. B. KELLY, C. LIN, M. M. OH, J. F. DISTERHOFT
Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: Increased human longevity has caused a steady rise in the prevalence of aging-related health issues, most notably age-related cognitive decline, including forms of dementia, such as Alzheimer's disease (AD). While many aged individuals experience some level of cognitive impairment (age impaired, AI), there are other individuals, 'super-agers' (age unimpaired, AU), that maintain cognitive performance similar to that of younger adults (Y). The lateral entorhinal cortex (LEC) is known to be vitally important for temporal associative learning, and is among the first areas of the brain to exhibit AD pathologies prior to the observation of behavioral deficits. One of the prominent features of layer V LEC pyramidal neurons is their ability to exhibit a graded persistent firing activity, a cholinergic dependent property that is a potential mechanism underlying associative learning and memory. Cholinergic activity is reduced in aging and AD, which could reduce cellular excitability and negatively impact persistent firing throughout the LEC. The LEC is thus a rich potential target in which to study memory and age-

related changes in cognition.
This project utilizes whole-cell patch clamp electrophysiology to evaluate age-related changes in the intrinsic excitability of layer V pyramidal neurons of the LEC. All recordings were derived from young adult (3-6 month) or aged (28-31 month) hybrid Fisher 344 x Brown Norway rats. To incorporate behavioral changes in learning and memory, I used trace eye blink conditioning (tEBC) to separate aged individuals into AU or AI cohorts.
I analyzed postburst AHP to investigate changes in intrinsic excitability. Results from recordings taken 24 hours after the final training session indicate that the slow AHP (sAHP) is reduced in young and AU rats that underwent tEBC, when compared to young pseudoconditioned and AI rats. Data indicates there is no difference between sAHP of young and AU rats. However, one month after the final training session, AU rats exhibit a sAHP similar to that seen in AI rats, indicating that the decrease in sAHP seen at the 24hr time point is transient in nature.
While it is currently unknown how cholinergic tone within deep layers of LEC is affected with age, one component of AD pathology is the degradation of cholinergic neurons and receptors. By applying the muscarinic receptor agonist carbachol I can elicit persistent firing in layer V LEC pyramidal neurons. Results indicate that persistent firing is less robust in aged tissue, potentially stemming from a loss of cholinergic tone. Combined, the observations from this study are among the first to reveal how aging and learning affect the cellular physiology of the LEC.

Title: Carbachol-induced increase in calcium transients is occluded in CA1 pyramidal neurons from aged-unimpaired rats

Authors: *M. M. OH, J. F. DISTERHOFT
Dept Physiol., Northwestern Univ. Med. Sch., Chicago, IL

Abstract: The enlarged postburst afterhyperpolarization (AHP) of CA1 pyramidal neurons is hypothesized to be a main source of the learning and memory (L&M) impairments observed in aging subjects (Disterhoft & Oh 2006). Since the AHP is comprised mainly of Ca^{2+}-dependent potassium conductances, the increased cytosolic Ca^{2+} levels ($[Ca^{2+}]$) during a train of action potentials (APs) observed in aged CA1 neurons (Oh et al. 2013) has also been hypothesized to be

a source of L&M deficits. Thus, many studies have focused on reducing the Ca^{2+} rise in aged CA1 neurons to rescue the aging-related deficits. Other pharmacological manipulations have also been proven to reduce the AHP and rescue aging-related deficits; such as increasing cholinergic levels with cholinesterase inhibitors in the brain (Disterhoft & Oh 2007). Our preliminary data strongly suggest that bath application of the cholinergic agonist, carbachol, reduces the AHP while increasing evoked [Ca^{2+}] in aged (~30%, n=16) and young (~20%, n=9) CA1 neurons from behaviorally naïve animals. However, it is unknown if learning alters the cholinergic-induced [Ca^{2+}] increase. Therefore, the present study was designed to determine if bath application of the cholinergic agonist, carbachol, causes a change in [Ca^{2+}] evoked with AP trains in young (3-4 mo) and/or aged (27-33 mo) CA1 neurons from male F344xBN rats trained on the hippocampus-dependent, trace eyeblink conditioning (TEBC) task.
Hippocampal slices were prepared 1 day after the last training session. Whole-cell current clamp and Ca^{2+}-imaging (OGB-6F and Alexa 594) data evoked with 100Hz AP trains were collected using a custom built 2-photon laser scanning microscope system before and 20 min after 10μM carbachol was added to the perfusate. Our preliminary data suggest that bath application of carbachol caused increases in evoked [Ca^{2+}] in CA1 neurons from young pseudoconditioned (~12%, n=5) and trained (~15%, n=11) rats. Bath application of carbachol increased the evoked [Ca^{2+}] by ~26% in CA1 neurons (n=3) from aged impaired rats. Surprisingly, carbachol-induced [Ca^{2+}] increase was considerably smaller in CA1 neurons from aged unimpaired (AU) rats: ~12% reduction in 4 neurons. These preliminary data suggest that cholinergic signaling pathway has been used for successful learning in the AU rats: i.e., occlusion. Alternatively, although highly unlikely, it is possible that the cholinergic signaling cascade (e.g., cholinergic receptors) is missing in CA1 neurons from the AU rats. Ongoing experiments are being conducted to address the latter possibility by conducting these experiments on CA1 neurons from hippocampal slices prepared 1 month after the last TEBC session.

Title: Entorhinal cortex cholinergic circuits in cognitive decline

Authors: *M. ANANTH[1], D. A. TALMAGE[2,3], L. W. ROLE[1,3]
[1]Program in Neurosci., [2]Pharmacol. Sci., [3]Neurobio. & Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: In the central nervous system, cholinergic neurons of the basal forebrain (BFCNs) exert tight, context specific control over cortical processes. The enormous reach of their projections makes cholinergic axonal arbors difficult to maintain and vulnerable to loss. Numerous studies since the 1970s have demonstrated that decreases in cholinergic markers accompany decline in cognitive function. As such, we asked what role the cholinergic system plays in cognitive decline. The entorhinal cortex (EC), a cortical region that receives an extensive cholinergic projection from the BFCNs has been shown to be vulnerable early on in aging. Using the entorhinal cortex as a model region of early cortical dysfunction, we investigated the relationship between altered cholinergic integrity and cortical function. To assess EC-function in cognitive decline, we used a mouse model where aging pathology (amyloid beta plaques and hyperphosphorylated tau tangles) was present at an earlier physical age (5XFAD X NOS2-/-; aging model). We found that aging model mice had impaired performance on an EC-based memory task. We postulated that this impaired performance was related to changes in engagement of the EC, and asked whether this was driven by alterations to cholinergic inputs to the EC. We found significant reductions to cholinergic terminal field density in the EC of the aging model mice as compared to control mice, and that baseline EC activity was markedly higher in aging model mice as compared to controls. We postulated that loss of cholinergic tone results in an imbalanced ratio of excitation to inhibition, leading to increased EC firing. Using viral labeling strategies, we investigated whether there were reductions in cholinergic synapse density in EC in the aging model, and whether these changes were specific to cholinergic synapses apposed to excitatory or inhibitory neurons. In addition, we asked whether augmenting endogenous ACh (using optogenetics) in the aging model mice. In parallel studies in humans, we used Positron Emission Tomography (PET) with a marker that targets cholinergic synapses to examine the relationship between altered EC cortical function (cognitive testing) and altered EC cholinergic circuits. Future experiments in both humans and rodents systematically map out changes to cholinergic circuits in health and cognitive decline and will determine whether changes to cholinergic EC circuits can be regarded as a marker of early cognitive impairment.

Title: Learning and aging affect functional characteristics of lateral entorhinal cortex layer iii pyramidal neurons

Authors: *C. LIN, K. B. KELLY, M. M. OH, J. F. DISTERHOFT
Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: Normal aging is often associated with a decline in hippocampus-dependent learning and memory, and altered intrinsic excitability of hippocampal neurons has been shown as contributing to these changes. In the CA1 region, for example, the intrinsic excitability of pyramidal neurons decreases with aging, reducing the probability that the neuron is recruited into a neural network for learning, and resulting in aging-related cognitive deficits. Previous research from our laboratory also indicates that CA1 neurons from animals, young or aged, that have acquired a hippocampal-dependent task are more excitable relative to control animals. As the entorhinal cortex is a relay station to the hippocampus, it is another important region in which to study aging and learning-related changes in excitability, to better understand the mechanisms underlying aging-related cognitive decline. The lateral entorhinal cortex (LEC) is the focus of this study, as it has been suggested to support hippocampus-dependent associative learning and is also an initial site of manifestation for Alzheimer's disease. In particular, pyramidal neurons from layer III, which project directly to the CA1 region via the temporoammonic pathway, are being examined in this study. Current clamp recordings were made from neurons of young adult (3-6-month-old) and aged (29-32-month-old) F1 F344xBN hybrid rats. Our data indicate that neurons from aging animals accommodate more than neurons from the young population, meaning they fire fewer action potentials to depolarizing input. The reduced excitability may contribute to the aging neurons' decreased ability to demonstrate persistent firing after the termination of a depolarizing stimulus, an EC phenomenon that has been suggested to underlie associative learning. Not only are neurons from the aging population less likely to persistently fire, but they are also less able to maintain the frequency of their firing. Current clamp recordings taken 24 hours after trace eyeblink conditioning, a hippocampus-dependent temporal associative task, indicate that there do not seem to be learning-related intrinsic excitability changes in either the young or aged population. There do, however, seem to be synaptic excitability changes, as neurons from animals that have learned the trace eyeblink task are able to fire more synaptically-evoked action potentials relative to neurons from control animals. In addition, synaptic stimulation that evokes one single spike in control or behaviorally naïve animals can elicit burst firing in neurons from trained animals, which may be an indicator of changes in persistent firing activity following learning.

Title: Dopamine dependent nicotine effects on cognitive control in non-smokers

Authors: *S. AHRENS[1], J. LAUX[1], C. MUELLER[1], C. M. THIEL[1,2]
[1]Univ. of Oldenburg, Oldenburg, Germany; [2]Cluster of Excellence "Hearing4all", Oldenburg, Germany

Abstract: Cognitive control compromises the functions cognitive stability and flexibility, which have often been tested by assessing distractor suppression and task switching respectively. Cognitive stability and flexibility are related to prefrontal cortex (PFC) and basal ganglia (BG) dopaminergic activity. While increased dopamine levels in PFC promote cognitive stability, enhanced dopamine in the BG support flexibility[1]. In addition, there is evidence for the cholinergic agonist nicotine to modulate distractor processing and flexible reorienting. However, nicotine effects show interindividual variability and baseline dependency presumably related to the dopaminergic system[2,3].
We addressed the question, whether the effects of nicotine on cognitive control depend on baseline dopamine levels. 29 young, healthy non-smokers (20 female / 9 male, age: 18-35) were tested twice on a cognitive control task with distractor and switch trials[4]. To manipulate dopamine levels, we administered 2 g L-Tyrosine or placebo in a between subject design 2 hours prior to task. 1 hour later, both groups received in a within subject design on one day a 7 mg nicotine patch and on another day an inactive placebo. Response time costs for distractor and switch trials were entered to a repeated measures ANOVA with between-subject factor dopamine level (placebo/L-Tyrosine) and the within-subject factors nicotine (placebo/nicotine) and cost (distractor/switch).
Switch-costs were higher than distractor-costs (main effect cost $p<0.05$). Subjects with L-Tyrosine had significantly higher costs than subjects with placebo (main effect dopamine level $p<0.05$), mainly driven by a stronger increase in switch-costs as compared to distractor-costs (trend for an interaction dopamine level*cost $p<0.1$). Nicotine reduced switch-costs but increased distractor-costs (interaction nicotine*cost $p<0.05$). Separate analyses in both groups (Placebo / L-Tyrosine), revealed stronger nicotine effects under L-Tyrosine, i.e. with higher baseline dopamine levels. The interaction of nicotine with costs was solely significant in those subjects ($p<0.05$).
Our data suggest that increased dopamine availability in young healthy subjects increases the

costs of task switching, hence reducing flexibility. Subjects with higher dopamine levels are further more prone to the behavioural effects of nicotine showing improvements in task switching, however at the costs of increased distractor interference.

Title: Neurophysiological indices of cannabis and impairment

Authors: *S. J. SMITH[1], B. STONE[1], A. MEGHDADI[1], A. SPURGIN[2], T. BROWN[2], C. BERKA[1]
[1]Res., Advanced Brain Monitoring, Carlsbad, CA; [2]Univ. of Iowa, Iowa City, IA

Abstract: Cannabis and its chemical constituent that is responsible for the majority of its psychoactive effects, Tetrahydrocannabinol (THC), is the most commonly used illicit substance in the United States. With state laws and regulations undergoing changes in terms of the legality of sales, distribution, and use of THC products, the prevalence of cannabis use and abuse is projected to increase. However, quantitative assessments of performance alterations, as well as, the underlying neurological mechanisms of cannabis intoxication have not undergone the same level of systematic investigation as other substances, such as alcohol. The objective of this study was to provide quantitative assessments to supplement subjective measures related to cannabis through the use of neurophysiology in conjunction with cognitive tasks. Participants were recruited through a database registry and through distributed flyers at smoke shops (selling legal drug paraphernalia) in the counties of Johnson and Lynn within the state of Iowa. The final dataset (n = 21) was comprised of 20.2% females with 92.36% of the participants identifying as Caucasian. This dataset had a mean age 24.5 yr (range: 18-42 yr). We assessed the psychoneurophysiological differences of drugged versus placebo subjects using a double-blind study design with four neurocognitive tasks: 3-Choice Vigilance Task (3CVT), Auditory Psycho-Vigilance Task (APVT), Visual Psycho-Vigilance Task (VPVT), and a Standard Image

Recognition task (SIR). Repeated measures ANOVAs revealed an increase in Heart Rate during the 3CVT and SIR tasks while under the influence of cannabis: $F(1,37) = 6.49$, $p < 0.05$, and $F(1,38) = 4.60$, $p < 0.05$, respectively; an increase in Central EEG alpha(8-10Hz) hemispheric asymmetries during the 3CVT:$F(1,37) = 3.56$, $p < 0.05$, an increase in Central EEG beta(13-30Hz) hemispheric asymmetries($F(1,39) = 5.77$, $p < 0.05$) and bilateral differences in alpha(8-10Hz; $F(1,39) = 4.53$, $p < 0.05$), and a decrease in Central EEG delta (1-3Hz) hemispheric asymmetries ($F(1,39) = 3.93$, $p < 0.05$)during the APVT due to cannabis. We observed a decrease in variability in correct response to the interference stimuli ($F(1,37) = 3.97$,$p < 0.05$) during the 3CVT, but an increase inaccuracy during the SIR ($F(1,38) = 3.97$, $p < 0.05$) while under the influence of cannabis. No significant differences were found within the VPVT. These results show promise for providing easily applied objective methods to assess quantitative indices of impairment resulting from marijuana use and offering further insight on behavior and physiological responses to determine an individual's impairment resulting from cannabis consumption.

Title: Attention and memory are predictors of worse performance on cognitive tasks in caffeine addiction

Authors: *C. R. SANTANA, P. E. MARINHO, N. L. ALMEIDA, T. M. P. FERNANDES, N. A. SANTOS
Univ. Federal da Paraíba, João Pessoa, Brazil

Abstract: Although caffeine increases alertness, wakefulness and prevent memory losses, the complete benefits of caffeine on cognitive functions remain unclear. There is evidence that caffeine effects are dose-related. The effects of caffeine addiction are under investigation; however, addictive use of caffeine can be classified as the use of more than 400 mg/day. Based on the known mechanisms of action, the main purpose of this research was to investigate the relationship between caffeine addiction, caffeine abstinence and cognitive functions such as

working memory, sustained and divided attention and cognitive flexibility. In the present study, 12 controls (CG), 12 caffeine- addicted (CAG) users, and 12 abstinence caffeine-addicted (ACG) users were recruited from the Federal University of Paraiba, Brazil. All caffeine users were classified by means of DSM-5 criteria for dependence. Participants who used caffeine were randomized into the groups. An abstinence period of six hours was used as a criterion for abstinence. Craving and anxiety levels were measured before and after the experiments. On the first study, cognitive functions were investigated using the Trail-Making Test (A and B), Stroop and Flanker Task. On the second study, we investigated if these tests would be predictive of a facial detection task. The results indicated that the participants of ACG had a worse performance than CG and CAG on all cognitive tasks. There were no significant differences between CG and CAG. It was also verified that cognitive measurements were predictors for facial detection. Our findings highlight the need to evaluate cognitive functioning in high caffeine users (with and without abstinence). The results here targeted contribute to psychological and neuroscience research.

Title: Impulsivity and self-perceived emotional feedback predict alcohol-related problems

Authors: I. COMNICK, *W. M. MEIL, M. BERMAN, E. MORGAN, R. FRAZIER, W. FARRELL, J. MILLS
Psychology, Indiana Univ. of Pennsylvania Dept. of Psychology, Indiana, PA

Abstract: Previous research has implicated the prefrontal cortex and associated executive functions in the development alcohol use and alcoholism. However, executive functions represent a diverse set of abilities that may differentially predict alcohol use and alcohol-related problems. This study examined the relationship between self-report and performance-based measures of executive function (impulsivity and emotion perception) and varying degrees of alcohol use and alcohol- related problems among 326 undergraduate college students. After controlling for participant sex, age, ethnicity, and frequency of nicotine and marijuana use, a hierarchical multiple regression was used to assess the effect of impulsivity as measured by The Urgency, Premeditation (lack of), Perseverance (lack of), Sensation Seeking, Positive Urgency

Impulsive Behavior Scale (UPPS-P) and emotion recognition of self (Facial Manipulation Expressions Task) and others (The Adult Eyes Test and The Reading the Mind in Films Task). Frequency of participants alcohol use was assessed as was the amount of alcohol consumed and time spent drinking using the Daily Drinking Questionnaire (DDQ). The Alcohol Use Disorders Identification Test (AUDIT) and The Rutgers Alcohol Problem Index (RAPI) were used to measure harmful drinking behavior. Impulsivity and emotion perception failed to predict drinking frequency and the number of drinks consumed in a typical week. However, impulsivity (UPPS-P subscales for Lack of Premeditation and Positive Urgency) predicted the number of hours spent drinking in a typical week and hazardous drinking on the AUDIT. Emotion Self-Perception was also a significant predictor on these drinking measures, though it did not add to the predictability of problematic drinking beyond impulsivity measures. The Positive Urgency subscale of the UPPS-P also predicted alcohol-related problems on the RAPI. These results are noteworthy as they illustrate specific domains of impulsivity differentially predict alcohol consumption and more problematic use and suggest self-perception of emotions via manipulation of facial expressions is also predictive of alcohol-related problems.

Title: Behavioral and neural correlates of response inhibition and error processing in binge drinkers: An fMRi study during the go/nogo task

Authors: *A. B. ALDERSONMYERS[1], S. M. MOLNAR[3], L. A. HOLCOMB[2], K. MARINKOVIC[1]
[2]Psychology, [1]San Diego State Univ., San Diego, CA; [3]Psychology, SDSU, San Diego, CA

Abstract: Inhibiting behaviors considered unsuitable for achieving goal-oriented outcomes and the ability to flexibly adapt following errors is an integral feature of executive functioning. Impaired response inhibition is associated with increased risk of problem drinking and has been considered an important dimension in the development of alcohol dependence. This is particularly relevant to binge drinking (BD), a mode of alcohol consumption especially common amongst college age youth and a public health concern of increasing importance. Neuroimaging studies in young binge drinkers have reported inconsistent results with some observing increased

and others decreased activation in prefrontal and parietal cortical areas during response inhibition tasks mainly in the absence of behavioral impairments.
The present study used functional magnetic resonance imaging (fMRI) to examine response inhibition in young adults performing an event-related Go/NoGo inhibitory task that induced a prepotency to respond. Participants assigned to the BD group reported consuming 5+/6+ drinks (females/males) within two hours five or more times within the previous six months. Light drinking (LD) individuals formed the comparison group, reporting two or fewer binge episodes in the past six months. These groups were otherwise matched for age, gender, IQ, race/ethnicity, and family history of alcoholism. Voxel-wise and region-of-interest analyses were carried out with AFNI (Analysis of Functional Neuroimages) on correct response inhibition (NoGo) trials and on those inducing commission errors. No significant group differences were found regarding task accuracy and reaction times. However, in comparison to light drinkers, BDs exhibited increased activity in the anterior cingulate, bilateral inferior prefrontal, and posterior cortices during correctly inhibited trials. This finding is consistent with studies in AUD cohorts suggesting compensatory recruitment of extended neural resources to maintain accurate task performance. Conversely, BDs had lower activation to errors in the anterior cingulate, rostral frontal, and temporo-occipital cortices implying deficient cognitive control ability to carry out post-error adjustments. Regional activity to correct rejections and commission errors correlated with various self-reported measures of alcohol intake, impulsivity, and risk-seeking behaviors. This study provides further evidence that binge drinking is associated with a deterioration of cognitive control that may precede the development of alcohol use disorders.

Title: Reward and top-down control network alterations in binge drinkers

Authors: *D. ARIENZO[1], S. MOLNAR[1], L. BEATON[1], J. HAPPER[1], K. MARINKOVIC[2]
[1]Psycology, [2]Psycology, Radiology, SDSU, San Diego, CA

Abstract: Effective cognitive processing requires efficient communication within and among different neurofunctional systems in the brain. Resting State Functional Connectivity (RSFC) analysis measures connections between brain regions based on temporal correlations of the

spontaneous fluctuations of the blood-oxygen-level-depend (BOLD) signal during wakeful rest. Studies of alcohol use disorders (AUD) have shown altered connectivity patterns especially in the reward-motivational and top-down control networks. Even though binge drinking has been on the rise among young adults and is a public health issue of increasing importance, there is a paucity of studies investigating neural changes associated with heavy episodic drinking. This study examined the functional connectivity as a function of binge drinking. Given extant evidence in AUD, we focused particularly on the reward-motivational and inhibitory control networks. fMRI BOLD images were acquired with a 3T scanner (GE) and analyzed with the CONN-fMRI Functional Connectivity toolbox. Young, healthy adult participants who reported consuming 5+/6+ drinks in two hours five or more times in the past six months were assigned to a binge drinking (BD) group. They were compared to light drinkers (LD) who reported two or fewer binge episodes but were matched on demographics, family history of alcoholism, and IQ. Seed-to-voxel connectivity maps were created using as seeds the brain regions that have been implicated in the reward function and top-down regulation in studies on AUD. False Discovery Rate at ≤ 0.05 was applied to correct for multiple comparisons. BD showed increased connectivity between the striatum (dorsal: caudate nucleus; ventral: nucleus accumbens) and the orbitofrontal cortex (OFC) which was positively correlated with binge episodes and the Alcohol Use Disorder Identification Test (AUDIT) scores. Conversely, BD showed decreased connectivity between the right inferior frontal cortex and the inferior temporal cortex which was negatively correlated with binge episodes, AUDIT scores, and harmful drinking consequences. These results suggest enhanced salience of alcohol-related reward mediated by ventral striatum and increased tendencies toward habitual and compulsive behavior mediated by dorsal striatum. This is accompanied by weakened top-down control associated with alcohol intake. In sum, these findings confirm that the initiation of alcohol addiction may depend on a combination of dysregulated reward circuitry and deficient top-down influence. Support:AA016624

Abstract: With deaths from opioid-related overdoses continuing to surge, the need for a deeper understanding of the neurobiological mechanisms behind the risky decision-making that can lead to overdose has never been more pressing. Recent work has begun to elucidate how individual differences in brain anatomy constrain individual preferences, particularly decision making in the face of known risk. While differences between substance users and healthy controls in brain structure, and separately risk-taking, have long been observed, it is not known whether the same anatomical correlates as those identified in health subserve risk taking behavior in addiction. We collected structural MRI scans in 17 individuals with opioid use disorder (OUD) (age = 39, 15 males) and 20 matched community controls (age = 42, 16 males). All participants also completed a decision making task for real monetary incentives that could be received with different known probability levels. We applied voxel-based morphometry to quantify regional grey matter volume (GMV) and standard economic models to quantify risk tolerance. Preliminary analyses focused on the relationship between opioid use and GMV in the brain's valuation system, the amygdala and the right posterior parietal cortex (rPPC). We further examined the relationship between GMV in these regions and risk tolerance in OUD. All analyses controlled for age, sex and total grey and white matter volume. OUD chronicity (years of opioid use, average = 11, range: 2 - 28) was associated with increased GMV in the ventral (vSTR) and dorsal striatum, ventromedial prefrontal cortex and amygdala (all $p < 0.04$). Of these, only increased GMV in the vSTR differed between patients and controls and increased GMV in this same region also correlated with greater risk tolerance. While we found no significant relationship between opioid use (chronicity or diagnosis of OUD) and GMV in the rPPC, higher GMV in the rPPC for controls correlated with greater risk tolerance - a finding we have previously reported. Interestingly, we found an interaction ($p < 0.003$) between rPPC GMV and recent heroin use in patients, such that, for patients who used more recently, greater rPPC GMV actually indicated lower risk tolerance. GMV in the vSTR and rPPC was uncorrelated, suggesting at least partially independent contributions. Our preliminary findings highlight the role of brain anatomy in both subcortical and cortical GMV in OUD, specifically, as related to chronic opioid use (vSTR) and risk tolerance (vSTR and rPPC). Implications of these findings suggest multiple neural mechanisms and, as such, therapies targeting both cortical and subcortical regions may be more effective.

Title: Relationship between cognition and nicotine dependence in smokers with mental illness

Authors: *C. BIANCO[1], S. I. PRATT[2], M. F. BRUNETTE[2], J. C. FERRON[2]
[1]Dept. of Psychiatry Res., Dartmouth-Hitchcock, Concord, NH; [2]Geisel Sch. of Med. at Dartmouth, Lebanon, NH

Abstract: Introduction Rates of cigarette smoking are significantly higher among people with a mental illness compared to the general population. This is particularly true for schizophrenia, with lifetime smoking rates up to 81%. The self-medication hypothesis posits that people with schizophrenia smoke to ameliorate negative symptoms and cognitive deficits. The high concentration of nicotinic acetylcholine receptors in the prefrontal cortex, an area essential for cognitive functioning, makes this hypothesis plausible. Furthermore, subjective perception of cognitive benefit may lead to more smoking even in the absence of a biological explanation. Approximately 90% of individuals with schizophrenia have impairments in cognitive functioning. Cognitive deficits are also prevalent in individuals with bipolar disorder, major depressive disorder, and PTSD. In a secondary analysis of baseline data from a large cessation study, we explored the relationships among cognitive functioning, perception of cognitive benefits from smoking, and severity of nicotine dependency. **Methods** Daily smoking Medicaid beneficiaries (n = 661) were assessed at baseline with a structured interview for smoking characteristics and attitudes, record review for diagnosis (schizophrenia spectrum (n = 148), bipolar (n = 150), major depression (n = 158), and other disorders (n = 205), and cognitive battery for cognition. A cognitive composite score was computed based on selected subscales from the Delis-Kaplan Executive Function System (Trails Conditions 2 and 4, Color-Word Interference Condition 4, FAS). Participants' level of agreement with the statement, "After a cigarette, I am able to concentrate better," served as the measure of perception of cognitive benefit from smoking. Linear regressions were conducted to examine whether baseline cognition and perceptions of cognitive benefit predicted baseline level of nicotine dependence accounting for diagnosis, level of education, IQ equivalency (using the WRAT-3 Reading score), and approximate time since last cigarette smoked. **Results** The final model including all variables, accounted for 8.8% of the total variance in nicotine dependence (F (8, 627) = 7.48, p <.001). Cognitive functioning (β = -.13, p = .002) and perceived cognitive benefits from smoking (β = .08, p = .033) significantly predicted level of nicotine dependence. **Conclusions** Greater cognitive impairment and higher levels of perceived cognitive benefits from smoking were associated with greater nicotine dependence among smokers with mental illness. Augmenting smoking cessation treatment with cognitive training tasks may prove beneficial for these individuals.

Title: Disadvantageous decision-making in methamphetamine users: Loss aversion and dopamine D2/D3 receptor availability

Authors: *Z. R. GUTTMAN[1], D. G. GHAHREMANI[2], C. L. ROBERTSON[3], K. OKITA[4], K. ISHIBASHI[5], M. A. MANDELKERN[6], E. D. LONDON[2]

Ctr., Tokyo Metropolitan Inst. of Gerontology, Tokyo, Japan; [6]Dept. of Research, VA Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Most people tend to display an aversion to loss. This phenomenon has been demonstrated using economic choice tasks in which choices are made involving potential losses and gains. Theories of decision-making assume that individuals compute the value of each option by transforming components of the choice (e.g., magnitude and probability of potential gain or loss) into subjectively equivalent quantities that can then be integrated and compared. When an option involves a cost, such as the potential to lose money, the value of the reward is discounted as a function of the loss. The degree to which loss contributes to the discounting of subjective value shows individual variation, which can be measured by modeling individual choice parameters that can then be related to markers of neural function. The context of reward-based choices that present potential losses is particularly relevant to individuals with addictive disorders, for whom maladaptive decision-making contributes to the vulnerability to and persistence of their disorders. Despite behavioral and neural studies of loss sensitivity in addictions, analysis of individual choice parameters to distinguish the nature of differences between healthy and more biased decision-making has not been assessed in individuals with substance use disorder. Moreover, loss aversion is modulated by brain regions associated with

dopamine function, which is dysregulated in addiction, yet the relationship between measures of dopamine function and loss aversion has not been directly assessed. Therefore, we aimed to determine whether dopamine function is related to individual differences in loss aversion. Individuals with Methamphetamine Use Disorder (MUD; n=19) and healthy controls (n=24), matched for age and sex, completed a standardized Loss Aversion Task where they were shown gambles offering a 50% chance of winning or losing different amounts of money, or the option to opt out and accept $5 for sure (e.g., 50% chance of winning $10, 50% chance of losing $8; accept $5 for sure). Participants also underwent positron emission tomography (PET) with [^{18}F]fallypride to assess dopamine D2/D3 receptor ($DRD_{2/3}$) binding potential (BPND). MUD participants were significantly more loss averse than healthy controls ($p=0.01$), in contrast to the prevailing view that loss aversion is lower in individuals with addictions. Loss aversion was also negatively correlated with $DRD_{2/3}$ BPND in the nucleus accumbens of healthy controls ($p<0.05$), but not in MUD participants, suggesting a role for dopamine function in sensitivity to loss that may be dysregulated in MUD.

Title: Inhibitory control deficits in patients with essential tremor

Authors: N. VAN WOUWE, S. HUGHES[1], D. CLAASSEN[2], F. PHIBBS[2], E. BRADLEY[1], S. WYLIE[3]
[1]Neurol., [2]Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Neurosurg., Univ. of Louisville Med. Ctr., Louisville, KY

Abstract: Objective: Essential Tremor (ET) is a movement disorder characterized by action tremor which impacts motor execution. Disruptions incerebellar-thalamo-cortical networks in ET could also interfere with cognitive control mechanisms involved in regulating motor performance, for example the ability to inhibit or stop actions . The current study investigated the speed of action initiation and two forms of action control, response stopping and proactive slowing in ET. **Method:** Thirty-three ET patients and 25 healthy controls (HCs) performed a simple choice reaction task and a stop signal task to assess going speed, proactive slowing and stop latencies. **Results:** Going speed was significantly slower in ET patients (649 ms) compared

to HCs (526 ms, $F(1, 56) = 42.37$, $p<.001$), but proactive slowing did not differ between groups. Stop signal reaction times were significantly slower in ET patients (320 ms) compared to HCs (258 ms, $F (1, 56)=15.3$, $p<.001$). Additionally, more severe motor symptoms of ET were associated with longer stopping latencies (*Spearman rho* = .48, $p<.05$). **Conclusions:** ET patients showed slower action initiation, similar to previous studies measuring reaction times. However, inhibitory control was impaired whereas proactive slowing remained intact in comparison to HCs. The more severe ET motor symptoms were associated with slower stopping speed which may reflect more progressive changes to the cerebellar-thalamo-cortical network. Imaging studies investigating structural and functional changes in ET could help explain changes in inhibitory action control.

Title: Impact of acute stress on decision-making

Authors: *C. RAMDANI
Inst. De Recherche Biomédicale Des Armées, france, France

Abstract: Prefrontal cortex seems to be particularly sensitive to stress which could generate an impairment of its functions including decision-making. To test this assumption and to evaluate the impact of an acute stress on decision-making, we submitted healthy subjects to an acute stress while they performed a response selection task that may be considered as the simplest form of decision-making
To induce an acute stress, we used a fear conditioned protocol Indeed, fear is a stressful emotional state. Fear conditioned was obtained by associating a sound (CS+ positive conditioned stimulus) to an unpleasant electric stimulation on the left leg whereas another sound (CS- negative conditioned stimulus) was not associate to any stimulations. After a certain time, CS+ was enough to generate a stress without any unpleasant stimulation.
Decision-making was explored thank to a choice reaction time task with spatial conflict. Stimulus were digits which were presented on the right or the left side of a fixation cross and we asked subjects to associate the parity of digits to a side of response. The position of the stimulus on the screen aimed to interfere with the stimulus-response association required. When the

stimulus was presented on the same side as the required response, the trial was congruent. When the stimulus was presented on the opposite side of the required response, the trial was incongruent. During the task, a sound (CS+ or CS-) was presented before each visual stimulus. Trials following CS+ represented the stress condition instead trials following CS- represented the control condition. The impact of stress on decision-making was evaluated with an electrophysiological marker : the N-40. It is a fronto-central event related potential which is a physiological index of response selection processes.
A expected, N-40 slopes were sensitive to congruity effect on control condition (CS-), slope was steeper on incongruent condition than on congruent condition. On the other hand, on stress condition (CS+), the congruity effect on N-40 slopes was not found. The difference between slopes on congruent and incongruent conditions has been interpreted in term of demand of the choice. Indeed, on incongruent condition, choice is more demanding than on congruent condition. It seems that on stress condition, the facilitation on congruent choices and the dysfacilitation on incongruent choices are modified.
This study shows that an acute stress affects selection processes as revealed by the different sensitivity of the N-40 to congruity effect on control and on stress condition.

Title: Structural imaging findings in individuals with PTEN Hamartoma tumor syndrome (PHTS) and cognitive dysfunction

Authors: *R. M. BUSCH, L. MOURANY, L. FERGUSON, S. DURGERIAN, K. A. KOENIG, M. J. LOWE, S. S. JONES, S. M. RAO, K. KRISHNAN, C. ENG

Abstract: *PTEN* Hamartoma Tumor Syndrome (PHTS) is the umbrella term for disorders associated with mutations in phosphatase and tensin homolog (*PTEN*), a major tumor suppressor gene located on chromosome band 10q23.3 with a documented role in heritable and sporadic malignancies. PHTS often presents with macrocephaly and cognitive dysfunction primarily involving frontal lobe systems (Busch, 2013). The objective of this pilot study was to determine if there are associated structural brain anomalies using MRI (Siemens Prisma 3T). Neuropsychological testing and structural MRI characteristics (i.e., cortical/subcortical volumes

and cortical thickness obtained with FreeSurfer 6.0) were compared between a subsample of patients with PHTS (n=4) and demographically matched healthy controls (HC; n=4). Given small sample size, Cohen's d was used to measure effect size (d≥0.80 represents large effect), and no correction was made for multiple comparisons. Individuals with PHTS demonstrated poorer performance on measures of executive functioning, learning, and fine manual dexterity (Cohen's d range 0.86 to 3.33). PHTS patients had significantly larger intracranial volumes than HC (1942 vs. 1351 cm^3, Cohen's d=2.32), consistent with the macrocephaly often associated with this disorder. After normalization for intracranial volume, volumetric differences in the hippocampus, putamen, and cerebellar cortex remained (d range 1.84 to 3.18). Cortical thickness was *higher* in PHTS compared to HC overall as well as for many brain regions. In contrast, PHTS patients showed *reduced* cortical thickness in regions of the right frontal lobe (d=0.97 to 1.34) as well as bilateral anterior cingulate (d=0.84 to 1.25) and parahippocampal (d=1.42 to 3.21) regions. These pilot data are the first to demonstrate structural brain changes in adults with PHTS as compared to HC in brain regions that are consistent with the cognitive deficits observed on neuropsychological testing. Connectivity and functional imaging studies are currently underway to provide further insight into the neuroanatomical abnormalities that may underlie cognitive dysfunction in PHTS.

Title: Test anxiety: A situation-specific trait

Authors: *W. ZHANG, Q. HUANG[1], R. ZHOU, SR[2,3]
[1]Sch. of Biol. Sci. and Med. Engin., Southeast Univ., Nanjing, China; [2]Dept. of Psychology, Nanjing Univ., Nanjing, China; [3]Ctr. for Exptl. Social and Behavioral Res. of Jiangsu Province (Nanjing University), Nanjing, China

Abstract: Introduction
Test anxiety is a situation-specific trait, high test-anxious (HTA) individuals experience more anxiety and react negatively to the examinations and tests (Keogh & French,2001). Previous studies found that HTA individuals are more susceptible to distraction and fail to inhibit attention to distraction (Alting& Markham, 1993; Mogg at el., 2008). However, it is still not clear that: (a) whether test anxiety is a stable trait or will change according to the test situation, and (b) the specificity of test anxiety. In this study we try to examine these two characteristics of test anxiety.
Method
According to the degree of test anxiety (by Test Anxiety Scale score; Sarason, 1978) and situations (be allocated in stress-free or test stress condition randomly) participants (agd from 18-26 years; all right handed) were divided into four groups: HTA stress-free (n=23; 11 males), HTA test stress (n=23; 10 males), LTA stress-free (n=20; 8 males), LTA test stress (n=22; 10 males) groups. Emotional-Stroop task (ES) was employed with ERP technology to observe the specificity of test anxiety by comparing the emotional interference of test-related threat and of general threat.
Results
In stress-free condition, HTA individuals show emotional interference both of test-related threat (on N2, P3 ERP components) and general threat (on P1, N1, N2, P3, LPP ERP components), and the emotional interference of general threat is stronger than of test-related threat (on N1, N2, LPP ERP components). While in test stress condition, HTA individuals just show emotional interference of test-related threat (on P1, N1, N2, P3, LPP ERP components), and show greater than in stress-free condition (on P1, N1, N2, LPP (450-600ms) ERP components).
Conclusion
The results show that HTA individuals have both of these two characteristics: trait and state-specificity. Specifically, in the stress-free condition, HTA individuals have problems of ability of attentional inhibition (both for test-related threat and general threat), which shows the anxious trait in HTA individuals. While in the test stress condition, this kind of problems just exists for test-related threat and be enhanced especially on perceptual stages of cognition and emotion, which shows the situation specificity of test anxiety in HTA individuals. Additionally, P3 may be a specific indicator of test anxiety because whether HTA felt test stress or not, the emotional interference of test-related threat words on P3 component exists persistently.

Title: Neural underpinnings of prolonged exposure (PE) treatment effect on inhibitory control in post-traumatic stress disorder (PTSD)

Authors: *K. M. HARLE[1,2], A. D. SPADONI[3], S. NORMAN[3], A. SIMMONS[4]
[1]VA San Diego Healthcare Syst., San Diego, CA; [2]UCSD Psychiatry, San Diego, CA; [3]UCSD, San Diego, CA; [4]UCSD, La Jolla, CA

Abstract: Prolonged Exposure (PE), a type of cognitive behavioral therapy, has been identified as a promising behavioral treatment for Post-traumatic Stress Disorder (PTSD). However the mechanisms by which this empirically based treatment helps to alleviate PTSD symptoms remain poorly understood. One hypothesis is inhibitory learning, that is PE may help individuals strengthen inhibitory control function. The purpose of this study was to isolate neuro-cognitive markers of change in inhibitory control associated with PE.
A total of 20 trauma-exposed Veterans diagnosed with PTSD were recruited and completed a course of PE treatment (each participant completed a range of 6 to 12 PE one-hour sessions). They completed a stop-signal task (SST), a standard inhibitory control task, while undergoing functional magnetic resonance imaging (fMRI) at two time points, i.e., both prior to starting treatment and post-treatment (immediately after completing treatment).
Preliminary analyses identified one area in the right lateral prefrontal cortex/supplemental motor area (SMA; Brodmann Area 6) in which activation on stop success trials with a longer stop signal delay (i.e., more difficult to inhibit) increased from baseline to post-treatment ($p<.001$; Cohen $d=1.65$). This result is consistent with the notion that PE treatment may help strengthen neural responses supporting successful inhibitory function among individuals with PTSD.

Title: Response inhibition in advanced Parkinson's disease patients on and off dopaminergic medication

Authors: *D. P. FLODEN[1], H.-J. PARK[1], J. BIARS[2], A. G. MACHADO[1]
[1]Ctr. for Neurolog. Restoration, [2]Dept. of Psychology & Psychiatry, Cleveland Clin., Cleveland, OH

Abstract: Response inhibition in advanced Parkinson's disease patients on and off dopaminergic medication.
Executive function deficits are common in Parkinson’s disease. However, dopaminergic medications can improve performance on some executive function tasks. The goal of this study was to examine whether dopaminergic medication would improve choice reaction time and response inhibition. We recruited 30 patients with moderate to severe Parkinson’s disease to complete a choice reaction time test and the stop signal paradigm both on and off their regular Parkinson’s medications as part of a larger experiment. Performance on the choice reaction time test was significantly slower while off medication ($t=2.3$, $p < .05$), whereas there was no difference in reaction times under conditions of uncertainty in the stop signal task ($t < 1$). Incorrect responses to the stop signal were significantly faster than average “go” signal responses ($t = 2.4$, $p < .05$), consistent with the independent race model of stop signal performance. Nonetheless, estimated stop signal reaction time did not differ between medications states ($t < 1$). This finding stands in contrast to evidence that Parkinson’s patients at earlier stages of the disease do demonstrate faster response inhibition while on medication. Together with other demonstrations of performance changes with high frequency stimulation in advanced Parkinson’s patients, this work may help to inform the pathophysiology of response inhibition deficits in this population.

Title: A time study of prefrontal activation during executive tasks in people with Parkinson's disease: A NIRS study

Authors: *J. K. LANGE KOCH, A. SMILEY-OYEN
Kinesiology, Iowa State Univ., Ames, IA

Abstract: We examined change in activation of the dorsolateral prefrontal cortex (DLPFC) during a working memory task using near-infrared spectroscopy (NIRS) to determine how people with Parkinson’s disease (PD) modulate prefrontal brain activation over time and the effect it has on accuracy and reaction time. We tested off and on medication while performing the N-back task, predicting greater accuracy, longer reaction times and less activation in the off-medication state. Greater activation was predicted in the more difficult conditions and to be right lateralized across n-back conditions. Time studies have not been previously reported, but theories of automatization suggest we can expect activation changes over time due to increasing

familiarity with non-executive aspects of the task (Milham et al., 2005). The right DLPFC is expected to maintain activation while the left decreases throughout task duration. **Methods.** Changes in concentration in the DLPFC were assessed while 23 PDs completed the 0-, 1- and 2-back working memory tasks. Zero-back was performed only once, but 1-back and 2-back were performed twice in both off and on-medication states in randomized order collecting 120 seconds of 0-back NIRS data and 240 seconds of 1- and 2-back NIRS data. Accuracy and reaction time were averaged for off and on medication states. Time was blocked into 10-second averages. Time blocks 1,3,5,7, and 9 were then analyzed in a repeated measures ANOVA to assess differences associated with medication status. **Results.** Accuracy was greater when off medication, but reaction time was faster when on medications across conditions. There was less change in oxygenation when PDs were on medication across conditions. Change in activation increased from 0-back to 1-back to 2-back and was lateralized to the right in both medication states. Interactions showed the right increasing and the left decreasing over time, with change increasing from 0-back to 1-back to 2-back in both medication states. **Discussion.** This is the first study to examine activation changes over time in DLPFC during a working memory task in people with PD. Overall, activation was lower while on medication and PDs demonstrated the ability to modulate activation over time across conditions regardless of medication status, suggesting that despite less dopaminergic activation in the striatum, a stable pattern of activation is exhibited. Condition-related differences in activation appear to be the result of the cognitive effort necessary to perform executive tasks that require inhibition or working memory.

Title: Functional reorganization of the inhibition network precedes cognitive impairment in Parkinson's disease

Authors: *D. L. HARRINGTON[1,4], Q. SHEN[5], R. J. THEILMANN[4], G. N. CASTILLO[4], I. LITVAN[6], J. V. FILOTEO[2], M. HUANG[7], R. R. LEE[4], C. S. TAKAHASHI[3]
[1]Res. Service (151), [2]Psychiatry, [3]Res., VA San Diego Healthcare Syst., San Diego, CA; [4]Radiology, [5]Neurosciences, Univ. of California San Diego, San Diego, CA; [6]UC San Diego, La Jolla, CA; [7]Radiology, UCSD, San Diego, CA

Abstract: Introduction: Deficient inhibitory control in Parkinson's disease (PD) is often observed in situations requiring inhibition of impulsive or prepotent behaviors. Although activation of a right-hemisphere frontal-basal ganglia response inhibition network is partly altered in PD, disturbances in interactions of these regions are poorly understood, especially in patients without cognitive impairment. Methods: The present study investigated context-dependent functional connectivity of the response inhibition network in cognitively unimpaired PD patients and controls while performing a stop single task during fMRI. Patients were tested off antiparkinsonian medication. To determine if functional disturbances depended on underlying brain structure, aberrant connectivity was correlated with brain volume and tissue diffusivity. Results: No group differences were found in response inhibition proficiency. Yet the PD group showed functional reorganization in the long-range connectivity of inhibition network regions, despite preserved within-network connectivity. Successful inhibition in PD differed from the control group by strengthened connectivity of the right dorsolateral prefrontal cortex, pre-supplementary motor area and right inferior frontal gyrus with the ventral and dorsal attention networks, the default mode network, and the substantia nigra. In contrast, successful inhibition in healthy controls was distinguished by strengthened long-range connectivity of the right rostral inferior frontal gyrus and subcortical inhibition network nodes (right caudate, substantia nigra, and subthalamic nucleus). In both groups, the strength of regional connectivity correlated with inhibition proficiency, but only for regions that distinguished successful inhibition in the control group. The absence of a relationship between inhibition proficiency and abnormal connectivity in PD may suggest that functional reorganization helps maintain performance at normal levels, but does not correlate with individual variations in inhibitory control. Aberrant functional connectivity for some regions was linked to individual differences in underlying brain structure only in PD participants, despite no group differences in the structural variables. Conclusions: Altogether, the findings demonstrate that functional reorganization of the inhibition network in PD predates the development of inhibition deficits and clinically significant cognitive impairment. Altered inhibition network interactions with attention-related networks and the dopaminergic system may presage future decline in inhibitory control in PD.

Title: Dopaminergic tone and apathy modulate foraging decisions in health and Parkinson's disease

Authors: M. A. APPS, C. LE HERON, N. KOLLING, O. PLANT, A. KIENAST, S. FALLON, M. HUSAIN
Univ. of Oxford, Oxford, United Kingdom

Abstract: Theories of mesolimbic dopamine have long highlighted the role of tonic firing for signalling the 'average' background reward rate in an environment, which in turn serves to invigorate movements. When the average reward rate is high, tonic firing is high, leading to faster movements. Yet, mesolimbic dopamine is also implicated in motivation and decision-making, with degeneration in Parkinson's Disease (PD) linked to apathy - a reduction in goal-directed behaviour. However, little is known about how - or whether - dopaminergic tone signals the average reward rate for more abstract behaviours, nor whether disrupted tonic dopamine can provide a framework for apathy in PD.

Here, to precisely manipulate both the average background and foreground (instantaneous) reward rates we used an abstract 'patch-leaving' foraging task in which participants have to decide "when to leave". Participants received rewards continuously within 'patches', with accrual exponentially depleting at one of three rates (high/medium/low yield). These patches were situated in either rich (more high yield patches on average) or poor environments (more low yield patches on average). By measuring time spent in a patch we could precisely quantify people's sensitivity to changes in foreground and background reward rates. We examined the effects of (i) dopamine D2-agonist Cabergoline compared to placebo in healthy people (n = 29) and (ii) dopaminergic medications (on vs off) in apathetic vs non-apathetic PD patients (n = 35). Strikingly, manipulating tonic dopamine in both healthy people and PD patients selectively modulated patch leaving times in response to changes in the background - and not foreground - reward rates. In addition, only apathetic PD patients, rather than non-apathetic, show an effect of dopamine on their sensitivity to the background rate.

These findings suggest that tonic dopamine may selectively modulate people's processing of the background average reward rates in an environment which impacts on abstract foraging decisions, and that disruptions to dopaminergic tone may underlie apathy in PD.

Title: Tired of working: Neurocomputational mechanisms of the effects of fatigue on effort-based decisions

Authors: *T. MÜLLER[1,2], C. LE HERON[3,2], M. HUSAIN[1,3,2], M. A. J. APPS[1,2]
[1]Dept. of Exptl. Psychology, [2]Wellcome Ctr. for Integrative Neuroimaging, [3]Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Prominent theories suggest that fatigue - a feeling of exhaustion arising from effortful exertion - has a significant impact on motivation, reducing the willingness to exert effort over time. A considerable body of research has identified the role of sensorimotor brain systems in effortful behaviour and implicated fronto-striatal systems in ascribing value to - and motivating - the exertion of effort. However, the majority of studies assume that motivation is static. As a result, how these systems change in response to fatigue, and how this modulates effort-based choices, is poorly understood. Using an effort-based decision-making paradigm in combination with computational modelling and fMRI, we were able to quantify the neural mechanisms underlying moment-to-moment fluctuations in fatigue and their effects on effort-based decisions. Young healthy participants (N = 32) made a series of choices between two alternatives: a rest option for a low reward (1 credit) or a work option, requiring the exertion of one of three levels of grip force (30-48% of their maximal grip strength), for one of three higher amounts of reward (6-10 credits). Computational modelling revealed that the willingness to exert effort, in particular high effort, declines over trials as a function of (i) the effort previously accumulated over the course of the whole task and (ii) a recoverable component that increases after effortful trials and is restored by rest trials. fMRI analysis suggests that the effects of fatigue on subsequent motivation are mediated by sensorimotor systems as well as by fronto-striatal systems previously implicated in effort-based decision-making.

Title: Effect of Neuroinflammation o the glymphatic clearance of macromolecules in an LPS model

Authors: *S. SUESH, K. JENROW
Neurosci., Central Michigan Univ., Mount Pleasant, MI

Abstract: Introduction: Recent evidence suggests that the clearance of macromolecular waste from the brain occurs primarily via the glymphatic system during slow wave sleep and also under anesthesia. Movement of subarachnoid CSF into and out of the brain occurs within perivascular space and the flux of CSF-ISF through interstitial space is facilitated by specialized water channels called aquaporins (AQP) localized on astrocytic endfeet processes. We hypothesized that chronic neuroinflammation, induced by lipopolysaccharide (LPS), might be sufficient to impair glymphatic clearance by disrupting the distribution of AQP and/or by restricting the movement CSF-ISF through intersititial space. Methods: Chronic

neuroinflammation was induced in male Sprague Dawley rats via single i.p. injections of LPS (5 mg/kg) or saline (Control). Four weeks later, florescently-tagged dextran tracers (3 KD Texas red, 10 KD FITC) were injected into the cisterna magna. Cohorts were sacrificed 15, 30 and 45 minutes post-injection, with 1 ml blood samples drawn from the heart prior to perfusion. Brains were removed and postfixed for 48 hours before being vibratome sectioned at 100 µm for ex vivo imaging. Separate groups of LPS and Control animals were assayed for cognitive deficits (open field, novel object recognition, and contextual fear conditioning) with brain tissue subsequently processed for immunohistochemistry and western blots for Aquaporin-4, amyloid beta, and GFAP. Results: Relative to Controls, serum dextran concentrations were significantly reduced in the LPS group. Ex vivo imaging analysis also revealed qualitative and quantitative reductions in tracer distribution. Contextual fear conditioning was also impaired in the LPS in group, however open field and novel object recognition were not impaired. Observable differences in amyloid beta and aquaporin distribution were seen in the LPS brains compared to control, whereas the distribution of GFAP was unchanged. Conclusions: Our results suggest that chronic neuroinflammation alone is sufficient to impair glymphatic clearance from the brain, resulting in selective functional impairment, and is likely a major contributor to age-related cognitive decline and associated neurodegenerative disease processes

Title: Oculomotor behavior as a measure of cognitive control in psychiatric illness

Authors: *R. YEP[1], B. COE[1], D. BRIEN[1], C.-A. WANG[1], J. HUANG[1], A. MARIN[2,1], D. MUNOZ[1,3]
[1]Ctr. for Neurosci. Studies, [2]Dept. of Psychiatry, [3]Dept. of Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: Diagnosing psychiatric illness is often complicated by the heterogeneity of clinical populations and the overlap in diagnostic criteria between disorders. This is evident in disorders such as attention-deficit hyperactivity disorder (ADHD), bipolar disorder (BD), and borderline personality disorder (BPD), which, despite differences in age of onset and course of illness, share symptomology and behavioural deficits which can be difficult to differentiate. Our understanding of the pathophysiology underlying these disorders is currently limited by a lack of behavioral

biomarkers to support clinical assessment and diagnosis. Deficits in cognitive control present as an ideal domain to assess to establish such biomarkers, however few studies have directly compared ADHD, BD, and BPD individuals using paradigms which reliably probe the fronto-striatal circuitry underlying these behaviors. The goal of this exploratory study was to characterize adults with ADHD, BD, and BPD on a saccade paradigm shown to be a robust measure of cognitive control. Given the extensive overlap of oculomotor circuitry with the regions of the brain involved in cognitive control, we hypothesize that performance on this task may identify subtle differences between clinical groups which traditional clinical assessments are not sensitive enough to capture. ADHD, BD, BPD, and sex- and age-matched healthy control participants performed an interleaved pro/antisaccade task (look towards vs. look away from a visual target, respectively). Oculomotor behavior, including saccadic reaction time, direction error percentage, microsaccade rate, and pupil response was compared between pro/antisaccade trials and participant groups. Consistent with previous findings, oculomotor measures differentiated prosaccade from antisaccade trials across all participant groups. Clinical groups performed poorly on this task as compared to healthy controls, indicating deficits in cognitive control. Differences between clinical groups in saccade, microsaccade, and pupil response behavior further indicated differences in the recruitment of fronto-striatal circuitry while performing the task. These findings support the notion for cognitive control as a candidate domain to assess in ADHD, BD, and BPD to establish valid behavioral biomarkers, and that oculomotor measures such as saccades, microsacccades, and pupil response can provide a sensitive means of assessing the circuitry underlying these deficits. Further characterization of these deficits will be an important step forward in developing behavioral biomarkers to aid in the understanding, diagnosis, and treatment of these disorders.

Ctr., Dallas, TX

Abstract: Saccadic eye movements have been implemented to examine behavioral and neural processes involved in cognitive control. Samples with psychosis show impairments to various aspects of cognitive control, including attention, inhibition and working memory, but it is still unclear what underlying neural functioning is implicated in these problems. The current study utilized a series of saccadic eye movement tasks and functional magnetic resonance imaging to examine behavior and brain function in samples with psychosis. Subjects were recruited from a sample of the Bipolar and Schizophrenia Network for Intermediate Phenotypes consortium and had a diagnosis of schizophrenia, schizoaffective disorder, or bipolar disorder with psychosis. Healthy control subjects were compared to the groups with psychosis in order to examine neural correlates of cognitively complex saccadic tasks. Participants performed prosaccades (a reflexive, more autonomic task) and antisaccades (a cognitively complex task) in the MRI scanner. Behavioral and brain responses were compared between the prosaccade task and the antisaccade task as well as between healthy control subjects and the differing psychosis groups. Individuals with psychosis made significantly more errors on the antisaccade task compared to healthy control subjects. Between the psychosis groups, individuals with schizophrenia made the highest percentage of errors, followed by the individuals with schizoaffective disorder, and those with bipolar disorder made the fewest. In terms of brain function, groups with psychosis had significantly less overall activation in the brain during these tasks compared to healthy control subjects. Additionally, groups with psychosis displayed distinct patterns of neural activation; in the right cuneus individuals with schizoaffective disorder had more overall activation than those with schizophrenia. However in frontal, parietal, and striatal regions individuals with schizophrenia had more overall activation than those with schizoaffective disorder. These differing patterns of neural activation may provide critical information for understanding similar and distinct networks contributing to clinical disorders characterized by psychosis.

Neurosci., UCSD, San Diego, CA

Abstract: Using methods from cognitive and computational neuroscience as well as the social sciences, we present a novel approach to studying creativity in children diagnosed with autism spectrum disorder (ASD). Previous research in this area tends to be divided between biological and social science approaches, with little integration. While laboratory research on the biological markers of autism tends to study children in isolation, performing decontextualized tasks, social science research focuses on the child in situated, daily interaction with family members, educators and clinicians. An influential study (Abell, Happé & Frith, 2000) asked ASD and typically-developing (TD) participants to watch stop-motion animations of moving triangles made to evoke descriptions of random interactions, goal-directed interactions, or mentalising. The study's findings—that while ASD populations used mentalising language, they identified *inappropriate* mental states, and were thus impaired in this domain—seem less robust in light of a subsequent finding that lower performance on *appropriateness* aligned neither with parent-reported behavior, nor with the child's interaction with an observer (Salter et al. 2008). In the present preliminary study, we took a different approach and instead attempted to capture *alternate styles of creativity*—including in regards to mentalizing as an interpretive or expressive strategy—in ASD-diagnosed and TD children (10-17 yrs, n=8), who were given the opportunity to create their own DIY stop motion animations in open-ended collaboration with a researcher. Their interaction was video recorded, and data from gaze tracking, body motion and EEG were collected from both the participant and researcher. Using qualitative social science methods, specifically an ethnomethodological approach that tracks locally emergent meaning in naturally occurring interaction, the video was analyzed to identify meaningful events characterized by shifts in communication strategies and the emergence of shared objects of attention. These events

of interest (EOIs) guided statistical analyses of the neuroscience data to identify patterns of correlated activity at the level of gaze and bodily movement, and were further correlated with neural activity during such EOIs. While in this pilot study each participant worked collaboratively with a researcher, a future study will examine peer-dyads (ASD-TD, TD-TD, ASD-ASD). We expect this work to contribute to supporting inclusion and expression for growing numbers of ASD children in educational contexts, as well as to broader methodological questions in creativity research.

Title: Predictive processing in changing environments in autism: Electrophysiological, pupillometric and behavioral assays

Authors: *S. TIKIR, S. MOLHOLM
Albert Einstein Col. of Med., Bronx, NY

Abstract: Autism Spectrum Disorder (ASD) is a complex neurodevelopmental condition characterized by deficits in social communication, as well as restricted and repetitive patterns of behavior. Several groups consider ASD a disorder of prediction, proposing a link between predictive impairments and insistence on rituals (Sinha et al., 2014; Van de Cruys et al., 2014). Given evidence that environmental unpredictability is strongly correlated with anxiety and ritualistic behaviors, repetitive behaviors and insistence on sameness may be a way to alleviate anxiety arising out of unpredictability. In a volatile environment where contingencies fluctuate often and predictions are violated recurrently, neurotypical individuals opt for a low level of confidence (precision), and thus prediction errors are less surprising; whereas in a low volatility environment, one tends to be highly confident in their predictions, and get surprised when they are violated. Individuals with ASD are often bothered by seemingly trivial changes in everyday life, leading us to hypothesize that they are lacking a specific ability that is crucial in predictive processing: flexibly adjusting the confidence level of predictions according to volatility in the environment. To test this, we first trained adults with and without ASD to perform a sequential pattern recognition task, where shapes are presented in specific orders. We then presented conditions with varying levels of pattern violation and environmental volatility, while high-density electroencephalography (EEG), behavioral responses and pupillometry were recorded.

To understand whether the environmental volatility was accurately estimated in ASD, we measured changes in pupil dilation, which served as a proxy for surprise (Lawson et al., 2017). An abnormal absence of surprise upon a prediction error is evaluated as volatility overestimation, while an abnormal increase in surprise levels upon prediction error is evaluated as volatility underestimation. Evoked response potentials (ERPs: CNV, P300, and error related responses) and reaction times were analyzed to infer predictive processing mechanisms (Thillay et al., 2016). Preliminary analysis of the data indicate that our manipulation of volatility is effective. Ongoing analysis is directed at determining whether the data support the thesis that volatility estimation is impaired in ASD.

Title: Use of pharmaceutical cognitive enhancers in the Australian financial services industry

Authors: *E. A. BOWMAN, B. FENG, C. MURAWSKI, P. BOSSAERTS
Brain, Mind and Markets Laboratory, Dept. of Finance, Univ. of Melbourne, Parkville, Australia

Abstract: There is growing interest in the non-medical use of so-called “smart drugs” (such as methylphenidate, amphetamine and modafinil) to enhance cognitive performance. This has been explored in college students, medical students and surgeons in the US and Europe. Here we present the an anonymous online survey of “smart drug” use among professionals working in the Australian financial services industry. Our primary hypothesis was that different industry sectors would report use of different drugs in response to different workplace task demands. The survey was advertised at presentations to industry groups, in online media articles, and social media outlets between September 2016 and October 2017. 372 responses were received, of which 140 were valid and complete, and 69 were variously incomplete but usable. 182 responses answered the major question of interest: “Do you believe your colleagues take any drugs that enhance their performance?”. 68 responded “Yes” and 114 responded “No” (37.4%). Different sectors of the financial services industry reported significantly different rates of use among colleagues (Pearson’s chi-squared test, $\chi^2(4)=19.39$, $p = 0.0006$). Respondents from capital markets and

trading, and from asset management, most frequently reported cocaine use in the workplace. However, respondents from commercial banking more frequently reported modafinil, amphetamine and methlyphenidate use. Participants were asked about their workplace, industry sector, hours worked per week, and other demographic and personal health factors. There was a significant difference in reported hours slept per night between those who reported workplace use and those who didn't ($\chi^2(6)= 19.54$, $p = 0.003$). A number of side effects were also reported, including headaches and mood swings. Significant variation in the total rates of reported use of pharmacological cognitive enhancement was found between different sectors of the Australian financial services industry. However, differences between rates of use of different substances nominated by respondents from different sectors did not reach significance. This is an important first step in exploring the use of attempted cognitive enhancement in professional competitive workplaces with diverse task demands.

Reported use by by sector, by substance.

	Capital markets and trading	Asset management	Commercial banking	Retail banking	Other	Totals

Title: Genetically determined cortical dopamine availability modulates alcohol-induced impairments in error-monitoring

Authors: J. HAPPER[1], C. A. HODGKINSON[2], D. GOLDMAN[2], *K. MARINKOVIC[1,3]
[1]San Diego State Univ., San Diego, CA; [2]Lab. of Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [3]Radiology, Univ. of California, San Diego, CA

Abstract: Moderate alcohol intoxication impairs inhibitory control and performance monitoring, resulting in the inability to flexibly respond to environmental demands and compensate for errors. Extensive evidence suggests the anterior cingulate cortex (ACC) is the central node subserving performance monitoring and post-error adjustments. It is a principal generator of theta oscillations during cognitive control tasks and is particularly sensitive to acute alcohol intoxication. It is also a major recipient of mesocortical dopaminergic projections. This study examined the role of dopamine (DA) availability in alcohol's disruptive effects on the oscillatory dynamics of performance monitoring during response inhibition. DA availability was estimated via *COMT* $Val^{158}Met$ (rs4680) genotype which has functional consequences for DA metabolism and has been shown to correlate with DA availability. Young, healthy social drinkers with no personal or familial alcohol-related problems homozygous for the Val^{158} (low DA) or Met^{158} (high DA) alleles participated in both alcohol (0.6 g/kg ethanol for men, 0.55 g/kg women) and placebo sessions in a counterbalanced design. The Go/NoGo task required response inhibition on 20% of the trials (NoGo). Whole-head magnetoencephalography signals during error and matched correct trials were decomposed with wavelets for the theta (4-7Hz) frequency band. Event-related spatiotemporal source power estimates were obtained with an anatomically-constrained minimum norm inverse method which combines MEG and structural MRI for each subject. Alcohol intoxication selectively decreased error reaction times overall, but no genotype differences were detected. Error-related processing was characterized by increased theta in the bilateral inferior frontal cortices, which was especially prominent for met/met homozygotes. With alcohol intoxication, met/met homozygotes showed greater theta power attenuation in the ACC and right prefrontal cortex compared to val/val homozygotes. This attenuation correlated with higher breath alcohol concentration and impulsivity scores for met/met homozygotes. Taken together, these data indicate that while greater frontal DA availability facilitates phasic responses to salient stimuli under placebo, alcohol-induced attenuation of neural activity to errors in met/met homozygotes is modulated by dopamine. These findings are consistent with other evidence suggesting that heritable variation in the *COMT* gene conferring greater frontal DA availability is associated with increased vulnerability to alcohol effects during performance monitoring.

Abstract: Obsessive-compulsive disorder (OCD), which affects approximately 2.5% of people worldwide and is characterized by intrusive thoughts and repetitive behaviour, also has cognitive flexibility as an endophenotype. Reversal learning, modulated by punishment and reward, has provided a powerful translational tool for investigating cognitive flexibility in humans, monkeys and rats. We used a probabilistic single reversal and a deterministic reversal learning paradigm with three reversals to determine how OCD patients were influenced in reversal learning, as well as by positive and negative feedback. We tested 49 OCD patients (28 medicated (predominantly with selective serotonin reuptake inhibitors (SSRI)) and 21 unmedicated) matched with 48 healthy controls. Our probabilistic paradigm (80% true feedback and 20% spurious feedback) revealed profound deficits in OCD patients in all four domains, with reduced adaptive behaviour (win-stay to true feedback and lose-stay to spurious feedback) and increased maladaptive behaviour (lose-shift to spurious feedback and win-shift to true feedback). Spurious negative feedback during acquisition prior to probabilistic reversal caused deficits only in medicated OCD patients, whereas both medicated and unmedicated OCD patients were impaired during reversal. Our novel deterministic paradigm, however, revealed a true reversal deficit in OCD patients under punishment (monetary loss), with intact performance only on the initial learned rule, and impaired performance after the first and final reversal, in both medicated and unmedicated patients. The combination of these two reversal paradigms demonstrates that cognitive inflexibility in OCD is exacerbated by uncertainty (probabilistic feedback) and by punishment, as shown by our novel deterministic reversal paradigm. They also show that the effects may occur independently of serotonergic medication, but is unclear whether this benefits or further impairs performance. The data are relevant to previous data showing abnormalities in

orbitofronto-striatal systems in OCD and to work with experimental animals confirming a role for homologous structures in reversal learning, modulated by serotonin transmission.

Abstract: The impact that selective serotonin reuptake inhibitors (SSRIs) have on adaptive learning signals delivered by serotonin, and also dopamine, in the human brain is unknown. Concentrations of these neuromodulators fluctuate on timescales of tens-to-hundreds of milliseconds. Until recently, technological barriers have prevented direct sub-second measurement of dopamine and serotonin in the human brain during conscious behavior. Here, we report and compare simultaneous and colocalized sub-second (10Hz) measurements of dopamine and serotonin release in the striatum of patients with Parkinson's disease (PD) who were (N=9) or were not (N=10) taking selective serotonin reuptake inhibitors (SSRIs). These measurements

were performed while volunteers performed a monetarily incentivized sequential investment game that has previously been shown to elicit positive and negative reinforcement learning signals that guide value-based choices (Lohrenz et al., 2007; Kishida et a., 2016; Moran et al., 2018). PD patients not taking SSRIs (N=10) perform this task in a manner similar to healthy participants. PD patients taking SSRI's (N=9) show significant differences in behavior (lower average investments and more impulsive changes in investment size), along with significant differences in dopamine and serotonin fluctuations on sub-second time scales. Whether the differences in behavior and neurochemical signals are caused by SSRIs or are the cause of the symptoms for which the SSRIs are prescribed is unknown; however, these data are consistent with SSRI driven enhancement of dopamine and serotonin co-release from the same terminals (Zhou et al., 2005). Further our results support the soft cross-wiring hypothesis (Montague et al, 2016), which proposes an efficiency framework for understanding how dopamine and serotonin co-release could enhance how value-predicting information is integrated into an adaptive decision-making process.

Title: A multimodal neuroimaging investigation of the neural correlates of doubt in obsessive-compulsive disorder

Authors: *A. I. GOLD[1,2], L. Y. CHEN[2], K. H. ALM[2], K. E. TOBIN[2], C. L. SPECK[2], J. KRASNOW[2], J. SAMUELS[2], V. KAMATH[2], G. NESTADT[2], A. BAKKER[3]
[1]Psychiatry, [2]Psychiatry and Behavioral Sci., Johns Hopkins Sch. of Med., Baltimore, MD; [3]Psychiatry and Behavioral Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Doubt can be defined as a lack of certainty or confidence in one's memory, attention, intuition, and perceptions, making it difficult to trust one's internal experiences and hindering satisfactory responses to information. In extreme cases, as is the case in patients with obsessive-compulsive disorder (OCD), this may present as a clinically-relevant trait, e.g. repetitive checking behaviors or contamination concerns, causing functional impairment. While a number of studies have observed alterations in brain regions implicated in decision-making, confidence, or uncertainty in patients with OCD, the neural correlates of doubt, in the context of anxiety disorders and OCD, remain poorly understood.

The current study aimed to identify neural correlates of doubt using high-resolution functional and diffusion-weighted neuroimaging methods in a sample of age- and education-matched female participants, stratified into high doubt and low doubt groups using the Doubt Questionnaire (DQ). In the scanner, participants were asked to make a perceptual decision in a random-dot matrix task, which was designed to induce doubt and explore brain regions involved in decision formation and subjective uncertainty.
Participants with high doubt showed elevated task-related activation when compared to those with low doubt. Specifically, the left insula and left fusiform gyrus showed significantly increased activation in the high doubt group compared to the low doubt group. Activation in the insula was positively correlated with scores on the DQ, the Decision-Making Questionnaire (DMQ), the State- and Trait-Anxiety Inventory, and the Beck Depression Inventory (BDI), but not with scores on the Obsessive-Compulsive Inventory (OCI-R). Fusiform activation did not correlate with any behavioral measures, including the DQ. Additionally, analyses of the diffusion-weighted images revealed significantly decreased fractional anisotropy (FA) values in the white matter surrounding the left insula, suggesting altered white matter integrity in participants with high doubt compared to those with low doubt. Across the total sample, mean FA was negatively correlated with the DQ, as well as state- and trait-anxiety levels, but was not significantly correlated with the DMQ, OCI-R, or the BDI.
These results suggest that the insula may play a critical role in the experience of subjective doubt and anxiety levels. Moreover, these findings are consistent with the idea that doubt may constitute a trait dimension common to cognitive function and perception that finds its pathological expression in psychopathologies like anxiety disorder and OCD.

Title: Deciding without consequences: Revisiting indecisiveness in individuals with obsessive-compulsive disorder

Authors: *B. ZUROWSKI[1], A. RUBART[2], T. VAN EIMEREN[3], A. WAHL-KORDON[2], H. R. SIEBNER[4], F. HOHAGEN[2]

Abstract: INTRODUCTION: The observation of every-day problems in decision making in patients with obsessive-compulsive disorder (OCD) is reflected by their inclusion in psychometric scales for OCD and even the existence of OCD-specific indecisiveness scales along with concepts formulating OCD as a disorder of decision-making (DM). Nevertheless, experimental studies in OCD patients did not consistently find deficits in DM. Most importantly, typically employed experimental paradigms like the Iowa Gambling Task often cannot disentangle DM deficits from possible deficits in working memory capacity, reward/punishment processing, planning and strategy switching or even symptom provocation by obsession-related experimental material. METHODS: We conducted an event-related 3T-fMRI study in 12 unmedicated OCD patients and 10 healthy controls. We used a forced-choice reaction time (RT) paradigm with parametrically increasing number of choice alternatives (0-4). Choices were based on abstract stimuli and rules, with no feedback provided. RESULTS: As expected both groups showed nearly errorless task performance and increasing RTs with increasing number of choice alternatives (0-4). This effect was paralleled by a parametrically increasing recruitment of a bilateral parieto-premotor-prefrontal cortical network and the cerebellum in all subjects. However, we did not observe any group differences applying a p=0.05 (FDR) threshold with correction for multiple comparisons in SPM8. Analoguously, patients with OCD did not differ from controls regarding error rate or RT. DISCUSSION: Using a "purified" DM task we suggest that forming and executing simple decisions without switching contingencies and without delivering reward or punishment is unimpaired in OCD, both in behavioural and neural terms. Further studies will need to determine which additional task requirements associated with DM may be responsible for observable deficits.

Title: Learning novel speech sounds reorganizes acoustic representations in the human superior temporal gyrus

Authors: *H. G. YI[1], M. K. LEONARD[1], B. CHANDRASEKARAN[2], K. V. NOURSKI[3], M. A. HOWARD, III[4], E. F. CHANG[1]

Abstract: Speech perception requires listeners to be sensitive to a wide range of acoustic cues for phonetic category, speaker identity, and pitch. Although these cues exist in all languages, they are often used differently, which presents challenges when listening to an unfamiliar language. For example, whereas English uses pitch primarily to signal a variety of prosodic cues, Mandarin Chinese also uses four distinct pitch patterns, called lexical tones, to change word-level meaning. Here, we ask whether learning to identify lexical tones is associated with the emergence of new neural representations, or whether existing pitch representations used for prosody are reorganized to accommodate lexical tone. To answer this question, we directly recorded cortical activity using electrocorticography in humans while they performed a multi-day training task to learn to identify tones from words produced by male and female native Mandarin Chinese speakers. We found neural populations in bilateral mid-anterior superior temporal gyrus (STG) that were highly selective for particular tones, independent of phonetic or speaker information. Crucially, behavioral performance was associated with neural clustering of tones in these populations, such that increased identification accuracy was associated with more distinct neural representations. Finally, we demonstrate that neural representation of Mandarin Chinese tones in STG reflected the same representation of relative pitch that encoded lexical stress in English sentences. Together, these results demonstrate that learning to identify unfamiliar speech sounds enhances pre-existing representations of the relevant acoustic cues, rather than generating novel encoding patterns.

Title: Parsing continuous speech into linguistic representations

Authors: *L. GWILLIAMS[1], J.-R. KING[2], D. POEPPEL[1]
[1]Psychology, New York Univ., New York, NY; [2]Frankfurt Inst. for Advanced Studies, Frankfurt, Germany

Abstract: Language comprises multiple levels of representation, from phonemes (e.g. /b/ /p/) to lexical items (e.g. bear, pear) to syntactic structures (e.g. bears [SUBJECT] eat [VERB] pears [OBJECT]). Here we address two research questions that arise in online processing of naturalistic speech: 1) which representational *states* are encoded in neural activity; 2) what overarching *algorithm* orchestrates these representations to ultimately derive meaning? Eighteen participants listened to four narratives that were fully annotated - from speech sounds to syntactic structures - such that each level could be correlated with brain activity. Two ~1 hour sessions were recorded from each participant. This naturalistic but controlled setup allowed us to decode, localise and track phonological, lexical and syntactic operations from magnetoencephalography recordings (MEG) using machine learning approaches. First, acoustic-phonetic features (e.g. voicing, manner, place of articulation) could be successfully discriminated from a sequence of neural responses unfolding between ~100 ms to ~400 ms after phoneme onset. Second, part of speech (e.g. verb, noun, adjective), indicative of lexical processing, was decodable between ~150 ms and ~800 ms after word onset. Third, we could decode and track proxies of both syntactic operations (e.g. number of closing nodes) and syntactic states (e.g. depth of tree). Interestingly, some of these syntactic representations were clearly present several hundreds of ms before word onset, whereas others maximally peaked ~300 ms later. These sustained and evoked MEG responses suggest that the human brain encodes each level of representation as proposed by linguistic theories. Importantly, the corresponding neural assemblies overlap in space and time, likely facilitating concurrent access across these low-to-high-level representations, in line with a cascade architecture. Finally, our study demonstrates how the combination of machine learning and traditional statistics can bridge the gap between spatiotemporally-resolved neuroimaging data and rich but tractable naturalistic stimuli.

Title: An electrocorticogram analysis based on the theoretical coupling between subpopulation network structure and cross-spectral power

Authors: *N. SATO[1], R. MATSUMOTO[2], A. SHIMOTAKE[3], M. MATSUHASHI[4], T. KIKUCHI[5], T. KUNIEDA[6,5], H. MIZUHARA[7], R. TAKAHASHI[2], A. IKEDA[3]

Abstract: Our recent computational simulation using biologically plausible network demonstrated the coupling between subpopulation network structure and local field potential (LFP) coherence. This finding has importance in developing an analytical method for evaluating subpopulation network structure based on signals generated in larger spatial scales, such as in electroencephalogram (EEG) and electrocorticogram (ECoG). This method can be used for various types of networks associated with distributed representation, and it is compatible with recent machine learning techniques for visual and auditory signals, or natural languages. The present study aimed to develop a theoretical formulation of the method for estimating the subpopulation network, and to test it using experimental data. First, the theoretical coupling between subpopulation network structure and LFP coherence was successfully transformed into the coupling of cross-spectral power in the EEG-level signals. Individual weights of distributed features at each electrode were calculated by applying multiple regression analysis with a constraint on the theoretical coupling. The estimated weights were used in predicting EEG cross-spectral power in response to novel stimuli. Second, the predictability of cross-spectral power based on the proposed method was tested using ECoG data obtained during a picture naming task from one subject. In the analysis, words were represented by 100-dimensional semantic vectors, which were calculated using the Word2Vec algorithm and a large text database. The predictability was tested with a 20-fold cross-validation procedure; the weights were calculated from training dataset and the predicted cross-spectral power to test set words was calculated by using the estimated weights and compared with true cross-spectral power. Results showed significant predictions in a frequency range of 4-20 Hz as well as 60-100 Hz, and the time period of 0.2-0.8s after the onset time of picture presentation. Pictures with 8 or 16 semantic features had higher predictability than those with 2 or 4 semantic features. This suggests that higher dimensional features contributed to the prediction. Standard regression analysis of cross-or auto-spectral power resulted in significantly lower predictability than that of the proposed method. This study demonstrates that the theoretical coupling between subpopulation network structure and cross-spectral power can be used in ECoG data analysis. However, the stability of the proposed method needs to be assessed further using larger experimental data.

Title: Predictor of programming language learning success: The development of the right inferior frontal cortex and the bilateral supramarginal cortex

Authors: *C. HOSODA, M. HAMDA, H. MAESHIMA, K. OKANOYA
Univ. of Tokyo, Tokyo, Japan

Abstract: About 60 % people could not acquire the ability of programming language(Dehnadi S. et al, 2006). However, an issue remains unsettled if programming language ability relies exclusively on the innately privileged brain structure or function, or is more flexibly shaped through neuroplasticity involving interactions among potentially relevant neural nodes. We investigated whether programming language ability relies on the brain structure or function of individuals, or is shaped through learning. 45 university male students with a mean age of 22.5 years (SD ±1.3, range 19-26) were enrolled. All participants who were new to the programming language underwent 12-week JAVA programming language intervention in everyday. Before and after intervention, we obtained structural magnetic resonance imaging (MRI), multi-angular diffusion-weighted magnetic resonance images (DWI), resting state MRI (rsMRI) and the Test for JAVA programming (Oracle certified Java programmer, Bronze). The average learning time per day was 70.4(±3.1)minutes. However, 25 out of 45 subjects could not acquire the programming ability (poor group). The total learning time was tend to be longer in poor group than in the subjects who could acquire the programming ability (good group, n=20) (p=0.06) but the score of JAVA programming test was higher in the good group than that in the poor group(p=0.02). Furthermore, the volume of greater GM before the intervention, the diffusion-based connectivity, and the resting state in the following regions predict whether the subjects could acquire the programming ablirity after intervention; the right inferior frontal cortex(IFG), and the functional and structural connectivity between and supramarginal gyrus(SMG)- inferior frontal pathway. In addition, after the invention, SMG volume and SMG-cerebellum connection changes were positively correlated with improvement of JAVA programming language comprehension. Therefore, the people in good group had greater increase in SMG volume and SMG-cerebellum functional and structural connection compared with others. The present findings provide the first evidence that the development of right IFG and the connectivity between and SMG-IFG pathway are essential factor of acquisition of programming language

ability. Moreover, the acquisition of programming language ability facilitates the plastic change of SMG structure and SMG-cerebellum connection.

Title: Resolving discrepancies between incoming auditory information and linguistic expectations

Authors: *C. SIGNORET[1], R. BLOMBERG[1], Ö. DAHLSTRÖM[1], L. MØLLER ANDERSEN[2], D. LUNDQVIST[2], M. RUDNER[1], J. RÖNNBERG[1]

Abstract: Speech perception in noise is dependent on stimulus-driven and knowledge-driven processes. Here we investigate the neural correlates and time course of discrepancies between incoming auditory information (i.e. stimulus-driven processing) and linguistic expectations (knowledge-driven processing) by including 20 normal hearing adults in a MEG study. Participants read 48 rhyming sentence pairs beforehand. In the scanner, they listened to sentences that corresponded exactly to the read sentences except that the last word (presented after 1600 millisecond delay and with 50% intelligibility) was only correct in half of the cases. Otherwise, it was 1) phonologically but not semantically related, 2) semantically but not phonologically related, or 3) neither phonologically nor semantically related to the sentence. Participants indicated by button press whether the last word matched the sentence they had read outside the scanner. Behavioural results showed more errors in condition 1 than in conditions 2 or 3, suggesting that phonological compatibility overrides semantic discrepancy when intelligibility is poor. Event-related field analysis demonstrated larger activity on frontal sites for correct than unrelated words, suggesting that the former were more accurately expected than the latter. An early M170 component was also observed, possibly reflecting expectation violation in the auditory modality. Dipole analysis will reveal whether M170 could be modulated by type of linguistic discrepancy. Distributed-network analysis will further our understanding of the time course and neural correlates of discrepancies between incoming auditory information and linguistic expectations.

Title: L2 word recognition in noise: Modulatory effects of semantic and crosslinguistic overlap on brain activity

Authors: *S. GUEDICHE[1], A. DE BRUIN[2], M. BAART[3], A. G. SAMUEL[4]
[1]Neurosci., Basque Ctr. On Cognition Brain and Language, Donostia-San Sebastian, Spain; [2]Basque Ctr. on Cognition Brain and Language, San Sebastian, Spain; [3]Tillburg Univ. and Basque Ctr. on Cognition Brain and Language, Tillburg, Netherlands; [4]Basque Ctr. on Cognition Brain and Language and Stony Brook Univ., San Sebastian, Spain

Abstract: Spoken language comprehension in a second language (L2) depends on the ability to map an acoustic signal onto one of two co-existing acoustic-perceptual systems. This mapping process commonly occurs in noisy listening conditions. The neural systems that support the mapping of sound-to-meaning in L2 and how they are affected by the presence of a native language (L1) are not well understood. Different models of bilingual spoken word recognition predict different types of interactions between L2 and L1. The aim of the current fMRI study is to probe the neuro-functional organization of L2 spoken word recognition. A recent study, conducted in a group of early balanced Spanish-Basque bilinguals, found improved L2 spoken word recognition accuracy in noise when it was preceded by a semantically related L2 prime (semantic priming effect). The semantic priming effect was modulated by the degree to which L2 words shared phonological-lexical overlap with their L1 translation equivalents (Guediche, Baart, Samuel, 2018); greater effects were found for L2 words that share a high degree of overlap (cognate words). Impaired performance was found for cognates in the unrelated context, potentially due to increased competition from L1; the semantic prime may facilitate L2 lexical-semantic integration and inhibit lexical competition effects from L1 over-riding the negative effects of recognition accuracy. We investigate how changes in brain activity are affected by 1) the degree to which L2 words share overlap with L1 translations, 2) semantic priming, and 3) their interaction. Listeners perform a lexical decision task on noisy L2 targets that are preceded by either a semantically related or unrelated L2 prime. Increased lexical competition from L2-L1 phonological lexical overlap should increase activity in brain regions that have been associated with phonological and lexical processing including the superior and middle temporal gyrus (STG) and (MTG). Semantic priming should modulate activity in areas similar to those found for

bilinguals in their L1 including areas such as the angular gyrus (AG) and MTG. Of most interest to the current study is the interaction between semantic priming and crosslinguistic overlap. If semantic priming improves inhibition of L1 competition, interaction effects should recruit brain regions involved in inhibitory control processes such as the inferior frontal gyrus (IFG), potentially affecting MTG activity. Preliminary analyses based of a limited dataset (data collection is ongoing) show semantic priming effects in ATG and MTG, crosslinguistic overlap in MTG and posterior STG, and interactions in middle ATG and left middle frontal gyrus.

Title: Spatial-temporal dynamics of neural activity in Broca's area during lexical selection: An intracranial EEG study

Authors: *Y. WANG[1], A. KORZENIEWSKA[2], K. USAMI[3], A. VALENZUELA[2], N. E. CRONE[4]
[1]Neurol., [2]Johns Hopkins Univ., Baltimore, MD; [3]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Neurol., Johns Hopkins Hosp., Baltimore, MD

Abstract: While it is widely accepted that Broca's area plays an important role in spoken word production, its exact role remains controversial. Previous studies have suggested that Broca's area and adjacent cortex serve as a key network hub for integration of syntactic, phonological, and lexical-semantic representations during comprehension and production of sentences. Using direct intracranial cortical recordings, we investigated the spatial-temporal dynamics of neural activity (indexed by 70-150Hz high gamma frequency band activation) in six patients undergoing invasive monitoring for seizure localization. All patients performed a sentence completion task in which the difficulty of lexical selection (indexed by sentence cloze probability) was systematically varied. Across all six patients, neural activity in Broca's area appeared to accumulate throughout stimulus presentation, and decreased before the onset of response articulation. More importantly, neural activity in Broca's area was significantly higher during completion of sentences with greater demands on lexical selection in the interval between onset of the cue to respond and the response itself, corresponding to lexical selection. Further, analyses of effective connectivity found that more demanding sentences elicited larger neural interactions within Broca's area, as well as between Broca's area and areas in posterior temporal

lobe that have been shown in other studies to store lexical representations. Our findings provide a detailed picture of the fine temporal dynamics by which Broca's area coordinates lexical selection during speech.

Title: The frequency-band specific information flows in speech network

Authors: *Y. YAN[1], H. HAN[1], D. ZHANG[2], W. ZHOU[3], B. HONG[1]
[1]Dept. of Biomed. Engin., [2]Dept. of Psychology, [3]Epilepsy Center, Yuquan Hosp., Tsinghua Univ., Beijing, China

Abstract: Characterizing the functional organization of speech network has been a focus of investigating the neural basis of language. Evidences have shown that there exists two cortical areas, roughly over superior temporal gyrus (STG) and inferior frontal gyrus (IFG), which are intensively involved during the speech related tasks, with STG more related to speech perception, and IFG to speech production (Hickok & Poeppel, 2007). Recent studies also found these two speech-related regions could be both activated in the perception and the production process (Cogan, 2014). However, the nature of interactions among this large-scale speech network, has not yet been elucidated. In this study, we recorded the intracranial EEG activities from 121 electrodes in brain-wide speech-related areas in three subjects, covering STG, IFG, anterior temporal lobe (AT), posterior temporal lobe (PT), parieto-temporal boundary (Spt) and motor areas. With high temporal resolution of the intracranial EEG, we characterized the dynamic activities in the speech networks, and quantified causal influences among these major network nodes during resting and speech-evoked states. In the intrinsic speech networks during resting, main information flows sourced from STG and IFG, and targeted to the other speech-related areas including AT, PT, Spt and motor areas. During speech perception and production tasks, strong information flow was found to modulate the high-gamma (60-140Hz) activities of STG & IFG ($p<0.01$, compared to resting state), exhibiting a recurrent pattern of the functional connectivity between STG/IFG and other major nodes of the speech network. We also found that the causal connections in speech network showed a frequency-band specific feature: the causal connections in alpha - beta range (8-32Hz) were insensitive to task involvements, while the high-

gamma band (60-140Hz) was strongly activated during the speech tasks ($p<0.01$). In short, our data revealed distinct pattern of causal connectivity of speech networks during resting and speech task states, with separated frequency bands for networking.

Title: Visual cues contribution to audio-visual speech intelligibility in natural speech

Authors: *I. TAL[1], J. L. HERRERO[2], M. LESZCZYNSKI[3], A. D. MEHTA[4], C. E. SCHROEDER[5]

Col. of Physicians and Surgeons, Orangeburg, NY

Abstract: Natural speech perception is multisensory; when conversing with someone that we can see, our brains combine visual information from face, postural and hand gestures with auditory information from the voice. The underlying speech processing is extremely rapid, with incoming audio-visual units arriving every few hundred milliseconds that must be encoded and passed on before the next syllable arrives. It has been suggested that low frequency neuronal oscillations play a key role in the integration of auditory-visual (AV) speech information and that phase reset of auditory oscillations by visual input is a critical step in the integration of auditory and visual speech cues. AV speech is usually studied by (1) using clear speech stimuli that create a ceiling effect for intelligibility, (2) comparing noisy and clear speech that differ in their acoustic properties or (3) presenting purely visual stimuli (lipreading) which is difficult for untrained participants and thus requires several repetitions of the same stimulus. To overcome these limitations, we designed a paradigm in which speech intelligibility is manipulated by presenting short gaps (at a rate of 3-7Hz) within the natural speech stimuli. Our aim was to test whether neuronal oscillations play a key role in the integration of auditory and visual speech information and the specific hypothesis that phase resetting in the low frequency range is the neural mechanism underlying increased intelligibility of AV relative to purely auditory (A) speech. Using ECoG we compared neuronal responses to AV segmented speech vs. auditory

segmented speech. We report that speech intelligibility increases when visual cues are present. Several brain regions showed significant high gamma power (HGP) speech tracking. Interestingly, speech tracking differences between the AV and A conditions were most prominent at electrodes that track the speech to a lesser degree. In addition, we found an increase in low frequency inter-trial coherence (ITC) for AV stimuli. These results suggest that visual speech cues influence auditory cortical processing of speech by phase-resetting its ongoing oscillations.

Title: The impoverished comprehension of non-native speech in noise

Authors: *E. BLANCO-ELORRIETA[1], L. PYLKKANEN[2], N. DING[3], D. POEPPEL[4]
[1]Dept. of Psychology, [2]New York Univ., New York, NY; [3]Zhejiang Univ., Zhejiang Sheng, China; [4]Neurosci., Max-Planck-Institute for Empirical Aesthetics, Frankfurt, Germany

Abstract: Introduction. There is strong evidence that under unfavorable listening conditions (e.g. noise) bilinguals have a deficit in the comprehension of their second language (L2) compared to their first language, despite performing similarly in quiet listening conditions. Although the prevalence of this phenomenon has been previously established, the causes and neurobiological bases of this dissociation have not been elucidated. In this study we used neural entrainment to different linguistic levels of representation to investigate the bases of the impoverished comprehension of L2 speech in noise.
Methods. We collected MEG data from 40 Chinese-English bilinguals. Participants listened to four-syllable isochronous sentences in English and in Chinese at 4 different levels of noise, ranging from completely clear speech (15 dB) to unintelligible speech in a noisy background (-15 dB), in 7.5 dB intervals. The sentences consisted of 4 monosyllabic words that were combined to form a two-word noun phrase (adjective/adverb + noun) and a two-word verb phrase (verb + noun). The combination of these two phrases resulted in a four-word sentence (e.g., “big rocks block roads”). In order to meaningfully characterize the effect of noise across

varied L2 proficiency levels, we tested bilinguals who were native speakers of Chinese with low level of English (16), with high level of English (12), and native speakers of Chinese who were currently English dominant (born to Chinese parents in the US; 12).
Results. Behavioral results show distinct psychometric curves for the comprehension of L1 and L2 speech, which vary by the language profile of the tested group. MEG results reveal two distinct phenomena: i) the tracking of syllabic rhythm decreases linearly as noise increases; and ii) the tracking of higher level phrasal structure is categorically disrupted by noise, as shown by a) the complete lack of entrainment to phrases at the highest level of noise (-15 dB) regardless of language profile and b) only native speakers (but not L2 speakers) tracking phrasal structures at -7.5 dB.
Conclusion. This study quantifies the influence of noise in the cortical tracking of linguistic structures in connected speech, and provides evidence to suggest that -7.5 dB may be the threshold level of noise at which L2 comprehension is disrupted. Previous research has posited that greater availability of higher-level top-down linguistic information may account for this difference in L1 vs. L2 comprehension. The present study shows that a more automatic lower-level phenomenon, oscillatory tracking of speech, may also underlie the prevalent effect of impoverished comprehension of L2 speech in noise.

Title: Auditory language localizer: An fMRI/ECoG study with epilepsy patients

Authors: *B. F. SNOAD[1], P. E. GANDER[1], C. K. KOVACH[1], K. V. NOURSKI[1], H. KAWASAKI[1], E. FEDORENKO[2], M. A. HOWARD, III[1]
[1]Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [2]MGH, Charlestown, MA

Abstract: Language processing is supported by an extensive network including temporal, frontal and parietal regions. Recent electrocorticographic (ECoG) investigations during language-based tasks have provided new insights in functional localization of mechanisms that support language processing. We set out to expand this work using a novel passive auditory language 'localizer' task (Scott et al., Cogn. Neurosci. 2017, 8:167-76) to identify key language cortical regions in surgical epilepsy patients. The 16 pairs of clear and degraded speech monologues presented

across two runs. We collected non-simultaneous functional magnetic resonance imaging (fMRI) and ECoG data in each subject.
The speech vs. silence contrast in fMRI data showed distinct activations in bilateral auditory cortex and planum temporale ($p<0.05$, uncorrected). In each subject, the clear vs. degraded speech contrast showed bilateral superior temporal gyrus activation ($p<0.001$, uncorrected). Less consistent was activation of inferior frontal and premotor cortex. In contrast, degraded stimuli preferentially activated insula, anterior cingulate, orbitofrontal cortex, and prefrontal cortex ($p<0.001$, uncorrected). Strength of activation in these brain regions varied across the subjects in each contrast. Ongoing ECoG analyses will determine the oscillatory correlates of regions activated in the fMRI scan for the same subject. To the extent the ECoG coverage overlaps we hope to uncover the pattern of connectivity among the language network.
These results identify a network of high-level language processing regions at the individual subject level in pre-surgical epilepsy patients and support findings from previous studies. In addition to guiding neuroscientific investigations of language processing, we will be able to compare network level activation between fMRI and ECoG. As language localization is critically important for surgical planning in epilepsy patients, we plan to compare the results we obtain from the localizer task to the gold-standard epilepsy surgical planning data from the Wada test and electrical stimulation mapping results.

Title: Neural correlates of cognitive state during volitional communication

Authors: *A. E. HADJINICOLAOU[1], G. BELOK[1], J. W. LEE[2], B. S. CHANG[3], S. S. CASH[1]
[1]Neurol., Mass. Gen. Hosp., Boston, MA; [2]Neurol., Brigham and Women's Hosp., Boston, MA; [3]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Over the course of a conversation we make multiple shifts in our overall cognitive state. An understanding of the neural activity underlying these state changes would provide crucial insight into the systems that govern communication, how they are disrupted by neuropsychiatric disease, and how such disruptions might be restored by therapeutic intervention. Although most research on communication and volition thus far has been based on

the results of structured, highly controlled experimental tasks, brain activity is fluid and continuous, with much cognitive activity of interest being internally generated. To examine such processes under more natural conditions, we developed a platform in which the analysis of intracranial recordings from epileptic patients, who are implanted with cortical and subcortical electrode arrays for clinical purposes, can be augmented by information collected from synchronized video and audio recordings. In the present work we analyzed data from N=3 patients, collected using a 128-256 channel neural signal processor recording system (Cerebus, Blackrock Microsystems). The activity of interest was either (i) a loosely-structured conversation (45-120 min) with the experimenter, or (ii) spontaneous conversations with visitors. The majority of spoken dialog during these activities, captured by an audio recorder (H4n, Zoom), was transcribed and processed (CoreNLP, Stanford; in-house software) to yield word lexical categories and their timing within the iEEG recordings. Videos cameras (FireflyMV, Point Grey) captured non-verbal communication and informed the classification of different cognitive states. Intracranial recordings were analyzed in MATLAB (MathWorks) with the NPMK (Blackrock Microsystems) and FieldTrip (Donders Institute) toolboxes. Preliminary analyses suggested that varying speech complexity invoked markedly different spectral content in recordings of patient responses to questions. Specifically, we observed that greater question complexity resulted in greater theta band power, expressed 1-2 s after question onset. In this work we explore the extent to which speech complexity and other factors (e.g. syntactic branching) can modulate or delineate cognitive state changes, and employ coherence analysis to describe these state changes.

Title: The role of pMTG in word learning

Authors: *P. RIPOLLES, D. POEPPEL
New York Univ., New York, NY

Abstract: The posterior middle temporal gyrus (pMTG) has been suggested as a candidate region to support the sound-to-meaning interface: semantic information—highly distributed throughout cortex—might be accessed (when lexicalized) through the pMTG, the main function of which would be to map phonological representations in superior temporal regions to

extensively distributed semantic representations (Hickok and Poeppel, 2007; Gow, 2012). Here we examine the emergence of new entries in the mental lexicon. Participants learned the name of real but unfamiliar objects (object drawings and descriptions of ancient artifacts previously used in Finnish households) in a gradual manner, over a two week period. In a first fMRI session, participants were aurally presented with 30 new words without meaning. Next, participants were presented with the drawings of 30 new objects with their descriptions (without their name). As control conditions, participants were also presented with 30 well-known objects and their names. In a first week of training, participants were repeatedly presented with the same stimuli once a day using an online training platform. After one week, subjects participated in a second fMRI session in which the first four fMRI runs were as those from the first fMRI session: 30 new (trained during the week) and 30 well-known aurally presented words and 30 new (trained during the week) and 30 well-known objects and their description. Then, on a fifth run we presented, for the first time and together, the new words with the objects that they represent. During the second week of training and once a day, participants were presented with the new words and the objects that they depicted: during the first week, participants had to learn and store phonological and semantic representations of each word separately; during the second, they had to create word-to-meaning mappings. Next, participants came to a final fMRI session in which the new words and their semantic representations were be presented once again. During these 3 fMRI sessions and 2 weeks of training, participants built, step by step, new entries in their mental lexicon: they created a new phonological entry, a new semantic entry and a new link between the two. Importantly to the hypothesis, fMRI activity within the pMTG was modulated by training, increasing from the first to the second MRI session and achieving activity levels similar to those elicited by well-known names of objects by the third MRI. These results further directly support the role of the pMTG as a lexical interface.

Title: Surgical resections reveal functional regions of the temporal lobe for learning and memory

Authors: *K. TOMBRIDGE[1], C. DONOS[1], J. BREIER[2], P. ROLLO[1], J. JOHNSON[1], N. TANDON[1,3]

Abstract: INTRODUCTION: Brain activation studies using functional MRI and electrocorticography have frequently been used to map language and memory in stroke and epilepsy patients. Voxel-wise lesion-based symptom mapping (VLSM) techniques, typically conducted in stroke patient populations, are vital in delineating the organization of language. This technique ignores both important pre-morbid individual differences and reorganization that might occur after damage while maximizing the predictive power connectivity has on behavioral outcome. By applying this technique in a controlled-lesioned epileptic patient population, we can disambiguate the components of the temporal lobe.
METHODS: We studied the brain-behavior relationships in a sample (n = 60) of individuals who underwent surgery to treat medically intractable epilepsy. These patients underwent one of three surgeries targeted at components of the left anterio-mesial temporal lobe: anterior temporal lobectomy (ATL, n = 10), ATL + Amygdalo-Hippocampectomy (ATL+AH, n = 20), or selective Laser interstitial thermal therapy-based amygdalo-hippocampectomy (LITT, n = 30). Pre- and post-operative behavioral and neuroimaging measures were conducted to measure pre-surgical differences and post-surgery reorganization of functional networks. The neuropsychological test battery included measures of verbal fluency, naming, and memory (semantic, verbal, and spatial). For each patient, we used FreeSurfer software to derive cortical and sub-cortical segmentation of the brain using the pre-operative MRI. Lesion volumes were outlined using a post-operative T1 contrasted MRI in MRIcron software. Seizure outcomes were measured using Engel classification.
RESULTS: Our between-subject analysis of voxel-based lesion symptom mapping yielded a more detailed measure of an individual's pattern of cortical reorganization. Power analyses provided a distinct relationship between percent damage to anterior temporal lobe sub-regions and neuropsychological task performance. Change in error type pre- to post-surgery provided a leveled representation of language.
CONCLUSIONS: This study leverages a unique patient population for lesion-symptom mapping that is unconstrained by limitations inherent to studies of post-stroke patients. Consequently, we can better quantify the functional organization of left language-dominant peri-Sylvian cortex. This will inform future refinement of psycholinguistic models of language and the instantiation of these models in specific neuroanatomic substrates.

Abstract: Visual word recognition (VWR) is the process of mapping the written form of a word to its underlying linguistic item and is crucial for successful written communication. Characterization of healthy VWR neural mechanisms holds promise for individuals with reading deficits. While noninvasive neuroimaging studies have identified putative brain regions (fMRI, PET) and event-related potentials (EEG, MEG) involved in VWR, the spatiotemporal flow of information through the brain remains unclear. In this study, we analyzed high gamma neural activity from more than 90 intracranial neurophysiology patients as they read visually-presented words. We find that 9.5% of electrodes show a task-sensitive response, including 34% of electrodes in occipital lobe, 7% in frontal lobe, 4.9% in parietal lobe, and 4.8% in temporal lobe. By clustering the responses of all task-sensitive electrodes, we identified a variety of response types, including excitatory and inhibitory responses, onset and offset responses, and responses sustained for the duration of the word presentation. We observe a difference in the excitatory/inhibitory balance between lobes: 90% of responses in occipital lobe are excitatory, while temporal lobe is 76% excitatory, frontal lobe is 55% excitatory, and parietal lobe is 53% excitatory. Latency analyses reveal that on average, occipital lobe responds most quickly, followed by temporal lobe, with the slowest responses from frontal and parietal lobes. Middle occipital gyrus, cuneus, and fusiform gyrus (which contains the visual word form area) are among the fastest areas on average. Together, these results provide a high-resolution look at the spatiotemporal pattern of neural activity during visual word recognition in the human brain.

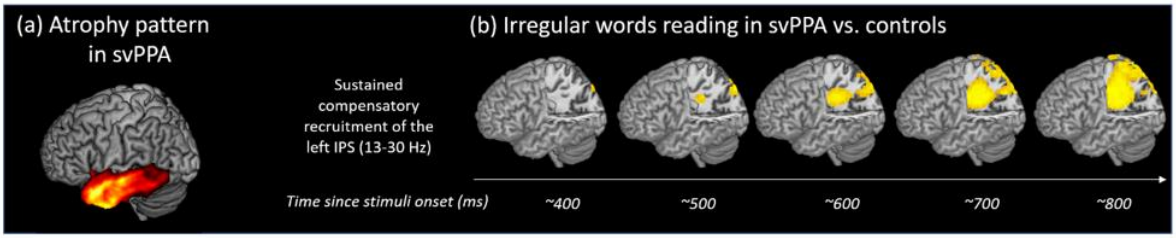
Title: Taking the sub-lexical route: The spatiotemporal dynamics of reading in semantic variant of primary progressive aphasia

Authors: *V. BORGHESANI[1], L. HINKLEY[2], K. RANASINGHE[1], M. THOMPSON[2], W. SHWE[1], D. MIZUIRI[2], S. HONMA[2], J. HOUDE[3], Z. MILLER[1], S. NAGARAJAN[2], M. GORNO-TEMPINI[1]
[1]Neurol., [2]Radiology and Biomed. Imaging, [3]Otolaryngology, Univ. of California, San Francisco, San Francisco, CA

Abstract: According to the dual route model of word reading, words never encountered before can be read only mapping their orthographic representations to plausible phonological forms (i.e., sub-lexical route). Conversely, words with irregular spelling can be read only mapping their orthographic representations to their meaning (e.g., lexical route). This route appears affected by neurodegeneration in patients with semantic variant of Primary Progressive Aphasia (svPPA), who present with surface dyslexia (i.e., an impairment in reading words with atypical spelling-to-sound mapping).We recruited 9 svPPA patients and 12 healthy age-matched controls. All participants underwent comprehensive neuropsychological testing, were right-handed English native speakers and had no history of developmental dyslexia. Participants read regular words (e.g., *fact*), irregular words (e.g., *choir*), and pseudowords (e.g., *pook*), while we recorded brain activity using a 306-channel whole-head MEG system (CTF). We reconstructed and analyzed whole brain oscillatory activity with Nutmeg (nutmeg.berkeley.edu). In controls, the key contrast between pseudowords vs. irregular words revealed differential activity in beta bad (13-20 Hz) over the left IPS (L-IPS, ramping up after stimulus onset and peaking at ~700ms), supporting the involvement of this region in sub-lexical processes. This effect was absent in svPPA patients, and, crucially, direct comparison of svPPA patients and controls during irregular words reading isolated the same spatio-temporal cluster. These findings suggest that patients recruit L-IPS to read not only pseudowords (as controls do), but also irregular words. Taken together, our results

indicate sustained activity over the L-IPS as the neural correlate of svPPA patients' over-reliance on the sub-lexical route, arguably an active compensation for their impairment on the lexical one.



(a) VBM results in svPPA patients illustrating the neurodegeneration affecting the anterior temporal lobe, which leads to the profound semantic knowledge loss manifested by these patients. (b) Results of the direct comparison between svPPA patients and controls during irregular words reading. It indicates heightened recruitment of left IPS in the patient cohort [beta band (13-30Hz), FDR cluster corrected].

Title: Causal role of specialized visual cortices in auditory foreign language vocabulary translation

Authors: *B. MATHIAS[1], L. SURETH[1], G. HARTWIGSEN[2], M. MACEDONIA[3], K. M. MAYER[4,5], K. VON KRIEGSTEIN[1,6]
[1]Independent Res. Group Neural Mechanisms of Human Communication, [2]Dept. of Neuropsychology, Max Planck Inst. for Human Cognitive and Brain, Leipzig, Germany; [3]Inst. for Information Engin., Johannes Kepler Univ. Linz, Linz, Austria; [4]Inst. for Psychology, [5]Otto Creutzfeldt Ctr. for Cognitive and Behavioral Neurosci., Univ. of Münster, Münster, Germany; [6]Dept. of Psychology, Tech. Univ. Dresden, Dresden, Germany

Abstract: Previous research suggests that multisensory training of foreign languages (L2) yields improved learning outcomes compared to unisensory training. One theory of multisensory learning (von Kriegstein & Giraud, 2006) proposes that improvements in learning outcomes following multisensory training are supported by visual brain responses to previously-learned auditory stimuli. We used the neurodisruptive effects of inhibitory transcranial magnetic

stimulation (TMS) to investigate whether visual cortical responses causally contribute to auditory L2 translation following multisensory L2 training. We targeted with TMS the biological motion superior temporal sulcus (bmSTS). bmSTS responses were previously found to associate with behavioral benefits of performing gestures during learning on L2 translation. According to the multisensory learning theory, inhibitory stimulation of the bmSTS should disrupt the translation of auditorily-presented L2 words if those words have become associated with visual biological motion during learning. Twenty-two adult learners were trained on L2 words and their native language translations over 4 consecutive days. Words were learned in two conditions: In one condition, participants viewed and performed gestures as L2 words were auditorily-presented, and in another condition, participants viewed pictures as L2 words were auditorily-presented. Gestures and pictures were congruent with word meanings. Following training, effective and sham TMS was applied to the bilateral bmSTS while participants listened to the L2 words that they had learned and translated the words into their native language. As expected, TMS of the bmSTS slowed translation response times for L2 words that had been learned while performing gestures compared to sham stimulation. TMS of the bmSTS did not affect translation response times for words learned while viewing pictures compared to sham stimulation. This result suggests that training with gestures led to changes in L2 representations within the bmSTS, which in turn facilitated the translation of L2 words. This effect was observed on the day following the learning period, as well as during a second TMS session that occurred 5 months post-learning, suggesting that cross-modal L2 vocabulary representations develop rapidly and decay slowly following learning. The current findings favor a framework in which improvements in learning outcomes following multisensory training originate in specialized sensory cortices.

Title: Dissociating language and logic using TMS

Authors: *J. P. COETZEE[1], M. M. MONTI[2], M. IACOBONI[3], A. D. WU[4], M. JOHNSON[1]
[2]Psychology, Neurosurg., [3]Psychiatry, Biobehavioral Sci., [4]Neurol., [1]UCLA, Los Angeles, CA

Abstract: The relationship between language and abstract thought has long been a topic of intense interest. One theory about this relationship is that the hierarchical and combinatorial operations that subserve natural language also serve as the basis for similar operations in a diverse range of abstract human though, such as mathematics, music cognition, and action

sequencing. With regard to deductive reasoning, there are two extant views about the relationship between this form of abstract thought and language. According to the first, deductive reasoning is parasitic on language, in the sense that the structure dependent operations which underlie deduction make use of the same neural machinery that underlies the structure dependent operations of language, with that common machinery being primarily found in the areas of the inferior frontal gyrus that have been traditionally referred to as Broca's area. According to the second, the structure dependent operations that underlie deductive reasoning, and the neural machinery that make them possible, are independent of and dissociable from the structure dependent operations of language. In this second view, the operations that support language occur primarily in Broca's area, while the operations that support deduction occur primarily in frontomedial (Brodmann area 8) and frontopolar (Brodmann area 10) cortices. We tested these two views using continuous theta burst stimulation (cTBS), a form of patterned transcranial magnetic stimulation (TMS) which has been shown to demonstrate relatively long lived inhibition of neural activity in a localized area. Using this approach, we were able to demonstrate that inhibition of Broca's area impairs accuracy on a linguistic task but not on a matched logic task. Additionally, we found that inhibition of frontomedial cortex (medial BA 8) produced a pattern opposite to that found in Broca's area. These results support the view the structure dependent operations which underlie deductive reasoning are not parasitic on those that support language, but are in fact ontologically distinct from them.

Title: Shared neural substrates for speech production and second-language word recognition in human motor cortex

Authors: *B. BARRAGAN[1], K. UEHARA[2], Y. JIAO[1], V. BERISHA[1], M. SANTELLO[3], J. LISS[1]
[2]Neural Control of Movement Laboratory, Sch. of Biol. and Hlth. Systems, [3]Sch. of Biol. and Hlth. Systems Engin., [1]Arizona State Univ., Tempe, AZ

Abstract: The primary motor cortex (M1) plays a role in speech perception tasks under difficult circumstances (Devlin, Aydelott, 2009; Adank, 2012; Nuttall et al., 2016), suggesting that recruitment of M1 facilitates speech perception (Du et al., 2016). Listening to sounds produced in a second language (L2) may be an instance of listening under difficult conditions, because it involves additional processing and cognitive-perceptual resources to distinguish among the new language sounds. The purpose of this study was to investigate the role of M1 representation of the lip orbicularis oris (OO) muscle in processing acoustic inputs in the native language (L1) and L2, using repetitive transcranial magnetic stimulation (rTMS)
A low-frequency rTMS protocol, which typically induces inhibitory changes in the stimulated brain area, was employed with a double-blinded, sham-controlled and crossover design, to alter neural activity in M1 in 13 healthy English/Spanish bilingual participants. The participants' voice was recorded reading a passage in L2 before and after 5 and 15 minutes of rTMS. Performance on a bilingual listening word-to-picture matching task was measured before and after the rTMS and sham conditions. rTMS was applied over the left representation of the OO muscle for 15 minutes at 0.6 Hz, and 100% of active motor threshold intensity, whereas sham was applied without magnetic pulses as a control condition. Single-pulse TMS-induced motor evoked potential (MEP) from the OO muscle, and an automated assessment of the vowel space area (VSA; Berisha et al., 2017; Sandoval et al., 2013), were used to assess the effect of rTMS on M1.
MEP area decreased after rTMS, indicating a successful inhibition of M1 activity. Similarly, VSA was compressed after rTMS, revealing functional speech production consequences of OO-associated M1 inhibition. Importantly, we also found evidence for a role of M1 for word recognition in L2: participants were significantly slower and less accurate in L2 word recognition after rTMS compared to the sham condition. The VSA and behavioral results suggest that rTMS-induced disruption of M1 associated with speech articulators interfered with L2 speech production and recognition, indicating that inhibition in the speech motor system during speech perception is functionally related to L2 word recognition ability. No effect of rTMS was found on L1. Our results provide support for the role of M1 on L2 word recognition, and highlights the notion that speech perception and production systems are intricately intertwined when listening to speech under difficult circumstances.

Title: The effect of semantic relatedness on learning ambiguous words in a second language: An event-related potential study

Authors: *Y. LU, B. CHEN
Sch. of Psychology, Beijing Normal Univ., Beijing, China

Abstract: Ambiguous words, or words with multiple meanings, is a prevalent phenomenon across languages. For learners of a second language (L2), as their proficiency improves, they are constantly learning new words or new meanings of already known words. Recent research has revealed that when learning a new meaning of already known L2 words, the new meaning is easier to acquire if it is semantically related to the prior meaning than when it is unrelated. However, the mechanism underlying the semantic similarity effect remains poorly understood. In the current study, we adopted event-related brain potential (ERP) technique to directly examine the neural correlates of semantic similarity effect in learning L2 ambiguous words. With semantic relatedness as the experimental variable, three type of words, i.e. unambiguous words (as the control condition), polysemous words (which had two semantically related meanings) and homonyms (which had two semantically unrelated meanings) were set as study items, yielding five conditions, i.e., unambiguous words, the first meaning of polysemous words, the second meaning of polysemous words, the first meaning of homonyms, and the second meaning of homonyms. During a three-day learning phase, Chinese-English bilinguals learned 105 novel English words, 35 for each word type, using bilingual flashcards. The learning of the first meaning started one-day earlier than the learning of the second meaning, and all types of words were studied six times. The electrical activities of the brain were recorded during the whole learning phase, and at the end of each day, the semantic representations established for the studied items were probed through a multiple choice test, in which the learned English words were presented with four candidate meanings and participants had to choose the correct meaning. Behavioral results showed the performance of the second meaning of polysemous words was better than any other conditions. ERP results revealed that for homonyms, the second meaning elicited a larger N400 than the first meaning; for polysemous words, the second meaning elicited a larger late positive component (LPC) than the first meaning. Moreover, the second meaning of homonyms elicited a larger N400 than the second meaning of polysemous words. Taken together, these results suggest that when the new meaning is semantically unrelated to the prior meaning, the establishment of the new meaning may be interfered with by the semantic representation of the prior meaning; and when the new meaning is semantically related to the prior meaning, the creating of the new meaning representation may be facilitated through semantic familiarization.

Title: Sleep and memory consolidation of higher-order language combinatorics: Insights from oscillatory brain activity

Authors: *Z. R. CROSS[1], L. ZOU-WILLIAMS[2], M. J. KOHLER[2], M. SCHLESEWSKY[2], I. BORNKESSEL-SCHLESEWSKY[2]
[1]Sch. of Psychology, Social Work and Social Policy, [2]Univ. of South Australia, Adelaide, Australia

Abstract: Language learning is a dynamic process involving the coordination of brain networks that extract, consolidate and generalise the meaning of linguistic units of varying complexity. Neocortical slow oscillations (SO) and thalamic spindles during sleep facilitate the reactivation of newly encoded memory traces, manifesting in distinct oscillatory activity during retrieval, particularly in the alpha-band (α, ~ 8 - 13Hz). However, it is currently unknown if the effect of sleep on memory extends to the mechanisms that subserve sentence comprehension. Here we report an exploratory EEG study that assessed the role of sleep in the consolidation of a modified miniature language containing various word orders.
24 monolingual English speakers (11 male, mean age=26.2, ± 1.65 years) participated in one of two conditions (Morning, Evening). Both conditions involved an implicit learning phase, baseline sentence comprehension task, followed by either an 8hr sleep opportunity (Evening, n=10) or an equivalent period of wake (Morning, n=14) and a delayed comprehension task. EEG was recorded during the tasks and sleep opportunity. Relative α power was computed during sentence presentation, while spindle-SO co-occurrence was quantified during non-rapid eye movement sleep.
Linear mixed-effects modelling revealed a significant Condition (Morning, Evening) by Session (Baseline, Delayed) interaction ($\chi^2(1)=45.86$, $p<.001$): α power during sentence comprehension decreased from baseline to delayed testing in the Morning condition, but increased in the Evening condition. There was also a significant increase in α power for sentences with incorrect word orders ($\chi^2(5)=67.78$, $p<.001$), the effect being larger for the Evening versus Morning condition at delayed testing ($\chi^2(5)=41.24$, $p<.001$). A linear regression revealed that spindle-SO co-occurrence positively predicted delayed comprehension performance ($\beta = 0.09$, $p = .003$, $R^2 = .69$).
Increased α synchronisation for incorrect word orders may reflect a gating mechanism, modulating the downstream flow of information and supporting internal (predictive) model updating. Further, we found that the beneficial effect of spindle-SO co-occurrence on memory

extends to sentence-level combinatorics and coincides with increased α synchronisation for incorrect word order identification, which may reflect the communication between neuronal ensembles responsible for the comprehension of a newly learned language.

Title: Electrical stimulation while memorizing verbs and nouns: Comparison of tACS and tDCS in a single case study

Authors: *H. M. MUELLER, S. WEISS
Neurolinguistics, Bielefeld, Germany

Abstract: Oscillatory brain activity typically up to the upper two-digit Hz-range can be measured during several cognitive tasks. Brain oscillations mostly associated with memory processes lay within the theta range (4-7 Hz) but higher frequencies are involved, too. In order to test the influence of frequency specific AC-stimulation on verbal memory processes, we compared transcranial alternating current stimulation (tACS) with the results obtained with transcranial direct current stimulation (tDCS).A right-handed female (27 y) had to memorize 300 different visually presented concrete words and freely recall them after each block. The stimuli consisted of 150 nouns and 150 verbs, each randomly presented in blocks á 25 words for two times. tDCS, tACS (18 Hz, beta band) as well as sham stimulation were applied on different days for 20 min via electrodes placed at left frontal and temporo-parietal sites in a double-blind design. Current intensity was 1000 µA (or below individual phosphene threshold).A significant difference between the stimulation and sham condition (Pearson $\chi 2 = 12.0$, $p = .03$, two-tailed) was found which differed for nouns and verbs. During tACS-stimulation the participant showed an 48% increase of recalled nouns (8% for verbs), during sham an 20% (36% for verbs) increase. Overall error rate was higher for verbs (Pearson $\chi 2 = 11.73$, $p = .008$, two-tailed). The tDCS-condition showed comparable results.Results support the notion that oscillatory activity within multiple rhythms plays an important role for verbal memory tasks. Rather, different rhythms are associated with different components of a cognitive operation and a direct relation between certain oscillatory frequencies and distinct language processes seems unrealistic. Presumably, participants will profit more, if the applied tACS frequency is adjusted to the participant's

individual beta frequency. This may be one of the reasons why tACS was not superior to tDCS results.

Title: Eye voice coordination in Parkinson's disease

Authors: *Y. TERAO[1], S.-I. TOKUSHIGE[2], S. INOMATA-TERADA[3], Y. UGAWA[4]
[1]Kyorin Univ., Tokyo, Japan; [2]Kyorin Univ., Mitaka, Japan; [3]Kyorin Univ., Mitaka, Tokyo, Japan; [4]Fukushima Med. Unversity, Fukushima, Japan

Abstract: Patients with Parkinson’s disease suffer from various reading abnormalities such as increased number of progressive saccades, smaller saccade amplitudes, increased number of regressive saccades, and longer fixation durations. This may partly be ascribed to the abnormal oculomotor control in relation to reading, although the exact nature of this disturbance is unknown. Methods: We compared eye-voice coordination while subjects read aloud Japanese texts presented on a monitor placed 50cm in front of their eyes. Subjects were 19 patients with Parkinson’s disease (11 males, 7 females, age: 70.3±4.0) and 19 age-matched normal subjects (7 males, 12 females, age: 68.8±9.6). The gaze position on the monitor was recorded using a video-based eye tracking system (Eyelink 1000). The voice was simultaneously recorded by a microphone. The texts were presented horizontally from left to right in 5-14 lines, and consisted of Chinese characters and hiraganas (Japanese phonograms), each subtending a visual angle of 0.6-1.3 degrees. The number of saccades per unit time, the mean amplitude of saccades, mean duration of fixation, and the amount of time by which gaze preceded the voice (eye-voice lead) were analyzed and compared between subject groups. Results: Reading speed was reduced in PD patients than in normal subjects for all texts. Reading speed was slower when the letter size was smaller, and as the readability of the text decreased, for PD patients and normal subjects alike. The fixation positions showed a more reduced distribution in PD patients than in normal subjects. On average, the number of saccades per unit time was reduced, the mean saccade amplitude was smaller (PD 3.4±1.3 deg, normal 3.9±1.6 deg), while the mean saccade fixation duration was longer in the PD group (PD 303.4±66.2ms, normal 236.7±70.4ms). The frequency of regressive gaze movements was comparable between the two groups (PD 26.4%, normal

24.1%), as was the eye-voice lead (PD 122.2±61.1ms, normal 131.6±23.8ms). Discussion: The longer fixation duration and the decreased number of saccades per unit time may contribute to slower reading in PD patients. Eye voice lead, presumed to reflect the phonological working memory buffer, was not impaired in PD. The results are discussed in comparison with eye voice coordination in spinocerebellar ataxia patients.

Title: Brains on books: Event-structure semantics predict cortical responses to naturalistic language

Authors: *A. A. HAFRI, M. F. BONNER, J. C. TRUESWELL, R. A. EPSTEIN
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Events are not atomic; they have internal semantic structures that specify the relations among entities in the world. For example, despite differences in content, “the witch melted” and “the planet vaporized” have a common structure: an entity undergoing a state change. We attempted to identify representations of event structure in the human brain by using naturalistic linguistic stimuli and a voxelwise fMRI encoding model approach. We were inspired by the insight in linguistics that the syntactic frames in which verbs appear provide clues to the semantic structure of events (e.g. “Vader vaporized the planet” is grammatical while “Vader pounced the cat” is not, likely because the former indicates a State Change, the latter a Motion). Six participants listened to 3 hours of audiobook excerpts while undergoing fMRI. We constructed two models of the stimuli and tested how well each model captured the fMRI response in each voxel: (1) An event-structure semantic model (VerbNet). VerbNet is a database in which verbs are grouped into classes that share similar syntactic alternations. In our implementation, a verb token is assigned VerbNet features (e.g. ±Cause, ±State) based both on its class and its syntactic frame (e.g. intransitive). (2) A word distributional model (word2vec) in which vectors for each word are learned by a neural network based on co-occurrence statistics in a corpus. This model served as a comparison for our event-structure model, since similar distributional models have been found to predict fMRI responses to naturalistic speech (Huth et

al., 2016). In each voxel we used ridge regression to learn the feature beta weights in a 9 scan-run training set. We then used the learned weights to predict the fMRI timecourse of a held-out test set (5 scan-runs, new stimuli). Using the word2vec model, we predicted fMRI responses across cortex in individual subjects (i.e. we found a significant correlation between predicted and actual timecourses). This replicated previous work using word embeddings. Using the VerbNet model, on the other hand, we significantly predicted responses in temporal and inferior frontal regions and angular gyrus, areas previously implicated in language processing. Notably, 45% of verbs at test were novel (i.e. they did not appear in the training set), indicating that the success of the model reflects coding of event structure features rather than specific verbs. A control model in which features were randomly permuted between verb tokens showed no prediction accuracy. Altogether, our findings support the theory that an important aspect of how the brain represents event semantics is event structure, i.e. the nature of relations between entities.

Title: How selective is Broca's area for language syntax? A Bayesian neurostimulation meta-analysis

Authors: *M. JOHNSON[1], Y. BAEK[2], J. P. COETZEE[2], M. M. MONTI[2]
[2]Psychology, [1]UCLA, Los Angeles, CA

Abstract: Popular hypotheses propose that the classical language region known as "Broca's area" (left inferior frontal gyrus, LIFG, BA 44/45) may actually function as a shared neural resource for processing hierarchical, relational structures across multiple domains of cognition. To test this prediction, we conducted a novel neurostimulation meta-analysis, inspired by Poldrack's (2006) fMRI meta-analysis, to assess the selectivity of Broca's area for processing higher-order structures in six cognitive domains - action cognition, algebraic reasoning, artificial grammar, deductive reasoning, language syntax, and music syntax. A comprehensive literature search yielded a total of 41 neurostimulation studies on higher-order or syntactic processing across the six cognitive domains and involving stimulation of any brain region. Statistical contrasts reported in these studies were binary coded as showing either a presence or absence of a neurostimulation effect for cognitive syntax, yielding a total of 395 contrasts for language studies and 895 tests for nonlanguage studies. These contrasts were summarized into three different 2 x 2 factorial models for Bayesian probability inference, each involving a forward

inference (i.e., inferring an effect of cognitive change from a neurostimulation cause) and a reverse inference (i.e., inferring a neurostimulation cause from an effect of cognitive change). Model 1 compared stimulation of Broca's area versus any other region to a change in language syntax versus nonlanguage syntax. Model 2 compared stimulation of Broca's area versus any other region to the presence of absence of a change in only language syntax. Model 3 compared stimulation of any left hemisphere region versus any right hemisphere region to a change in language syntax versus nonlanguage syntax. The results for Model 3 indicated that the left hemisphere seems selective for language syntax, which is consistent with the known hemispheric laterality of language. For each model, the strengths of the inferences were assessed with Bayes factors as well as specificity and sensitivity metrics. The results for Models 1 and 2 indicated that, in general, Broca's area does not seem selective for language syntax, which supports proposed hypotheses of the domain-general role of Broca's area in higher-order cognition.

Title: The neural computations underlying relational reasoning

Authors: *J. CHIANG[1], Y. PENG[2], K. J. HOLYOAK[2], H. LU[2], M. M. MONTI[2]
[1]Psychology, [2]UCLA, Los Angeles, CA

Abstract: Analogical reasoning, a powerful tool for human thinking and learning, involves complex computations applied to abstract semantic representations. Solving a verbal analogy problem requires retrieving or constructing a relation for each of two pairs of concepts, and then mapping the two relations to determine whether they are identical. Previous studies have identified neural correlates of analogical reasoning, specifically regions of the prefrontal cortex (BA10 in particular), but the neural basis for specific subprocesses have not been clearly established. In the present study, we combine behavioral fMRI with computational modeling to probe the neural computations underlying relational reasoning. In a rapid event-related fMRI design, 16 healthy volunteers were asked to determine the relationship between two pairs of semantic concepts. Each analogy was presented as two pairs of words, an AB pair (e.g., up:down) followed by a CD pair (e.g., high:low). On each trial, the two pairs were presented sequentially, and the participant was asked to judge whether the relationship matched between the two pairs. Each participant performed 288 trials distributed over 8 blocks. Data were analyzed using a univariate GLM approach (FSL) to identify regions engaged in forming semantic relations and mapping. This analysis was extended by a multivariate analysis to relate

BOLD activity with computational models of semantic and analogical processing.
The primary univariate contrast of interest was the C:D - A:B subtraction, which can be interpreted as the neural activity associated with mapping the two relations. This contrast revealed parietal areas in addition to the expected prefrontal areas, corroborating previous findings. Multivariate analyses on the A:B pairs also revealed prefrontal, parietal and temporal regions that were involved in representing semantic relations. Representational similarity analysis also reveals that, at least at the computational level, our explicit models of relational mapping are implemented by prefrontal regions, in particular BA10.

Title: Evaluating the reliability of fMRI for single subject language mapping

Authors: *A. BAJRACHARYA[1,2], C. S. ROGERS[2], M. S. JONES[2], S. M. MCCONKEY[2], J. E. PEELLE[2,1]
[2]Dept. of Otolaryngology, [1]Washington Univ., Saint Louis, MO

Abstract: Accurate mapping of language areas in the brain is integral to pre-surgical planning and research. However, a gold standard that obtains test-retest reliability in a single subject level has not been achieved. Functional magnetic resonance imaging (fMRI) is one of the most widely-used non-invasive methods for brain imaging. We conducted a systematic search of published literature through Oct 2017 that addressed language mapping using fMRI. The search resulted in 421 papers which were screened for the presence of single subject data. Out of the 62 papers that passed the screening, less than 5% discussed reliability measures.
To quantify the test-retest reliability of a straightforward speech perception task, we analyzed two sessions of an event-related study of spoken word perception. We scanned 26 young adults (18-35 yrs) for 8 mins per measure using sparse fMRI. Participants heard either a word or noise (1-channel noise vocoded speech) and were instructed to repeat only the words.
Test-retest comparisons for whole brain activity were made for noise and word>noise conditions using two complementary approaches. First, we used the Dice coefficient for each subject, calculated on binarized t-maps (voxelwise $p < .001$, uncorrected) as a measure of the extent of reproducibility of the activation. Second, we conducted correlations across the whole brain on

unthresholded t-maps. Figures a and b show the test-retest overlaps from thresholded t-maps for the subject with highest correlation, scatter plot for test vs retest activations for the same subject, and bar graphs for Dice coefficients (top) and Pearson correlation coefficient (bottom) for all subjects. We observed that, word>noise condition produced greater overlap (higher Dice coefficient) in language regions compared to the noise condition.
The result suggests that certain tasks might be better suited for generating reproducible activation maps. The lack of reliability in the test-retest comparisons highlights the need for stringent methods with considerations for scan duration, and motion parameters for assuring data quality.

Title: Associations between music training and language learning on cognitive performance

Authors: *A. ZHU[1], J. A. BUGOS[2], J. BRYANT[2]
[1]Music Educ., [2]Univ. of South Florida, Tampa, FL

Abstract: This research examines the associations between musical training and multilingualism on cognitive control in adults. Neurological evidence suggests that musicians have an enlarged corpus callosum as compared to non-musicians which may result in better cognitive performance on cognitive control and task switching measures (Habibi et al., 2017; Moradzadeh, Blumentahl, & Wiseheart, 2014; Moreno & Farzan, 2014). Similarly, research in bilinguals suggests neurological differences attributed to enhanced performance on executive functions as compared to monolinguals (Blanco-Elorrieta & Pylkkänen, 2017; Perani et al., 2017). Although music is considered a language, very little is known about the relationship between instrumental musical training and language learning. There is theoretical and practical significance in the OPERA hypothesis (Patel, 2011a) and the language and music hierarchy parallel (Patel, 2011b), which would explain why music training could lead to neuroplasticity in speech and language processing. Fifty-six adults (19 bilingual non-musicians, 18 bilingual musicians, and 19 multilinguals) completed a series of measures in cognitive control and processing speed. Cognitive control was measured through the auditory and visual modalities using a standardized Stroop paradigm. Results suggest that multilinguals process visual information slower than bilingual non-musicians and musicians. Data also suggests that bilingual non-musicians process auditory information slower than bilingual musicians and multilinguals. Additionally, increased processing speed was found for bilingual musicians compared to multilinguals. However, bilingual musicians and bilingual non-musicians were seen to have performed similarly on measures of processing speed. This research suggests differential benefits in music training and language learning.

Title: Frontal and temporal mobile EEG characterization of the preparation and generation phases of the creative writing process: A pilot study

Authors: *J. G. CRUZ-GARZA[1], A. S. RAVINDRAN[1], M. J. DELGADILLO[2], A. E. KOPTEVA[1], C. RIVERA GARZA, Ph.D.[2], J. L. CONTRERAS-VIDAL, Ph.D.[1]
[1]Electrical and Computer Engin., [2]Hispanic Studies, Univ. of Houston, Houston, TX

Abstract: The development of mobile brain-body imaging (MoBI) technology allows the study the human creative process outside of constrained laboratory settings. We conducted a pilot study to investigate the neural features associated with creative writing using EEG metrics to compare different phases of the process (i.e. Preparation, Generation) within a creative writing course.
We used portable dry EEG systems (four channels: TP09, AF07, AF08, TP10) and video cameras, to record the brain activity of seven Spanish heritage students as they developed their creative writing skills in an undergraduate course on creative writing in Spanish. The students recorded their own brain activity as they walked through and experienced areas in the city (Preparation phase), and while they worked on their creative texts (Generation phase). Differences in brain activity for the distinct stages of the creative writing process have been unexplored in the EEG domain.
The EEG data was pre-processed and cleaned by identifying time segments where the acceleration surpassed 1 ms^{-2}, there was an indication of poor contact quality, and by using artifact subspace reconstruction. The data was then segmented in 6s windows with 25% overlap. From the time windows, we measured Partial Directed Coherence, sample entropy, and band-power changes between the Preparation and Generation phases of the creative writing task.
We found *a)* higher average Partial Directed Coherence during the Preparation phase. High coherence was observed in connections originating in the temporal electrodes towards frontal and temporal electrodes. *b)* We found higher values of sample entropy and *c)* higher relative power in the alpha, beta and gamma bands (8-50 Hz), with lower theta and theta band-power (1-12 Hz) during the Generation phase.
These findings suggest that ideation, exploration, and observation during the Preparation phase of a creative writing task can be characterized by a state of long-range cortico-cortical communication between multisensory integration brain areas (temporal regions) and high-order execution and planning areas of the brain (prefrontal regions), perhaps leading to selective storage of ideas, concepts or observations candidate for creating writing during the generation phase. During creative writing, slower cortical rhythms underlying long-range cortico-cortical communication decreased and the brain activity could be better characterized by focal activity in alpha, beta and gamma range. We hypothesize this focal activity may be related to working memory, sequence production, and processing of filtered information from the Preparation Phase.

Abstract: The ability to synchronize a motor output to an auditory input is a basic trait present in humans from birth with important cognitive implications. Infants' proficiency in following a beat, for example, is a predictor of language skills. From a phylogenetic perspective, spontaneous synchronization (i.e. without explicit training) to an external rhythm is argued to be a unique characteristic of vocal learning species, including humans. The study of this distinctive attribute has typically focused on how body movements are entrained by non-speech signals - e.g. music or a beat. Here, instead, we investigate how humans spontaneously align their speech motor output to auditory speech input.
To begin with, we introduce a simple behavioral task, where individuals simultaneously perceive and produce syllables, with a remarkable outcome. The general population shows two qualitatively different behaviors: while some individuals are compelled to temporally align their utterances to the external stimulus, others show no interaction between the perceived and produced rhythms. Subsequently, we investigate the neurophysiology and brain structure features underlying the segregation. First, with a magnetoencephalography protocol we show that, when passively listening to speech, synchronizers show increased brain-to- stimulus alignment over frontal areas as well as reduced rightward asymmetry in auditory cortex. Secondly, using diffusion weighted MRI technique, we find a distinct lateralization pattern in a white matter cluster -likely part of the arcuate fasciculus, pathway connecting frontal and auditory areas- that differentiated the groups, with synchronizers showing significantly greater left lateralization. Crucially, this structural difference relates to both the auditory and frontal neurophysiological results: increased leftward lateralization in the white matter was related to higher brain-to-stimulus synchrony in left frontal regions and to more symmetrical auditory entrainment. Finally, we demonstrate that the behavioral findings on audio-motor synchronization and its neural

substrate have ecologically relevant consequences: the synchronizers perform better on a word learning task.
In summary, the combined behavioral, neurophysiological, and neuroanatomic results reveal a fundamental phenomenon: whereas some individuals are compelled to spontaneously align their speech output to the speech input, others remained impervious to the external rhythm.

Title: "Where is she and what did she say?": Web-testing differentiates spatial and verbal episodic memory

Authors: *J. PANI, D. SOKOLOWSKI, H. RØE EVENSMOEN, T. HANSEN, A. HABERG
Dept. of neuromedicine and movement science, NTNU, Trondheim, Norway

Abstract: Impairment in episodic memory is an early symptom of dementia. Using our self-administered web-based neuropsychological test platform Memoro, we are currently investigating the distribution of cognitive abilities in one of the world's largest prospective population studies, Helseundersøkelsen i Nord Trøndelag 4 (HUNT4). The aim of this study is to assess whether Memoro can separate spatial and verbal episodic memory function, as changes in these cognitive functions can be differently affected in normal aging and disease.
Participants are recruited through an invitation letter sent via regular mail. Participants log on to Memoro with a subject specific userID and pin code. Here results from two memory tasks were included: Verbal Memory Test (VMT) which is a 18 word list learning task using a similar structure as the CVLT-II where measures of learning, immediate recall, delayed recall were extracted; the Spatial Memory Test (SMT) which is a 10 stimuli object-location memory task where measures of object identity, immediate recall and delayed recall were extracted. Factor analysis was performed through Parallel Analysis using "minres" extraction and oblivion rotation in Rstudio (version 3.3.3).
Data from 1359 participants (13-90 years of age, 731 female) completing the test to date were used. The factor analysis gave a two factor model with RMSR=0.01, RMSEA=0.05; Tucker-Lewis=0.988. With intercorrelation between factors of -0.31. Loadings are presented in Table 1.

Table 1
Summary of exploratory factor analysis (n=1359)

Measure	Verbal factor (3.13)	Spatial factor (1.57)
Verbal memory learning	0.83	-0.04
Verbal memory delayed recall	0.93	0.01
Verbal memory immediate	0.95	0.02
Spatial immediate recall [a]	0.03	0.98
Spatial object identity [b]	0.06	-0.68
Spatial delayed recall [a]	-0.09	0.51

Note. Yellow denotes verbal and blue spatial memory factors.
[a] higher value indicates worst performance
[b] higher value indicates better performance

Our preliminary results in 1359 participants show that the Memoro platform separated between spatial and verbal episodic memory functions. A similar separation is not seen with traditional pen/paper testing. Separating these memory functions, known to be underpinned by partly distinct brain regions, can increase our understanding and help distinguish normal aging from pathological. Moreover, this distinction will help us design specific ways to preserve cognitive capacities and hopefully stimulate a positive effect on the affected abilities.

Title: How do older and younger people do it? Assessing web-based neuropsychological participation in a large-scale population study

Authors: *D. SOKOLOWSKI[1], T. HANSEN[2], J. PANI[2], A. K. HABERG[2]
[1]Dept. of Neuromedicine and Movement Sci., [2]NTNU, Trondheim, Norway

Abstract: Web-based neuropsychological test batteries provide a unique opportunity to assess cognitive abilities in large-scale population studies. Using Memoro, our web-based battery, we

are currently investigating the distribution of cognitive abilities in one of the world's largest prospective general population studies; Helseundersøkelsen i Nord-Trøndelag (HUNT4). The aim of this study was to assess who participates, and how they participate in a study involving a web-based neuropsychological test battery.
People taking part in the HUNT4 study above age 13 are invited by regular mail to participate in this study. Participants are asked to log on to the Memoro website with a participant specific userID and pin code and perform 13 tasks using their PC or any other device with internet connection. Data concerning demographics and hardware/software used is also collected.
Out of the 2656 people (age 13 – 90) who participated in the study to date, 56.2% (n=1492) were female, 43.7% (n=1161) were male and 0.1% (n=3) declared other gender.
Most participants used PCs (66.2%), followed by iPads (14.6%), Mac computers (10.1%) and Android devices (5.8%).
The most widely used browser was Google Chrome (41.6%), followed by Safari (21.4%), Internet Explorer (14.3%) and Microsoft Edge (13.4%).
People in the age groups 50-59 and 60-69 had highest participation rates, making up 45.4% of all participants.
The older participants were, the earlier they took the test during the day ($F(1,76) = 1.865$, $p<0.000$, with $R^2 = 0.052$), with 3:20 pm being the average time for people in the age group 13-19 and 1:11 pm for the 70+ group.
Completing a whole battery took 43 min on average. People between 20-29 years were fastest with a mean completion time of 40 min while 70+ were the slowest, mean of 46m.
The vast majority of participants who completed the battery did so in one session (91.7%). The rest took two (7.3%), three (0.8%) or four (0.2%) sessions.
Across all ages, participants reported that they were "rather comfortable" (4) or "very comfortable" (5) with using computers ($\mu=4.41$, $SD=0.79$) using a 5-point Likert scale.
Out of all participants, 65.4% completed every task and 82.5% completed 11 or more.
In summary, those who participate in web-based cognitive testing and invited via regular mail are likely to be older adults, and all age groups feel proficient using computers. Older people take the test earlier in the day and take longer to complete. Knowledge about these details can help with interpreting results and creating test batteries with high participation and completion rate.

Geriatric Care, North York, ON, Canada

Abstract: Aim: Loss of ovarian hormones following spontaneous (natural) or surgical menopause is implicated in the elevated incidence of Alzheimer's Disease observed in women (Rocca et.al, 2007). It remains unclear how the loss of ovarian hormones contributes to cognitive decline; there is evidence that loss of estrogens leads to decreased hippocampal volume and function (Duchesne et al, 2017; Eberling et al, 2004), but research on the neocortex has been scarce with the exception of Witt et al., 2018. To continue investigating the effect of estrogen loss on the neocortex we compared structural scans of women with the BRCA mutation with preventative bilateral salpingo-oophorectomy (BSO) prior to spontaneous menopause to those of age matched controls (AMC). We asked whether early loss of ovarian hormones affects cortical thickness or performance on measures of attention and working memory. **Methods:** Participants in this study (n=34) were women recruited in Sweden and Canada who were divided into three groups: women with BSO not on hormone replacement therapy (HT; BSOnoHT), women with BSO on HT (BSOwHT), and AMC. All participants completed demographic and neurocognitive measures to assess attention and working memory. Scores on these tasks were compared between groups using a bootstrap approach with a General Linear Model (GLM). T1-weighted structural images were obtained using a Siemens or Phillips 3-T scanner and analyzed using the CIVET 2.1 pipeline. SurfStat software was used in the MATLAB environment to create a GLM that compared cortical thickness between BSO and AMC groups. **Results:** The BSOnoHT group performed significantly worse than the AMC and BSOwHT groups on the measure of attention and working memory, suggesting that HT protects against these cognitive declines following BSO. Correspondingly, the BSOnoHT group had significantly thinner right frontal cortices than AMCs, including the orbito, lateral, caudal, and dorsal frontal cortices. If the BSOwHT group is included in the analysis this effect disappears, suggesting that HT may also protect against the cortical thinning that can occur following BSO. **Conclusions:** These findings are preliminary and require further data collection to confirm the results. However, they suggest that early loss of

ovarian hormones following BSO is related to decreases in the thickness of the right frontal cortex (Witt et al., 2018) and poorer performance on working memory and attention tasks. Since attention and working memory depend, in part, on the prefrontal cortices (Kane & Engle, 2002), the thinning of the right frontal cortex may contribute to the poorer performance on tests of attention and working memory.

Title: Bilateral salpingo-oophorectomy reduces CA1 volume and impairs hippocampal-dependent memory in middle-aged women: Preliminary findings

Authors: *N. GERVAIS[1], A. ALMEY[2,1], A. DUCHESNE[3], R. REUBEN[1], L. GRAVELSINS[1], E. BAKER-SULLIVAN[1], A. WONG[1], R. K. OLSEN[4], C. L. GRADY[5], G. EINSTEIN[1]

Abstract: Considerable evidence demonstrates that estrogens have neuroprotective effects on the hippocampus (HPC). Estrogen loss via surgical menopause is associated with reduced verbal memory, and estrogen therapy (ET) prevents this reduction (Sherwin, 1988). Little is known about the impact of surgical menopause on the integrity of the HPC. Preliminary findings suggest that ET is protective in women that have had a BSO (Duchesne et al., 2017), yet no studies have examined the impact on HPC subfields. In addition to verbal memory, other abilities including associative memory are also sensitive to HPC function, yet limited studies have addressed the impact of estrogen deprivation on this ability. The aim of the present study is to determine whether BSO results in impaired associative memory and lower volume of HPC subfields. An additional aim is to determine whether ET is neuroprotective by preventing

negative changes resulting from BSO. Women with the BRCA mutation (BRCA 1/2) with a prophylactic BSO to reduce breast and ovarian cancer risk were recruited and comparisons were made between those taking estradiol-based ET (BSO-E2) and those not taking ET (BSO). Age-matched premenopausal women were also recruited and served as the comparison group (AMC) to both BSO groups. Demographic information was collected and a visual associative task was administered. This task involves an encoding phase, when face/name pairs are presented and participants are instructed to rate how well the name matches the face, and a test phase given 30 min later, when participants must identify the name previously paired with the presented face. Structural scans were obtained using a 3T Siemens scanner and volumes of HPC subfields were quantified manually using high-resolution T2-weighted scans. Preliminary group analyses (N = 21) were conducted on accuracy and response times obtained during the test phase of the memory task. While no group differences were observed on accuracy, the BSO group took longer to respond to correct trials, but not incorrect ones, indicating that they needed more time to recognize the correct association. The BSO group also had reduced CA1 volume. Performance and volume measures in BSO-E2 matched those in the AMC group. Taken together, these preliminary results suggest that BSO is associated with modest impairments in associative memory and a reduction in CA1 volume. E2-based ET appears to protect against these effects.

Title: Relation of white matter lesion load to cortical gray matter thickness in healthy aging

Authors: *P. K. BHARADWAJ[1,2], L. A. NGUYEN[1,2], G. A. HISHAW[3], T. P. TROUARD[4], J. R. MOELLER[7], C. G. HABECK[8], G. E. ALEXANDER[1,2,5,6,9]

Abstract: Cerebral white matter hyperintensities (WMH) measured by magnetic resonance imaging (MRI) are associated with vascular risk factors and are thought to reflect small vessel disease. Recently, Kern et al. (2017), used a multivariate technique, the Scaled Subprofile Model (SSM; Alexander & Moeller, 1994) to identify a WMH-related covariance network of regional gray matter volume related to differences in blood pressure control. Here, we sought to extend this multimodal multivariate approach, by deriving a covariance network of WMH-related cortical thickness (WMH-CTh), and to evaluate its relation to age and vascular risk in a cohort of community-dwelling, healthy older adults, 50 to 89 years of age. Volumetric T1 and T2-FLAIR MRI scans were acquired in 182 older adults (mean Age = 69.8 ± 10.4, 90F/92M, hypertension = 122N/60Y). Systolic blood pressure (SBP) was computed from average ambulatory blood pressure over 24 hours. T1 scans were processed using FreeSurfer v5.3 (Fischl et al., 2002) to extract cortical thickness values from 64 regions. Global WMH maps were generated from T1 and T2-FLAIR scans using a multispectral algorithm (Schmidt et al., 2012). The SSM was applied to regional cortical thickness measures to derive the covariance pattern related to total WMH load. The WMH-CTh pattern accounted for 15.1% of the variance in WMH load and was characterized by cortical thickness reductions bilaterally in superior temporal and right precentral regions, with bilateral relative increases in rostral and caudal anterior cingulate regions. Greater expression of the WMH-CTh pattern was associated with increasing age (r^2=0.36, p≤4.72E-19) and hypertension (r^2=0.03, p≤1.98E-2), but was not related to SBP (p = 0.15). After we controlled for gender, hypertension, diabetes, smoking history, and SBP, the relation between WMH-CTh and age remained significant (R^2 change=0.31, p≤2.49E-17). These results suggest that, in healthy older adults, aging is associated with an increasing relation between WMH lesion load and regional cortical thickness that is distinct from common vascular risk factors. Together, these findings support the use of multimodal network covariance methods to advance understanding of the relation between gray and white matter differences in the context of brain aging.

Title: Hippocampal mediation of subjective memory complaints differs by hypertension status in healthy older adults

Authors: *E. VAN ETTEN[1,4], P. K. BHARADWAJ[1,4], L. A. NGUYEN[1,4], G. A. HISHAW[2], T. P. TROUARD[3,4], G. E. ALEXANDER[1,4,5,6,7]
[1]Dept. of Psychology, [2]Dept. of Neurol., [3]Dept. of Biomed. Engin., Univ. of Arizona, Tucson, AZ; [4]Evelyn F. McKnight Brain Inst., Tucson, AZ; [5]Dept. of Psychiatry, Tucson, AZ; [6]Neurosci. & Physiological Sci. Grad. Interdisciplinary Program, Tucson, AZ; [7]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: Subjective memory complaints may be an important early indicator of cognitive aging. We previously found that in healthy older adults with hypertension, having mild memory complaints was associated with poorer objective memory performance than in those without memory complaints, but this difference was not observed in those without hypertension (Nguyen et al., 2016). In the present study, we sought to investigate whether differences in hippocampal volume underlie subjective memory complaints, if this relationship differs by hypertension status, and how the association is related to objective memory performance in healthy older adults. A cohort of 208 older adults [104F/104M, mean±sd age = 69.9±10.4, mean±sd Mini-Mental State Exam = 29±1.2, hypertension (yes/no) = 69/139], 50 to 89 years of age, completed a scale of subjective memory complaints and a battery of neuropsychological tests. T1-weighted 3T volumetric MRIs were processed using Freesurfer (v5.3) software to obtain right and left hippocampal volumes. Total intracranial volume (TIV) was computed using T1 scans with SPM12 and white matter hyperintensities (WMH) were computed using T1 and T2 FLAIR scans and a lesion segmentation toolbox. Mediation analyses were performed using PROCESS macro software in SPSS (Hayes, 2012). Analyses revealed that the mediation of the relation between age and mild subjective memory complaints by right hippocampal volume was moderated by hypertension status (-.03 (SE= .01), 95% CI, [-.06, -.01]). These findings remained significant after including gender, education, hypertension duration, WMH volume, and total recall on word list learning test as covariates. There were no significant mediation effects of the relation between age and memory complaints for left hippocampal volume with or without covariates. Additionally, a sequential mediation model in individuals with hypertension revealed that age predicted right hippocampal volume, which then predicted subjective memory complaints, and in turn predicted objective memory performance (-.16 (SE= .08), 95% CI, [-.38, -.05]). There were no significant sequential mediation models for left hippocampal volume or in individuals without hypertension. These results indicate that, in healthy older adults, the combination of mild subjective memory complaints and hypertension has an anatomical substrate, reflected by reduced right hippocampal volume, which in turn leads to differences in objective memory performance. Together, these findings suggest that mild memory complaints may provide an

early marker of cognitive aging, when observed in the context of hypertension, a common age-related vascular risk factor.

Title: Relation between physical sport activity and white matter hyperintensity volume in older adults

Authors: *M. FRANCHETTI[1,8,9], P. K. BHARADWAJ[1,8,9], L. A. NGUYEN[1,8,9], Y. C. KLIMENTIDIS[2], G. HISHAW[3], T. P. TROUARD[4], D. A. RAICHLEN[5], G. E. ALEXANDER[1,6,7,8,9]
[1]Dept. of Psychology, [2]Epidemiology and Biostatistics, Col. of Publ. Hlth., [3]Dept. of Neurol., [4]Biomed. Engin., [5]Sch. of Anthrop., [6]Neurosci. & Physiological Sci. Grad. Interdisciplinary Program, [7]Psychiatry, Univ. of Arizona, Tucson, AZ; [8]Evelyn F. McKnight Brain Inst., Tucson, AZ; [9]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: Cerebral white matter lesion load, as measured by white matter hyperintensities (WMHs) on MRI, have been associated with cardiovascular risk factors like hypertension as well as increasing age and poorer cognitive performance. Physical activity (PA) may play an important role in maintaining cerebral white matter (WM) in the context of healthy aging. We sought to determine whether high levels of self-reported physical sport activity are associated with lower WMH volume. Self-report ratings of physical sport activity were obtained from 196 healthy older adults (mean ± SD age = 69.8 ± 10.6 years). Participants reporting high sport activity (n=36) were compared to those with low sport activity (n=160). MRI scans were acquired at 3T, including volumetric T1 and T2 FLAIR scans. Total WMH volume was computed with a multispectral, automated lesion segmentation method to produce probability maps using Statistical Parametric Mapping (SPM12) and the lesion segmentation toolbox (LST; Schmidt et al., 2012). ANCOVA tested age group (young-old (YO) = 50-69 years; old-old (OO)

= 70-89 years), PA group, and age by PA group interaction effects after controlling for gender and hypertension status. No main effect for PA group ($p > 0.05$) was observed. We found a main effect for age group ($p = 0.005$) and age by PA group interaction ($p = 0.005$). Simple effect analyses indicated that total WMH volume for the high PA group is comparable between the YO and OO. In addition, the OO with low PA had a significantly higher WMH volume than both the YO with low PA ($p = 2.72E-10$) and the OO with high PA ($p = 0.00038$). These findings remained significant after correcting for total intracranial volume (TIV). These results suggest that high levels of physical sport activity may be an important lifestyle factor that can help to diminish WMH lesion load in old age, potentially reducing the impact of brain aging.

Title: Systemic inflammation is associated with longitudinal changes in cognitive performance among urban adults

Authors: *M. A. BEYDOUN[1], G. A. DORE[1], J. A. CANAS[4], H. LIANG[5], H. A. BEYDOUN[6], M. K. EVANS[2], A. B. ZONDERMAN[3]
[2]Lab. of Epidemiology and Population Sci., [3]Lab. Of Epidemiology And Population Sci., [1]NIA/NIH/IRP, Baltimore, MD; [4]Pediatric Endocrinol., Nemours Children'S Clin., Jacksonville, FL; [5]Hlth. Policy And Mgmt., Johns Hopkins Sch. Of Med., Baltimore, MD; [6]Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: BACKGROUND: Chronic systemic inflammation is a risk factor for neurodegeneration. In two waves of data, we examined the association of systemic inflammation with cognitive performance in 1,555-1,719 White and African-American adults aged 30-64y at baseline (2004-2013, mean±SD time(y) between visits: 4.64±0.93y). **METHODS**: Baseline cognitive performance and annual rate of cognitive change were assessed by eleven cognitive tests measuring mental status, attention, memory, executive function, visuo-spatial, psychomotor speed, and verbal abilities. Exposures were baseline serum C-reactive protein, Erythrocyte Sedimentation Rate (ESR), albumin, iron and an inflammation composite score combining all four markers (ICS). Linear mixed-effects regression models were conducted. **RESULTS**: Baseline serum CRP was associated with poorer baseline mental status among younger women (γ_{01}=-0.03±0.01, p=0.002) and poorer attention among older women(γ_{01}=-0.024±0.007, p<0.004)

and African-Americans(γ_{01}=-0.029±0.008, p<0.001). Baseline ESR was associated with a faster decline in verbal memory among older men (γ_{11}=-0.008±0.003, P=0.009); with poorer performance on tests of attention overall (γ_{01}=-0.010±0.003, P=0.003) and among African-Americans (γ_{01}=-0.013±0.004, P=0.002); on a test of verbal fluency among older women (γ_{01}=-0.037±0.013, P=0.004) and on a test of executive function, overall (γ_{01}=+0.62±0.21, P=0.004), among older men (γ_{01}=+1.69±0.53, P=0.001) and among African-Americans ((γ_{01}=+0.84±0.28, P=0.002). In contrast, serum albumin was linked to slower attention decline among older men (γ_{11}=+0.329±0.103, P=0.009), over-time improvement in executive function in the total population (γ_{11}=-6.00±2.26, P=0.008), and a better baseline performance in psychomotor speed among African-Americans (γ_{01}=+0.56±0.19, P=0.003). There were no significant associations between serum iron and cognitive outcomes. Finally, the ICS was associated with faster decline on a test of visual memory/visuo-constructive abilities, among older men only (γ_{11}=+0.17±0.06, p=0.003). **CONCLUSIONS**: There were strong associations between systemic inflammation and cognitive performance at baseline and over time for several domains of cognition, largely among older individuals and African-Americans. Future randomized trials should monitor systemic markers of inflammation and cognitive performance over time.

Title: Sex differences in brain-behaviour correlations in episodic memory: An adult lifespan study

Authors: *S. SUBRAMANIAPILLAI[1,3], S. RAJAGOPAL[3], S. PASVANIS[3], D. TITONE[1], M. RAJAH[2,3]
[1]Psychology, [2]Psychiatry, McGill Univ., Montreal, QC, Canada; [3]Douglas Brain Imaging Centre, Douglas Inst., Montreal, QC, Canada

Abstract: Healthy aging is associated with episodic memory decline (i.e., our ability to encode, store and retrieve personally experienced events in rich contextual detail). Prior studies have shown a tendency for women to outperform men on episodic memory tasks. For example, women perform better than men on object-location associative and face memory tasks (Herlitz

and Rehman, 2008). Many sociocultural and biological factors likely contribute to these sex differences in performance, which in turn may impact the functional neural networks supporting episodic memory in women, compared to men. This raises the possibility for the presence of sex differences in brain aging, particularly in episodic memory networks. In the current event-related fMRI study, we investigated sex differences in brain activity during face-location associative memory tasks across the adult lifespan (N = 86, mean age = 46.5 yrs, 50% females). Participants were scanned during encoding and retrieval. Our behavioural results indicate a robust effect of age on memory performance but no sex differences in face-location retrieval accuracy nor reaction time. However, our multivariate behaviour Partial Least Squares fMRI analysis revealed significant interaction between age and sex at encoding and retrieval. Specifically, in women, there was an age-related increase in parahippocampal activity at encoding. In contrast, in men, there was an age-related increase in parahippocampal activity at retrieval. In addition, only in men, there was a generalized pattern of inferior parietal activity across encoding and retrieval with advanced age. Overall, men and women engaged similar brain networks during memory encoding, but sex differences were observed in retrieval-related activity.

Title: Frontal functional connectivity as a measure of cognitive reserve: An optical imaging study

Authors: *A. V. MEDVEDEV
Ctr. for Functional and Mol. Imaging, Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Aims. Cognitive reserve (CR) is the ability to preserve cognitive functions in the presence of brain pathology. One commonly used proxy measure of CR is IQ. In the context of Alzheimer's disease (AD), patients with higher CR show better cognitive performance relative to brain damage therefore higher CR reduces the risk of dementia. There is a strong need to develop a reliable biomarker of CR given the growing interest in understanding protective brain mechanisms in AD. Recent fMRI studies indicate that frontoparietal network may play an important role in the maintenance of CR. The goal of this study was to demonstrate that near

infrared spectroscopy (NIRS) can be used to assess functional connectivity (FC) of the prefrontal cortex (PFC) in correlation with IQ, a proxy measure of cognitive reserve.
Methods. We analyzed resting state optical data from prefrontal cortex in 13 healthy individuals who were also assessed by Wechsler Abbreviated Scale of Intelligence (WASI) test and the Purdue Pegboard test (PPT). For each participant, activity of each prefrontal channel was correlated with all other channels and positive correlation coefficients were Fisher-transformed and averaged over all PFC channels giving the Global Functional Connectivity (GFC) of PFC. The resulting GFC number was then correlated with the individual IQ (WASI full score) and the PPT scores.
Results. Frontal connectivity was found to be significantly greater in the quartile subgroup of participants with higher IQ scores (the mean IQ = 131 ± 1.2; the mean GFC = 0.69 ± 0.18) compared to the quartile subgroup with lower IQ scores (the mean IQ = 113 ± 4.3; the mean GFC = 0.36 ± 0.16; the differences between subgroups in IQ and GFC are significant). Moreover, the individual GFC values were found to positively correlate with the individual IQ scores and negatively correlate with the PPT scores. These results demonstrate that optically measured PFC GFC can be used as a physiological measure of cognitive reserve.
Conclusions. Our data provide further confirmation that cognitive reserve depends on the functional integrity of the frontoparietal network, a major cognitive control hub. Also, our experimental approach demonstrates that functional connectivity can be assessed by optical imaging using the NIRS technology. As a cost-efficient and noninvasive technology, NIRS can be used in the development of new neurophysiological measures of cognitive reserve with numerous possible applications in the context of healthy aging and cognitive disorders.

Title: Ultrastructural mapping of phosphodiesterase 4D (PDE4D) in rhesus macaque dorsolateral prefrontal cortex: Plausible role in the etiology of Alzheimer's disease

Authors: *D. DATTA[1], Y. M. MOROZOV[3], J. I. ARELLANO[2], P. RAKIC[5], A. F. ARNSTEN[4]
[2]Neurobio., [1]Yale Univ., New Haven, CT; [3]Dept Neurobiol, [4]Yale Univ. Sch. Med., New Haven, CT; [5]Yale Univ. Sch. Med, Dept of Neurosci., New Haven, CT

Abstract: Tau pathology in Alzheimer's disease (AD) targets pyramidal cells in the aging association cortices, including the newly evolved dorsolateral prefrontal cortex (dlPFC). Our recent data revealed that aging rhesus macaques can be used to study late-onset AD pathology, as they recapitulate the qualitative pattern and sequence of tau and amyloid pathology seen in humans (Paspalas et al, Alzh&Dementia, epub Dec 11, 2017). Tau normally stabilizes microtubules, but phosphorylation by cAMP-PKA signaling at pS214Tau causes tau to detach from microtubules and fibrillate into classical paired helical filaments in tangles, and primes tau for hyperphosphorylation by GSK3β. These pathological alterations are associated with concurrent phosphorylation by cAMP-PKA signaling of type II ryanodine receptors (RyR2) at pS2808RyR2, suggesting calcium dysregulation. cAMP-PKA signaling becomes dysregulated in the aging dlPFC due to loss of phosphodiesterase (PDE4) activity, contributing to cognitive impairment and PKA-phosphorylation at pS214Tau (Carlyle et al, PNAS 111:5036-41, 2014). Previous research focused on the PDE4A isozyme, but PDE4D is of greater interest, as it is the predominate PDE4 in cortex, and PDE4D expression decreases with advancing age in the human dlPFC. However, the subcellular localization of PDE4D in dlPFC neurons is unknown. The current study used high-spatial resolution immunoelectron (immunoEM) microscopy to examine the subcellular distribution of PDE4D in layer III of the young adult primate dlPFC, the neurons that generate working memory. PDE4D was especially prominent in dendrites near microtubules and on the smooth endoplasmic reticulum (SER), in close proximity to mitochondria. There was also significant postsynaptic labeling in dendritic spines, in association with the SER spine apparatus near glutamate-like axospinous synapses. Importantly, these are the same sites where PKA pS214Tau accumulates in aged dlPFC. Our findings suggest that PDE4D is critically positioned in dlPFC glutamatergic microcircuits to modulate cAMP regulation of calcium signaling. Loss of PDE4D expression with advancing age may render association cortices particularly susceptible to cAMP dysregulation of internal calcium release, and cAMP-PKA phosphorylation of tau, factors which increase risk of AD. These events in the aging association cortex may provide an opportunity for therapeutic intervention at early stages of disease.

Title: “How do you feel about your future?” Results of the study of knowledge and reactions to amyloid testing (SOKRATES), a qualitative study of cognitively normal older adults’ reactions to learning an “elevated” or “not elevated” PET scan result

Authors: *J. H. KARLAWISH, S. STITES, E. LARGENT, B. BEAR, K. HARKINS
Univ. of Pennsylvania, Philadelphia, PA

Abstract: The diagnostic criteria of late-life neurodegenerative diseases such as Alzheimer’s disease is transforming from using clinical to biomarker-based features. Measures of brain amyloid are, for example, used to define a pre-clinical stage of Alzheimer’s disease, and several clinical trials are testing anti-amyloid drugs in adults who are cognitively unimpaired but have PET scan measured evidence of “elevated” brain amyloid. One goal of the SOKRATES Study is to discover how knowledge of an amyloid result impacts on an adult’s perception of their future and the behaviors they adopt. Samples of persons with “elevated” amyloid (n=50, median age 72, range 65 to 85) who were enrolled in a five year long, multi-center, 1,800 subject, randomized and placebo controlled trial of an anti-amyloid drug and persons with “not elevated” amyloid (n=30, median age 70, range 65 to 80) who were ineligible for the trial participated in telephonic semi-structured interviews 1-3 months after learning their PET scan results and again 12 months later. Subjects were recruited from 10 research centers in the U.S. Answers to “*How do you feel about your future?*” and “*How did learning your result change how you feel about your future?*” were analyzed qualitatively. Persons with not elevated amyloid reported sustained feelings of relief and optimism. Initial reports of expansive remaining time had somewhat diminished. In contrast, persons with elevated amyloid provided nuanced responses, reporting that the future is unknown but hopeful, being present focused, not thinking about the future, or feeling that remaining time is limited. Some described optimism. Initial reports of pessimism and a bleak future diminished at 12 months. None reported feelings of relief, and few felt an expansive sense of remaining time. Answers to “*Are you changing or reassessing any plans in your life since learning your result?*” showed that about half of the persons with elevated amyloid were not at either time point. The other half were considering making plans related to a variety of life and health matters. Few with not elevated amyloid were considering any changes. These results suggest that knowledge of “elevated” brain amyloid causes a cognitively normal older to experience changes in how they feel about their future and these feelings may in turn lead to changes in behavior. In contrast, persons who learn a “not elevated” result generally report relief with little behavior change. The presentation will discuss how these results are explained by future time perspective, and their implications for how we define and understand cognitive aging and the decisions older adults make.

Title: Genetic predisposition for inflammation exacerbates effects of striatal iron content on cognitive switching in healthy aging

Authors: A. M. DAUGHERTY[1], K. M. KENNEDY[2], *K. M. RODRIGUE[3,2]
[1]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois, Urbana-Champaign, Urbana, IL; [2]Ctr. for Vital Longevity, The Universty of Texas at Dallas, Dallas, TX; [3]Univ. Texas, Dallas, Dallas, TX

Abstract: Non-heme iron homeostasis interacts with inflammation bidirectionally, and both factors contribute to age-related decline in brain structure and function via oxidative stress. Thus, individuals with genetic predisposition toward inflammation may be at greater risk for brain iron accumulation during aging and more vulnerable to cognitive decline. We examine this hypothesis in a lifespan sample of healthy adults (N = 183, age 20-94 years) who underwent R2*-weighted magnetic resonance imaging (MRI) to estimate regional brain iron content. Interleukin 1β (IL-1β) is a pro-inflammatory cytokine and the T allelle of the single nucleotide polymorphism increases risk for chronic neuroinflammation; thus, heterozygote (n = 87) and homozygote (n = 23) T-carriers were considered to have greater inflammation risk than non-carriers (n = 73). Hypotheses were tested in a grouped latent modeling framework and all estimates were bootstrapped with bias-correction to produce 95% confidence intervals (BS 95% CI). Across individuals, older age was associated with greater striatal iron content ($b = 0.21$, $p < 0.001$; BS 95% CI: 0.16/0.29) that in turn accounted for poorer cognitive switching performance ($b = -0.26$, $p < 0.001$; BS 95% CI: -0.45/-0.17). However, heterozygote IL-1β T-carriers demonstrated worse switching performance in relation to striatal iron content ($b = -0.43$, $p < 0.001$; BS 95% CI: -0.80/-0.22) as compared to their no-risk counterparts (difference = 0.26, $p = 0.02$; BS 95% CI: 0.00/0.68), despite the two groups being of similar age. With increasing genetic inflammation risk, homozygote IL-1β T-carriers had lesser age-related variance in striatal iron content as compared to the other groups (difference = 0.19 and 0.15, p's = 0.002), but showed a similar association of greater striatal iron content predicting poorer cognitive switching (both p's > 0.80). Non-heme iron and inflammation, although necessary for normal neuronal function, both promote oxidative stress that when accumulated in excess, drives a complex

mechanism of neural and cognitive decline in aging. These findings highlight the importance and utility of investigating epigenetic effects in the study of individual differences in brain and cognitive aging.

Title: Age-related striatal iron accumulation is associated with decreased dynamic range of activation to working memory load and predicts executive function performance

Authors: K. M. RODRIGUE[1], A. M. DAUGHERTY[2], C. M. FOSTER[1], *K. M. KENNEDY[3]
[1]Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX; [2]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois, Urbana-Champaign, Urbana, IL; [3]Behavioral & Brain Sci., Univ. Texas, Dallas, Dallas, TX

Abstract: Non-heme iron accumulation contributes to age-related decline in brain structure and function via a cascade of oxidative stress and inflammation. Although recent evidence illustrates the negative effects of increased iron content on human brain structure and cognition, its effect on brain function is largely unexplored. Thus, we examine, in vivo, using R2*-weighted magnetic resonance imaging (MRI), the impact of basal ganglia (BG) iron accumulation on the dynamic range of BOLD modulation to increasing cognitive challenge across the adult lifespan. Participants included 166 healthy adults (age 20-94 years) who underwent cognitive testing and an imaging session including n-back (0-, 2-, 3-, and 4-back fMRI collected across 3 blocks for 20min), R2*-weighted imaging, and pcASL to measure cerebral blood flow. A first-level linear contrast was computed that identified regions that either up- or down-modulated in response to task difficulty. At the second level, BOLD modulation was predicted by age, BG iron, age by BG iron, controlling for cerebral blood flow, sex, and task response time. We found a traditional set of working memory-related brain regions that up-modulated in response to task difficulty (bilateral dorsolateral prefrontal cortex, anterior cingulate, caudate, posterior parietal, cerebellum). Regions that down-modulated in response to difficulty included typical regions associated with the default mode network. Importantly, we found a significant interaction between age and BG iron burden on positive BOLD modulation in a cluster located primarily in

the putamen, caudate, and inferior frontal gyrus. The interaction indicated that greater iron content was associated with reduced modulation to difficulty, and this effect was strongest in younger adults with greater iron burden. Further, iron-related decreases in modulation were associated with poorer executive function performance outside the scanner in an age-dependent manner (BOLD modulation x iron x age interaction, p = .056). A simple slopes analysis of the interaction indicated that the slope of age on executive function is less steep in high-modulating, low iron individuals, and also less steep in low-modulating, high iron individuals. These findings suggest that striatal iron accumulation negatively alters dynamic range of modulation to difficulty locally and in prefrontal cortex. This iron-related alteration in BOLD response is also associated with poorer executive function performance, linking the iron cascade to brain function and cognitive outcome.

Title: Amyloid-beta spreads from multiple sources in healthy aging

Authors: *K. ARNEMANN[1], L. DIGMA[2], W. J. JAGUST[3,4]
[1]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA; [2]Helen Wills Neurosci. Inst., Berkeley, CA; [3]Helen Wills Neurosci Inst., Univ. of California, Berkeley, CA; [4]Div. of Mol. Biophysics and Integrated Bioimaging, Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: The hallmark pathology of Alzheimer's disease, amyloid-β plaques (Aβ), typically exhibits advanced progression throughout cortex by the time cognitive symptoms manifest. Despite a characteristic spatiotemporal progression of Aβ pathology in the pre-symptomatic phase, there is no consensus on the earliest brain areas that accumulate Aβ. We developed a novel cross-sectional approach to examine regional accumulation relative to the total amount of Aβ pathology in the brain within different stages of Aβ progression in healthy aging - PIB-, Early PIB+, and Late PIB+ - by examining PIB-PET from 147 cognitively normal older adults (aged 65 to 91 years old) as well as from 16 young adults (aged 21 to 30 years old). We modeled the cross-sectional rates of accumulation to generate directed progression networks, which

measure progression from earlier to a later Aβ stages by drawing connections emanating from regions with accelerated accumulation in earlier Aβ stages and emanating to regions with accelerated accumulation in later Aβ stages. We identified potential sources of Aβ pathology in the PIB- stage, relays in the Early PIB+ stage, and targets in the Late PIB+ stage. The sources, relays, and targets of Aβ pathology were distributed across the brain, comprising multiple brain networks. The largest number of sources and relays were in the default mode network, however all regions of the memory network were impacted. Relays, and to a lesser extent sources, additionally impacted the other higher order brain networks whereas the targets primarily impacted sensory networks. This framework suggests that distributed brain areas across multiple networks may serve as sources of Aβ even before substantial Aβ pathology is detected in healthy aging. While specific brain networks such as the default mode and memory networks may be particularly impacted, especially as Aβ pathology progresses, accumulation of Aβ pathology is diffuse, multifocal, and does not appear to emanate from any single source or brain network.

Title: Cortical excitability as a marker of global cognitive function in pathological cognitive aging

Authors: *P. J. FRIED[1], S. S. BUSS[1], K. M. MCDONALD[1], D. Z. PRESS[1], A. PASCUAL-LEONE[1,2]
[1]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Inst. Guttman, Univ. Autonoma de Barcelona, Barcelona, Spain

Abstract: Background. Transcranial magnetic stimulation (TMS) provides a noninvasive means to assess cortical excitability and the efficacy of neuroplastic mechanisms in humans. Recently, cortical hyperexcitability, as indexed by the TMS resting motor threshold (RMT), has emerged as a potentially meaningful correlate of cognitive function in mild-to-moderate Alzheimer's disease (AD). Previous work has shown that RMT tends to be lower in AD patients than healthy controls and negatively associated with global cognitive dysfunction (lower RMT = greater dysfunction). It is unknown whether this relationship extends to older adults with Type-2 diabetes mellitus (T2DM) or mild cognitive impairment (MCI), who are at a higher risk of

developing AD.
Objective. The objective of the present study is to assess the relationship of RMT to measures of global cognitive function in patients with T2DM and those with MCI.
Methods. In a cross-cohort study, data were obtained from 18 patients with a diagnosis of probable amnestic MCI (mean ± SD age: 69.4 ± 9.3 years, 47% female) and 28 patients with T2DM (mean ± SD age: 65.8 ± 7.7 years, 43% female). Data included RMT (% of maximum stimulator output) and two measures of global cognitive function, the Mini Mental Status Examination (MMSE) and the Cognitive subscale of the Alzheimer's Disease Assessment Scale (ADAS-Cog).
Results. The MCI group performed significantly worse than T2DM on the MMSE (MCI: 25.8 ± 2.8; T2DM: 29.0 ± 1.0, $p < .001$) and the ADAS-Cog (MCI: 11.5 ± 4.4; T2DM: 6.0 ± 2.8, $p < .001$). RMT was significantly ($p = .012$) lower in MCI (58.8 ± 8.3) than T2DM (66.4 ± 11.4). Linear regression analyses yielded significant relationships between RMT and both MMSE ($p = .009$) and ADAS-Cog scores ($p = .009$), controlling for group. Specifically, lower RMT was associated with worse performance on both measures.
Conclusion. Lower RMT is associated with worse global cognitive function in individuals at risk of developing AD. Future longitudinal studies are needed to determine if cortical hyperexcitability, as indexed by TMS, can serve as a prognostic marker of cognitive decline in preclinical dementia.

Title: Eight-year longitudinal change in association cortical thickness: Progression from cognitively healthy to dementia

Authors: *S. L. WILLIS, P. R. ROBINSON, E. ULZIIBAATAR, T. J. GRABOWSKI, K. SCHAIE
Univ. of Washington, Seattle, WA

Abstract: Understanding the transition from cognitively normal status to a diagnosis of dementia and the risk factors predicting this transition is a major public health goal. This requires

longitudinal studies, following individuals over time. This study examined 8-year longitudinal change in cortical thinning in progression from cognitively healthy to dementia diagnosis. At baseline, all participants in the Seattle Longitudinal Study were nondemented (N=185; mean age = 16.3; 58% female; 31% APOE e4; and 42% hypertensive. Over 5 measurement occasions (8 years), N = 15 participants progressed to dementia. These participants were older, had higher proportion APOE e4, and hypertensive, but did not differ in education. Multivariate multilevel modeling was used to examine cross-sectional differences and longitudinal change in cortical thinning for 5 cortical composites (Frontal, Parietal, Temporal, Occipital, Cingulate). Using the Freesurfer suite, regions from the Desikan Parcelation were aggregated to form lobar composites of association cortex. Composites were modeled together at the whole brain level; regions within each composite were also modeled together. The modifying effects of APOE e4 and hypertension were examined. Results: Significant age differences (cross sectional) were found for all 5 composites. Dementing participants had thinner cortex at baseline in Frontal, Parietal, Temporal and Cingulate composites; and were more likely to be hypertensive (HB x Dementia) for these composites. For the Parietal composite and Parietal regions (inferior, precuneus), a faster rate of thinning occurred for participants progressing to dementia (Time x Dementia). No interactions of dementia status and APOE were found. These longitudinal findings extend prior cross-sectional reports between cortical thinning and progression to dementia.

Title: Age-related neural dedifferentiation extends beyond visual cortex and is driven by less reliable neural activation

Authors: *M. SIMMONITE[1], K. E. CASSADY[1], H. C. GAGNON[1], P. S. LALWANI[1], S. F. TAYLOR[2], D. H. WEISSMAN[1], R. D. SEIDLER[3], T. A. POLK[1]
[1]Dept. of Psychology, [2]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI; [3]Dept. of Applied Physiol. and Kinesiology, Univ. of Florida, Gainsville, FL

Abstract: According to the neural dedifferentiation hypothesis, age-related cognitive declines stem in part from reductions in the distinctiveness of neural representations; that is, neural activity associated with different stimulus categories becomes less distinguishable with age and

behavioral performance suffers as a result. Almost all previous studies have investigated age-related dedifferentiation in the visual cortex, using visual tasks. Increasing evidence however, suggests that dedifferentiation may be a more general feature of the aging brain, present in other brain regions. In the present study, we used 3T functional MRI to investigate age-related dedifferentiation not only in the visual cortex during a visual task (oddball detection during face and house blocks), but also in the auditory cortex during an auditory task (oddball detection during speech and music blocks), in somatosensory cortex during a somatosensory task (oddball detection during vibrotactile stimulation to fingers of the left and right hand), and in motor cortex during a motor task (directed movement of left and right hand). Participants were 21 young adults (aged 18 to 29) and 24 older adults (aged 65 +), who completed all four tasks. Activation patterns across different blocks within the same conditions were correlated (within-condition correlation, a measure of reliability) as were activation patterns across blocks from different conditions (between-condition correlations, a measure of dissimilarity). Neural distinctiveness was defined as the difference between the mean within- and between-condition correlations, averaged over all such pairwise comparisons. We found age-related reductions in neural distinctiveness in the visual, auditory and motor cortices, but not somatosensory cortex. In visual and auditory cortex, these effects were driven by age-related differences in within-condition correlations, not between-condition correlations. Additionally, neural distinctiveness in each brain region was not significantly correlated with distinctiveness in the other regions after correcting for multiple comparisons. These findings indicate that age-related reductions in neural distinctiveness extend beyond the visual cortex, and may be driven primarily by age-related reductions in the reliability of neural activity.

Title: Decline in functional connectivity between resting state networks after total knee arthroplasty with general anesthesia in older adults

Authors: *H. HUANG, C. HARDCASTLE, J. TANNER, H. PARVATANENI, C. PRICE, M. DING
Univ. of Florida, Gainesville, FL

Abstract: Our previous work has shown that functional connectivity within each of the three major resting state networks (RSNs), including default mode network (DMN), salience network (SN) and central executive network (CEN), declines after total knee arthroplasty with general anesthesia in older adults. In this study we examined the changes in functional connectivity between the three RSNs before and after surgery. Particular emphasis was placed on the impact of pre-surgery cognitive status on pre- to post-surgery changes in internetwork functional connectivity. Participants included 69 non-demented older individuals (average age: 68.7, 36 women) who elected for unilateral total knee arthroplasty surgery and 65 non-surgery controls (average age: 68.4, 37 women) matched on age, sex, education, and race. 13 surgery patients and 10 controls met the criteria for mild cognitive impairment (MCI). Resting state fMRI scans were acquired before surgery and within 48 hours after surgery (a pseudo surgery date was defined for each control). Pre-surgery and post-surgery functional connectivity between DMN, SN and CEN was computed and compared. The following results were found. For patients, the magnitude of functional connectivity between DMN and SN declined significantly after surgery. Comparing effect size, relative to patients without MCI, patients with MCI exhibited more pronounced DMN-SN functional connectivity decline (d=1.5 for MCI versus d=0.7 for non-MCI). There were no significant changes in DMN-CEN and SN-CEN internetwork functional connectivity. For controls, there were no significant changes in any of the internetwork functional connectivities. These results suggest that (1) DMN-SN functional relationship, one of the most important in the brain, is vulnerable to the disruption of major surgery and (2) impaired cognition is a major risk factor.

Title: Little effect of computerized cognitive training or expectations in healthy older adults

Authors: *S. RABIPOUR, C. MORRISON, J. CROMPTON, M. PETRUCELLI, M. GERMANO, A. POPESCU, P. S. R. DAVIDSON
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Computerized cognitive training is becoming increasingly popular and practical, holding promise for both patients and healthy individuals. Nevertheless, basic questions remain about the benefits of such programs, and about the degree to which expectations might influence training and transfer. Here we examined the potential transfer effects of a commercial cognitive training program (*Activate*) in a 5-week double blind, randomized placebo-controlled trial. We recruited 99 healthy older adults 59-91 years of age (*M*=68.87, *SD*=6.31; 69 women), randomly assigning them to either the intervention or an active control program (Sudoku and n-back working memory exercises). We subdivided both groups into high and low expectation priming conditions, to probe for effects of participant expectations on training and transfer effects. We assessed transfer using standard cognitive and neuropsychological tests, and self-reports of psychosocial function. The majority (88%) of participants completed the training, with positive feedback about their experience. Moreover, participants in all groups were largely optimistic about outcomes at baseline ($t_{(86)} \leq 3.97$, $p<0.0001$, Cohen's $d \geq .86$). Expectation ratings indicated that our expectation priming effectively increased or decreased participant expectations at the outset ($F_{(1,83)} \geq 7.32$, $p \leq .008$, $\eta_p^2 \geq .081$). Yet, transfer of training was minimal in all groups. Also minimal were any effects of expectations on training and transfer: results suggested that, if anything, the low expectation priming groups had higher scores on several transfer tests before and after training. Interestingly, participants in the active control groups reported significantly higher enjoyment ($F_{(1,83)} = 7.48$, $p=.008$, $\eta_p^2=.083$) and lower boredom ($F_{(1,83)}=9.42$, $p=.003$, $\eta_p^2=.102$), compared to the *Activate* groups. Our results suggest that such cognitive training interventions are feasible and enjoyable, but - using the current parameters - unlikely to improve cognitive function or psychosocial wellbeing.

Title: The effect of cardiovascular risk factors on fMRI activations to multi-tasking in healthy older adults

Authors: *S. QIN[1], C. BASAK[2]
[2]The Ctr. for Vital Longevity, [1]Univ. of Texas at Dallas, Dallas, TX

Abstract: Cardiovascular risk factors, such as high blood pressure (BP) and high Body Mass Index (BMI), have been associated with sharp age-related declines in executive functions in

normal aging. Past neuroimaging studies have identified age-related differences in brain activation patterns, as well as differences in brain-behavior relationship, between healthy older adults and younger adults during executive function tasks. It is possible that high cardiovascular risks in older adults contribute to these age-related differences in brain activations. The current study was aimed to examine the effects of cardiovascular risks on age-related differences in brain activation patterns in task-related regions during multi-tasking. A multi-tasking paradigm used in our prior study (Nashiro, Qin, O'Connell & Basak, 2018) was used, where a hybrid design allowed examination of both sustained (global switch cost: block design) and transient (local switch cost: event-related design) activations during different types of executive controls. Twenty seven younger and forty older adults were recruited. Older adults were then assigned to either high risk (20) or low risk (20) category based on a composite score of BP and BMI. Differences in activation patterns between high risk older adults and younger adults, and between high risk older adults and low risk older adults were examined in whole brain group contrasts. Preliminary results from block design analyses showed that high risk older adults had a) increased activation compared to low risk older adults in the paracingulate gyrus, and b) increased activation compared to younger adults at the posterior cingulate cortex. Increased activations in high risk older adults from these two regions were not related to task performance, and did not overlap with task-sensitive regions. Taken together, our results suggest that high cardiovascular risk results in both non-compensatory over-activation and disrupted brain-behavior relationships in healthy older adults.

Title: Modeling the individual brain dynamics by a data assimilation approach

Authors: *T. SASE[1,2], K. KITAJO[2]
[1]Intl. Islamic Univ. Malaysia, Kuala Lumpur, Malaysia; [2]RIKEN Ctr. for Brain Sci., Wako, Saitama, Japan

Abstract: The human brain yields rhythms—which, in fact, originate from the underlying nonlinear dynamical system. Their properties, such as the interaction between different rhythms, spontaneously vary; i.e., the brain has the potential for making transitions among multiple

oscillatory states of the large-scale network. Those states can be referred to as the metastable states from a dynamical systems point of view (Tognoli & Kelso, 2014). The dynamics of such a state is likely to move into another one by small fluctuations, resulting in spontaneous transitions successively. Recently, we have shown the first experimental evidence that metastable phase-amplitude coupling (PAC) dynamics in the human brain is associated with the autism spectrum [Sase & Kitajo, The 47th Annual Meeting of Neuroscience, 2017]. This previous study has suggested that the following elements are necessary to model the resting human brain: slow and fast oscillators, connectivity with PAC, fluctuations, and metastability.
Based on this suggestion, in this study, we aim to generate individual models for the resting human brain by a data assimilation (DA) approach. The present DA study consists of: (I) Generating a universal model for the resting human brain among individuals; (II) Developing an adjoint method for the model; and (III) Applying the method to the model combined with the resting-state electroencephalography (EEG) data.
To generate the universal human brain model, in stage (I), we propose a methodology starting from a general system for metastable PAC systems driven by fluctuations. This system was reduced to (i) the small-amplitude system using the reductive perturbation method, (ii) the coupled phase oscillators system at a microscopic level, (iii) its macroscopic version derived from the Ott-Antonsen ansatz, and (iv) the coupled phase oscillators system at a macroscopic level, in turn. The reduced system was applied to the proposed DA method, and then, the individually specific parameters were estimated.
We conclude that the resting-state EEG-DA framework, proposed here, has the potential for unraveling individual differences. In the future, the present DA study should be validated by our previous data-driven study.

Title: "Thin slice" functional connectome fingerprinting

Authors: *L. BYRGE, D. P. KENNEDY
Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: In many domains, individual identity can be predicted using only a fraction of all possible diagnostic information, such as from a partial fingerprint or DNA segment or from a brief glimpse at a facial expression or gait. We now know that individual identity can be predicted using functional connectomes – correlation matrices among fMRI time series spanning the whole brain or cortex. However, whether individual identity can be predicted from a "thin slice" of a functional connectome has not yet been systematically explored. We analyzed functional connectomes constructed from Human Connectome Project resting-state fMRI scans (4 14 min. scans per subject, TR=720ms, *N*=883) preprocessed using ICA-FIX+GSR and various (901) parcellations. We used connectomes from half the subjects to determine the diagnostic value of each functional connection ("edge") based on the ratio of across-subject variability and within-subject variability. Using the remaining scans, we then attempted to "fingerprint" – to predict individual identity on the basis of maximal similarity among connectomes – using various subsets or "thin slices" of the complete connectome. First, we attempted to identify individuals using slices comprised of only the connectome edges with highest diagnostic value, increasing the slice size until ceiling identification accuracy (>99%) was reached. For all but the coarsest parcellations, ceiling accuracy was obtained using a remarkably tiny fraction of the complete connectome: under 0.25% of the connectome (and only 45 edges for the 360 ROI "Glasser" parcellation) was sufficient to accurately identify individuals. The most diagnostic edges were largely located in frontoparietal regions consistent with other reports. However, nearly all edges had some diagnostic value. We thus asked whether the edges with highest diagnostic value were required for high identification accuracy. Using the Glasser parcellation, we found accuracy above 98% for slices comprised of the 26th percentile of diagnostic value (e.g. without using the most diagnostic 25% of the connectome) and for larger slices from which the frontoparietal network (Yeo parcellation) was entirely excluded. Finally, we also obtained 98% accuracy using randomly-selected slices as small as 400 edges (0.7% of connectome). Our results indicate that while individual variability may be particularly *concentrated* in the frontoparietal regions previously reported, uniqueness in functional coupling is far more diffusely distributed throughout the brain than previously appreciated, with both practical and conceptual implications for thinking about the detection and sources of uniqueness in the brain.

Title: Identifying twin pairs by classifying variability in whole-brain functional connectivity

Authors: *D. V. DEMETER[1], L. E. ENGELHARDT[1], R. MALLETT[1], M. A. ROE[1], T. NUGIEL[1], M. E. MITCHELL[1], J. JURANEK[4], K. P. HARDEN[1,2], E. M. TUCKER-DROB[1,2], J. A. LEWIS-PEACOCK[1,3], J. A. CHURCH[1,3]

Abstract: Multivoxel pattern analysis (MVPA) of fMRI data can provide insight into individual differences in functional brain network organization. Capitalizing on the increased sensitivity and specificity of machine learning methods, resting-state functional connectivity (rsfc) studies have predicted age, clinical diagnosis, and heritability. Can this approach be extended to identify a unique biomarker for a specific individual? The current study tested this using a novel application of MVPA to rsfc data to classify patterns of pairwise connectivity between a priori nodes distributed throughout the whole brain. This approach successfully matched pairs of school-aged twins by identifying heritable variance in rsfc patterns.
Methods: Three analysis sets were defined after strict motion censoring methods. The first test set consisted of 9 monozygotic (MZ) twin pairs (10.5 to 13.8 years old, M=11.04) and the second test set consisted of 10 dizygotic (DZ) twin pairs (9.4 to 13.2 years old, M=11.95). Our validation set consisted of 12 non-related individuals (9.8 to 17.2 years old, M=12.84) with two scans collected either six months or one year apart. Support vector machine MVPA and leave-one-out cross validation was used to first validate our methods and then to test individual whole-brain rsfc pattern variance. To increase sensitivity to individualized patterns over time, each resting-state timecourse was chunked into smaller samples to provide multiple instances of the rsfc signal for each individual. A vector of correlation values between all regions of interest (ROIs) in a 264 ROI set was then used for feature selection, model training, and testing. The robustness of this analysis was evaluated by parametrically varying the chunk size and feature selection threshold.
Results: Final model settings included 10 rsfc segments (40 sec each) using the top 5% of ANOVA-selected features. Models that included whole-brain connectivity between all ROIs performed better than those restricted to within-network connections. MZ twins were accurately identified based on their co-twin with 62% accuracy ($p < .001$, chance = 0.125) and DZ twins were identified with 27% accuracy ($p < .001$, chance = 0.10). In the validation set, an individual's second scan was identified from training a model on their first scan with 99% accuracy ($p < .001$, chance = 0.10).
We find the patterns of whole-brain measures of rsfc in fMRI are highly stable within individuals and are also heritable with a decrease in similarity from MZ to DZ co-twins. This novel analysis approach has the potential to increase accuracy in studies that aim to identify individual and group differences in resting-state fMRI.

Title: Metabolic cost of structural hubs in the human connectome

Authors: *R. CHIN[1], K. M. ANDERSON[1], M. A. COLLINS[1], A. YENDIKI[3], A. J. HOLMES[1,2]
[1]Dept. of Psychology, [2]Dept. of Psychiatry, Yale Univ., New Haven, CT; [3]Dept. of Radiology, Athinoula A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA

Abstract: The brain is expensive to build and maintain, incurring outsized material and metabolic costs for its size relative to the rest of the body. It has been proposed that brain organization balances cost and advantageous topological properties that enable higher communication efficiency. Network studies across species and modalities identify core sets of highly connected "hub" brain regions that are critical for efficient neuronal signaling and communication. These candidate "hub" regions tend to be mutually and densely interconnected, forming a "rich club". Due to its density and spatial layout, the rich club constitutes a costly feature of brain architecture, which may be offset by significant functional benefits that it confers to the overall brain network. Recent work in the mouse connectome uncovered a distinctive transcriptional profile of neural hubs, characterized by co-expression of oxidative metabolism genes (Fulcher & Fornito, 2016). The current study seeks to extend these findings by determining whether structural hubs in the human connectome also show enriched expression for genes regulating neuronal metabolism. In this ongoing project, topological characteristics of structural network organization were established in a large community sample using graph theory measures. Brain white matter structural connectivity was examined using diffusion magnetic resonance imaging (dMRI) data in 6,988 generally healthy individuals aged 40-70 years from the UK Biobank. We demonstrate that hub regions, being more mutually and densely interconnected, exhibit both central (i.e. playing a vital role in neural communication) and costly (i.e. exhibiting long distance anatomical projections) attributes of network organization. Ongoing analyses using gene transcription data from the Allen Human Brain Atlas, as well as follow-up investigations using genome-wide association (GWA) data from the UK Biobank, aim to identify

if a transcriptional signature for genes regulating metabolic processes is associated with topologically central, but costly hub connectivity in the human brain. Results from this large community cohort provide a current best estimate and one of the most extensive topological characterizations of structural network organization in the human connectome.

Title: The influence of genetics on individual differences in neural activation patterns in the visual and frontoparietal communities

Authors: *Y. COURTNEY[1], J. A. ETZEL[2], T. S. BRAVER[3]
[1]Kent State Univ., Kent, OH; [2]Psychology, Cognitive Control & Psychopathology Lab., Saint Louis, MO; [3]Cognitive Control and Psychopathology Lab., Washington Univ. in St. Louis, St. Louis, MO

Abstract: Individual differences in brain function play an important role in executive control, and are linked to general cognitive ability as well as characteristics in the areas of personality and emotion processing. These differences arise from both genetic and environmental influences and enable further understanding of how varying complex cognitive traits arise. By collecting task fMRI and behavioral data for monozygotic (MZ) twins, dizygotic (DZ) twins, siblings (SIB), and unrelated people, the Human Connectome Project (HCP) allows investigation of the degree to which genetics shapes these differences. This study compared activation similarity patterns in the FrontoParietal and Visual networks for 766 participants across these subject groups. Activation similarity was correlated for the N-back task under conditions of high or low working memory load and across two object stimulus categories. If heritability plays a substantial role in determining neural activation, groups of higher genetic similarity should have more similar activation patterns. Indeed, in both the FrontoParietal and Visual networks, MZ twins showed a higher similarity than DZ twins or siblings, and DZ twins and siblings showed a higher similarity than unrelated participants. Furthermore, this correlation is emphasized under conditions of higher cognitive load in the FrontoParietal network. As such, this study demonstrated that heredity is correlated to neural activation in both examined communities. This

provides evidence that genetic influences play a substantial role in the neural basis of individual differences, and may ultimately help to lay the foundation for task-related brain activation to be considered as an endophenotype for psychiatric or neural disorders.

Title: Idiosyncratic community organization of cortical functional networks in Autism Spectrum Disorder

Authors: *Y. HE[1], L. BYRGE[1], O. SPORNS[1,2], D. KENNEDY[1]
[1]Indiana Universtiy, Bloomington, IN; [2]Indiana Univ. Network Sci. Inst., Bloomington, IN

Abstract: Neuroimaging studies of the functional connectome in Autism Spectrum Disorder (ASD) have suggested generally abnormal patterns in various functional systems (e.g., default network, saliency network). However, systematic exploration of the system-level community organization has been quite limited, and findings at the group level have been largely inconsistent across the few studies that do exist. Given the enormous biological heterogeneity underlying ASD, an emerging perspective is that individuals with ASD will exhibit heterogeneous alterations of brain organization (Byrge, Dubois et al., 2015; Hahamy et al., 2015) that may not be well represented by group-level analyses. Here, we take this perspective in exploring individual, idiosyncratic variations of the community organization of the functional connectome in ASD, using densely sampled resting-state fMRI data acquired from 19 individuals with ASD and 28 matched controls. Two 16-minute scans were acquired from each individual, allowing for assessment of test-retest reliability of system-level organization. We used a multi-scale community detection algorithm for each scan to get a series of community structures from coarse to fine partition resolutions. We then derived an agreement matrix for each individual by combining each partition resolution together, thus defining an individual's multi-scale community organization, and allowing comparison within and across individuals. For both groups, agreement matrices were highly self-similar across scan 1 to scan 2, to the point of serving as a "connectome fingerprint", and indicating reliable within-subject measurement in both ASD and control individuals. However, the lower between-subjects similarity within the

ASD group suggested an idiosyncratic community organization. We further mapped the community agreement to a canonical network partition, and found that the functional systems with abnormal agreements were indeed more prevalent and more diverse in ASD. These findings suggest that system-level alterations can be reliably observed in ASD, and that group-level analyses seeking common alterations may be misguided and have limited utility. Future studies with larger samples may be able to subtype individuals based on their shared patterns of system-level abnormality, perhaps reflecting different underlying neuropathological mechanisms in ASD.

Title: Microstructure of the human corpus callosum is modulated by genetic variation in PLP1 and CNTN1: A neurite orientation dispersion and density imaging (NODDI) study

Authors: *S. OCKLENBURG[1], C. ANDERSON[2], W. M. GERDING[3], C. FRAENZ[5], C. SCHLÜTER[4], P. FRIEDRICH[5], M. J. RAANE[4], L. ARNING[4], J. T. EPPLEN[4], O. GUNTURKUN[6], C. BESTE[7], E. GENC[8]
[1]Ruhr-University of Bochum, Bochum, Germany; [2]Univ. of Otago, Dunedin, New Zealand; [3]Dept. of Human Genetics,, [4]Ruhr-University Bochum, Bochum, Germany; [5]Dept. of Biopsychology, Ruhr-University, Bochum, Germany; [6]Ruhr-Universitat Bochum, Bochum, Germany; [7]Universitätsklinikum Carl Gustav Carus, Dresden, Germany; [8]Ruhr Univ. Bochum, Bochum, Germany

Abstract: The corpus callosum is the brain's largest commissural fiber tract and is crucial for interhemispheric integration of neural information. Despite the high relevance of the corpus callosum for several cognitive systems, the molecular determinants of callosal microstructure are largely unknown. Recently, it was shown that genetic variations in the proteolipid 1 gene *PLP1* and the contactin 1 gene *CNTN1* were associated with differences in interhemispheric integration at the behavioral level. Since interhemispheric integration of neuronal information is the main function of the corpus callosum, it can be assumed that variation in these genes might affect callosal microstructure. To investigate this question, we used an innovative new diffusion

neuroimaging technique called neurite orientation dispersion and density imaging (NODDI). NODDI uses a multi-shell high-angular-resolution diffusion imaging protocol and features a three-compartment model distinguishing intra-neurite, extra-neurite and cerebrospinal fluid environments. Here, we used it to quantify axonal and neurite morphology in subsections of the corpus callosum, and to link them to genetic variation in *PLP1* and *CNTN1*. In a cohort of 263 healthy human adults, we found that polymorphisms in both *PLP1* and *CNTN1* were significantly associated with callosal microstructure. Importantly, we found a double dissociation between gene function and neuroimaging variables. Our results suggest that genetic variation in the myelin-related gene *PLP1* impacts white matter microstructure in the corpus callosum, possibly by affecting myelin structure. In contrast, genetic variation in the axon-guidance related gene *CNTN1* impacts neurite density in the corpus callosum.

Title: Neurotransmitter model of temperament traits

Authors: *I. TROFIMOVA
Psychiatry and Behavioral Neurosciences, McMaster Univ., Hamilton, ON, Canada

Abstract: This presentation reviews findings in neurochemistry that link temperament traits to complex relationships between neurotransmitter systems. Temperament traits, i.e. biologically based individual differences, are observable not only in humans, but also in animals and very young children, i.e. in pre-cultural individuals. Specialization between neurotransmitter systems underlying temperament traits is analyzed here from a functional ecology perspective that considers the structure of adult temperament corresponding to the structure of human activities. The roles of monoamine neurotransmitters (serotonin, dopamine, noradrenalin), as well as the roles of acetylcholine, neuropeptides and opioid receptor systems in the regulation of specific dynamical properties of behavior will be discussed. The functional differentiation within neurochemical systems is compared to models in kinesiology and neurophysiology that investigated key stages of human actions. Parallels to main models of temperament are summarized within the neurochemical Functional Ensemble of Temperament (FET) model. The FET framework allows having both, a common taxonomy for biologically based traits in healthy individuals and for taxonomies of mental illnesses. Temperament and mental illness are

considered to be variations along the same continuum of imbalance in the neurophysiological regulation of behavior. The presentation will give examples of how the FET framework can be used in psychiatry and clinical psychology.

Abstract: Trait anxiety has been associated with altered activity within corticolimbic pathways connecting the amygdala and rostral anterior cingulate cortex (rACC), which receive rich dopaminergic input. Current pharmacological interventions for clinical anxiety primarily target serotonergic and GABAergic neurotransmitter systems. However, early lines of research emphasized a role of dopamine in the pathophysiology of anxiety (Taylor et al., 1982), which have recently been reinvigorated (e.g. Kienast et al., 2008). To date, little work has examined the conjoint influence of endogenous dopamine function and corticolimbic functional connectivity on trait anxiety in humans. We sought to address this by examining inter-individual variability in dopamine release, fMRI resting-state amygdala-rACC functional connectivity, and trait anxiety in healthy adults (n = 31; 18-25 years old, mean = 21.42, standard deviation = 2.08, 20 female). We estimated dopamine release by contrasting the [^{11}C]raclopride PET measure of D2/3 receptor binding with D2/3 receptor binding following oral methylphenidate administration. We demonstrate for the first time that normal variation in trait anxiety is associated with individual differences in dopamine release in amygdala and rACC. Analysis of correlations among the three measurements revealed greater dopamine release in amygdala and rACC was associated with lower trait anxiety (r = -.43, bootstrapped 95% confidence interval = [-.66, -.11]), and lower resting amygdala-rACC functional connectivity (r = -.38 [-.65, -.01]). Further, dopamine release mediated the influence of functional connectivity on anxiety (unstandardized indirect effect =

4.19 [0.24, 12.14]). These data support a model by which elevated functional connectivity reduces dopamine release within the amygdala and rACC to produce higher trait anxiety within normal individuals.

Title: Investigating the role of GABA and glutamate on dorsal anterior cingulate activity associated with hypnosis

Authors: *D. D. DESOUZA[1], K. STIMPSON[1], L. BALTUSIS[2], M. GU[3], R. HURD[3], H. WU[2], D. C. YEOMANS[4], N. WILLIAMS[1], D. SPIEGEL[1]
[1]Psychiatry and Behavioral Sci., [2]Ctr. for Cognitive and Neurobiological Imaging, [3]Radiology, Stanford Univ., Palo Alto, CA; [4]Stanford Univ., Stanford, CA

Abstract: Background: Hypnosis is the oldest form of Western psychotherapy and serves as a powerful evidence-based tool in the treatment of many disorders. Hypnotizability is a stable trait over time, suggesting neurophysiological factors underlying hypnotic responsiveness. We previously demonstrated differential functional brain activity in high vs. low hypnotizable individuals during hypnosis compared to rest. Specifically, highly hypnotizable participants had increased resting-state functional connectivity between the dorsolateral prefrontal cortex and dorsal anterior cingulate cortex (dACC), and showed decreased dACC activity during hypnosis. Brain activity, as measured by the blood-oxygen-level-dependent (BOLD) signal, has been shown to be specifically coupled with neural activity. Neurochemical processes including the cycling of neurotransmitters such as GABA and glutamate, the major inhibitory and excitatory neurotransmitters of the central nervous system respectively, regulate neuronal activity. Studies have demonstrated a negative relationship between GABA concentration and BOLD signals and a positive correlation between glutamate and BOLD signals. **Rationale:** While it is clear that the dACC plays an important role in hypnosis, the relationship between dACC neurotransmitters in hypnotic response remains to be determined. **Objective:** To determine the relationship between GABA and glutamate in the dACC and measures of hypnotizability. **Methods:** 20 healthy participants with varying levels of hypnotizability as assessed by the Hypnotic Induction Profile (HIP) were recruited to undergo magnetic resonance imaging (MRI) and completed standardized

questionnaires to assess depression/anxiety (DASS-21), absorption (Tellegen Absorption Scale), and dissociation (Dissociative Experiences Scale). The MRI session included the following scans: T1-weighted anatomical, MEGA-PRESS spectroscopy to assess GABA and glutamate measures with a voxel of interest over the dACC, resting-state fMRI. **Results:** 1. a significant positive relationship was observed between dACC GABA measures and HIP scores (R- 0.590, p= 0.016). 2. dACC glutamate measures were negatively associated with the absorption subscale of the dissociative experiences scale (R= -0.584, p=0.011). **Conclusion:** We provide evidence for significant relationships between GABA and glutamate measures in the dACC and measures of hypnotizability. Having an understanding of these relationships provide a putative neurobiological basis for individual differences in hypnotizability and can inform our understanding of treatment response to this growing psychotherapeutic tool.

Title: Genetic variants of MAOA influence oscillatory EEG & ECG activity in response to aggression-inducing stimuli

Authors: *S. IM[1,2,3], J. JEONG[1,4], G. JIN[1,3], J. YEOM[1,3], J. JEKAL[1,3], S.-I. LEE[1,3], S. LEE[1,3], Y. LEE[1,3], J. CHO[1,3], D. KIM[1,3], C. MOON[1,2], C.-H. LEE[1,3]
[2]Brain & Cognitive Sci., [3]Sch. of Undergraduate Studies, [4]Well Aging Res. Ctr., [1]DGIST, Daegu, Korea, Republic of

Abstract: The monoamine oxidase A (MAOA) gene, which encodes an enzyme that breaks down monoamine neurotransmitters, is associated with human physiology and aggressive behavior. Genetic variation in upstream variable tandem repeats (uVNTR) of the *MAOA* promoter is believed to contribute to individual differences in aggression at the transcription level. However, research on the relationship of *MAOA* uVNTR with molecular change, neural activity, and psychological indices of aggression has reported inconsistent findings. Intriguingly, significant difference in *MAOA* allelic frequencies exist across ethnic groups as well as the

information of their sequences is insufficient. Therefore it is necessary to provide complete sequence analysis of *MAOA* uVNTR and its effects at multiple levels of human biology. Here, we identified three alleles of *MAOA* uVNTR in the Korean population: predominantly 3.5R and 4.5R plus the rare 2.5R. Functional promoter fusion assay demonstrated that the 3.5R allele has more efficient transcription than the 4.5R allele, while the 2.5R allele has the highest efficiency. This finding implies differential molecular effects of *MAOA* uVNTR on the neurobiological response to aggression. Our neurobiological studies revealed oscillatory changes in electroencephalogram and electrocardiogram patterns under aggression stimuli as novel functional phenotypes of *MAOA* uVNTR genotypes. Specifically, hemi- or homozygous 4.5R carriers with low *MAOA* transcriptional efficiency showed greater oscillatory variability of the γ wave from the prefrontal/frontal cortex and larger changes in heart rate. This suggests extended explanations on a neurobiological characteristics related to aggression in regard to *MAOA* variants. Our findings provide novel genetic insight into *MAOA* functions, which offer grounds for the various human socio-emotional mechanism in healthy individuals.

Title: Implicit and explicit risk taking on the balloon analogue risk task and its relationship with positive personality characteristics in working adults

Authors: *S. R. BOETTCHER[1], A. ALTHOFF[2], A. C. S. VAZQUEZ[3], K. R. VIACAVA[4]
[1]Inst. of Human Cognition and Behavior (INCh), Porto Alegre, Brazil; [2]Psycology, Ctr. of Studies in Organizational and Work Psychology (NEPOT). Federal Univ. of Hlth. Sci. of Porto Alegre, Porto Alegre, Brazil; [3]Psycology, Ctr. of Studies in Organizational and Work Psychology. Federal Univ. of Hlth. Sci. of Porto Alegre, Porto Alegre, Brazil; [4]Decision Making Lab. (DM Lab). Inst. of Human Cognition and Behavior (INCh), Porto Alegre, Brazil

Abstract: Many are the choices in face of risks in the organizational dynamic environment, especially when involving structure review, with changes of leadership and teams. Positive individual characteristics as optimism, hope and self-efficacy seem to contribute in this process (Seligman & Csikszentmihalyi, 2000). Despite this, little is known about how these characteristics relate to risk-taking, mainly when implicit and explicit levels of cognitive processing are considered. Thus, the aim of this study was to investigate the relationship between

risk-taking and positive characteristics of personality in an uncertainty organizational context. The sample was composed of 97 adults (average age=37 years old; 46% women), all employees from global companies involved in merging processes and that completed the Balloon Analogue Risk Task - BART (Lejuez et al., 2002). Besides BART, questionnaires accessing optimism (Bastianello, Pacico, & Hutz, 2015), hope (Bastianello, Pacico, & Hutz, 2015) and self-efficacy (Pacico, Ferraz & Hutz, 2015) were applied. The hypothesis was that individuals with higher levels of optimism, hope and self-efficacy would show higher propensity to implicit risk-taking (captured through the latency in pumping the balloons) and explicit (measured by the latency in collecting money). Consistent with the hypothesis, the results pointed out a positive relationship between implicit risk-taking and hope (r= .235; p < .05), indicating that the greater the hope, greater was the risk assumed at an automatic level. Also, was observed a positive relationship between explicit risk-taking and self-efficacy (r= .229; p < .05), supporting the notion that the self-efficacy is associated with planned processes. Additionally, leaders and non-leaders differed in time spent for total risk-taking, when implicit and explicit risk-taking were analyzed altogether (U= 637; p<.05), demonstrating that leadership positions seem to play a role in the way people deal with risks in organizations. The lower hierarchical level employees showed greater implicit risk-taking (H= 11,11; p< .05), in comparison with upper-level employees. In addition, it was observed a positive relation between explicit risk-taking and years of services (H= 10,44; p < .05), pointed that for longer time of services, longer was the planning to deliberate about the risk. The findings corroborate with the dual-process model, once they present risk-taking results at implicit and explicit levels. Also adds to the emerging fields of organizational neuroscience and positive psychology indicating relations between risk-taking and positive personality characteristics.

Title: Social networking service talk about your personality and resting-state brain network

Authors: *K. MORI, M. HARUNO
Ctr. for Information and Neural Networks, NICT, Suita, Japan

Abstract: Social networking service (SNS) is the essential communication tool in the current life. The central problem of SNS in social science is whether SNS have good or bad mental effect. Past studies have offered mixed evidence about the good and bad side of SNS use. In the current study, we try to show the SNS mental effect using the framework of SNS neuroscience. We examined the relationship between twitter, one of the major SNS, behavior and psychological personality, brain resting state network. The results indicated that tweet by oneself is associated with negative personality / high IQ, whereas reply with others is associated with positive personality / free will. In line with the personality emotion, tweet by oneself includes more negative / less positive words and reply with others includes more positive / less negative words. Further, tweet by oneself can be predicted by resting nucleus accumbens functional connectivity network implying the addiction of tweet behavior. Our findings thus reveal positive and negative association of SNS and well-being, and the brain mechanism of SNS usage.

Tuebingen, Tuebingen, Germany

Abstract: Psychometric research has identified stable traits that predict inter-individual differences in relationship and attachment behavior. Avoidance and anxiety (AV/AX) scales

have been developed to quantitatively assess these traits. However, neural mechanisms corresponding to the proposed constructs reflected in av/ax are still poorly defined. The ventral medial orbito-frontal cortex (vmOFC) is implicated in social approach network (SAN) function, and lateral orbitofrontal cortex (lOFC) is related in subserving emotion regulation on social processing . In this study, we examined whether functional connectivity between these regions predicts components of these scales. We employed resting-state functional connectivity and av/ax scores assessed by a personality questionnaire. Participants completed a resting state run and the Experiences in Close Relationships Questionnaire (ECR-R). Using resting-state BOLD, we assessed correlations between structures of SAN (Fig. 1) and those related subserving emotion, establishing single subject connectivity summary scores. Summary scores were correlated with components of av/ax scores. Results demonstrate a novel correlation between AV and resting-state connectivity between vmOFC and lOFC (Fig. 2), implying that spontaneous synchrony between social approach processing regions may play a role in defining personality characteristics related to attachment.

Title: Brain network predictors of TMS-induced changes in cognitive control performance

Authors: *C. L. GALLEN, T. P. ZANTO, A. GAZZALEY
Neurol., UCSF, San Francisco, CA

Abstract: Previous research has demonstrated a critical role for the right inferior frontal junction (rIFJ) in cognitive control processes, such as selective attention and working memory (WM). In a previous study, we perturbed rIFJ function with TMS during a selective attention, delayed recognition task and observed a decrease in WM accuracy (Zanto et al., 2011). However, this

and other brain stimulation studies have shown variability in responses across individuals. Recent work has shown that baseline properties of brain networks predict cognitive control gains after long-term cognitive interventions, such as through video games and exercise. It remains poorly understood, however, whether brain network properties can similarly predict behavioral changes associated with TMS.

Here, we examined the relationship between network properties and TMS-induced changes in behavior during a selective attention WM task for color and motion. TMS-related changes in behavior were quantified from previous work showing that repetitive rIFJ TMS decreased WM accuracy during the remember color (ignore motion) condition. Network properties were quantified from a similar task performed during fMRI scanning in a baseline session. We created a focal 'segregation' metric that quantifies the balance of a region's connectivity to others in its own network, compared to that of another network. Given the importance of fronto-parietal (FP) and visual network interactions during the WM task, we focused on rIFJ segregation between FP and visual networks ('rIFJ segregation'). Larger rIFJ segregation values reflect higher connectivity between rIFJ (TMS target) and the rest of the FP network.

Greater rIFJ segregation was predictive of larger TMS-induced behavioral changes during remember color and not remember motion. Importantly, a bottom-up control metric focusing on V4 segregation was not related to behavioral changes. In addition to individual differences in TMS susceptibility, participants also exhibited variability in rIFJ-V4 structural connectivity. Individuals with cortico-cortical structural connections between rIFJ and rV4 (~60%), primarily along FP tracts, had larger rIFJ segregation during remember color. Additionally, greater integrity of this tract was related to larger rIFJ segregation.

These results demonstrate that individuals with greater rIFJ segregation have larger TMS-related behavioral changes and, further, that these individuals have greater integrity of FP tracts connecting rIFJ and rV4. More generally, these findings suggest that properties of brain networks can predict susceptibility to TMS-induced changes in cognitive control performance.

Title: Identifying distinct alpha band oscillatory dynamics in the EEG as targets for rhythmic transcranial magnetic stimulation (rTMS)

Authors: *M. K. GOLA[1], J. WAGNER[2], J. A. ONTON[4], K. MURPHY[3], S. MAKEIG[3]
[1]UC San Diego, INC, SCCN, San Diego, CA; [2]Dept. of Psychology, [3]Univ. of California San Diego, La Jolla, CA; [4]Inst. for Neural Computation, UC San Diego, La Jolla, CA

Abstract: Associations between cognitive performance and spontaneous modulations of oscillatory neuronal activity in the alpha frequency range have been established in a number of studies (Klimesch, 1999, Haegens, 2014). Recently it has been suggested that alpha oscillations can be reinforced using rhythmic transcranial magnetic stimulation (rTMS) to improve health and cognition. If the effects of rTMS are mediated by phase-coupling (entraining) endogenous oscillatory brain activity to the externally applied electromagnetic stimulus, immediate as well as long lasting effects of rTMS may thereby depend on the matching the stimulation frequency and phase to the individual's natural brain dynamics (Ziemann & Siebner 2015). To tune rTMS therapy to the frequency and phase of each subject's brain dynamics, optimized individual peak frequency and phase detection are essential. Cortical alpha oscillations typically have a peak power value (between 8 Hz and 12 Hz) that has often been claimed to be a single, stable and heritable neurophysiological ''trait" marker reflecting anatomical properties of the brain and linked to each individual's personality and cognitive capacity. However, growing evidence suggests that the alpha peak frequency is actually volatile on short time scales, may depend on cognitive state, and can differ between cortical source areas. Many studies of EEG spectral dynamics measure power in pre-defined frequency bins. To better understand the functional roles of brain local field dynamics, more flexible, data-driven models of spectral dynamics are desirable. Here, we attempt to characterize the alpha frequency modulations occurring in continuously recorded EEG data during rest, to determine the inter-relationship of observed alpha band features in source-resolved EEG activities (Onton & Makeig, 2009). Multi-channel EEG data are linearly decomposed using independent component analysis (ICA) into maximally independent component (IC) processes. Then IC log spectrograms are jointly decomposed into source-resolved modes, independent modulators (IMs). Such processes might reflect coordinated actions of modulatory factors, for example thalamocortical feedback loops and/or brainstem-based neuromodulatory systems. Better understanding the landscape of alpha band dynamics may help identify and target distinct alpha oscillatory brain networks for stimulation.

Title: The utility of off-the-shelf EEG devices for the study of psychoactive substance use in non-laboratory settings

Authors: *J. DREO[1], D. SAKIć[2], Z. PIRTOŠEK[2]
[1]Fac. of Medicine, Univ. of Ljubljana, Ljubljana, Slovenia; [2]Chair of Neurology, Fac. of Medicine, Univ. of Ljubljana, Ljubljana, Slovenia

Abstract: Since the early 2010s several mobile, inexpensive, consumer-grade EEG devices have entered the market. These devices seem to be opening new avenues for neuroscientific research into areas that, for a multitude of reasons, might not be compatible with traditional laboratory environments. These reasons might include: the rarity of the events we wish to observe, the unwillingness of participants to visit labs, the privacy concerns of participants, or the unsuitability of laboratory environments for experiences that only lend themselves to more informal settings. We pragmatically tested the utility of one consumer-grade EEG device (Emotiv, Insight) for the use in neuroscientific field-work, namely observing the effects of psychoactive drug use on EEG activity. Based on NIH data, illicit drug use seems to be increasing. Given this trend, more and better research into this area of human experience is clearly indicated. Since most recreational psychoactive substances have very complex and individual-specific effects on the psychology of their users, elucidating their underlying neurophysiological effects must also be subject-specific. Due to their often-illicit nature and resulting legal issues, studying phenomena related to psychoactive drug use is severely limited in traditional laboratory settings. Additionally, and understandably, many participants are quite reluctant to relinquish their anonymity by coming to a public lab for neuroscientific testing. In order to address these concerns, we opted to observe psychoactive drug use where it usually occurs - in the homes of the users. We did not induce our participants towards drug use and we did not incentivize them in any way. We simply circulated notices that an EEG study of psychoactive drug use is underway and that any interested parties may discretely contact us if they wish to have their experiences recorded at their homes. We therefore only observed events that would have taken place anyway. Great care was taken to ensure the privacy of all recordings. Participants were recorded for a total of 45 min while watching a nature documentary (Planet Earth, BBC). The first 5 min served as a baseline, after which participants inhaled cannabis with the aid of a vaporizer. Preliminary findings on 8 individuals (of 20 planned) show that the subjects' subjective experiences track the changes in their EEGs. EEG spectra showed a shift to lower frequencies and a higher total power. There were, however, great inter-individual differences in EEG responsivity, which also correspond to different reported psychological effects. We conclude that this kind of observational field-neuroscience is a promising avenue of research.

Title: Connectome based predictive modeling predicts individual differences in processing speed in health young adults

Authors: *P. LI[1], H. HE[2], Y. STERN[4], Y. GAZES[3], C. G. HABECK[3]
[1]Col. of Physician and Surgeon, Neurol., Columbia Univ. Med. Ctr., New York, NY; [3]Taub Inst., [2]Columbia Univ., New York, NY; [4]Cognitive Neurosience Division, Columbia Univ., New York, NY

Abstract: Processing speed as a core cognitive ability plays a key role in everyday life and differs significantly across individuals. Here we used a recently developed method by Rosenberg et al. (2016) and Shen et al. (2017) to predict individual differences in processing speed based on resting-state functional connectivity. 128 healthy young adults aged 20-35 years were included in the current study. Each subject underwent 10 minutes resting state fMRI scan. Neuropsychological tests included digit symbol, trail making test A, and Stroop test. The index of processing speed was the mean of the zscores for digit symbol accuracy, stroop color accuracy score, and trail making test A reaction time. The last measure was inverted such that higher score denotes better performance.The following steps were performed to apply the connectome-based predictive modeling. First, each subject's whole brain was parcellated into 264 network nodes based on a recently developed functional atlas. For each subject, a mean time course was calculated for each node by averaging BOLD signals from all of its component voxels at each time point. Pearson correlations were computed among all pairs of 264 nodes. The Pearson correlation coefficients were Fisher-Z transformed to generate symmetric 264*264 connectivity matrices. Leave-one-out cross-validation was used in which the data was divided into a training and a testing set. Partial correlations between each edge in the connectivity matrices and processing speed were calculated across subjects. The resulting r values were thresholded at $p<0.01$ for feature selection and separated into positive and negative tails based on the correlation sign.A single summary statistic, network strength, was calculated to define each subject's degree of connectivity in the positive and negative tails. Positive and negative network strengths were calculated by summing the edge strength from a subject's connectivity matrix in the positive and the negative tail. A simple linear regression model was built to predict processing speed based on the network strengths of each subject in the training set. Then, the same model was validated on the subjects in the testing set. Results showed that the positive and

the negative network strengths both significantly predicted novel subjects' processing speed.Edges that predicted individual differences in better processing speed consisted of edges within the default mode network and of edges between the default mode network and other networks. Edges within the visual network and edges between the visual and the default mode network and with the somatosensory network predicted worse processing speed.

Title: Narrative context and gaming experience moderate presence and cybersickness in virtual reality

Authors: *S. KENNY, S. WEECH, M. BARNETT-COWAN
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Minimizing an observer's experience of bodily discomfort (cybersickness) and maximizing the sense of truly 'being there' in a simulated environment (presence) are important considerations in order to take advantage of the potential offered by the virtual reality (VR) medium. We explore the possibility that experimental manipulations of presence can lead to decreased reports of cybersickness. Specifically, we examine whether a top-down intervention based on enriched narrative context can increase the personal relevance and believability of the VR environment, protecting against cybersickness that arises from multisensory conflict. In a laboratory experiment, we randomly assigned 20 volunteer university students to a minimal- or enriched- narrative context between-subject condition prior to exploring a high-quality interactive VR environment for a 7-minute session. After the play session, we acquired self-report measures of presence and cybersickness using the Player Experience of Needs Questionnaire and the Simulator Sickness Questionnaire. We found evidence that these percepts are inversely correlated, and that experimental manipulation of narrative reduced reports of cybersickness. To replicate and extend the generalizability of these findings, we conducted a second experiment using the same methodology in a public research setting. Over the course of one week, we collected a comprehensive set of data including demographics, gaming experience, player engagement, and task performance from 153 visitors to a public museum. We replicated the finding that participants who reported high presence also tended to report lower sickness

severity. Highlights of the results include an interaction between narrative context and video game experience: Those who reported playing video games less than five hours a week (non-gamers) reported higher sickness severity if they were assigned to the minimal-narrative context condition than the enriched-narrative condition. On the other hand, those who played games regularly were unaffected by the narrative context manipulation. In addition, the association between presence and sickness was stronger for non-gamers than regular gamers. These results show the potential for top-down modulation of susceptibility to sickness for non-gamers in particular, who may have less exposure to experiences that generate multisensory conflict compared to regular gamers.

Title: Mechanisms of skill improvement across 100 sessions of an online attention training game

Authors: *O. CLAFLIN
Lumos Labs, San Francisco, CA

Abstract: One largely unexplored question in the field of cognitive training is how individual differences manifest during learning of a cognitive task. Understanding individual differences may enable more sophisticated trainers in the future including timely and customized guidance or supplementary specialized training. Previous studies of cognitive training have used correlative methods among relatively small sample sizes to infer at the broader population trends. Here, we used a large, observational dataset comprising of over 50,000 Lumosity participants who completed 100 sessions of a cognitive trainer (Highway Hazards) to shed light on the stages of task learning during cognitive training. Participants spanned from 13 to 90 years of age (median of 46) and across different education levels. By breaking down our participant's microbehaviors across their first 100 sessions of learning (with participants achieving half of their eventual performance gains by approximately session 20), we characterize several different mechanisms of skill acquisition during the different stages of learning.

Title: Individual variation in the cortical response to word predictability in naturalistic reading

Authors: *B. T. CARTER[1], S. G. LUKE[2]
[1]Neurosci., [2]Brigham Young Univ., Provo, UT

Abstract: Lexical predictability is the degree to which the linguistic features of a word can be predicted based on prior experience. How these predictions are made and the regions of the brain responsible for making these predictions are not well understood. Prior studies have shown lexical predictability is inversely related to gaze duration. Gaze duration is defined as the time spent viewing a word and can be used to assess cognitive effort. Changes in gaze duration are associated with lexical predictability. Cortical regions demonstrating activity associated with changes in gaze duration and lexical predictability are likely involved in the behavioral response to words and serve as potential indicators of reading proficiency. 41 participants with normal or corrected to normal vision, and no history of reading or learning disability were recruited. Participants were presented with 54 standardized paragraphs of text from Luke & Christiansen (2016). Eye movements were recorded via an Eyelink 1000 plus long range MRI eye tracker at 1000 Hz. fMRI was performed concurrently. Eye movement data were co-registered with fMRI data. fMRI analysis was performed using Analysis of Functional NeuroImages (Cox, 1996) and a group structural model was created using Advanced Normalization Tools (Avants, Tustison, & Song, 2011). The ideal hemodynamic response function was modeled with one binary regressor (fixation onset), and two parametric regressors coding for lexical predictability and gaze duration. This was contrasted with the baseline response function. 15 functional regions of interest were then identified at the group level and individual participant statistics were calculated for each region. A linear mixed-effects model was applied to fixation duration and lexical predictability. Slopes were extracted for each participant and correlated with the

maximum activation observed in each ROI. The hemodynamic response in the following regions was significant (df = 39, $\alpha < 0.05$, $|r| > 0.308$): the right anterior cingulate gyrus (r = 0.327), right posterior cingulate gyrus (r = 0.423), left middle frontal gyrus (r = 0.309), and right posterior insula (r = 0.417). This exploratory study highlights regions of interest for further investigation of linguistic function and skill. Individuals with greater overall sensitivity to word predictability, as revealed by eye tracking, showed a more negative hemodynamic response during reading within these regions. This association indicates these regions may be related to prediction, experience and the development of reading. Future research should focus on how this activity changes with development of reading skill.

Title: Neural correlates underlying the individual difference of positive psychological effect by remembering nostalgic memories

Authors: *K. OBA[1], M. BARTHEL[2], K. ABE[1], K. HIRANO[1], R. ISHIBASHI[1], R. NOUCHI[1], R. KAWASHIMA[1], M. SUGIURA[1]
[1]Tohoku Univ., Sendai, Japan; [2]Bordeaux Univ., Bordeaux, France

Abstract: It has been revealed that remembering nostalgic memory has positive psychological effects on self-esteem and mood (Wildschut et al., 2006). However, it is also the truth that there are individual differences on the effect of reminiscence (Fry 1991). Despite the amount of literatures reporting positive psychological effect by remembering memories, underlying psychological and neural mechanisms of this individual difference remain unknown. In the present study, we investigated the neural correlates underlying the change in self-esteem by remembering nostalgic memory using functional MRI (fMRI). Right-handed healthy students (n=29, 21.08±1.18 years old, 16 males) participated in this study. All participants gave written informed consent prior to the experiment. This study was approved by the institutional review board in the Tohoku University. Prior to the experiment, we collected 24 pictures that could remind nostalgic memories such as elementary school days, or 24 pictures for ordinary memories such as shopping at the supermarket. During fMRI scanning, participants saw these pictures for fourteen seconds each, remembered autobiographical memories and rated the nostalgia feeling

by Likert scale (1-4). Immediately before and after the remembering task, they answered the state self-esteem (SSE) questionnaire (Abe and Konno 2007). In the fMRI data analysis, we first compared the brain activity between the high (3 and 4) and low (1 and 2) nostalgia conditions (high vs low contrast) based on each participants' rating. Then, to investigate the neural correlates underlying the individual difference of SSE change, we performed regression analysis between SSE change (post minus pre) and brain activity (high vs low contrast). The behavioral data showed that there was no significant change in SSE before and after the task in the sample ($t(28) = 2.05$, $p = 0.40$). However, there were individual differences as some participants' SSE increased ($n = 16$), some decreased ($n = 11$), and some showed no change ($n = 2$). In the fMRI analysis, we identified a region covering left lateral parietal and medial parietal areas, which includes precuneus, that activated in correspondence with the individual difference of the SSE change ($p<0.001$ at voxel level and $p<0.05$ FWE corrected at cluster level). Previous study has shown the positive correlation between the precuneus activity and state self-esteem changed by positive social feedback (Eisenberger et al., 2011). Considering this finding, the present result suggests a possibility that there is a process mediating positive psychological effect which is common in both nostalgia and social feedback and is implemented on the precuneus.

Title: Music preferences are radically idiosyncratic yet internally consistent

Authors: *S. SPIVACK, W. ERSLY, N. SPILKA, I. PASSMAN, S. PHILIBOTTE, P. WALLISCH
New York Univ., New York, NY

Abstract: To what degree do our subjective appraisals of reality correspond with those of other people? To investigate this question, we exposed a large sample of participants to a diverse selection of songs and compared ratings both between and within listeners to compute the inter-rater reliability and internal consistency of musical preferences. We found that there is low agreement between individuals but that ratings are highly consistent within individuals. We conclude that music taste is highly idiosyncratic yet stable, which renders music attractive as stimulus material for psychological research.

Title: Personality, as it manifests in the temporal fine structure of musical appraisal judgments

Authors: I. PASSMAN[1], N. H. SPILKA[1], S. SPIVACK[2], S. J. PHILIBOTTE[3], *P. WALLISCH[4]
[1]New York Univ., New York, NY; [2]New York Univ., Brooklyn, NY; [3]Dept. of Psychology, [4]Ctr. Neural Sci., New York Univ., New York, NY

Abstract: What can we learn about human cognition from the way in which people interact with music? Our prior research suggests that the appraisal of musical stimuli reflects that human cognition is highly complex and idiosyncratic. This research focused on summary measures of appraisal, whereas here we were interested in the temporal fine structure of appraisal judgments in response to musical stimuli. To explore this topic, we presented music selected from a set of representative songs to over 600 participants and recorded their instantaneous appraisals throughout each song. Doing so, we were able to answer the following questions: 1) How long does it take for an individual's preference towards a song to stabilize after stimulus onset? 2) What is the influence of significant musical/sonic changes on appraisal throughout the song? 3) Which of these changes are idiosyncratic and can be related to individual personality and which are universal? We also related appraisal updating behavior to how engaging a particular song is and to measures of personality such as conscientiousness. Finally, with respect to these questions, we explored the role of the human voice in music and investigated whether vocals make songs more memorable. We conclude that most people respond to songs as they would to other auditory textures, but that this response is modulated by the personality characteristics of individuals.

Title: Deep dynamic phenotyping of the individual: Daily life event analysis using actigraphy from wearable devices

Authors: *H. RAHIMI EICHI[1], G. COOMBS III[1], J.-P. ONNELA[2], J. T. BAKER[3,1,4], R. L. BUCKNER[1,5,4]
[1]Harvard Univ., Cambridge, MA; [2]Harvard T.H. Chan Sch. of Publ. Hlth., Cambridge, MA; [3]McLean Hosp., Belmont, MA; [4]Harvard Med. Sch., Cambridge, MA; [5]Massachusetts Gen. Hosp., Cambridge, MA

Abstract: Wearable devices are commonly available to record activity of individuals and provide information about their lifestyle and daily activity levels. There are several existing software technologies bundled with wearable devices, which are tailored to provide standard biometrics such as sleep and footsteps. To detect and categorize different life-related activities of individuals such as walking, running, exercise and sexual activity in addition to standard sleep and activity level measures, here we apply data-driven analysis to the raw data recoded by actigraphy wristband devices and validate them with other objective GPS measures as an analytical platform for deep dynamic phenotyping of the individual. For this purpose, actigraphy data of 74 college students (for 57-250 days with 30Hz sampling rate) and 10 individuals with bipolar disorder or schizophrenia spectrum (for 100-300 days with 20Hz sampling rate) are collected using low cost wristband devices. One-minute bin frequency spectrum of the actigraphy signal is deployed along with moving window analysis to detect sleep epochs (sleep onset, wake time, and quality of sleep) differentiated from watch-off intervals. Moreover, correlation-based clustering of the frequency spectrums is utilized to identify the most commonly repeated activities of the individual during the day. The daily behavioral map based on actigraphy clustering is evaluated by a previously developed daily map based on the most visited GPS locations collected using Beiwe, a research platform for smartphone-based digital phenotyping (Torous et al., 2016 *JMIR Ment Health*). The annotated in-house data collection

shows that the algorithm detects the sleep epochs, bedtime and wake time accurately. Moreover, this algorithm provides visual representation of sleep interruptions such as bathroom trips or in-bed sleepless minutes. Furthermore, the algorithm shows that the daily color-coded map of the most repeated activities such as walking, running, exercise and sexual activity are consistent with the separately collected GPS locations; such that the walking activity is at the transition time between locations, exercise is at the same location and same time of the week, and sexual activity can be detected as vigorous activities at the sleeping location with a trip to the bathroom afterwards. In conclusion, frequency-based analysis of the raw actigraphy data provides an accurate objective indicator of an individual's life events such as sleeping, walking, running, exercise, and even sexual activities.

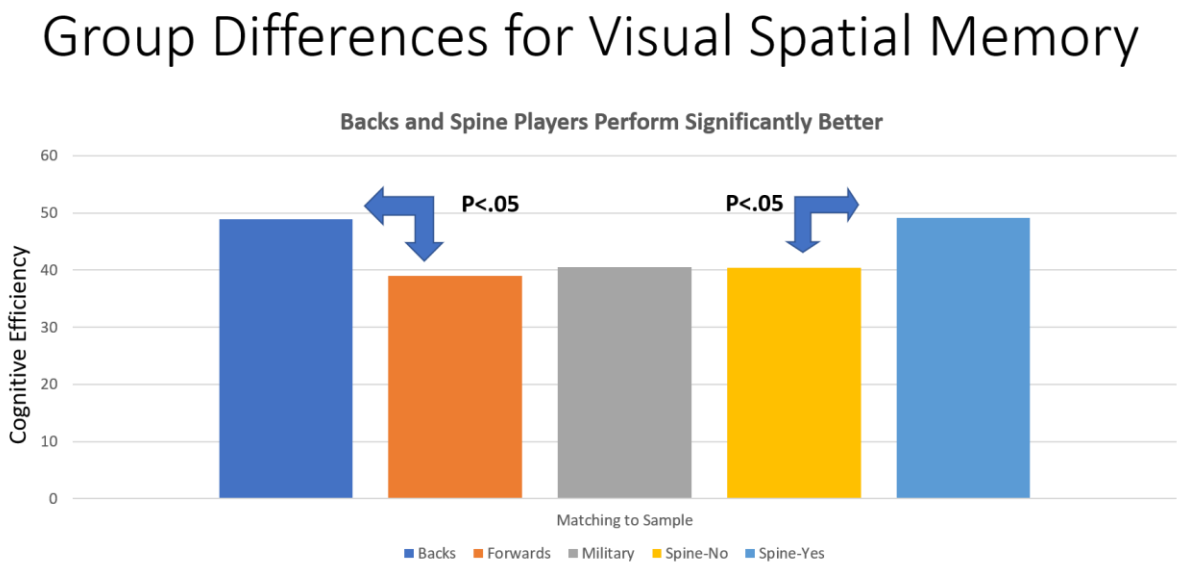
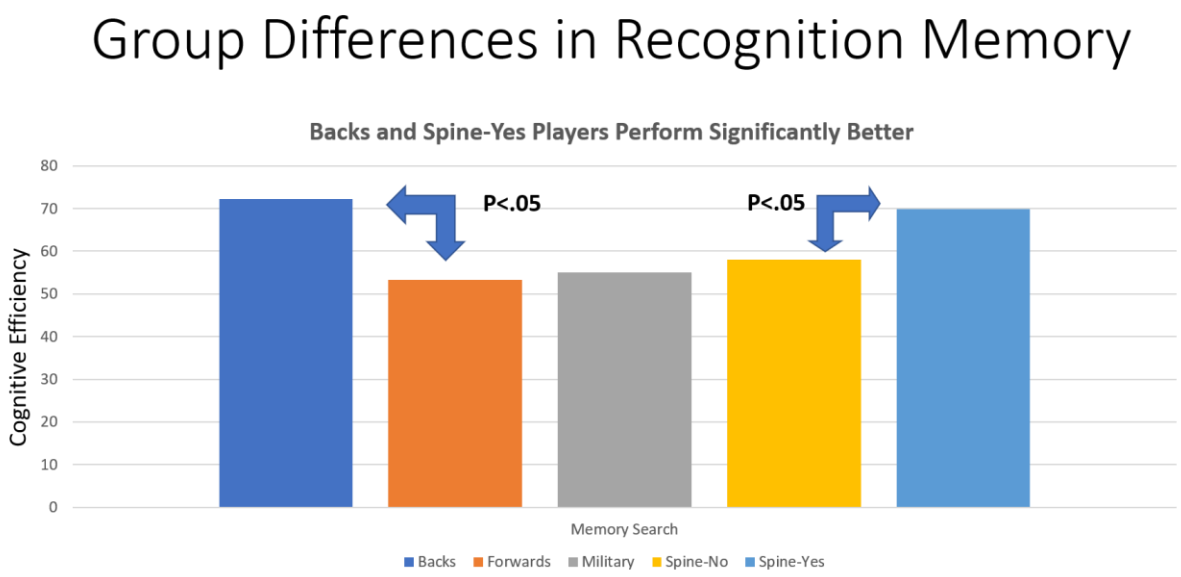
Title: Neurocognitive measures dissociate elite athletes in rugby league by position

Authors: *T. F. NUGENT III, S. L. MILLER, A. A. KRUSE, D. BACH
Platypus Inst., San Diego, CA

Abstract:





Rugby league is a full contact sport played internationally known for its fast action, player strength and decision making under stressful situations. Prior to the 2017 Men's Rugby League World Cup, a professional national league team underwent a series of cognitive assessments as part of an exploratory investigation into understanding the elite brains of professional athletes. 26 male players were subjected to a series of tests while instrumented with EEG. Data was collected for both neurophysiological brain-based metrics (workload, engagement, distraction), self-reported surveys on sleep, stress, and game performance anxiety, as well as more traditional behavioral measures through neuropsychological test batteries. Test batteries were selected for

cognitive metrics associated with high levels of performance in the sporting domain, such as visual spatial processing, executive function, reaction time, procedural reaction time and more. Data was collected and presented to both the team management and players to provide insight into cognitive levels of performance and how this could be related to their overall performance during rugby league play. When the players were grouped by position (forwards vs backs) we found significant difference for a match to sample task, memory search task, and fear of failure assessment ($p<.05$). These findings will lead to tailored training to improve cognitive performance of athletes, with longitudinal tracking of both their behavioral and cognitive outputs.

Abstract: Exposure to microgravity and elevated CO_2 as a result of residing in a confined compartment such as the International Space Station (ISS) may lead to neural structural and functional alterations in astronauts. In this study, evaluation of cognitive performance was carried out in 11 healthy participants (M=6, mean ± SD age: 33.91 ± 8.03 yr) who were exposed to 0.5% CO_2 concentrations over a 30 day period while in −6° head-down tilt bed rest (CO_2+ HDBR), simulating several conditions of the ISS including elevated CO_2, axial body unloading, and fluid shifts towards the head. Neurocognitive assessments of spatial working memory and visuomotor skills were administered on average 7 days before, 7 and 29 days during HDBR. The assessment results of the CO_2+ HDBR group were compared to that of 15 HDBR subjects (all males, mean ± SD age: 31.23 ± 5.07 yr) without 0.5% CO_2 exposure (CO_2 - HDBR) assessed on average 8 days prior, 8 and 50 days during HDBR, obtained for a separate spaceflight analog study. A significant group by time effect was observed for digit symbol substitution test

performance, where the CO_2+ HDBR group showed decreased task completion time with no change in accuracy. These findings are in line with a previous shorter duration HDBR study with increased CO_2 concentration. Behavioral improvements may be related to hypercapnia-induced cerebrovascular reactivity that favors brain regions such as the cerebellum and the visual cortex, areas that are involved in digit symbol substitution test performance. Results from the current study will help us better understand the mechanisms underlying neurocognitive changes occurring with spaceflight.

Title: Neurobehavioural correlates of obesity are largely heritable

Authors: *U. VAINIK[1,2], T. BAKER[3], M. DADAR[1], Y. ZEIGHAMI[1], A. MICHAUD[1], Y. ZHANG[1], J. C. G. ALANIS[4], B. MISIC[1], D. L. COLLINS[1], A. DAGHER[1]
[1]Montreal Neurolog. Inst., Montreal, QC, Canada; [2]Inst. of Psychology, Univ. of Tartu, Tartu, Estonia; [3]Rutgers Univ., Newark, NJ; [4]Dept. of Psychology, Philipps Univ. of Marburg, Marburg, Germany

Abstract: Recent molecular genetic studies have shown that the majority of genes associated with obesity are expressed in the central nervous system. Obesity has also been associated with neurobehavioural factors such as brain morphology, cognitive performance, and personality. Here, we tested whether these neurobehavioural factors were associated with the heritable variance in obesity measured by body mass index (BMI) in the Human Connectome Project (N=895 siblings). Phenotypically, cortical thickness findings supported the “right brain hypothesis” for obesity. Namely, increased BMI associated with decreased cortical thickness in right frontal lobe and increased thickness in the left frontal lobe, notably in lateral prefrontal cortex. In addition, lower thickness and volume in entorhinal-parahippocampal structures, and increased thickness in parietal-occipital structures in obese participants supported the role of visuospatial function in obesity. Brain morphometry results were supported by cognitive tests,

which outlined obesity's negative association with visuospatial function, verbal episodic memory, impulsivity, and cognitive flexibility. Personality-obesity correlations were inconsistent. We then aggregated the effects for each neurobehavioural factor for a behavioural genetics analysis and demonstrated the factors' genetic overlap with obesity. Namely, cognitive test scores and brain morphometry had 0.25 - 0.45 genetic correlations with obesity, and the phenotypic correlations with obesity were 77-89% explained by genetic factors. Neurobehavioural factors also had some genetic overlap with each other. In summary, obesity has considerable genetic overlap with brain and cognitive measures. This supports the theory that obesity is inherited via brain function, and may inform intervention strategies.

Title: Individual differences in social punishment of unfair individuals and groups

Authors: *M. EL ZEIN, C. SEIKUS, L. DE-WIT, B. BAHRAMI
Univ. Col. London, London, United Kingdom

Abstract: In the last few decades, research on collective decisions has mainly focused on whether they are better or worse than individual decisions, but rarely on the motives that drive individuals to engage in group decisions. Besides improving accuracy, an important and less explored motive for individuals joining collectives is *shared responsibility* for decision outcomes. It can protect them against negative consequences of decisions especially if they trigger punishment (unfair behaviors, crimes), as individual punishment often decreases when shared among group members. Following the reasoning that groups share responsibility for harmful decisions, we predicted that a group would be punished less than an individual for the same decision. We tested this hypothesis by investigating social punishment in two well-known cooperation games: (1) the ultimatum and (2) the dictator game with third party punishment). In each game, one (individual condition) vs three (group condition) proposers made offers to a recipient in several rounds In the ultimatum game, recipient could reject (i.e. costly social punishment as proposers and recipients are left with nothing) or accept the offer. In the dictator game, a third party would incur a cost to punish the proposer(s) for their unfair offer. 81 healthy human participants (40 females, mean age=23.7±4.9) took part in the study. To investigate individual differences in social punishment of groups and individuals, questionnaires measuring social value orientation, political orientation, and psychopathy traits were collected from all participants. Punishment of individual and group proposers increased gradually with offers' unfairness. Critically, groups were punished less than individuals who made the same unfair offers. Punishment across all offers varied as a function of social value orientation and political orientation: the more prosocial and liberal recipient or third-party participants were more likely to administer punishment. Punishment difference between groups and individuals was only observed for individuals who scored low on psychopathy traits. Social punishment in

cooperation games reflecting sensitivity to others' unfairness relate to individual differences in political views and pro-sociality. The results importantly confirm our hypothesis that groups benefit from decreased punishment demonstrating a most useful motive to join collectives: shared responsibility. Finally, this decreased punishment for groups co-varied with psychopathy traits highlighting interesting individual differences in judgments of individuals vs groups.

Title: The songs of my people: Appraisal differences of popular music as a function of ideology

Authors: *C. F. MYERS[1], S. SPIVACK[1], N. H. SPILKA[1], S. J. PHILIBOTTE[2], I. PASSMAN[1], P. WALLISCH[3]
[2]Dept. of Psychology, [3]Ctr. Neural Sci., [1]New York Univ., New York, NY

Abstract: Music powerfully engages brain and mind, yet remains largely underutilized as experimental stimulus material. Here, we wondered how ideological differences manifest in terms of musical preferences. To explore this question, we studied a large sample of research participants by exposing them to a representative corpus of musical stimuli while also eliciting their ideological position. Doing so, we found that ideological differences are linked to specific signatures of musical appraisal - there are significant genre-based differences in self-reported listening behavior as well as appraisal differences in how people with different ideological affiliations experience the music when listening to it. This effect is strong: ideology can be used to predict whether an ambiguous stimulus in terms of valence - e.g. country music - is experienced as aversive or enjoyable. As political preferences affect aesthetic judgments, we conclude that ideological positions are more deeply rooted than suggested by a discourse model of political exchange.

Title: Shared brain microstructure across genetic models of schizophrenia and autism spectrum disorder

Authors: *B. R. BARNETT[1], C. P. CASEY[2], M. TORRES-VELÁZQUEZ[3], S. Y. YI[2], J.-P. J. YU[4]
[2]Neurosci. Training Program, [3]Biomed. Engin., [4]Radiology, [1]Univ. of Wisconsin, Madison, Madison, WI

Abstract: Autism spectrum disorder (ASD) is a complex and genetically heterogeneous neuropsychiatric disease affecting as many as 1 in 68 children. Large scale genetic sequencing of individuals along the autism spectrum has uncovered several genetic risk factors for ASD; however, understanding how, and to what extent, individual genes contribute to the overall disease phenotype remains unclear. Recent work has also uncovered strong evidence for the unanticipated genetic and neurostructural convergence of several psychiatric diseases including ASD, schizophrenia, and major depression. DISC1 is one such gene that stands at the intersection of numerous psychiatric diseases. As with other genetic variants that have been shown to confer an increased risk for disease, the balanced chromosomal t(1;11)(q42.1;q14.3) translocation of the DISC1 gene has been implicated in several psychiatric illnesses including schizophrenia, autism spectrum disorder, and major depressive disorder. Neuroimaging studies of ASD and schizophrenia have revealed a wide spectrum of structural and functional perturbations that are thought to reflect, in part, the complex genetic heterogeneity underpinning both diseases. These perturbations, in both preclinical models and clinical patients, were identified in preclinical genetic models and clinical patients as compared to control subjects; however, few studies have explicitly explored the intrinsic differences between the models themselves. To better understand the degree and extent to which individual genes associated with ASD and schizophrenia differ in their contribution to global measures of neurite density and white matter structural integrity, diffusion tensor imaging (DTI) and neurite orientation dispersion and density imaging (NODDI) was acquired from three novel rat genetic models of ASD (Fmr1, Nrxn1, and Pten) and from a novel Disc1 knockout rat model of schizophrenia. DTI parameters of fractional anisotropy, mean, axial, and radial diffusivity and NODDI parameters of

neurite density and neurite orientation were measured and compared. Our findings demonstrate unexpected convergence in brain structures across all four genetic models and buttresses an emerging understanding of neurostructural phenotypic convergence in psychiatric disease.

Title: Gene therapy reverses physiological and behavioral deficits in a rodent model of schizophrenia

Authors: *J. J. DONEGAN, A. M. BOLEY, D. J. LODGE
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Schizophrenia is a devastating psychiatric disorder characterized by positive symptoms, like delusions and hallucinations, negative symptoms, like social withdrawal, and cognitive deficits. The dopamine hypothesis of schizophrenia suggests that enhanced activity in the mesolimbic dopamine system underlies symptoms of the disorder. Yet, no primary pathology exists in the dopamine system of schizophrenia patients and antipsychotic medications, which target dopamine receptors, only alleviate positive symptoms. This has led to the suggestion that the pathology lies in upstream brain regions, such as the ventral hippocampus (vHipp). Schizophrenia patients display hippocampal hyperactivity and our lab has shown that vHipp hyperactivity underlies increased dopamine cell activity and schizophrenia-like symptoms in the methylazoxymethanol acetate (MAM) rodent model. The increase in vHipp activity is thought to be caused by a deficit in inhibitory GABAergic interneurons. Therefore, we hypothesized that using gene therapy to restore GABAergic signaling in the vHipp would reverse schizophrenia-like deficits in the MAM model. A lenti virus expressing the α5 subunit or α1 subunit of the $GABA_A$ receptor under the control of the CAMKII promoter was injected into the vHipp and rats were allowed 6 weeks recovery before behavioral testing and *in vivo* extracellular recordings were performed. We found that MAM-treated rats had an increase in pyramidal cell firing rate in the vHipp compared to saline-treated controls. This aberrant firing was completely normalized in rats that received the virus to over-express the α5 subunit but not those that received the α1 subunit. To model positive symptoms, we measured latent inhibition and found that MAM-induced deficits in latent inhibition were attenuated by over-expression of the α5, but not the α1,

subunit of the $GABA_A$ receptor. Latent inhibition requires dopamine signaling; and over-expression of the α5, but not the α1, subunit also normalized dopamine cell activity in the ventral tegmental area. Next, using the attentional set-shifting test, we measured two forms of cognitive flexibility disrupted in schizophrenia, reversal learning and extradimensional set-shifting. We found that the MAM-induced deficits in reversal learning were not affected by over-expression of either the α1 or the α5 subunit while extradimensional set-shifting deficits were attenuated by both subunits. Together, these results suggest that gene therapy to restore GABAergic signaling in vHipp pyramidal neurons may be an effective treatment strategy to target multiple symptom domains of schizophrenia.

Title: Nuclear paraspeckle lncRNA, Neat1 is an epigenetic modulator of oligodendroglial function with suppressed transcription in schizophrenia

Authors: *P. L. KATSEL[1], P. ROUSSOS[2], M. PLETNIKOV[3], P. FAM[2], V. HAROUTUNIAN[4], S. NAKAGAWA[5], T. HIROSE[5]
[1]Dept Psych, Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Icahn school of medicine at Mount sinai, New York, NY; [3]Johns Hopkins Univ., Baltimore, MD; [4]Director, Neurobio. Labs., Bronx, NY; [5]Hokkaido Univ., Sapporo, Japan

Abstract: Oligodendrocyte (OLG)/myelin - related abnormalities are strongly corroborated observations in the pathophysiology of schizophrenia. The cause(s) of these abnormalities is unknown. Noncoding RNAs (ncRNAs) are important part of multifaceted transcriptional complexes participating in neurogenic commitment and regulation of post-mitotic cell maturation and function. A long ncRNA, NEAT1, is a structural component of paraspeckles, subnuclear bodies in interchromatin regions that may control activity of developmental enhancers of OLG fate specification. Gene expression studies of multiple cortical regions from individuals with schizophrenia showed strong downregulation of NEAT1 levels compare to controls. Evaluation of "quaking-Qk" mice which exhibit demyelination and $NEAT1^{-/-}$ mice revealed that NEAT1 loss is strongly associated with decrease of number of OLG lineage cells in the frontal cortex. To gain insight into biological processes affected by deficiency of NEAT1

expression we analyzed RNA-Seq data from frontal cortex of NEAT1$^{-/-}$ mice. Analyses of differentially expressed gene signature from NEAT1$^{-/-}$ mice reveal a significant impact on processes related to OLG differentiation and RNA post-transcriptional modification. We present evidence of coexpression of SOX10 and NEAT1 in OLG nuclei, and show enrichment of OLG specific transcripts in NEAT1 purified chromatin isolates (ChIRP) from human frontal cortex. Reduced nuclei retention of Qki isoform 5 in NEAT1$^{-/-}$ mice shed light on possible mechanism(s) responsible for reduced expression of OLG proteins and support strong involvement of NEAT1 in the mechanisms underlining myelin deficit in schizophrenia.

Title: Psychopathology in a 15q13.3 microdeletion mouse model to probe mechanisms for early intervention

Authors: K. D. BORNEMANN, M. HEIL, S. JAEGER, *J. R. NICHOLSON, N. SCHUELERT, H. ROSENBROCK, V. MACK
Boehringer Ingelheim Pharma GmbH & Co.KG, Biberach, Germany

Abstract: Rodent models for rare gene copy number variants, which confer high risk for psychiatric diseases such as schizophrenia (SCZ), are attractive to test new therapeutic concepts. With a particular focus on early pathophysiology as e.g. observed in patients with clinical high risk for psychosis, we explored biomarkers of cortical network synchrony and GABAergic interneuron function in the Df(15q13)/+ mouse model. This mouse line carries a deletion in chromosome 7, which corresponds to the human chromosome 15q13.3 region, comprising six genes linked to psychiatric risk. As shown by others, we could reveal a reduced density of parvalbumin-positive interneurons (PVI) in the prefrontal cortex (PFC) of young adult mice, indicative of impaired cortical excitatory-inhibitory (E/I) balance and network synchronization. The deficits in PVI density were accompanied by reduced size of perineuronal nets (PNN), which are crucial for PVI function and protection against oxidative stress. To address neurophysiological consequences linked to cortical pathology, we are about to assess changes in network synchrony and sensory processing by in vivo electroencephalography in the PFC and auditory cortex. We aim for monitoring translational biomarkers that have been reported to be abnormal in several psychiatric diseases, such as event-related potentials and γ oscillation (evoked power and inter-trial coherence). Taken together, the Df(15q13)/+ mouse might serve as

a preclinical model for early psychiatric pathophysiology and, thereby, offers the possibility to probe therapeutic concepts aimed at early intervention in the disease progress.

Title: Hearing loss, auditory sensorimotor gating deficits, and cortical interneuron abnormalities in a mouse model of 22q11.2 Deletion Syndrome

Authors: *J. F. LINDEN[1], F. A. ZINNAMON[2], F. G. HARRISON[1], S. S. WENAS[1], A. F. MEYER[1], Q. LIU[3], K. H. WANG[3]
[1]Univ. Col. London, London, United Kingdom; [2]Univ. Col. London and Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The chromosomal microdeletion that causes 22q11.2 Deletion Syndrome (22q11DS) confers a 25-30% risk of developing schizophrenia. An estimated 40-70% of patients with 22q11DS also have hearing loss, mostly from otitis media (OM). In the *Df1/+* mouse model of 22q11DS, similar rates of hearing loss and OM occur (Fuchs et al. *PLoS One* 2013) and have been shown to arise from haploinsufficiency of the *TBX1* gene within the minimum 22q11DS deletion region (Fuchs et al. *Hum Mol Genet* 2015). However, the relationship between hearing loss and susceptibility to schizophrenia-relevant brain and behavioural abnormalities in 22q11DS is unknown. Here we report a link between hearing loss, deficits in auditory sensorimotor gating, and abnormalities in parvalbumin-positive auditory cortical interneurons in a mouse model of 22q11DS.
Using the auditory brainstem response (ABR), we found that 60% of *Df1/+* mice had hearing loss in one or both ears. However, suprathreshold cortical auditory evoked potentials (AEPs) were similar in *Df1/+* and WT mice. The ratio between AEP P1-N1 or N1-P2 amplitude and ABR wave I amplitude was significantly higher in *Df1/+* mice with hearing loss than in WT mice or *Df1/+* mice without hearing loss, suggesting a compensatory increase in central auditory gain in *Df1/+* mice with hearing loss.
Behavioural measures similarly revealed an influence of hearing loss. Acoustic startle response (ASR) thresholds were significantly higher in *Df1/+* than WT mice. Prepulse inhibition (PPI) of

ASR was reduced in *Df1/+* mice relative to WT for prepulse cues with fixed sound level, as has previously been reported elsewhere. However, we found that there was no significant difference in PPI between *Df1/+* and WT mice when the prepulse cue sound level was adjusted to be constant relative to the startle threshold for each animal.
Finally, in immunohistochemical studies, we found that the density of parvalbumin-positive (PV+) interneurons in the auditory cortex was significantly reduced in *Df1/+* compared to WT mice. This abnormality arose primarily in *Df1/+* mice with hearing loss, suggesting cortical compensation for loss of input.
Overall, the findings indicate that *Df1/+* mice have reduced hearing sensitivity and elevated startle thresholds, but also increased central auditory gain and reduced density of PV+ inhibitory interneurons in auditory cortex. Moreover, PPI of acoustic startle in *Df1/+* and WT mice differs for prepulse cues of fixed sound level, but not when the cue level is adjusted relative to startle threshold. Thus, the findings suggest a complex interaction between hearing loss and auditory brain and behavioural abnormalities in 22q11DS models.

Abstract: A chromosomal translocation linked to schizophrenia in a large Scottish family disrupts the DISC1 gene. To identify translocation-induced disease pathways we have carried out RNASeq analysis of induced pluripotent stem cell (IPSC)-derived cortical neurons from translocation family members, and of brain cortex from a corresponding mouse model that recapitulates the effects of the translocation upon DISC1 expression. The set of dysregulated genes in the human cortical neurons is enriched for matches to genes whose expression is altered by independent DISC1 mutations in IPSC-derived human neurons. A substantially overlapping set of genes is dysregulated in both human cortical neurons and mutant mouse cortex. Moreover, gene ontology and pathway analysis predict largely the same major dysregulated functions in both datasets, including excitatory synapse dysfunction. Multiple putative schizophrenia genes identified through recent large-scale genome-wide association and copy number variant studies are dysregulated in the human cortical neurons and mutant mouse cortex. These sets of dysregulated putative schizophrenia genes highlight defective synapse function and plasticity as likely disease pathways. Altogether these observations indicate that i) many of the gene expression changes in the human cortical neurons are due to disruption of DISC1, ii) DISC1 disruption may act as a trigger for common shared disease pathways in schizophrenia, and iii) defective excitatory synapse function and plasticity due to the translocation may be a disease mechanism.

Title: Src deficient mice demonstrate behavioral and electrophysiological alterations relevant to schizophrenia

Authors: O. MELNYCHENKO[1], K. R. WARD[2], C.-G. HAHN[3], *R. E. FEATHERSTONE[1], S. J. SIEGEL[1]
[1]Psychiatry and Behavioral Sci., USC, Los Angeles, CA; [2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [3]Dept Psychiat, Univ. Pennsylvania Sch. Med., Philadelphia, PA

Abstract: While much evidence suggests that hypofunction of the *N*-methyl-D-aspartate glutamate receptor (NMDAR) hypofunction is a primary cause of schizophrenia (SCZ), little is known about the molecular basis of NMDAR dysfunction. Sarcoma tyrosine kinase (Src) serves as a hub for signaling mechanisms affecting GluN2 phosphorylation, and can be disrupted by convergent alterations of various schizophrenia susceptibility pathways. Src signaling is reduced in post mortem tissue from schizophrenia patients, despite increased MK-801 binding and NMDA receptor complex expression in the postsynaptic density (PSD), suggesting that Src dysregulation may be a primary mechanism responsible for reduced glutamate signaling in schizophrenia (Banerjee et al. 2015). Despite evidence for a central role of Src in NMDAR signaling, little is known about how reductions in Src activity might regulate phenotypic changes relevant to schizophrenia. As such, the current study sought to characterize behavioral, electrophysiological and anxiety related phenotypes in mice heterozygous for the Src *Acl* gene (Src+/- mice). Male and female Src+/- mice were compared with litter mate controls on a series of behavioral and EEG related measures relevant to schizophrenia. Src+/- mice demonstrated decreased sociability and working memory relative to Src+/+ (WT) mice while no significant differences were seen on locomotive activity and anxiety. In relation to WT mice, Src+/- mice showed decreased P20 and N40 event related potential (ERP) amplitudes, decreased mismatch negativity (MMN) and decreased evoked gamma power, which was only present in males. Decreased MMN was reversed following a single administration of the mGluR5 antagonist MPEP (2-Methyl-6-(phenylethynyl)pyridine). Src+/- mice express behavioral, cognitive, and electrophysiological phenotypes, consistent with those seen in patients with SCZ. This data indicates that Src+/- mice are a promising model for the negative symptoms of schizophrenia.

Title: Behavioral phenotype of glyoxalase 1 knockout mice

Authors: *K. SUZUKI, K. TORIUMI, Y. HORIUCHI, M. MIYASHITA, M. ITOKAWA, M. ARAI
Tokyo Metoropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: Schizophrenia is considered to be a heterogeneous psychiatric disorder, since symptom and severity seen in patients with schizophrenia varies widely among individuals. Recently, we found a characteristic group in which patients exhibit high plasma pentosidine, one of advanced glycation end products (AGEs), and depletion of serum vitamin B_6, known as a scavenger of AGEs. Schizophrenic patients in the group account for approximately 20%. Furthermore, we found several schizophrenic patients with novel heterozygous frameshift and missense mutations in Glyoxalase 1 (*GLO1)* gene with 40-50% and 15-20% reduction of enzymatic activity, respectively. GLO1 is one of enzymes to detoxify reactive carbonyl compounds such as methylglyoxal, preventing the eventual formation of AGEs. However, the association between GLO1 deficit and schizophrenia development remains unclear.
In order to evaluate effects of GLO1 deficits on behavior, we generated *Glo1* knockout (KO) mice and assessed their behavioral phenotypes. In the open field test, *Glo1* KO mice showed less locomotor activity compared with wild-type (WT), but no significant difference in time spent in the center zone. Furthermore, *Glo1* KO mice showed shortened immobility time in the forced-swimming test and exhibited remarkable reduction in the acoustic startle response, resulting in enhanced prepulse inhibition. *Glo1* KO mice showed no changes in the Y maze test and the social interaction test. Additionally, in order to assess stress vulnerability of *Glo1* KO mice, we performed social avoidance test after chronic social defeat stress, but we have not detected significant difference between WT and KO mice so far.
These results suggest that GLO1 deficits induce some behavioral changes. However, the behavioral deficits observed in *Glo1* KO mice were not typical schizophrenia like-behaviors. As it is widely accepted that not only genetic but also environmental factors play key roles in development of schizophrenia, further experiments using more suitable and gene-environment interaction models, such as *Glo1* mice fed with VB6-deficient diet, will be needed in the future.

Title: Behavioral flexibility of male and female rats in the MAM animal model of schizophrenia

Authors: *M. GHASEMZADEH, D. KRAVTSOV, L. KELBLE
Dept. of Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Schizophrenia is a neurodevelopmental disorder with distinct abnormal behaviors and cognitive deficits. Since the MAM neurodevelopmental animal model (E17 gestational methylazoxymethanol acetate administration) displays some anatomical and neurochemical deficits associated with schizophrenia, we examined the performance of the MAM-treated animals (Sprague-Dawley rats) in behavioral cognitive tasks to evaluate the extent and nature of the deficits in this model. Rats were bred on site and MAM (22 mg/kg, ip) or saline (1 ml/kg, ip) was administered on gestation day 17. Male and female offspring were housed 3-4 per cage and were provided with enrichment. All efforts were made to eliminate sources of stress in these animals during development and behavioral testing. We examined adult male and female rats (PND > 90) for performance in behavioral flexibility using an automated operant procedure. Since MAM animals show abnormal development of prefrontal cortex, we employed strategy set-shifting and reversal learning tasks to examine their performance. Adult female and male MAM rats performed as well as controls in initial learning of a response or a visual-cue. However, both adult female and male MAM rats displayed a deficit in visual-cue to response strategy shift by requiring a higher number of trials to achieve criterion. In addition, both adult female and male MAM rats demonstrated impairment in reversal learning of a discrimination task. Notably, the deficits in behavioral flexibility in MAM rats became more prominent as the relative difficulty in type of strategy shift and reversal learning increased. In other studies, adult MAM rats displayed decreased level of anxiety, higher social interaction, and augmented locomotor response in a novel environment. In order to examine the developmental nature of behaviors displayed by adult MAM rats, we examined the male and female rats during adolescence (PND 35-45). The adolescent MAM rats (male and female) responded with higher locomotor activity in a novel environment, which continued through adulthood. In an open field arena, adolescent rats (male and female) spent more time in the center of the arena compared to the saline-treated animals. In addition, adolescent MAM animals (male and female) spent more time on the open arm of the elevated plus maze compare to saline-treated rats which continued into adulthood. The overall pattern of behaviors displayed by the MAM developmental animal model is suggestive of a deficit in cognitive flexibility and behavioral inhibition and may be a useful model in examining the neuronal basis of these abnormalities in mental disorders.

Title: Neonatal blockade of NR2A-containing NMDA receptors induces schizophrenia-like behavior in adult rats

Authors: *H. FURUIE, H. KUNIISHI, M. YAMADA
Dept. of Neuropsychopharm., Natl. Ctr. of Neurol. and Psychiatry, Kodaira-shi, Tokyo, Japan

Abstract: N-methyl-D-aspartate (NMDA) receptor, an ionotropic glutamate receptor subtype, plays pivotal roles in brain development. Chronic neonatal blockade of NMDA receptors causes various behavioral abnormalities similar to those observed in schizophrenia in adulthood, and it is suggested that these effects are due to the neurodevelopmental interference. NMDA receptors are composed of NR1 and NR2A-D and/or NR3A-B subunit, and NR2A- and 2B-containing receptors are principally expressed in the postnatal rodent forebrain. However, differential roles of NR2A and NR2B- containing NMDA receptors in the postnatal brain development are unknown. To address this issue, we compared the effects of neonatal treatment with an NR2A-preferring antagonist PEAQX, an NR2B-selective antagonist ifenprodil, and a non-selective NMDA receptor antagonist MK-801 on the expression of schizophrenia-like behavior in adulthood.
Seventy-nine male pups obtained from 14 female Wistar-Imamichi rats were used in the experiments. On postnatal day (PND) 7, pups were randomly assigned to four treatment conditions. From PND 7 through 20, they were administered one of the following four drugs twice per day: PEAQX (10 mg/kg), ifenprodil (7.5 mg/kg), MK-801 (0.4 mg/kg), or saline. Rats were weaned at PND 28 and housed in groups of 2 or 3 rats per cage. At PND 70, the rats were tested in the prepulse inhibition (PPI) test, the social interaction test, the spontaneous alternation test, and the MK-801-induced locomotor test.
Interestingly, PEAQX-, ifenprodil- and MK-801-treated rats showed equivalent PPI compared with SAL-treated control. On the other hand, PEAQX- and MK-801-treated rats exhibited greater startle response when compare to SAL- and ifenprodil-treated rats. PEAQX- and MK-801-treated rats also showed significantly lower spontaneous alternation ratio than SAL- and ifenprodil-treated rats. Furthermore, neonatal PEAQX treatment increased sensitivity to locomotor-stimulating effect of acute MK-801 challenge. In conclusion, our results suggest that NR2A-containing NMDA receptor is essential for normal brain development during neonatal

period, and the blockade of this receptor in this period induces schizophrenia-like behavior in adulthood.

Title: Phenotypic characterization of mice lacking exons 4-13 of Disc1 gene

Authors: *P. SIOW, L.-J. LEE
Grad. Inst. of Anat. and Cell Biol., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Schizophrenia is a chronic mental disorder that affects a person's feeling, thoughts, and behaviors. One of the candidate susceptibility gene related to the pathogenesis of this disease is *Disrupted-in-Schizophrenia 1* (*DISC1*). We have established a *Disc1* mutant mouse line in which the exons 4 to13 were deleted by the expression of *Emx1-Cre* in the excitatory neurons of the forebrain. Both homozygous (Homo) and heterozygous (Het) forebrain-specific *Disc1* knockout (Fb*Disc1* KO) mice were apparently normal with no significant physical impairment. Behavioral examinations were then conducted. In the open field test, mice of all three genotypes (wildtype, WT, Het and Homo) behaved similarly in distance travelled and time spent in central and peripheral regions. In the novel object recognition test, Homo mice displayed impaired short-term recognition memory, while WT and Het mice had comparable performances . In the elevated plus maze test, Homo mice spent more time in the open arms than WT and Het mice and no difference was noticed between WT and Het groups. In the forced swim test, no significant difference was found among the three genotypes. Our preliminary results showed behavioral abnormalities in Homo Fb*Disc1* KO mice in cognition and emotional aspects while Het mutants seemed to be normal.

Title: Maternal infection alters methylome of schizophrenia loci in female brain

Authors: *Z. YU[1], K. UENO[2], R. FUNAYAMA[1], M. SAKAI[3], C. ONO[1], K. NAKAYAMA[1], M. NAGASAKI[1], H. TOMITA[1]
[1]Tohoku Univ., Sendai, Japan; [2]Tohoku Univ., Tohoku Medical Megabank Organization, Japan; [3]Dept. of Disaster Psychiatry, Grad. Sch. of Medicine, Tohoku Univ., Sendai, Japan

Abstract: Schizophrenia is a severe and relatively common mental disorders, affecting approximately 1% of the world's population. Maternal infection during pregnancy has been considered a plausible risk factor for schizophrenia. Although differential DNA methylation at CpG is a well-characterized epigenetic hallmark for schizophrenia, the mechanisms is unknown.Here we use murine maternal viral infection schizophrenic model, after behavioral evaluations of offspring from polyriboinosinic-polyribocytidilic acid (poly I:C)- and phosphate-buffered saline (PBS)-treated pregnant mice, prefrontal contextual gene expression and DNA methylation profiling were analyzed. Female offspring show more methylated CpG sites, as well as higher levels of *Dnmt1*mRNA expression.DNA hyper-methylation that contribute to genes transcript reduction was observed in poly I:C-treated female offspring along with more striking schizophrenia like behavior than PBS-treated females, but not males. Poly I:C significantly induced *Dnmt* expression in female offspring of poly I:C treated dams. Neuron and synapse-relevant genes were significantly over-represented among poly I:C affected genes in females, whereas no specific category of genes was over-represented in males. An in-depth investigation of astrocyte marker gene showed significant hyper-methylation DNA and reduced gene expression in female offspring of poly I:C-treated dam and female schizophrenia patients postmortem tissues.Present results not only generated gender different genome-wide DNA methylation, but also identified new candidate genes for maternal infection during pregnancy which may affect neuron and glia cell development. Our study suggest that based on significant gender difference in genome-wide DNA methylation profiling, and provide a breakthrough in elucidating the pathogenesis of schizophrenia via studies into gender differences in the susceptibility.

Title: Maternal immune activation in rats blunts brain cytokine and kynurenine pathway responses to a second immune challenge in early adulthood

Authors: *S. M. CLARK[1], F. M. NOTARANGELO[2], X. LI[1], S. CHEN[2], R. SCHWARCZ[2], L. TONELLI[1]
[1]Psychiatry, [2]Maryland Psychiatric Res. Center, Dept of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Maternal immune activation (MIA) with the viral mimic poly (I:C) provides an established rodent model for studying schizophrenia (SZ) and other human neurodevelopmental disorders. Postnatal infections are additional risk factors in SZ and may cumulatively contribute to the emergence of pathophysiology. Underlying mechanisms may involve metabolites of the kynurenine pathway (KP) of tryptophan degradation, which is readily induced by inflammatory stimuli. In the present study, the expression of selected cytokines and KP enzymes, and the levels of selected KP metabolites, were evaluated in the brains of MIA offspring following a second, acute immune challenge with lipopolysaccharides (LPS) on postnatal day (PND) 35 (adolescence) or PND 60 (early adulthood). Peripheral measures of kynurenine (KYN) and kynurenic acid (KYNA) were also determined in the plasma. Assessed in adolescence, MIA did not alter the expression of pro-inflammatory cytokines (except TNF-α) or KP metabolite levels compared to controls, but substantially reduced the expression of the anti-inflammatory cytokines IL-4 and IL-10 and influenced the expression of two of the four KP enzymes examined (IDO1 and TDO2). LPS treatment caused distinct changes in central expression of pro- and anti-inflammatory cytokines, as well as KP enzymes in MIA offspring, with no effect on KP metabolites compared to control rats. Additionally, while LPS increased plasma KYN levels, there was no effect on peripheral KYNA. Several of these effects were blunted in MIA offspring receiving LPS on PND 60. Notably, LPS caused a significant reduction in brain kynurenine levels in these animals. Of relevance for SZ-related hypotheses, these results indicate that MIA leads to an increasingly defective, rather than overactive, regulation of cerebral KP metabolism during the postnatal period.

Title: NFAT5 regulates psychotomimetic behaviors of mice through modulating brain dopaminergic neurotransmission

Authors: *S. KIM[1], H. PARK[2], Y. KIM[1], Y. AHN[3], H. KWON[4]
[1]Dongguk Univ. Intl. Hosp., Ilsandong-Gu, Goyang-Si, Gyeonggi-Do, Korea, Republic of; [2]Dept. of Biomed. Sciences, Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [3]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [4]Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

Abstract: Nuclear factor of activated T-cells 5 (NFAT5), also known as tonicity enhancer element binding protein (TonEBP), is the osmosensitive transcription factor, which plays a crucial role in protection of renal medullary cells against hyperosmotic stress, urinary concentration, the adaptive immune response. NFAT5 is expressed abundantly in the brain, while the functions in nervous systems have not been understood yet. We examined the role of NFAT5 on the behaviors in terms of mood and psychotomimetic domains and the behavios-related regulatory mechanisms. NFAT5 heterozygote (+/-) mice did not show significant differences compared to wild type (WT) mice in forced swim test, sucrose preference test, and open field activity. When chronic unpredictable stress (CUS) has been applied, WT mice demonstrated depression-like behavioral phenotypes, while NFAT5 (+/-) mice showed attenuated response to CUS compared to WT. The reponse to cocaine injection was also in NFAT (+/-) mice compared to WT. While overexpression of TonEBP gene in mice striatum using adenovirus iuduced the increased behavioral response to cocaine. The dopamine level was reduced in the striatum of NFAT5 (+/-) mice compare to WT. NFAT5 gene knockdown using siRNA showed reduced expression of dopamine decarboxylase and tyrosine hydroxylase genes. The findings suggest the important role of NFAT5 gene in dopamine neurotransmission and related psychotomimetic behaviors in the brain.

Title: Impaired latent inhibition in NrCAM-deficient mice exposed to chronic stress

Authors: C. K. BROWN, 84322[1], C. V. BUHUSI[2], *M. BUHUSI[1]
[1]Dept. Psychology, [2]Interdisciplinary Program in Neurosci., Utah State Univ., Logan, UT

Abstract: Schizophrenia is a neurodevelopmental disorder characterized by abnormal processing of information and attentional deficits. Schizophrenia has a high genetic component but is precipitated by environmental factors, as proposed by the 'two-hit' theory of schizophrenia. One of the top candidate genes related to vulnerability to schizophrenia is NrCAM, with essential roles in neuronal connectivity and function. Here we compared latent inhibition as a measure of learning and attention, in NrCAM-deficient mice, and their wild-type littermates, under no-stress and chronic stress conditions. Freezing behavior in response to pre-exposed and non-pre-exposed stimuli paired with foot shocks was analyzed to assess latent inhibition. Analyses indicated a main effect of pre-exposure (F(1,36)=37.24, p < 0.01), a pre-exposure x stress interaction (F(1,36)=5.24, p < 0.05), and a pre-exposure x stress x genotype interaction (F(1,36)=4.28, p < 0.05). Post-hoc analyses showed that all unstressed mice as well as the wild-type stressed mice showed latent inhibition (p < 0.01); in contrast, NrCAM-deficient mice did not show latent inhibition after chronic stress (p > 0.05). Differences in activation in brain regions associated with latent inhibition - such as the prefrontal cortex and nucleus accumbens - were identified using c-Fos immunostaining. These results provide strong support for a 'two-hit' (genes x environment) effect on latent inhibition in NrCAM-deficient mice, and identify NrCAM-deficient mice as a model of schizophrenia-like learning and attention impairments.

Title: Adolescent stress induces a schizophrenia-like phenotype in a rodent model of susceptibility

Authors: *S. M. PEREZ[1], D. J. LODGE[2]
[1]Pharmacol., [2]UTHSCSA, San Antonio, TX

Abstract: Factors that contribute to the development of schizophrenia include both, genetic and environmental conditions. Rodent models are used to recapitulate various aspects of the disease; however, to our knowledge there are no models routinely used to examine schizophrenia susceptibility. Here, we employ the use of a verified gestation disruption model, the methylazoxymethanol acetate (MAM) E17 model, to produce a model of susceptibility to circuit level alterations and behavioral deficits consistent with those observed in schizophrenia. Specifically, first filial generation (F1) MAM-treated rats were mated to produce second filial generation (F2) offspring. We have previously demonstrated that only a proportion (~30%) of F2 MAM-treated rats display a schizophrenia-like phenotype, defined as an increase in ventral tegmental area (VTA) dopamine neuron population activity. This aberrant dopamine neuron activity has been previously attributed to hyperactivity in the ventral hippocampus (vHipp). Thus, we posit that the F2 generation MAM rats provide a model of susceptibility whereby the effect of environmental risk factors can be investigated. We now examine the effect of adolescent stress (a known risk factor for psychiatric disease) in this model and report that a significantly greater proportion of F2 MAM-treated rats (~70%) displayed a schizophrenia-like phenotype, determined by dopamine neuron electrophysiology, following adolescent stress (predator odor). Indeed, this was correlated with increases in the firing rates of vHipp putative pyramidal neurons. Taken together, these data provide mechanistic insights into how adolescent stress may contribute to the pathophysiology of psychiatric diseases, such as schizophrenia.

Title: The mPTP-regulating protein cyclophilin D contributes to oxidative stress in a developmental rodent model of schizophrenia

Authors: *A. J. PHENSY[1], K. A. LINDQUIST[4], D. BAIRUTY[2], K. RAPOLU[3], K. KING[3], H. DU[5], S. KROENER[6]
[1]Behavioral and Brain Sci., [2]Biol., [3]Univ. of Texas At Dallas, Richardson, TX; [4]Psychiatry, Univ. of Texas at Southwestern, Dallas, TX; [5]Biol. Sci., [6]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Cognitive deficits are a major predictor for clinical outcome in schizophrenia; however, current treatments are ineffective in treating these deficits. Pathological changes in NMDAR signaling and a loss of GABAergic parvalbumin interneurons (PVI) in the PFC and hippocampus appear to be crucial to the development of network dysfunction and the emergence of cognitive deficits. The loss of PVI is an important biomarker in post-mortem studies of schizophrenia; however, the mechanisms behind this loss are still unknown. The fast-spiking PVI have high metabolic needs which render them susceptible to periods of oxidative stress. Excessive stress can activate cyclophilin D (CypD), which alters the mitochondrial membrane permeability and results in reduced ATP production, as well as an efflux of reactive oxygen species (ROS) and calcium from the mitochondrial matrix into the cytosol, further increasing oxidative stress and eventually disrupting neuronal development and function. Perinatal blockade of NMDA receptors with ketamine induces a persistent schizophrenia-like phenotype in adult mice, which includes deficits in cognition, as well as positive and negative symptoms. These changes correlate with reduced PVI immunoreactivity and increased levels of mitochondrial-derived ROS in PVI of the PFC. Here, we examined if genetic deletion of CypD (via ablation of the *Ppif* gene) can protect against ketamine-induced loss of PVI and the development of behavioral deficits. CypD knockout (CypD-KO) and wild-type (CypD-WT) mice were treated with ketamine (30mg/kg) on postnatal days (PND) 7, 9, and 11. In adult animals (PND 60-90) we then assessed behavioral alterations in a battery of cognitive and memory tasks. In addition, we used immunohistochemistry to measure changes in PVI expression in the PFC after PND 90. Our data show that CypD-KO animals are protected from PVI loss, as well as deficits in attentional set-shifting, novel-object recognition, and social interaction that result from perinatal

ketamine exposure. Thus, CypD activation and subsequent mitochondrial ROS release may provide a novel mechanism that contributes to the pathological changes in schizophrenia.

Title: Behavioral and electrophysiological characterization of a post-weaning isolation model of schizophrenia

Authors: *L. ANDREOLI, E. MORYA
Inst. Santos Dumont, Macaiba, Brazil

Abstract: There is still a lot to learn about the physiopathology of mental disorders, among them, schizophrenia, but recent studies suggest an involvement of mesolimbic and mesocortical structures. This work aims to investigate behavioral characteristics and electrophysiological interaction of mesolimbic and mesocortical activity in a post-weaning isolation animal model of schizophrenia. This project used 20 Wistar rats to analyze behavioral differences between healthy controls and post-weaning isolated rats as a model for schizophrenia and 16 rats to study electrophysiology. Animals performed three behavioral tasks: (1) socialization, (2) prepulse inhibition (PPI) and (3) novel object recognition (NOR) while recorded in videos with the Cineplex software (80 Hz, Plexon Inc, USA). In all tasks, the animals assigned to electrophysiology studies went through local field potentials (1 kHz, Plexon Inc, USA) and spike activity recording (40 kHz, Plexon Inc, USA). Animals in electrophysiology group went through stereotaxic neurosurgery for microelectrode arrays implant (32 channels, tungsten wire of 50 um diameter) in five areas: ventral tegmental area (VTA), amygdala (AMG), nucleus accumbens (NACC), hippocampus (HIPC) and pre-frontal cortex (PFC). Our preliminary analysis evaluated if there were behavioral differences between GC and SCZ groups to investigate the electrophysiological mechanisms of such differences through firing rate and power spectral density analysis. SCZ animals interacted socially more time ($U = 12$, $p = 0.050$) and more frequently ($U = 6$, $p = 0.008$) then GC animals. There was no statistical difference in exploration time on new ($t(12.68) = 0.142$, $p = 0.889$) or old ($t(18) = -1.536$, $p = 0.142$) object between SCZ and GC groups and there was no difference on PPI startle response in any type of pulse between SCZ and GC (pulse1: $t(17) = -0.177$, $p = 0.862$, pulse2: $t(17) = 0.540$, $p = 0.596$, pulse3: $t(17) = -$

0.410, p = 0.687, pulse4: t(17) = 0.483, p = 0.635). Our preliminary data showed two units in PRL and NACC of GC animals and seven units in SCZ animals in PRL and VTA correlated to social interaction. Additionally, VTA neurons were related to objects exploration (both new and old) in NOR task and NACC neuron were related to tone presentation in PPI test. These results are important towards an increase in the comprehension of the physiopathology of schizophrenia and, in consequence, to assist in creating new therapies and technologies to assist people affected by the disorder.

Title: Behavioral and microdialysis studies indicate E/I imbalance contributes to cognitive impairment, psychosis and deficit in social interaction in subchronic phencyclidine-treated mice

Authors: *H. Y. MELTZER[1], L. RAJAGOPAL[2], W. HE[4], M. HUANG[3]
[1]Northwestern Univ. Sch. of Med., Chicago, IL; [2]Psychiatry and Behavioral Sci., [3]Psychiatry and Behavior Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [4]Northwestern Univ., Chicago, IL

Abstract: E/I imbalance as a cause of cognitive impairment (CI), psychosis, and negative symptoms in schizophrenia (SCH) is based, in part, on the effects of phencyclidine (PCP), an NMDAR antagonist, in SCH patients and normal subjects. There is conflicting evidence concerning the role of $GABA_A$ receptors (R) and NMDARs in causing these behavioral disturbance and contributing to the efficacy of atypical antipsychotic drugs (APDs). We have now examined drugs affecting GABARs and other aspects of GABA interneuron activity and targets, alone and in combination with the atypical APD, lurasidone (Lur), in WT and scPCP-treated mice (7 days treatment and withdrawal for > seven days) to clarify the contribution of GABA and E/I balance to specific PCP-induced behavioral abnormalities. These include deficits in novel object recognition (NOR), reversal learning (RL), social interaction (SI), PCP- and amphetamine(AMP)-induced locomotor activity (LMA) in scPCP or WT mice. We used microdialysis to measure efflux of DA, NE, ACh, 5-HT, GABA, and glutamate (Glu) in mPFC, ventral HIP, or dorsal STR in awake, freely moving WT and scPCP-treated adult mice. Gabazine (GZ), a $GABA_A$ antagonist, did not rescue NOR, RL or SI. Lur alone, and the $GABA_A$ agonists, gaboxadol, the $alpha_5$-targeting $GABA_A$ agonists, AA29504, , and L655708, restored NOR, RL

and SI. Lur blocked PCP- and AMP-induced LMA in WT- and scPCP-treated mice. GZ enhanced AMP-induced LMA in WT and scPCP mice. GZ blocked PCP-induced LMA in scPCP mice but not in WT mice. GZ also blocked the effect of Lur to decrease PCP-induced LMA in scPCP mice, but had the opposite effect on PCP-induce LMA in scPCP mice in the absence of Lur. The combination of the classical $GABA_A$ antagonist, bicuculline, which we will show also may act like an agonist in the scPCP model, and Lur, enhanced cortical and dorsal hippocampal DA, Glu and especially GABA efflux whereas bicuculline alone or Lur alone had no effect on GABA efflux, in either region. Thus, enhancing GABA efflux was of benefit in rescuing cognitive deficits in the scPCP-treated mice. Cortical and hippocampal GABA efflux were positively correlated in scPCP-treated mice, but negatively correlated in the PFC of the WT mice. DA, GLU, and GABA efflux in PFC were significantly negatively correlated in WT mice, but not in scPCP-treated mice. These results are in accord with other data showing disrupted E/I balance in both mPFC and HIP in scPCP mice. They suggest the scPCP model is useful for studying E/I imbalance in schizophrenia and that Lur and other AAPDs are effective to restore E/I balance. Important differences between the AMP and PCP-models of psychosis are highlighted by these findings.

Abstract: Optogenetics has proven to be a transformative approach to various fields of basic research, particularly in neuroscience. It allows a non-invasive, localized, and temporally selective optical modulation of selected cells within an animal. Chemo-optogenetic tools,

combining chemicals and optogenetics, have been under rapid development. An important aspect for future advancement in optogenetics/chemo-optogenetics is to identify and/or engineer light-driven proteins with novel properties. We have previously developed and characterized a novel high conductance light-controlled chemo-optogenetic system based of the Trpa1b/ligand pairing. With the goal of discovering novel chemo-optogenetic actuators of vertebrate protein targets, we have further developed and optimized a medium-throughput, semi-automated behavioral screening assay to identify novel photoactivatable ligands for endogenous targets. We conducted a pilot screen using 2000 compounds selected for their molecular photoswitch moieties such as acylhydrazones, azobenezene and stilbenes. From this screen, we identified several hits including two lead compounds that have novel and distinct light-induced biological properties, as determined by constellation pharmacology and gene specific knockout approaches. Discovery of novel optogenetic actuators that possess novel and unique properties will undoubtedly enhance our ability to dissect biological processes such as the complex neuronal network of the brain.

Title: Ablating inhibitory synapses with novel optogenetic tool

Authors: *A. BAREGHAMYAN[1], G. G. GROSS[2], W. ZHANG[3], R. E. CAMPBELL[3], D. B. ARNOLD[1]
[1]Neurosci., [2]Mol. Biol., USC, Los Angeles, CA; [3]Univ. of Alberta, Edmonton, AB, Canada

Abstract: We have generated a novel, recombinant, photo-activatable protein complex, with extremely low background activity in the dark. This system is based on the photocleavable protein PhoCl, whose amino acid backbone is cleaved following absorption of 400 nm light, causing a 13-mer peptide to be released from its C-terminus. Using mRNA display we have generated a 10 amino acid peptide (PhoCl binding peptide, Pbp) that binds with high affinity and specificity to the pocket that is created by release of the native C-terminus of PhoCl. Because there is virtually no cleavage of PhoCl in the dark, and because Pbp does not bind to uncleaved PhoCl there is negligible interaction between PhoCl and Pbp in the absence of light. To demonstrate the efficacy of this system we have targeted PhoCl to different subcellular locations such as to the Golgi, and shown that we can inducibly target protein fused to PBP to those

locations with light.
Furthermore, we have shown that using this system we can ablate inhibitory synapses in a light-dependent manner using a split version of the protein GFE3, which uses an E3 ligase targeted to inhibitory synapses to degrade Gephyrin. In the dark, ablation of Gephyrin by the PhoCL/GFE3 complex is undetectable, even when it has been expressed for over one week. This low level of background activity is remarkable given that existing photodimerization systems, when combined with split GFE3, caused almost complete elimination of inhibitory synapses in the dark. Because of its low background activation, even over long periods of time, we believe that this system will be practical for applications requiring photo-activation in vivo.

Title: Acoustically targeted chemogenetics for noninvasive control of neural circuits

Authors: *J. O. SZABLOWSKI, A. LEE-GOSSELIN, B. LUE, D. MALOUNDA, M. SHAPIRO
Chem. Engin., Caltech, Pasadena, CA

Abstract: Neuropsychiatric diseases often involve the dysfunction of specific neural circuits. Ideal treatment would involve noninvasive control of the right brain regions and cell-types at the right time. Existing treatments, including drugs and brain stimulators, modulate the activity of neural circuits, but are either not cell type-specific, lack spatial targeting, or require invasive procedures. Here, we introduce an approach to modulating neural circuits noninvasively with spatial, cell-type, and temporal specificity. This approach, called acoustically targeted chemogenetics, or ATAC, uses transient ultrasonic opening of the blood brain barrier (FUS-BBBO) to transduce neurons at specific locations in the brain with virally-encoded chemogenetic receptors. We used ATAC to noninvasively transduce and subsequently control hippocampus (HPC) and SNc/VTA in mice. For testing the activation, we expressed activatory DREADD (hM3Dq) in the HPC of mice and measured the accumulation of c-Fos. Neurons expressing activatory DREADD were 5.8-fold more likely to also show c-Fos accumulation ($p<1E-3$). To

show neuronal inhibition we evaluated ATAC mice with expression of inhibitory DREADD (hM4Di) throughout the HPC by a context fear conditioning protocol. Mice treated with saline had 2.4-fold higher context fear than those treated with CNO ($p<2E-5$), revealing that noninvasive inactivation of hippocampus prevents memory acquisition. All mice showed normal exploratory behavior the next day and responded to the sound cues equivalently ($p=0.22$), indicating lack of effects on response to painful shocks. The CNO injection alone had no significant effect on the context fear in mice with no FUS-BBBO or WT mice ($p=0.38$). To achieve sub-millimeter targeting precision we combined FUS-BBBO delivery with methods of intersectional genetics. We noninvasively transduced unilateral SNc/VTA region in mice with activatory DREADD (hM3Dq) to induce c-Fos activity with CNO ($p<1.1E-3$). With ATAC selected cells in brain regions of large animals could be placed under chronic pharmacological control.

Title: DART: A new way to revitalize behavioral neuropharmacology

Authors: *M. R. TADROSS[1], B. C. SHIELDS[1], E. W. KAHUNO[1], G. SCHILTZ[2], P. VAGADIA[2], J. IZQUIERDO-FERRER[2], A. REITZ[3], M. LOUGHRAN[3]
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]CMIDD, Chicago, IL; [3]FCCDC, Philadelphia, PA

Abstract: The neuropharmaceutical revolution of the 1950's provided hope to millions that would have otherwise suffered in isolation. Since then, progress has largely stalled. A major

impediment to rational neuropharmaceutical advances can be attributed to a poor understanding of how drugs exert their effects at the circuit level; in particular, how behavioral effects of drugs are mediated by individual cell types in the brain. To address this gap, we developed DART (drugs acutely restricted by tethering), a system in which drugs home to a defined cell type. The method is simple, robust in behaving animals, and *unique* because it functions without mutation or overexpression of the targeted native receptor. *DART is the only method to date that can cell type-specifically map behavioral effects of clinical drugs.* Here, we will provide a progress report, highlighting recent technology advances, summarizing immediate future goals, and engaging with the neuroscience community to forge collaborations and shape future priorities.

Title: Characterizing the expression and function of designer receptors exclusively activated by designer drugs (DREADDs) in the non-human primate

Authors: *S. MUELLER[1], J. A. OLER[1], P. H. ROSEBOOM[1], M. RIEDEL[1], E. FEKETE[1], J. L. GOMEZ[2], J. BONAVENTURA[2], M. MICHAELIDES[2], J.-F. PARE[3], A. GALVAN[3], R. KOVNER[1], M. KENWOOD[1], N. H. KALIN[1]
[1]Univ. of Wisconsin Madison, Madison, WI; [2]Natl. Inst. on Drug Abuse, Baltimore, MD; [3]Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA

Abstract: Anxiety disorders are the most prevalent form of psychiatric illness and constitute an ongoing major public health concern. Nonhuman primates (NHPs) are an ideal translational model for studying the underlying biological mechanisms of anxiety, as well as for developing treatment strategies for future clinical use. DREADDs (designer receptors exclusively activated by designer drugs) technology has the unique potential for pharmacologically manipulating neuronal activity in freely-moving animals for extended periods of time via systemic administration of selective DREADD-activating compounds. In pursuit of developing DREADDs as a tool in the NHP, we sought to validate the expression and functionality of DREADDs in the amygdala, a critical brain region with a central role in anxiety-related behaviors. Here we present data from 3 case studies where we performed viral vector delivery using intraoperative MRI. In subject 1 (*Macaca fascicularis*), which received dorsal amygdala injections of rAAV5-hSyn-hM4Di-mCherry, neuronal expression of DREADDs was quantified across 4.8 mm in the A/P plane surrounding the injection site. Average expression rates within a 2.5 x 2.5 mm region sampled ranged between 17-46%, with subregions near the center of the injection reaching as high as 100%. In two other subjects (*Macaca mulatta*), we injected rAAV5-hSyn-hM4Di-HA into the center of the amygdala (unilaterally in subject 2, and bilaterally in subject 3), and DREADDs expression was assessed 4 weeks later with *in vivo* [^{11}C]clozapine PET imaging. In subject 2, results demonstrated comparatively greater [^{11}C]clozapine binding in the injected amygdala as compared to the non-injected amygdala. In subject 3, bilateral amygdala binding was comparatively greater than pre-surgery baseline levels. Using *in vitro* autoradiography on tissue from subject 2, [^{3}H]clozapine binding was detected in the injected amygdala, with very little binding observed in the non-injected hemisphere. GTPγS exchange in the presence of clozapine also showed greater radio signal relative to baseline in the injected amygdala, suggesting that the expressed DREADDs receptors can functionally couple to the G-protein. In subject 3, electron microscopy using immunogold staining demonstrated that HA-tagged DREADDs localized almost exclusively to the cell membrane, suggesting cell surface expression. Together, these results provide evidence validating the expression and function of DREADDs in NHPs, setting the stage for more detailed behavioral experiments using DREADDs technology, as well as the systematic investigation of hypotheses related to the neural circuits that underlie primate anxiety.

Title: Generation of glycine receptor alpha 4 knockout mice using high-efficient modified CRISPR-Cas9 protocol

Authors: *M. I. DARWISH[1], K. UNO[1], K. TAKAO[2], H. NISHIZONO[2]
[1]Univ. of Toyama, Toyama, Japan; [2]Life Sci. Res. Ctr., Univ. of Toyama, Toyama-Shi, Japan

Abstract: Human glycine receptor α4 (GLRA4) was thought to be a pseudogene due to lack of transmembrane domain, but surprisingly it was recently reported that microdeletion at Xq22.2 including GLRA4 shows symptoms similar to Pelizaeus-Merzbacher disease (PMD). PMD is a hereditary disease that develops due to abnormalities in myelination in the central nervous system and the patient dies in infancy in most cases. To understand the biological role of glycine receptor α4 (Glra4) in cognitive brain functions and whether it is involved in X-linked syndromic intellectual disability, we disrupted Glra4 gene using a developed CRISPR/cas9 protocol for genome editing. Our optimized protocol shows many advantages compared to currently used genome editing protocols. First, we are using C57BL/6J frozen embryos instead of F1 hybrid embryos which will enable the researchers to shorten the time required for preparation of mice by around 2 years (backcrossing is not needed). Second, the genetic recombination rate is as high as 100%, and the mosaic mutation rate is low. Third, it is the first protocol showing that cryopreserved embryos are effective for the production of genetically modified mice. Using our protocol, we generated several lines of knockout and knock-in mice with high reproducibility. Glra4 Systemic knockout mice were generated by designing gRNA targeting exon 4 and introducing it into 1-cell stage embryos of C57BL/6J mice by electroporation. As a result, three lines of mice, namely, 11 bases deletion, five bases deletion, and one base insertion were produced due to the difference in the cleavage site by Cas9 protein. The sequences of F0 mouse and F1 mouse genome were analyzed and we found short truncated protein was expressed in all strains. It had an extracellular neurotransmitter-gated ion channel domain and a glycine binding site, but it lacked transmembrane and intracellular domains. Furthermore, the homozygous deletions of 11 bases and five bases were embryonic lethal. This is an unexpected result, as Glra4 is considered as a pseudogene in humans. Currently, behavioral analysis experiments of Glra4

knockout mice are being conducted. These results show that we developed an improved protocol, by using CRISPR/Cas9 system, which generated rapid, high efficient and non-mosaic mutant mice using cryo-embryo of inbred mice.

Title: Multiplex CRISPR/Cas9-based gene activation in cultured microglia

Authors: *P. MILLER-RHODES[1], H. A. GELBARD[2]
[2]Ctr. for Neurotherapeutics Discovery, [1]Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Next-generation sequencing technologies have vastly expanded our knowledge of factors that regulate the development and homeostasis of microglia. However, the generation of floxed mouse strains capable of achieving cell-specific gene knockout remains a significant bottle-neck in the investigation of such factors *in vivo*. Moreover, current *in vitro* approaches for studying gene function in cultured hematopoietic cells are limited by difficulties associated with expressing full-length cDNAs and/or generating knockout or knockdown cell lines. To circumvent these limitations, we developed a straightforward *in vitro* approach for studying gene function in cultured microglia that relies on recent advances in CRISPR/Cas9 technology. We stably expressed the CRISPR/Cas9 synergistic activation mediator (SAM) complex in the BV2 microglial cell line. When combined with a single guide RNA that targets a desired genomic promoter element, the Cas9-SAM complex activates gene transcription by recruiting endogenous transcriptional machinery to the targeted locus. To establish the utility of this reagent, we used this system to overexpress the transcription factor Mafb from the endogenous locus. Expression of Mafb-targeting sgRNAs resulted in an upregulation of Mafb mRNA and protein. Upregulation of Mafb via this method also resulted in increased expression of the putative Mafb target genes. We also describe a method for multiplex gene activation in BV2-SAM cells whereby tRNA-flanked sgRNAs are expressed in a single polycistronic transcript that is processed by tRNA processing enzymes upon expression in the target cell. Altogether, the reagents described here

can be used broadly to study the function of newly identified microglia-specific genes in the microglia-like BV2 cell line.

Title: Modeling Huntington's disease (HD) by Cas9-based HTT gene editing in isogenic patient-specific induced pluripotent stem cells (hiPSCs)

Authors: *P. LISOWSKI[1], B. MLODY[2], S. SINGH[2], H. TOBIAS[2], J. PRILLER[3], E. WANKER[2], R. KUEHN[2], A. PRIGIONE[2]
[1]iPS Cell Based Dis. Modeling Group, [2]Max-Delbrück-Center for Mol. Med. (MDC), Berlin, Germany; [3]Dept. of Neuropsychiatry, Charité-Universitätsmedizin, Berlin, Germany

Abstract: Huntington’s disease (HD) is an autosomal dominant neurodegenerative disorder characterized by a progressive loss of GABAergic medium spiny neurons (MSNs) in the striatum. The disease is caused by a mutation in the CAG repeat tract of the huntingtin gene HTT, which leads to an expanded polyglutamine stretch (polyQ) in the huntingtin protein HTT. The presence of 40 CAG repeats or more give rise to the disease, with longer repeats associated with more aggressive forms. In order to clearly dissect the impact of the disease-causing HTT mutation, we have taken an advantage of Cas9-based genome editing technology that allowed for generation of isogenic lines within the same nuclear background of the patients by manipulation of DNA repair pathways based on inhibition of the key NHEJ regulators and upregulation of the HDR proteins. As a results we generated (1) precisely corrected iPSC clones carrying a healthy length of CAG repeats by homologous recombination (HR) and (2) NHEJ mediated excision of the Q/P repeat region by reannealing of the DSB resulted into an in-frame HTT coding region lacking the N-terminal Q/P repeat and (3) to fast forward disease phenotype we generated iPSC isogenic clones with introduced 70 CAG repeats. Edited iPSC clones were differentiated into neurons of interest and subjected for the high-content screening (HCA).

Title: CRISPR/Cas9 engineered IDH1^{R132H}isogenic luciferase expressing cell models for *in vitro* and *in vivo* glioma studies

Authors: *F. TIAN[1], D. DIANA[3], J. FOULK[2], L. CHEN[2], M. ENUAMEH[3], S. JACOB[3], W. SHU[3]
[1]ATCC, Gaithersburg, MD; [2]ATCC, Manassas, VA; [3]ATCC Cell Systems, Gaithersburg, MD

Abstract: Isocitrate dehydrogenase (IDH) is a metabolic enzyme that converts isocitrate to a-ketoglutarate, which is involved in the control of oxidative cellular damage. The mutation affecting IDH1 amino acid 132 has been linked to grade II and III astrocytomas and oligodendrogliomas, and glioblastomas. IDH1 mutations result in the production of 2-hydroxyglutarate (2-HG), which acts as a-KG antagonist to competitively inhibit multiple a-KG-dependent dioxygenases, causing widespread changes in histone and DNA methylation and potentially promoting tumorigenesis. Although mutant IDH has been identified as a valid target for a new class of brain tumor therapeutics, there is a lack of well-established and characterized cell models containing IDH mutants. In this study, we sought to use the CRISPR/Cas9 gene editing technology to create an *in vitro* isogenic model harboring the IDH1^{R132H} mutation. To develop the most clinically relevant disease model we selected a commonly used glioblastoma cell line, U-87 MG, as the parental line to introduce the IDH1^{R132H} mutation. The precise point mutation knock in was confirmed via sequencing at the genomic and transcriptional levels. We tested the intracellular and extracellular levels of 2-HG to validate that the isogenic IDH1^{R132H} mutation confers gain-of-function to the mutant enzyme that is produced. Data indicated that IDH1^{R132H} U-87 MG isogenic cells exhibit a significant increase in cellular 2-HG levels and an elevated level of histone methylation compared to the parental cell line. Based on the *in vitro* model described above, we developed additional models for use in live-animal bioluminescence brain tumor imaging by introducing a stable luciferase reporter into the U-87 MG and the IDH1^{R132H} U-87 MG isogenic cell lines. Both relative and absolute bioluminescence signals within the cells were quantified. Data show that the U-87 MG-Luc2 cells emit $1.04x10^6$ photons/cell/sec and the IDH1^{R132H} U-87 MG-Luc2 cells emit $1.0x10^6$ photons/cell/sec. Moreover, the cells were injected into nude mice to establish tumors for *in vivo* live bioluminescence imaging. A subcutaneous flank tumor xenograft model and an intracranial glioblastoma orthotopic model were utilized in a study, and the *in vivo* live bioluminescence signal was quantified by Xenogen IVIS imaging system. Taken together, the U-87 MG luciferase-expressing cell line and the IDH1^{R132H} U-87 MG isogenic luciferase expressing cell

line are valuable tools for elucidating mechanisms involved in IDH-associated tumorigenesis, studying brain tumors in vivo, and screening anti-cancer compounds for drug discovery and development.

Abstract: Embryonic lethality following global knockout is a major obstacle in the study of essential genes. Embryonic lethality may be overcome with heterozygous knockout, however haploinsufficiency and related phenotypes may not necessarily result. The most common solution tends to be tissue-specific knockout via the cre-lox system, however this method is dependent upon the availability of tissue-specific promoters as well as cre-driver mice. Additionally, only gene function in the targeted tissue may be studied.
The observation that insertion of polyA tracks into the coding region of target genes results in predictable reduction of gene expression presents an opportunity to study hypomorphic mutations in essential genes. Furthermore, length of polyA tracks is inversely correlated with gene expression, allowing for the generation of multiple animal models with defined levels of gene knockdown. Animal models with defined, diverse, heritable levels of gene knockdown represent novel tools to study essential genes, model small molecule inhibition of a target, examine diverse expression of a biomarker representative of human patient populations, among many other potential applications.
Here we will give an overview of the polyA track system, demonstrate its function in in vitro systems and conservation amongst diverse model systems. We will demonstrate its use with CRISPR-Cas9 to target endogenous genes, and lastly will present our progress in the generation of mouse models.

Title: Adenoviral vector mediated genetic interrogation and visualization of the olfactory sensory neurons

Authors: *Y. WU[1], R. YU[1,2]
[1]Stowers Insitute for Med. Res., Kansas City, MO; [2]Dept. of Anat. and Cell Biol., Univ. of Kansas Med. Ctr., Kansas city, KS

Abstract: The olfactory sensory neurons provide a good model of axon guidance study for their specific projection pattern and regenerative capacity. Classical method to study the system involves genomic targeting of the genes of interest in embryonic stem cells and fluorescent protein labeled olfactory receptor reporter mouse. An alternative approach using viral vectors is widely adapted in the central nervous system. However, the widely used adeno-associated viruses are limited by its loading capacity and by their transduction efficiency, especially for the olfactory sensory neurons. There is also a lack of standardized method to quantify the efficiency of the genetic manipulation *in vivo* using virus-based approaches. Here we present a set of adenovirus-based molecular toolkits to knockout, overexpress genes, or to visualize axon projection at single cell resolution. We validated the approaches in the mouse olfactory system. These tools potentially can be used for other cell types, providing utility to the broader neuroscience community.

Title: Transposon-mediated cell type-specific enhancer profiling in the mouse brain

Authors: *A. CAMMACK[1], T. LAGUNAS[2], M. VASEK[2], A. MOUGDIL[2], M. WILKINSON[2], J. HE[2], M. SHABSOVICH[1], X. CHEN[2], M. HOODA[1], T. MILLER[1], J. DOUGHERTY[2], R. MITRA[2]
[1]Neurol., [2]Genet., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Enhancers are abundant and central controllers of gene transcription throughout the brain. Consequently, profiling these cis-regulatory elements across the genome has been instrumental in understanding gene regulatory networks. To date, this work has largely been accomplished through chromatin immunoprecipitation followed by high-throughput sequencing (ChIP-Seq) of histone modifications associated with active enhancers such as H3K27ac and H2K4me1. Enhancers display extensive tissue and cell type diversity, highlighting their importance in defining and maintaining cellular identity. While histone ChIP-Seq has been crucial in uncovering the importance of non-coding cis-regulators in the brain, it has been challenging to adapt this method for cell type-specific use *in vivo*. Here we present a novel methodology for mapping enhancer profiles in the mouse brain in a cell type-specific manner. By introducing the hyperPiggyBAC transposase (hypPB) and donor transposons via AAV9 directly to the postnatal day 1 (P1) mouse brain, we are able to achieve widespread transduction across the brain. HypPB, likely through interactions with enhancer-associated bromodomain proteins such as Brd4, inserts donor transposons near active enhancer sites throughout the genome, which are later read out with high-throughput sequencing. We show that hypPB insertion profiles are highly reproducible between mice and display a high concordance with the active enhancer mark H3K27ac. Finally, using a cre-dependent hypPB virus, we show utility of this tool in defining cell type-specific enhancer profiles in the brain without physical separation of cellular pools. This approach will enable important investigations into the non-coding regulatory networks of the brain and will provide valuable insights into brain development, homeostasis, and disease.

Title: Temporally precise labeling of oxytocin sensitive neuronal populations

Authors: *N. L. MIGNOCCHI[1], H.-B. KWON[2]
[1]Max Planck FL Inst., Davie, FL; [2]Max Planck Florida Insititute, Jupiter, FL

Abstract: Oxytocin (OXT) is a neuropeptide originating in the paraventricular nucleus (PVN) of the hypothalamus, with a role in influencing brain areas designed to process social stimuli, such as midbrain dopaminergic (DA) neurons in the ventral tegmental area (VTA). However, techniques to measure the extent and specificity of oxytocin modulation on a cellular level remain unavailable. *i*Tango2 is an optogenetic gene reporter technique designed to detect ligand-receptor interactions and is used to study specific neuromodulatory signals in a temporally precise manner. The present research study aimed to develop the OXT-sensitive iTango2 technique (OXT-iTango2) to distinctively measure the quantitative OXT modulation onto neuronal populations. Results demonstrated that this OXT-iTango2 was capable of allowing gene expression in a ligand- and light-dependent manner both *in vitro* cultured cells and *in vivo*. Thus, OXT-iTango2 will allow us to dissect neural circuits activated by OXT at high temporal resolution in behaving animals.

Title: Studying cortical circuitry using a retrograde trans-synaptic tracing system driven by a cortical layer-specific promoter

Authors: *J. LIM[1], D. JGAMADZE[1], J. A. WOLF[1,3], T. DUONG[2], J. MILLS[2], H. I. CHEN[1,3]
[1]Neurosurg., [2]Ophthalmology, Univ. of Pennsylvania, Philadelphia, PA; [3]Corporal Michael J. Crescenz Veterans Affairs Med. Ctr., Philadelphia, PA

Abstract: Introduction: Trans-synaptic neuronal tracing has become an essential tool for investigating brain circuitry and function. Glycoprotein-negative rabies virus (RABVdG) systems have been developed for monosynaptic retrograde tracing, and can be combined with genetic techniques to interrogate specific neural circuits. Much remains to be learned about how cortical circuits develop and how different areas of cortex communicate with each other. Layer V receives afferents from upper-layer cortex but is also involved in the propagation of horizontal activity. Here, we present a novel RABVdG system driven by the CTIP2 promoter that is capable of examining layer V-specific afferent connectivity. Methods: We constructed a plasmid expressing the CTIP2 promoter sequence followed by a fluorescent marker (mRuby). This construct was transfected into dissociated rat embryonic day 18 cortical neurons, and promoter specificity was evaluated with immunocytochemical and flow cytometry techniques using CTIP2 antibodies. In parallel, a polycistronic plasmid expressing a fluorescent marker (dsRed), the Rabies virus glycoprotein (G), and an avian leukosis virus receptor (TVA) under the CAG promoter was transfected into rat embryonic cortical neurons *in vitro* and then infected with RABVdG-GFP to confirm the viability of this tracing system. Subsequent steps involve replacing the CAG promoter in the polycistronic plasmid with the CTIP2 promoter and generating lentiviral vectors from this plasmid. Layer V-specific tracing can be validated in dissociated rat embryonic cortical neurons. **Results:** In rat cortical neurons transfected with CTIP2-mRuby, we found that nearly 70% of the mRuby+ cells were CTIP2+ by antibody staining. Rat cortical neurons transfected with CAG-dsRed-G-TVA were identified by fluorescence microscopy, and a network of GFP+ upstream monosynaptic partners were found surrounding these “starter cells” after RABVdG-GFP infection. Transduction of rat cortical neurons with lenti-CTIP2-dsRed-G-TVA should result in the generation of starter cells that are primarily CTIP2+, which would allow interrogation of the cortical-layer phenotype of neurons sending afferent inputs to layer V cells.Conclusion: Our results demonstrate the feasibility of using cortical layer-specific promoters to drive trans-synaptic tracing. This novel technology could be utilized to examine cortical connectivity both *in vitro* and *in vivo.* In particular, these tools could help map the evolution of cortical circuitry during fetal development and in cerebral organoids and elucidate the mechanisms by which transplanted neurons integrate with the host brain.

Title: Expanding the mouse genetic toolkit: New transgenic and viral strategies for cell-type specific investigations

Authors: E. SZELENYI[1], T. L. DAIGLE[2], L. SIVERTS[2], M. WALKER[2], G. LENZ[2], L. T. GRAYBUCK[3], R. LARSEN[2], L. MADISEN[2], S. YAO[2], A. H. CETIN[2], H. ZENG[4], B. TASIC[5]
[1]Transgenic Technol., [3]Mol. Genet., [4]Structured Sci., [5]Cell and Circuit Genet., [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Ultimate understanding of brain function relies on the precise identification of its working parts and interrogation of the parts' functions. Towards this end, great leaps have recently been made in defining, through transcriptomic and epigenetic approaches, the rich diversity of neurons that encompass the nervous system. Taking advantage of this information and in combination with our established transgenic technology approaches, we report here the latest advancements in our mouse genetic tool repertoire designed for precise cell-type based studies. Overall, these new tools are more versatile, enable functional experiments, and offer simplified breeding schemes for fast research goal completion. Specifically, we will describe our most recent additions made to the previously engineered TIGRE locus. Our new Cre-dependent TIGRE2.0 reporters express viral-like levels of a variety of molecular tools, such as synaptic or nuclear targeted fluorescent proteins, an electron microscopy tag, genetically encoded calcium indicators (GECIs), genetically encoded voltage indicators (GEVIs), and new channelrhodopsin variants. In addition, we will describe the development of a new TIGRE2.0-based transgenic platform, which utilizes four different recombinases and has enabled the generation of Cre- and Flp-dependent reporter lines. Lastly, we will present data from a new and complementary viral-based approach to achieve cell-type specificity in our reporters, which utilizes enhancer elements identified via single cell ATACseq to drive expression of transgenes in restricted cortical layers. This approach circumvents transgenesis, and may enable reliable genetic access to diverse cell types in a minimally invasive manner due to the use of retro-orbitally delivered virus. Characterization for several reporter lines, viruses, and the latest additions to our Cre- and Flp-driver line suite of transgenics will be presented, and the challenges of their development and current work will be shared. In summary, our latest toolset will greatly benefit researchers by allowing for better labeling, monitoring and manipulation of broad and unique cell types, and by

extension neural circuits. This foundational work will therefore greatly accelerate the speed of attaining detailed mechanistic insight on brain function.

Title: Characterization and application of a genetically modified rat toolbox for neuron-specific activity modulation

Authors: *Z. LIU, G. ZHAO, A. BROWN, K. FORBES
Horizon Discovery, Saint Louis, MO

Abstract: Rats were once the most popular models for neuroscience research thanks to its higher intelligence and richer behaviors when compared to mice. The recent rapid progress of the CRISPR/Cas9-based gene editing technologies has made the creation of genetically modified rats relatively straightforward and paved the way for its return. We therefore initiated the efforts to create an optogenetic toolbox, consisting of about a dozen of knock-in rats including various neuron-type-specific Cre driver lines (such as CamKII-cre, VGAT-Cre and Parvalbumin-cre), Cre-activity-dependent excitatory and inhibitory opsin expression lines as well as a fluorescent protein-based Cre-activity reporter line a few years ago. Here we are going to update our continued efforts in characterizing this toolbox and showcase how it might be applied for basic research and drug development.

Title: Optimization of a GCaMP expression system for functional calcium imagining in the marmoset brain

Authors: *M. UEMURA, T. MATSUI, T. HASHIMOTO, T. MURAKAMI, K. KIKUTA, T. KATO, K. OHKI
The Dept. of Integrative Physiol., The Univ. of Tokyo, Tokyo, Japan

Abstract: Calcium imaging using genetically encoded calcium indicator (GECI) is a powerful technique to elucidate the brain function. The licencephalic brain of the common marmoset, *Callithrix jacchus*, provides a unique opportunity to apply modern optical approaches, such as calcium imaging, to the primate visual system. Although a pioneering system of adeno-associated virus (AAV) mediated GCaMP expression using Tet-off system was established in the marmoset brain (Sadakane et al., 2015), Thy1s-tetracycline transactivator (tTA) driven GCaMP6 expression level was still unsatisfactory and its expression was limited in a small subset of neurons expressing Thy1s. Moreover, in the previous calcium imaging studies using primates, neuronal expression of GCaMP was limited in a small region of cortex (typically 1 mm by 1 mm region). The licencephalic brain of the marmoset should allow imaging in a much larger field-of-view if GCaMP expression in such a large area is possible. In order to improve the calcium response in larger population of cells, fine optimization of GCaMP expression system was required. First we designed new AAV vectors which contain the tetracycline response element (TRE) promoter driving both GCaMP6 and tTA (TLoop system, Cetin and Callaway, 2014) or two in-tandem of GCaMP6. To further improve the expression, we inserted the chimeric intron, and replaced the woodchuck hepatitis post-transcriptional regulatory element (WPRE) with shortened WPRE, and human growth hormone polyadenylation (poly(A)) with the tandem arrangement of SV40 late poly(A) signal element. As expected, transduction of those new vectors and conventional Thy1s-tTA with AAV increased the GCaMP6 expression level in much larger population of cells in both mouse and marmoset brains. With our improved vectors, we were able to record reliable visual responses in the primary and other visual areas of the marmoset brain both with two-photon and wide-field calcium imaging. Furthermore, as a Tet driver, we constructed a single or tandem tTA transgene under the neuron specific and ubiquitous promoters instead of Thy1s, resulting GCaMP expression in a broader population of neurons and neurons with glial cells, respectively. Finally, we optimized the protocol for the virus injection and the window implantation to allow imaging in a large field-of-view containing multiple cortical areas. Taken together, our new GCaMP expression tools provide a unique

opportunity to apply calcium imaging to understand the information processing in the marmoset brain.

Abstract: The nervous systems are composed of diverse cell types that present distinct molecular, morphological and physiological features. To enable spatiotemporally controlled activation of individual neurons, we have developed a light-inducible recombinase system, in which the site-specific recombinases become active only upon light induction. We have verified in cultured cells that the expression of recombinase-dependent reporters can be effectively triggered by light induction, whereas reporter expression remains undetectable in the absence of light. In vivo expression of the light-inducible recombinases in the mouse brain can be successfully achieved using adeno-associated viral vectors. We demonstrated in live mouse brains that spatiotemporally controlled induction of light-inducible recombinases by one-photo or two-photo illumination can efficiently produce precise and strong labeling of individual neurons. Our toolbox of light-inducible recombinases will facilitate the functional and anatomical dissection of different cell types by enabling specific and efficient genomic modification at the single cell level.

Title: Interneuron diversity in the dorsal striatum revealed by single-cell RNA-sequencing: The Pthlh population

Authors: *A. B. MUÑOZ MANCHADO[1], C. BENGTSSON-GONZALES[1], A. ZEISEL[1], H. MUNGUBA[1], B. BEKKOUCHE[2], N. SKENE[1], P. LÖNNERBERG[1], J. RYGE[3], K. D. HARRIS[4], S. LINNARSSON[1], J. HJERLING-LEFFLER[1]
[1]Karolinska Institutet, Stockholm, Sweden; [2]Lund Univ., Lund, Sweden; [3]Brain Mind Inst., Lausanne, Switzerland; [4]Univ. Col. London, London, United Kingdom

Abstract: The striatum, the largest nucleus of the basal ganglia, plays an important role in motor planning, decision-making, motivation and reward. The most abundant striatal neurons are the Spiny Projecting Neurons (SPNs) that comprise 95% of the neuronal population. The remaining 5% are locally-projecting interneurons that although less in number play a key role in regulating the output from the striatum to the rest of the basal ganglia. Alterations in this circuitry can lead to neurological disorders as Parkinson's disease, Huntington's disease and others. Currently, the interneuron populations can be divided into several subtypes including the largest heterogeneous population expressing 5HT3a that we recently identified (Muñoz-Manchado *et* al., Cereb Cortex 26(1): 96-105, 2016). This study together with others, pointed towards that the diversity of interneuron subtypes has been underestimated. In order to elucidate this diversity we have taken advantage of a recent developed technique, such as the large-scale single-cell mRNA-sequencing (Zeisel, Muñoz-Manchado *et al*., Science 347(6226): 1138-42, 2015). We have performed a study of 4552 cells in the striatum covering a wide range of ages and using two different platforms to independently confirm our findings. To enrich for the interneuron population, besides CD1 wild-type mice, we have used two transgenic mouse lines, 5HT3a^{EGFP} and Lhx6^{cre}::R26R-tdTomato. As a result we have molecularly characterized all interneuron subpopulations and validate our findings with *in situ* hybridization and/or immunohistochemistry. In addition, we have revealed a *Cck*$^{+}$ interneuron population, and also a population of *Pthlh*$^{+}$ interneurons, which contains the cells expressing *Pvalb*. Interestingly, for

the largest interneuron populations we found additional internal structure shown as gradients of gene expression. For example, the *Pvalb*-expression within the Pthlh-population exists on a transcriptional gradient correlating with a dorso-medial to ventro-lateral axis. Using PatchSeq, we could confirm that this gradient is also correlated to the fast-spiking electrophysiological properties. Furthermore, we found significant molecular differences that correlated with differences in electrophysiological properties between developmentally, morphologically and functionally related *Pvalb*-expressing cells of the striatum and cortex.

Title: Molecular/electrophysiological heterogeneity and circuit function of striatal Pvalb expressing cells revealed by PatchSeq

Authors: *C. L. BENGTSSON GONZALES[1], A. MUÑOZ MANCHADO[1], A. ZEISEL[1], H. MUNGUBA[1], B. BEKKOUCHE[1], N. SKENE[1], P. LÖNNBERG[1], J. RYGE[2], K. D. HARRIS[3], S. LINNARSSON[1], C. J. MCBAIN[4], J. HJERLING-LEFFLER[1]
[1]MBB, Karolinska Inst., Solna, Sweden; [2]Brain Mind Institute, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland; [3]Univ. Col. London, London, United Kingdom; [4]Lab. Cell/Molec Neurosci, NIH, Bethesda, MD

Abstract: *Pvalb* expressing fast-spiking basket cells across the telencephalon share the same developmental origin and have been considered a homogenous group with a canonical circuit function including feed-forward inhibition. Their unique high-frequency firing and dense local axonal arborization allows them to exhibit a strong somatic inhibition onto their target cells, making them crucial for fine-tuning the circuit output.
Using Striatal single-cell RNA-sequencing in combination with patch clamp recordings (PatchSeq) we reveal that striatal Pvalb-cells differ from their cortical and hippocampal counterparts, both in terms of molecular profiles and intrinsic properties. In addition, molecularly striatal Pvalb cells do not cluster into a discrete cluster but are found within a larger group of cells defined by the expression of *Pthlh*. Within this population *Pvalb* expression is detected in a gradient wise manner with a ventro-lateral bias. Using PatchSeq we showed that Pthlh-cells

exhibited another continuum of electrophysiological properties, correlated to *Pvalb* expression. Gradient like differences in both molecular profiles and intrinsic properties, raises the question if striatal *Pvalb*-high and low cells within the Pthlh-population could be states rather than discrete subtypes. This is determined by studying differences in their morphology and local connectivity, traits that are more stable than intrinsic properties and gene expression and therefore will change minimally between different states of a neuronal population.

Title: Identification of novel neurogenic transcription factors driving neurogenesis in human stem cells

Authors: *V. BUSSKAMP[1], A. H. M. NG[2], A. KEMPE[1], K. LENK[1], E. ROJO[1], J. HOERSTEN[1], A. EUGSTER[1], A. DAHL[1], G. M. CHURCH[2]

Abstract: There are more than 300 neuronal cell classes with an unknown number of subtypes in the human brain. However, access to high quality human tissue samples from donors is extremely limited. Therefore, one can bypass the shortage on human brain samples by programming somatic or human stem cells into neuronal-like cell types or by generating human brain organoids.
Elegant ways to obtain human neurons are transdifferentiating fibroblasts or inducing neuronal differentiation in stem cells. In comparison to many different neuronal induction techniques, the ectopic overexpression of neurogenic transcription factors (TFs) can result in rapid and homogeneous neurogenesis. Still, the set of neurogenic TFs, mostly inspired by *in vivo* development, only results in very few neuronal cell types. To expand the breadth and access of *in vitro* neuronal cell types, we conducted large-scale cell fate engineering to generate neurons from human induced pluripotent stem cells (iPSCs).

We created a comprehensive inducible human TF expression library within a lentiviral backbone to systematically screen TFs that differentiate human stem cells. Next, we tagged human iPSCs with a fluorescent reporter cassette driven by a human Synapsin promoter enabling us to identify neurons upon differentiation. We transduced this reporter line with lentiviral particles at different multiplicities of infections to obtain single and combinatorial integrations of the conditional TF constructs. Upon induction for four days, we sorted fluorescently labeled cells using FACS into single wells, extracted the RNA to perform both, single cell qPCR to identify the neurotransmitter identity and sequencing to reveal the overexpressed TFs.
By this unbiased neurogenic TF screening, we analyzed hundreds of individual neurons at single cell resolution, identified known but more importantly novel single TFs and TF combinations that drove human iPSCs into postmitotic neurons in just four days. We subject these neurons to in-depth characterization using transcriptomics as well as imaging and functional assays.
Our large-scale unbiased TF-mediated neuronal induction system at single cell resolution can pave the way towards the production of many human neuronal cell types *in vitro* useful for basic and biomedical approaches.

Title: Automated phenotyping screen for mosquito larvicides

Authors: *D. B. SATTELLE[1], S. BUCKINGHAM[1], G. LYCETT[2]
[1]The Rayne Bldg, Univ. Col. London, London, United Kingdom; [2]Liverpool Sch. of Tropical Med., Liverpool, United Kingdom

Abstract: Pyrethroid impregnated nets have halved the burden of malaria in the past decade but resistance threatens their future efficacy and the pipeline of new insecticides is short. We report the application of automated phenotyping to mosquito larvae. The INVertebrate Automated Phenotyping Platform (INVAPP) for use with 96-well plates combined with the algorithm Vectorgon provides a robust assay for *Anopheles gambiae* and *Aedes aegypti* larval motility. By this means the actions of chemical insecticides can be measured quickly and reliably. We illustrate how the assay is convenient for measuring dose-dependent actions of the insecticide deltamethrin on larval motility over time and use it to demonstrate that larval resistance to deltamethrin can be detected in both species. As proof-of-principle of its capacity for library-scale chemical screening we screened the Pathogen-Box library for novel candidate larvicides

from which Tolfenpyrad emerged as an effective larvicide. The system enables screening for novel and re-profiled chemicals as candidate larvicides.

Title: Selectively inhibiting small-diameter axons with glucose

Authors: *J. ZHUO[1], M. T. MCPHEETERS[1], E. D. JANSEN[5], S. J. LEWIS[2], H. J. CHIEL[3,1,4], M. W. JENKINS[2,1]
[1]Dept. of Biomed. Engin., [2]Dept. of Pediatrics, [3]Dept. of Biol., [4]Dept. of Neurosci., Case Western Reserve Univ., Cleveland, OH; [5]Dept. of Biomed. Engin., Vanderbilt Univ., Nashville, TN

Abstract: Neuromodulation has the potential to treat various diseases (e.g., rheumatoid arthritis, obesity, heart failure), but needs finer selectivity for more targeted treatments. Small-diameter fibers in the peripheral nervous system carry important sensory information crucial for altering organ function. Previously, we have shown that IR neuromodulation can preferentially modulate sensory peripheral nerves. We are actively studying the potential of small fiber modulation for further clinical applications. In our previous work, a mathematical analysis suggested that any modality acting primarily on the axonal surface (e.g., ion channels) would preferentially affect the small-diameter axons. Isotonic glucose solution primarily blocks ion channels on the axonal surface. Therefore, we hypothesize that isotonic glucose solution can also selectively inhibit small-diameter axons.
To test our hypothesis, we stimulated and recorded compound action potentials (CAP) from the pleural-abdominal connective of *Aplysia californica* (n = 3). This nerve's length allows the different component of CAPs with different conduction velocity to separate from each other. The nerve was placed across a triple-chamber platform, where the chambers are sealed from each other but the nerve could course through all three. Suction electrodes were placed on both ends of the nerve, one for electrical stimulation and a second for monopolar recording. The suction electrodes also stretch the nerve, allowing control of length and strain. The nerve was stimulated at 0.5 Hz and the CAPs were amplified before digitizing. *Aplysia* saline is placed in the two outer chambers while the middle chamber can be perfused with *Aplysia* saline or isotonic glucose

solution (10.21 w/v %). The width of the middle chamber is adjustable to vary the exposed length of the nerve in the solution. With *Aplysia* saline in the middle chamber and minimum exposure length (250 um), stimulation current threshold was determined to reliably evoke all CAP components. With glucose solution in the middle chamber, as the exposure length is increased from its minimum, recorded CAPs change from undistorted, to selective inhibition of small-diameter axons and eventually full block. Using the characterized selective inhibition exposure length, and by perfusing different solution in the middle chamber, we were able to inhibit small-diameter axons with isotonic glucose solution and restore the full CAP with *Aplysia* saline. This test was conducted at least 2 times per nerve and the response was stable and repeatable. These results support the hypothesis that isotonic glucose solution can also selectively inhibit small-diameter axons.

Title: Proteomic profiling of extracellular vesicles from IL-1β stimulated human primary astrocytes by quantitative mass spectrometry

Authors: *Y. YOU[1], K. BORGMANN[3], S. STACY[3], A. GHORPADE[3], T. IKEZU[1,2]
[1]Dept. of Pharmacol. & Exptl. Therapeut., [2]Dept. of Neurol., Boston Univ. Sch. of Med., Boston, MA; [3]Dept. of Microbiology, Immunol. & Genet., Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Astrocytes are abundant glial cells in the central nervous system (CNS) that provide supportive neuronal functions. Increasing evidence has specified their critical roles in regulating neuronal activities in response to pro-inflammatory factors such as cytokines, amyloid-β peptides and lipopolysaccharides in infectious and neurodegenerative diseases. However, a greater understanding of underlying mechanisms and specific mediators during these processes is still emerging. Exosomes, typically 30-150nm extracellular microvesicles, are known to carry a large diversity of molecules such as proteins and RNA species that can modify the physiology of recipient cells. Here, we hypothesized that astrocyte-derived exosomal proteins are regulated

upon exposure to pro-inflammatory factors and are likely regulators of neuronal function and plasticity. We present a quantitative proteomics analysis of exosomes purified from human primary astrocytes with or without interleukin-1β (IL-1β) stimulation in vitro. Exosome-enriched fractions were purified by size-exclusion columns and the size distribution was determined by nanoparticle tracking analysis. Overall, a total of 539 common proteins were identified with an overlap of 89 proteins among ExoCarta Top100 proteins. Abundant molecules were specifically present in exosomes from IL-1β-stimulated astrocytes. Bioinformatics analysis shows that they are not only involved in activation of immune response and modulation of cell adhesions, but also regulating actin cytoskeleton, which could result in cytoskeletal reorganization of target cells. The exosomal proteins specific to resting astrocytes play a role in protein metabolism, cell growth and maintenance. Otherwise, 37 differentially expressed proteins (a cutoff of absolute fold change ≥1.5 and p value <0.05) from IL-1β stimulated exosomes were selected. Among them 35 proteins, most of them contribute to innate immunity and cytoskeleton organization. Finally, similar proteomic results were also obtained from exosomes derived from astrocytes cultured in exosome-depleted media with IL-1β stimulation, further validating the alteration of exosomal proteins in activated astrocytes, which can be transferred to regulate neuronal function and plasticity. Our findings will be helpful to elucidate the pathophysiological functions of astrocyte-derived exosomes in regulating neuronal networks and provide new insights into the diagnostics and therapeutics of inflammatory diseases.

Title: PhosphoSitePlus as a resource to explore PTM-mediated signaling in neuronal physiology and disease

Authors: *J. M. KORNHAUSER[1], B. ZHANG[2], E. SKRZYPEK[2], B. MURRAY[2], V. LATHAM[2], V. NANDHIKONDA[2], P. V. HORNBECK[2], F. GNAD[2]
[1]Bioinformatics, Cell Signaling Technology, Inc, Danvers, MA; [2]Bioinformatics, Cell Signaling Technol., Danvers, MA

Abstract: Protein post-translational modifications (PTMs) are critical events in cellular signaling that mediate a wide variety of biological processes. In the context of neuronal cells, PTMs regulate normal physiological functions including neuronal development and synaptic plasticity, and also play important roles in neurological and degenerative diseases states as well as cancers

of the nervous system.
PhosphoSitePlus (PSP) is an open, manually-curated online resource that aggregates comprehensive information about known sites of protein PTMs, including sites discovered in high-throughput publications. Curated information about each PTM site includes upstream signaling receptors and enzymes that catalyze the modifications, downstream consequences of the modification on protein function, and implication of the modification site for disease. Among the >400,000 individual PTM sites in PSP curated from over 22,000 published articles, over 100,000 have been observed in the context of either brain tissue or cells of CNS origin. PSP also curates information about protein modifications that are regulated in response to specific neurotransmitters, and observed in the context of CNS diseases. This aggregated data can be searched in flexible ways, and can be analyzed to illuminate signaling networks that are involved in specific neuronal responses and disease states.
Recently introduced updates to the PSP web interface enhance a users' ability to analyze PTMs in the context of mutations and sequence variants implicated in disease. A lollipop plot representing the linear protein sequence allows co-visualization of PTMs, their mutation frequencies in cancer, and somatic cancer mutations and disease polymorphisms neighboring the PTM sites. Among other ongoing enhancements, we are also currently improving methods for visualization of PTM quantification in large mass spectrometric studies, to facilitate the analysis of signaling network involved in neuronal physiological responses, therapeutic treatments, and disease processes.

Title: Genetic and functional study of LAMA5 for its role in nicotine dependence

Authors: *F. RONGLI[1], M. D. LI[2]
[1]Zhejiang Univ., Zhejiang province, China; [2]Inst. NeuroImmune Pharmacol., Seton Hall Univ., South Orange, NJ

Abstract: Nicotine dependence (ND) is a common brain disorder that is extremely harmful to the individual and society. Heritability for ND is estimated to be 50%~60%. Although previous whole genome-wide association studies (GWAS) have indicated a number of genetic variants associated with ND, they could explain only a small proportion of heritability and most of these detected variants are not causative ones. In this study, we conducted a whole genome-wide exome genotyping study in the Mid-South Tobacco Case-Control (MSTCC) population, consisting of 1,656 smokers and 1,740 no-smokers, which revealed several genes of interest, such as *LAMA5* (laminin subunit alpha 5). We found that 6 common SNPs in *LAMA5* are significantly associated with smoking status and other 8 SNPs are significantly associated with FTND. To determine the involvement of *LAMA5* in the etiology of ND, we treated HEK293T cells with different nicotine concentrations (1μM, 10μM, 100μM) for 48 hours and found that the expression of *LAMA5* was significantly down-regulated by nicotine (p value <0.001 for all groups). Further, we showed that nicotine treatment enhanced HEK293T cells migration (p value <0.001), an indicator of contribution to neuronal plasticity and meditated drug memory and drug withdrawal. Subsequently, we used CRISPR/Cas9 technique to edit *LAMA5* gene, which indicated that knockout of *LAMA5* greatly enhanced cell migration and affected the expression of other members of laminin family which composed of heterotrimers with *LAMA5*. Consistently, we showed there existed significant interactions among variants in *LAMB2, LAMC2* and *LAMC1* with *LAMA5*. Combined with the findings from both genetic and functional studies, we concluded that *LAMA5* along with other members of the family are involved in etiology of ND and deserve to be further investigated.

Title: Sex-specific long non-coding RNA regulates genes expression in human depression

Authors: *Q. LIU[1], M. D. LI[2]
[1]Zhejiang Univ., Zhejiang, China; [2]Inst. NeuroImmune Pharmacol., Seton Hall Univ., South Orange, NJ

Abstract: Major depressive disorder (MDD) is a debilitating disease for public health, which affects 350 million individuals worldwide annually. Although it has been shown that the long non-coding RNAs (lncRNAs) play an important role in activating gene expression for various disorders, involvement of lncRNA in MDD is largely unknown. By performing differentially expression and co-expression network analysis, we found lncRNAs PACERR and BDNF-AS in female and HIF1A-AS2 in male, whose expression patterns are significantly associated with transcriptional profiles of MDD in human brain in a sex-specific manner. We showed that the PACERR and BDNF-AS ($p = 4.9 \times 10^{-4}$; $p = 1.4 \times 10^{-4}$), antisense lncRNA for *PTGS2* and *BDNF* ($p = 1.0 \times 10^{-6}$; $p = 2.7 \times 10^{-2}$), respectively, were significantly differentially expressed in female MDD patients compared with female healthy controls. We also found that the lncRNA of HIF1A-AS2, which is antisense for *HIF1A* ($p = 1.2 \times 10^{-5}$), were differentially expressed in male MDD patients compared with male healthy controls ($p = 8.4 \times 10^{-7}$). Interestingly, *BDNF*, *PTGS2* and *HIF1A* have all been implied to play critical roles in MDD and in several other physiological diseases. Our results also showed that the expression patterns of these lncRNAs were positively correlated with their host mRNAs. In addition, we detected 10 significantly enriched pathways (adjusted $p < 0.05$) in females and 7 in males, with only two pathways overlapped between males and females (i.e., Osteoclast Differentiation, NF-kappa B Signaling pathway). In sum, our findings highlighted the sexual dimorphism of the MDD mechanisms at the transcriptional level, providing novel insights into the regulation of three lncRNAs underlying the physiology of MDD.

Title: Integrative Genome-wide association analyses reveal the genetic link between smoking and schizophrenia

Authors: *Y. MA[1], M. D. LI[2]
[1]Zhejiang Univ., Hangzhou, China; [2]Inst. NeuroImmune Pharmacol., Seton Hall Univ., South Orange, NJ

Abstract: Prevalence of cigarette smoking is significantly higher in schizophrenia (SCZ) patients compared with general population. However, the underlying biological mechanisms of the comorbidity between smoking and SCZ are largely unknown. We sought to reveal shared

biological pathways in genome-wide association study (GWAS) data containing a total of 153,898 samples. By using gene-based analysis, 208 genes associated significantly with SCZ were common with that for smoking behaviors. With the pathway-based enrichment analysis for four gene-set datasets (i.e., KEGG, GO, BioCarta, and Reactome), we identified 175 significantly enriched pathways (q-value < 0.1) for SCZ, 172 for smoking quantity, 233 for ever smoking, 225 for former smoking, and 158 for age at smoking initiation. Importantly, we revealed 18 enriched pathways which were shared between SCZ and all five smoking phenotypes. By using multidimensional scaling to cluster these common pathways in terms of shared genes, we identified five clusters for these pathways: postsynaptic density, cadherin binding, dendritic spine, long-term depression, and axon guidance. To reveal the expression profiles in human brain of these common pathways, we performed a coexpression analysis. Among genes in these identified pathways, there were 1,443 genes coexpressed in six modules. After summarizing the mean expression level of genes in each module, we found there existed two distinct and dynamic expression patterns in brain regions and developmental stages. In sum, our results indicate that risk variants from GWAS data for SCZ and smoking aggregate in particular biological pathways, providing novel insights into the etiology of the comorbidity between SCZ and smoking behaviors.

Title: Cross-laboratory analysis of patch-seq datasets reveals shared features of within-cell type electrophysiological heterogeneity

Authors: *S. TRIPATHY, C. BOMKAMP, L. TOKER, O. MANCARCI, P. PAVLIDIS
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Patch-seq, enabling simultaneous measurement of transcriptomic, electrophysiological, and morphological features, has recently emerged as a powerful tool for neuronal characterization. Here, we present a re-analysis of 4 patch-seq datasets (3 from mouse acute brain slices and 1 from human cultured neurons) and present methods for quality controling and cross-analyzing these data.

Across each of the datasets we re-analyzed, we found widespread evidence for multi-cell contamination. We suggest that this off-cell type contamination is due to the passage of the patch-pipette through the processes of other cells before and after collection of cellular mRNA. We present a straightforward marker gene-based approach for identifying this contamination, based on atlases of dissociated-cell single-cell RNAseq from analogous cell types. Down-weighting lower quality single-cell transcriptomes in subsequent analyses allows us to control the confounding influence of off cell-type contamination.
Next, we correlated single-cell gene expression with electrophysiological features measured from the same cells. We specifically wanted to assess if the same genes contribute to electrophysiological heterogeneity across cell types: for example, in fast-spiking basket cells, is higher sodium channel expression correlated with more narrow action potential widths? and if so, is this also the case in non-fast-spiking interneurons? We further compared these within-cell type correlations to our previous analyses correlating gene expression with electorphysiology using data from pooled neuron types. We report a few suggestive examples of robust cross-dataset gene-ephys correlations, such as Scn1b and AP width, and Kcnab3 and AHP amplitude. Our work highlights the promise in using the patch-seq methodology to help reveal how combinatorial gene expression gives rise to cellular electrophysiological features. However, we note that relatively small sample sizes and high technical noise of the currently available patch-seq datasets limits the resolution of these analyses.

Title: Combined singe-neuron methylome & trascriptome profiling from repeatedly identifiable neurons

Authors: *E. C. DABE[1], A. B. KOHN[2], A. RIVA[3], L. L. MOROZ[4]
[1]Univ. of Florida Whitney Lab., Saint Augustine, FL; [2]Universtiy of Florida Whitney Lab., Saint Augustine, FL; [3]Univ. of Flordia, Gainesville, FL; [4]The Whitney laboratory for Marine Biosci., Univ. of Florida, Saint Augustine, FL

Abstract: On the genomic level, neuronal identity is encoded by complex epigenetic mechanisms leading to coordinated expression of ~10,000 proteincoding genes per neuron. To assess these mechanisms, we performed the singlecell bisulfite sequencing (BSseq) from individual functionally identifiable neurons of *Aplysia californica. Aplysia* neurons are some of the largest somatic cells in the animal kingdom, allowing us to directly correlate both genome-wide methylation and gene expression from the very same identified neurons . We produced methylome profiles (n=3 per cell type) for 2 symmetrical serotonergic (5HT) interneurons (MCC) & 2 homologous cholinergic (ACh) motor neurons (R2 and LPl1), Sensory neuron clusters (VC,BuccalSN), & from non-neuronal tissues. Each BSseq library had an average of 18 million paired-end reads per run. On average, 10.4 million uniquely mapped as pairs & 2.2 million as single-end reads, which is ~12x the reads currently reported per single human neuron BSseq. PCA analyses show that globally neither CpG or CH gene body methylation (gbm) clustered neurons by their known functional or transmitter identity. In contrast to previous single-neuron methylomes studies in mammals, we did not find an inverse correlation between high CH gbm & transcription. We analyzed CpG & CH gbm for cell-type specific individual genes. *Sensorin*, a neuropeptide specific to SNs, showed a marked increase in mCH gbm in VC & BuccalSNs vs. outgroups. In ACh (*ChAT, VAchT*) & 5-HT (*TPH,VMAT, SERT*) neurotransmitter biosynthesis genes there is no total gbm to transcription correlation, but sub-regions show differential CH methylation across neurotransmitter phenotypes . It also suggests much more complex epigenomic regulation of neuronal phenotypes than anticipated.

Title: Novel subtypes of retinal ganglion cells identified by single cell RNA-seq analysis

Authors: B. A. RHEAUME[1], A. JEREEN[3], M. BOLISETTY[4], M. S. SAJID[3], Y. YANG[3], K. RENNA[3], L. SUN[4], P. ROBSON[4,2], *E. F. TRAKHTENBERG[3]

Abstract: Retinal ganglion cell (RGC) is one of the broad classes of retinal cells that pre-process and pass to the brain visual information collected in the eye. Thirty subtypes of RGCs have been identified to date. Here, we have analyzed 6,225 purified by Thy1 immunopanning postnatal day 5 RGCs (with on average 5,000 genes per cell) separately from the right and left eyes by single cell RNA-seq, and classified them into 40 subtypes using clustering algorithms. The cells were similarly enriched for pan-RGC markers such as RBPMS, Tubb3, and Thy1. We have identified novel subtypes and markers, as well as the transcription factors predicted to cooperate in specifying RGC subtypes. Markers of 5 previously identified subtypes, Jam2, NPY, Pde1a, Trhr, and Gna14, were amongst the markers predicted to be unique to 5 out of the 40 RGC subtypes. We validated two novel RGC subtypes by fluorescent in situ hybridization (FISH) and immunostaining for markers we predicted to be uniquely enriched in these subtypes (subtype marker-positive RGCs were quantified as fraction of all RBPMS-positive RGCs). We also identified the right eye enriched subtype, which we validated by immunostaining in situ, using another novel marker predicted to be unique for this RGC subtype. In total, out of the 40 predicted subtypes, 5 were validated by markers in previous studies and 3 more we validated here using novel markers. A number of other established RGC markers were enriched in more than one subtype, suggesting that they label larger subpopulations of RGCs, that are further subdivided into subtypes based on the molecular differences in their transcriptomes. For example, Cartpt, Cdh6, and Col25a1 markers of the ON-OFF direction-selective RGCs were enriched in one group of subtypes, whereas Opn4, Eomes, and Igf1 markers of the intrinsically photosensitive RGCs were enriched in a different group of subtypes. These findings contribute to our understanding of the retinal component of the visual system through characterization of the molecular differences between RGC subtypes.

Title: Profiling claustral and layer 6 neocortical neurons using single-cell transcriptomics

Authors: *L. FODOULIAN[1,2], A. CARLETON[1], I. RODRIGUEZ[2]
[1]Dept. of Basic Neurosciences, [2]Dept. of Genet. and Evolution, Univ. of Geneva, Geneva, Switzerland

Abstract: The claustrum (CLA) is a thin sheet of subcortical grey matter located between the insular cortex and the putamen. It has dense reciprocal connections with a large number of neocortical regions, which suggests a role in attention, consciousness and saliency detection. However, its function and the underlying neuronal mechanisms remain elusive. This lack of evidence results from the scarcity of tools to specifically modulate CLA activity. In particular, gene-targeted mouse lines are lacking, due to the poorly defined genetic characteristics of CLA neurons. Here, we aimed at identifying the transcriptional identity of mouse CLA projection neurons. To ensure an unbiased sampling of CLA neurons, we injected a fluorophore-encoding transsynaptic adeno-associated virus in the primary motor cortex of the mouse. Anatomical validation of this tracing showed the transsynaptic labelling of CLA neurons. Subsequent to CLA dissection and cell dissociation, GFP^+ cells were FACS sorted and captured on a $C1^{TM}$ high-throughput (HT) integrated fluidic circuit (IFC) (Fluidigm). Following single-cell RNA-sequencing, an unsupervised graph-based clustering of 579 cells identified 4 main cellular populations. Differential gene expression analysis revealed that one of these clusters corresponds to CLA projection neurons, while the three remaining were formed of cortical layer 6 (L6) pyramidal neurons, oligodendrocytes and striatal medium spiny neurons. CLA neurons were differentiated from L6 pyramidal neurons by a wide range of specific markers. Consistent with previous reports, typical CLA markers were also identified by our analysis. However, some of those genes, considered as canonical markers of the CLA, such as *Nr4a2* and *Gnb4*, also appeared to be expressed by a substantial proportion of L6 neurons. In conclusion, we identified a series of genes discriminating claustral from cortical neurons, which represents a first step in the molecular dissection of the claustral circuitry.

Genome Sci., Univ. of Maryland Sch. of Med., Baltimore, MD; [6]Dept. of Computer Sci., Univ. of Maryland, College Park, MD; [7]Dept. of Neurol., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The national Brain Research through Advancing Innovative Neurotechnologies (BRAIN) Initiative promotes the development and application of technologies to describe the temporal and spatial dynamics of cell types and neural circuits in the brain. The wealth, depth and quality of multi-omic data generated through funding from the BRAIN initiative is unprecedented. It ranges from bulk and single cell RNA-seq and epigenomic data throughout the developing and adult brain, as well as multi-modal datasets that integrate these genomic data with the brain's spatial organization, neuronal morphology, and neurophysiology. To promote smooth interactions across a large research consortium, we are developing the Neuroscience Multi-Omic Archive (NeMO Archive; www.nemoarchive.org), a data repository that is specifically focused on the storage and dissemination of omic data from the BRAIN Initiative and related brain research projects. The information incorporating into the NeMO Archive will, in part, enable understanding of cell types in the mammalian brain and of cell states associated with disease. In parallel, we are developing a suite of web-accessible tools to analyze and visualize these and other neurogenomic data (NeMO Analytics). NeMO Analytics is based on two existing webtools for visualization of omic data - the gene Expression Analysis Resource (UMgEAR.org) and EpiViz (epiviz.github.io) with further integration of advanced analytics for

single-cell genomics, network analysis (www.trena.org), and integration across datasets (https://rdrr.io/github/genesofeve/ProjectR/). Our goal is to enable users to answer diverse questions of relevance to brain research, ranging from simple queries on the expression of individual genes to complex multi-omic workflows. It will also provide the basic knowledge to guide the development and execution of predictive and machine learning algorithms in the future.

Abstract: The epigenome is an ensemble of chemical modifications of DNA and chromatin. Genome-wide mapping of epigenomic signatures is one of the most effective approaches for identifying gene regulatory elements such as enhancers. Our recent study demonstrated robust classification of brain cell types using single-cell DNA methylation profiles. Single-cell epigenomic approaches enable unbiased mapping of the regulatory landscape for virtually all brain cell populations. With support from NIMH and NINDS as part of the BRAIN Initiative

Cell Census Network (BICCN), we are analyzing cell type and gene regulation diversity of the entire mouse brain with fine spatial resolution. Single-cell DNA methylome profiles are being produced from 116 dissected brain regions. To date we have generated over 46,000 single-cell methylomes from over 23 brain regions. We uncovered pervasive DNA methylation differences between excitatory neurons located in distinct cortical regions, whereas inhibitory neurons show less regional specification in the cortex.
We are further applying our single-cell DNA methylation assay to study the cell type diversity of human frontal cortex. DNA methylation signatures allow robust classification of both neuronal and glial cell sub-types, and prediction of regulatory sequences for human cortical cell populations. We identified enrichment of genetic variants associated with brain diseases such as schizophrenia in subtypes of excitatory and glial cells. Our single-cell epigenomic strategy provides opportunities to determine cell-type specific contributions of non-coding sequences in brain diseases.

Abstract: Anatomy is a central and often defining feature for classification of neuronal cell types. While recent advances in single cell genomics have led to several high-resolution molecular characterizations of cell type diversity in the brain, neuronal cell types are often

studied out of the context of their anatomical properties. Our study aims to link molecular properties of cell types to neuronal connectivity by combining retrograde tracing with single cell DNA methylome sequencing. As part of the NIH Brain Initiative Cell Census Network (BICCN) effort, we are profiling epigenetic signatures of long-distance projecting neurons throughout the mouse brain. Our initial studies focus on cortical neurons from primary motor cortex (MOp), primary somatosensory cortex (SSp), anterior cingulate cortex (ACA), agranular insular cortex (AI), primary auditory cortex (AUDp), retrosplenial cortex (RSP), posterior parietal cortex (PTLp), and primary visual cortex (VISp) that project to various subcortical targets including striatum (STR), superior colliculus (SC), thalamus (TH), and pons (P), as well as other cortical areas. To ensure high-resolution and high-quality DNA methylation profiling of the projecting neurons, we generate single nuclei methylome profiles for at least 250 neurons (post-QC) of each cortico-subcortical projection. With these data, we are, for the first time, able to examine the molecular properties of these distinct groups of projection neurons. Our preliminary results show that the laminar location, cortical region, and projection target all contribute to the unique epigenetic signatures of individual neurons. In addition, we are identifying potential regulatory sequences such as enhancers that could be tested to specifically target and label each projection neuron type, enabling the targeted study and manipulation of projection neurons of interest. Supported by NIH grant MH114831.

Abstract: Transcriptional regulatory regions in the genome including promoters and distal acting enhancers play fundamental roles for development and disease. These genomic regions can be identified by the presence of open chromatin as measured by ATAC-seq (Assay for transposase-accessible chromatin using sequencing). However, heterogeneity of primary tissues poses a significant challenge in mapping the precise chromatin landscape in specific cell types. Therefore, we optimized a combinatorial barcoding-assisted single-cell assay for transposase-accessible chromatin for use on flash-frozen primary tissue samples (single nuclei ATAC-seq, snATAC-seq). We applied the methodology to deconvolute the cellular composition of the mouse forebrain, defined cell-type-specific transcriptional regulatory sequences and inferred potential master transcriptional regulators. In addition, we identified cell-type specific enrichment of gene sequence variants associated with human disease in genome-wide association studies (GWAS). For example, regulatory elements accessible in the microglia population were highly enriched for Alzheimer's disease associated risk variants. Further process optimization including liquid handling robotics enables us now to robustly generate libraries for more than 5,000 single nuclei chromatin accessibility profiles in a single experiment. We use this approach to map the epigenetic heterogeneity in distinct regions dissected from the adult mouse brain. Initial analysis of more than 20,000 nuclei isolated from the primary motor cortex revealed more than 30 cell populations corresponding to all major neuronal and non-neuronal cell types. I will present the most recent insights from our analysis. This work is supported by NIH Grant MH114831.

Abstract: The mammalian brain is comprised of a complex network of unique cell types. Powerful techniques for measuring mRNA abundance in single cells and nuclei have enabled unbiased surveys of brain cell types in mouse (Zeisel et al. 2015; Tasic et al. 2016; Tasic et al. 2017) and human (Lake et al. 2016). High throughput sequencing of DNA from single nuclei has also been applied to measure DNA methylation and regions of open chromatin. However, these data types have not yet been integrated to provide a unified, multimodal classification of brain cell types. Although mRNA expression provides highly informative signature of cell types, it can be affected by transient state changes as well as by neural activity. The regulatory information provided by epigenomic data identifies cell type specific gene regulatory elements such as enhancers. Integrating transcriptional and epigenetic data can provide a comprehensive framework for determining the molecular-genetic landscape of individual cell types.
We generated thousands of single neuron DNA methylomes from adult mouse motor cortex using single nucleus methylcytosine sequencing (snmC-Seq) as part of the BRAIN Initiative Cell Census Network (BICCN). In parallel, we used single nucleus assay for transposase-accessible chromatin (snATAC-Seq) to detect regions of open chromatin We identify putative gene regulatory elements (GREs) in these data sets using differentially methylated regions (DMRs) as well as peaks of snATAC-Seq read density that indicate accessible chromatin regions. We focus on GREs located far from gene promoters (>2 kb), many of which have a unique cell type specific profile. We find that GREs that are active in a specific cell type have low methylation and high snATAC-Seq read density. This correspondence allows us to identify cell types in the two datasets using the negative correlation between signals from cells of the same type. For example, we find a strong correlation between non-CG DNA methylation and snATAC read density for cells of the same type (Spearman r = -0.65 for PV cells). By contrast, the correlation between non-CG methylation in PV cells and snATAC read density in VIP cells is significantly lower (r = -0.35). By integrating data modalities we can produce a comprehensive picture of the epigenetic landscape of specific cell types in the mouse brain.

Abstract: Single-cell sequencing technology enables an objective molecular taxonomy of human cortical neurons. Although the broad classes and fine distinctions among brain cell types are likely to be strongly conserved across individuals, genetic variation in the human population as well as differences in individual experience may lead to inter-individual differences in gene expression and epigenetic regulation of brain cells. The diversity of transcriptomic and epigenomic regulation of brain cell types across individuals is not well understood.
We performed single nuclei DNA methycytosine sequencing on 6,435 cells from frontal cortex samples from 3 adult males. We identified cell types by jointly clustering cells from all datasets using DNA methylation at CG and non-CG sites (mCG and mCH) in 100 kilobase bins across genome. This analysis identified more than 20 highly distinct putative cell types, including at least 10 excitatory and 8 inhibitory neuron types, as well glial cells.
By comparing mCH across 3 individuals, we found that excitatory neurons have a greater degree of variability between individuals within the same cell type than inhibitory neurons. Excitatory neurons clustered mainly by layer-specific cell type, but also had differences in methylation that correlated with biosample of origin. By contrast, inhibitory neurons from different biosamples clustered together. The top 40 genes with most variable DNA methylation (mCH) across biosamples have higher variability in excitatory neurons than in inhibitory cell types. A classifier based on linear discriminant analysis could predict the biosample of origin for each cell based on DNA methylation in gene bodies. The classifier performs better for excitatory cells (area under the receiver operating characteristic, AUROC = 0.90-0.98, range across cell types) than for inhibitory cells (AUROC = 0.68-0.78). To examine inter-individual differences at the transcriptional level, we analyzed single nuclei RNA sequencing data from 15,928 cells from cortex of 8 individuals (Allen Brain Institute). These data indicate that, like DNA methylation,

transcription in excitatory cells is more diverse across individuals than in inhibitory cells. Inter-individual variation could be due to genetic differences, such as single nucleotide polymorphisms. Alternatively, differences in development and environment between individuals could have greater impact on some cell types compared with others. Understanding the origin of conserved and variable molecular signatures of brain cell types across individuals is important for the functional interpretation of these cell type signatures.

Abstract: The brain exhibits a considerable assortment of neurons that diverge in terms of morphology, electrophysiological proprieties, and gene expression. While other techniques can explore single-cell variability across one or two of these dimensions, we recently developed Patch-seq, which combines whole-cell patch-clamp recording with single-cell RNA- sequencing and immunohistochemistry, to comprehensively profile the transcriptomic, morphological and biophysical features of single neurons in brain slices.
Here, we present a detailed description of our recent modifications to the Patch-seq protocol, as well as the preliminary analysis of primary motor cortex (MOp) as part of the Brain Initiative Cell Census Network (BICCN) project.
Utilizing Patch-seq on brain slices of adult wild-type and several Cre line mice (PV+, SST+, VIP+, and HTR3a+/Vip-), along with algorithms to perform automatic electrophysiological and morphological analysis, we profiled pyramidal and γ-aminobutyric acid-releasing (GABAergic) neurons from MOp layers 2/3 and 5.

We mapped transcription profiles of cells obtained by Patch-seq to cells obtained from dissociated tissue using fluorescence-activated cell sorting (FACS), revealing a clear correspondence among gene expression profiles.
The generation of a comprehensive cell type atlas, based on genome expression data, electrophysiological, and morphological features, could significantly contribute to the study of central nervous system structure and function; as well as neuropsychiatric disorders by identifying the specific cell types that express disease-associated genes.

Abstract: Neurons exhibit a rich diversity of morphological phenotypes, electrophysiological properties and gene expression patterns, and understanding how this tremendous cellular diversity is generated during the course of normal development remains poorly understood. We recently developed Patch-seq, a technique that combines whole-cell patch clamp recording,

immunohistochemistry and single-cell RNA-sequencing (scRNA-seq) to comprehensively profile single neurons from mouse brain slices. By streamlining this technique and making additional modifications to the patching mechanics and recording procedure, reagents and recipes, procedures for immunohistochemistry and other protocol steps, we are able to obtain high-quality morphological, electrophysiological and transcriptomic data from single neurons with increasing rates of success and throughput. We applied Patch-seq to explore the multidimensional phenotypic variability among excitatory neurons with a shared developmental lineage and show that clonally related cells within the same clone recapitulate the diversity of neocortical cell types. Our findings support the idea that clonal units may serve as developmental building blocks of the neocortical circuit.

Abstract: Building high-quality atlas of cell types in the mouse brain is a critical step towards understanding the complicated mammalian nervous system. As part of the BRAIN Initiative Cell Census Network (BICCN), we will create a most comprehensive to this date, single-cell transcriptomic cell type atlas from all brain regions of adult male and female mice, using highly standardized methods to achieve consistency and comparability across different brain regions. In order to determine the optimal profiling strategy, BICCN launched a Mouse Mini-Atlas project to test and compare multiple single-cell RNA-sequencing platforms on mouse primary motor cortex. We have generated data using several scRNA-seq methods including SmartSeq V4 whole cells, SmartSeq V4 nulcei, 10X whole cells, 10X nuclei, and SplitSeq. The number of cells or nuclei profiled are from 6K to 130K. Preliminary results suggest that the number of genes detected by these methods vary significantly, and consequently, so does the number of

clusters for each dataset produced by the same clustering pipeline. While all the datasets provide very similar major type separation, the cell type resolution for finer splits as well as cell type compositions are different. Further comprehensive evaluation that accounts for sequencing depth, number of cells, cost per cell and cell type resolution will be informative for determining optimal strategies to profile the entire mouse brain.
Towards building whole brain atlas, we have currently analyzed 54602 cells collected thus far by SmartSeq V4 from 16 cortical and subcortical regions and identified 259 clusters. We observe cell type/cluster dependent regional specificities as well as gradients across regions. Overall, these large-scale transcriptomic datasets are revealing organizational rules of molecularly defined cell types across a range of brain areas.

Abstract: Modern high-throughput methods for single cell or single nucleus RNA-seq allow a comprehensive interrogation of cellular diversity in dissected samples, but these methods do not provide the spatial organization of those cell types in tissue. Highly multiplexed spatial transcriptomics methods provide a means to directly map molecularly-defined cell types back to the originating tissues by analyzing sets of genes that discriminate among those types. However, these various methods have not yet been systematically applied to highly complex cellular tissues such as neocortex. The Chan-Zuckerberg Initiative (CZI)-funded SpaceTx consortium

seeks to (1) evaluate and compare the performance of different methods and (2) to build consensus maps of cortical cell type distributions in human and mouse neocortex based on combined analysis of single cell, single nucleus, and spatially-resolved transcriptomics. Essential elements of this strategy are the rigorous definition of transcriptomic types and the optimal selection of gene panels to discriminate among them.
Here we address these two key challenges for the mouse and human neocortex. We sought to compare and then combine clustering results on two reference data sets published on the Allen Cell Types Database (http://celltypes.brain-map.org/): single cell RNA-seq from >20,000 cells in mouse primary visual cortex and anterior lateral motor cortex, and single nucleus RNA-seq from >15,000 cells in human middle temporal gyrus. We first applied multiple computational methods to generate clustering results, and then derived consensus clusters in both date sets as the target for spatial transcriptomics methods. The consensus clustering found remarkably good agreement in broader cell classes and highly distinct types, and we intentionally over-partitioned heterogeneous cell types to capture more subtle features like gradient changes in expression in broader clusters.
We next addressed the challenge of optimizing gene panel selection for each spatial transcriptomics method, which is non-trivial given differing limitations on the lengths, expression level, and total number of genes that can be concurrently assayed. We describe here a multi-pronged approach including use of prior knowledge, generation of new tools for gene discovery, application of multiple computational strategies, and extensive cross-group collaboration to select gene panels for each experimental protocol. The results provide a set of generalized tools for reference cell type classification and marker gene panels generation that should be useful for creating spatial cell type censuses or study of specific cell types in complex tissues.

Abstract: Spatial relationships between distinct types of cells are fundamental to the function of the brain and other complex organs. To define relationships between transcriptomically defined cell types and cellular morphology, electrophysiological properties, and connectivity, we have developed a pipeline that examines brain tissue in a sequential manner for various cellular characteristics. For defining molecular cell types in the tissue, we are using multiplexed fluorescence RNA *in situ* hybridization (mFISH), and are mapping the mFISH-derived single cell profiles to our benchmark dataset derived by single cell RNA-sequencing.
As a use case, we defined the transcriptomic types of cells previously targeted by optogenetic stimulation at cellular resolution in slice physiology experiments. We use light-sheet microscopy to interrogate intact 350-micron-thick physiology slices to identify cell morphology, anatomical location, connectivity, and transcriptomic identity on a cell-by-cell basis. Connecting the results of the patch clamp and optogenetic experiments to the those from mFISH and potentially morphology yields correspondences between these different modalities.
This pipeline is aimed at robust and repeatable interrogation of mouse and human brain tissue. Scaling these methods to the necessary throughput involved many challenges we have overcome with solutions that should be widely applicable in the field. We will share our approaches to these challenges as well as alternatives that allow us to assign molecular types to single cells previously interrogated for their intrinsic physiology, anatomy, and connectivity.

Abstract: The molecular identity of the building blocks of the brain have recently been elucidated in using large-scale transcriptomic methods on single cells and single nuclei. Definition of transcriptomic identities of neuronal cell types is an important milestone, but single-cell transcriptomic methods have very limited spatial resolution and lack the spatially-unbiased anatomical context needed to accurately quantify abundance of the many cell types in the brain. This limitation has motivated a growing number of spatial transcriptomic methods that seek to measure mRNA expression in single cells in intact tissue. Here we present our results in developing a multiplex fluorescence in situ hybridization (FISH) pipeline capable of mapping neuronal cell types in mouse and human brain. We routinely apply multiround single molecule (smFISH) and hybridization chain reaction (HCR) FISH labeling methods to thin tissue sections, including multiround image collection, registration, mRNA localization, cell segmentation and cell type identification across hundreds of image tiles and many square millimeters of mouse and human brain tissue. We will present recent results on cell type identification in human middle temporal gyrus, computational removal of lipofuscin autofluorescence in human brain tissue and scalable image analysis for large datasets.

Abstract: Single-nucleus transcriptomics data derived from human medial temporal gyrus (MTG) indicates that there are at least 69 neuronal cell types in the human cortex. To place select cell classes and types in spatial context and determine the proportion of each cell type in a given area of human cortical tissue, we applied multiplexed fluorescent in situ hybridization techniques to human brain slices. Both amplified (hairpin chain reaction) and unamplified (sequential smFISH) methods of detection were used to allow us to visualize genes within a wide window of expression level and gene length. To analyze our spatial transcriptomics data, we utilized image quantification and analysis tools developed in collaboration with the Chan Zuckerberg Initiative's SpaceTx consortium. Our data suggest that the proportion and layer location of certain GABAergic and Glutamatergic neuronal classes and types differs between mouse and human. This could have significant implications for circuit architecture and information processing.

Abstract: ABSTRACT: Spatial transcriptomic methods such as multiplex fluorescence in situ hybridization (FISH) and in situ sequencing have the potential to provide detailed transcriptional profiling of thousands of single cells in tissue. As part of the SpaceTx effort to compare these methods we are developing *FISH (pronounced "starfish"), a computational pipeline to produce standardized outputs from input images originating from a wide range of spatial transcriptomic methods. This open source pipeline will be designed to scale from running on a personal computer with locally stored data to to using cloud-based compute and storage resources. The pipeline allows users to build an analysis recipe for their data from various computational modules for image filtering, mRNA spot localization, cell segmentation and decoding of barcoded mRNA identities. By standardizing intermediate data formats and final output, the

*FISH pipeline will facilitate direct comparison of critical parameters across methods, including mRNA detection sensitivity and dynamic range, total mRNA counts per cell and number of genes measured in each experiment. After mapping to previously-defined transcriptomic cell types, SpaceTx output will generate single cell transcriptomic profiles and spatial maps of cell types as well as detailed maps of gene expression in mouse and human brain tissue.

Abstract: A major goal for understanding human cortical function is to understand the cellular makeup of the cortical microcircuit and the connectivity among those circuit elements. Recent advances in single cell transcriptomics now allow a molecular classification of cell types, but the relationship between gene expression and other cellular phenotypes including their electrophysiology, anatomy, and local synaptic connectivity remain largely uncharacterized. To approach this problem, we are probing the synaptic connectivity between human cortical cell types in neurosurgical resections of human middle temporal cortex and defining cell types through a combination of electrophysiology, cellular morphology, synaptic physiology and gene expression, by combining multipatch slice physiology with single molecular fluorescent in situ hybridization (FISH). In addition to intrinsic membrane properties and cellular morphology, cell types can be defined by their synaptic connectivity rates to other neurons, and properties of short-term synaptic dynamics when they are connected. In order to identify both synapse-specific cell types and transcriptional cell types in the same neurons, we combined methods to do multiple patch-clamp recordings and post-hoc FISH using the method of multiplexed hybridization chain reaction (HCR) in thick brain slice tissue. After simultaneous patch-clamp recordings in multiple neurons, the electrophysiological cell type in each neuron is identified and characterized by current stimulus sets. Then, we analyze synaptic connectivity by brief

sequential current injections in patched neurons. As a post-hoc process, we recover clustered neuronal morphologies by streptavidin antibody staining with biocytin diffused through patch pipettes during electrophysiological recordings. Finally, after this procedure, we visualize spatial gene expression discriminating different cell types in cortical slices at the single cell level including clustered patched neurons with FISH with the amplified HCR. We describe here progress on developing and using these tools to be able to define human cortical cell types/classes in individual neurons simultaneously at different levels in cortical columnar network.

Title: A 3-D digital human brain common coordinate framework for positional mapping of single cell data

Authors: *S.-L. DING, J. J. ROYALL, P. LESNAR, B. A. C. FACER, Y. LI, M. NAEEMI, D. FENG, S. M. SUNKIN, H. ZENG, L. NG, J. A. HARRIS, E. S. LEIN
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Human brain mapping at multiple spatial scales and across data modalities has become a routine approach for understanding brain structure, function, lesion and treatment in the neuroimaging community. These approaches have been facilitated by the availability of population average atlases such as the MNI_ICBM152 template and tools such as Freesurfer. In contrast, histological and cellular analyses of human brain typically utilize traditional plate-based atlases of individual brains as reference atlases. With the increase in higher resolution anatomical and cellular analysis approaches such as those of the BRAIN Initiative Cell Census Network (BICCN), there is a need for a whole brain 3D annotated common coordinate framework (CCF) to map single cell data and allow spatial and cross-modal analyses. This cellular resolution presents significant challenges for accurate representation in probabilistic atlases, but a

meaningful coarse mapping to probabilistic templates will allow meaningful analyses and correlation between single cell and neuroimaging data, especially if that template space has a 3D annotation of all brain regions. To better meet these needs and provide a human brain CCF, we present here a 3-D digital Human Brain CCF annotated on the MNI_ICBM152 template. Cortical annotations were based on sulcal patterns of the MNI152 template while subcortical structures were based on a combined analysis of intrinsic template features and histology-based parcellation resources of the human brain (i.e. Allen Human Brain Reference Atlas; see Ding et al. J Comp Neurol, 524: 3127-3481, 2016) using ITK-SNAP. In this CCF, we delineated and segmented approximately 53 cortical gyri/regions using the ontology created for Allen Human Brain Reference Atlas including subdivisions of the previously defined large fusiform gyrus into perirhinal gyrus (anterior part) and real fusiform gyrus (posterior part). For subcortical regions, a total of 45 parent and/or large structures were identified and segmented in basal forebrain, basal ganglia, amygdaloid complex, thalamus, hypothalamus, cerebellum, and brainstem. Finally, 15 representative white matter fiber bundles and the ventricular structures were also annotated for landmark reference. In summary, the Human Brain CCF presented here represents the first manual 3-D segmentation of whole human brain structures on the commonly used MNI_ICBM152 template and will provide a useful tool for documentation, visualization, analysis and comparison of large-scale mapping data across different laboratories.

Abstract: Behaviors can reflect the internal state of an animal. One such behavior, active locomotion, or running, is easily assessed, correlates with an array of brain states, and impacts neural activity, including in primary sensory regions. In mice, voluntary wheel running is used often in tandem with a head-fixing protocol to keep the brain stable for electrophysiological or imaging experiments. To habituate animals to this paradigm, progressive periods of training are used, ensuring that subsequent experiments are not confounded by the novelty of being head restrained in an unfamiliar environment. While the training period is generally thought of as a precursor to an actual experimental manipulation or assessment, how animals behave during this phase can impact how they respond in the future. Thus, to assess behavior during training, we recorded running for 15 minutes during a 1-hour training session over 7 consecutive days in head-restrained mice (males and females) on a circular one-dimensional running wheel. First, we found an increase in both the probability of running and velocity for all animals over the seven days of training. Second, when we examined the running behaviors of males and females, we found significant sex differences between the two groups. Although there was no significant change in the probability of running or velocity of running between males and females, we found sex differences in the direction of running on early days of training. In this paradigm, animals can run forward or reverse, with forward running reflecting a more natural behavior. On day 2 of training, near 90% of female mice (N=8/9) were running forward while only 44% of the male mice were running forward (N=4/9). By day 3, 100% of the female mice ran forward ($P<0.0001$, Wilcoxon Rank Sum, N=9 males, N=9 females). By contrast, only following 5 days of training did all the male mice run forward. Finally, once the animals learned to run in the forward direction, there was no reversion to the reverse direction in following days. These results demonstrate that animals habituate differently during experiments, and that one source of variation is the sex of the animal. Consequently, paradigms that use both males and females in experimental design should monitor differences during training, as these differences may impact subsequent behavioral manipulations, including how those manipulations reflect neural circuit function.

Title: PiRat: An autonomous rat-sized robot as a social companion for studying social behavior in rats using real-time tracking

Authors: S. HEATH[1], C. A. RAMIREZ-BRINEZ[1], J. ARNOLD[1], O. OLSSON[1], J. TAUFATOFUA[1], P. POUNDS[1], *J. WILES[1], E. LEONARDIS[2], E. GYGI[2], E. LEIJA[2], L. QUINN[2], A. A. CHIBA[2]
[1]The Univ. of Queensland, Brisbane, Australia; [2]UCSD, La Jolla, CA

Abstract: Rats are highly social creatures, so measuring the neural and behavioural responses from rats during social interactions is important to studying and understanding the rodent brain. However, the study of rat dyads presents a number of challenges, including preventing injury to a rat or damage to instrumentation from the other rat, and identifying and isolating responses to different social behaviours. Robot-rat studies provide an alternative to dyadic interactions where the use of the robot helps to address these challenges: the robot can be controlled to prevent injury or damage, and individual social behaviours can be added or removed to isolate responses. In the current research, we designed and evaluated a robot framework for performing robot-rat interaction studies, consisting of a new, rat-sized robot platform, the PiRat, an overhead real-time tracking system that uses a depth sensor, and a behaviour manager that allows different behaviours or models to be implemented and run on the PiRat.
Our framework was pilot tested by individually running the robot rat with several different rats (male Sprague-Dawleys and Brown Norways). The rats were first run through a habituation phase, and then with PiRat performing different types of behaviour, including an avoiding behaviour, and an approaching behaviour. The PiRat and real rats were autonomously tracked in the majority of trials, with system-support for real time human-in-the-loop tracking adjustments when required. The quality of the interactions were evaluated using: the mean distance between rat and robot, number of meetings, and sum of velocity towards PiRat. The habituation ranked better in all metrics than either the avoid or approach behaviours. This study presents the first demonstration of a closed-loop robot-rat framework and lays the foundation for further autonomous robot-rat interactions, where different behaviours can be implemented using the positions of the rat and iRat as inputs.

Title: Real-time tools for the classification of social behavior and correlated brain activity in rodents

Authors: *M. AGUILAR-RIVERA[1], E. GYGI[2], A. THAI[2], J. MATSUMOTO[3], H. NISHIJO[3], T. P. COLEMAN[1], L. K. QUINN[2], A. A. CHIBA[2]
[1]Bioengineering, [2]Cognitive Sci., UCSD, La Jolla, CA; [3]Univ. of Toyama, Toyama-Shi, Japan

Abstract: Behavioral coding based on video data is a time-consuming task involving more than one highly trained human classifier. This load increases when multiple rodents are involved,

particularly when engaging in social interactions. Within the field of social neuroscience, there is a growing interest in studying prosociality from a behavioral to an electrophysiological perspective. In this regard, the interoceptive system composed of the amygdala, insular cortex, and the autonomic system, is of particular interest in the study of prosocial behaviors and emotions. It is known that the amygdala is involved in the control of facial expression and face processing. In addition, there is evidence showing facial expression control by the insula, as well as a correlation between its activity and facial and behavioral expression of physical discomfort. Providing frame-by-frame behavioral coding with sufficient temporal resolution and precise synchronization to examine the physiological and electrophysiological correlates of such behaviors is arduous at best. We, therefore, present a real-time behavioral sorter based on videos and inertial measurement units (IMUs) for the classification of social behaviors, affect, and distress, which can be coupled with electrophysiological recordings. Automatic classification of behavior and detailed facial expression are obtained through 3D video of interacting rodents and through the use of high-resolution (4K) cameras. The 3D video system receives input from IMUs (gyroscope, accelerometer, and magnetometer) mounted on the rats' electrophysiological implant increasing its temporal resolution. The IMUs also enable the system to continuously track and provide behavioral classification when rodents are in naturalistic environments where they may be obscured from the camera. The 3D system generates a train of TTL pulses that allow precise synchronization of the system with the 4K cameras, IMUs, and the electrophysiological and physiological recording devices. Together, this technology provides the affordances necessary to build an integrated view of social dynamics and physiology in real time, the first steps towards examining the correlates of prosocial behavior.

Title: Assessing forelimb motor learning and kinematics within the mouse home-cage: An open-source system for the study of rodent models of disease

Authors: *C. L. WOODARD, J. D. BOYD, T. H. MURPHY, L. A. RAYMOND
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Behavioural testing of genetically modified mice is an important step in determining the validity of these animals as models of human disease and assessing the effects of potential therapeutics. To improve both the throughput and reproducibility of this testing, there has been an increase in the use of automated systems that assess behavioural phenotypes of mice within their own home-cage. These allow for the 24-hour testing and monitoring of group-housed mice, who can be individually tracked through subcutaneously implanted RFID chips. However, current commercially available systems are expensive and limited in their ability to test certain behaviours relevant to the study of neurological disorders, such as motor skill learning and fine motor control. To address this, we have developed an open-source system to assess forelimb motor learning, reversal learning and kinematic measures of motor control within the mouse home-cage. Animals learn to pull a metal lever to a defined range over several weeks of continuous testing, and high-resolution lever position analysis as well as video recording allows for automated assessment of learning and behaviour. In previous work with an earlier version of this system, we found several motor learning and control deficits in the YAC128 model of Huntington disease (HD) at an early stage of disease progression. Current work has focused on refining the testing methodology and hardware of the system, and the development of new software applications. We continue to assess both the YAC128 and Q175FDN models of HD for motor, cognitive and circadian phenotypes, and to characterize progression over time. This platform should prove useful for preclinical drug trials toward improved treatments in HD and other neurodegenerative disorders.

Title: A simple method of analyzing spatial learning, prosocial behavior, and empathy in mice utilizing the Barnes maze and damsel-in-distress paradigm

Authors: *E. B. CLABOUGH[1], J. INGERSOLL[1], M. MOODY[1], R. HOLLAND[1], J. WINSLOW[1], W. KUEGLER[1], C. MURRAH JR.[1], B. DUGAN[1], N. REYNOLDS[1], N. LLOYD[1], M. HAMMOCK[1], K. HOULE[2]
[1]Dept. of Biol., Hampden-Sydney Col., Hampden Sydney, VA; [2]Col. of Med. at the Med. Univ. of South Carolina, Charleston, SC

Abstract: The Barnes maze is a reliable measure of spatial learning and memory that does not require food restriction or exposure to extremely stressful stimuli. The Barnes maze can also be used to assess other mouse behaviors, such as general motivation to escape from the maze

platform and exploratory behavior. We explore the use of an aversive ultrasonic noise to enhance motivation to enter the target hole. This behavioral test can be adapted in several ways to assess acquisition and retention of memory in the context of a genetic mutation or environmental variable, as well as provide information about the search strategy employed by the mice. Representative results use the Barnes maze to detect a memory deficit in adult mice following a single developmental ethanol exposure event. The newly described Damsel-in-Distress paradigm exposes a mouse to a female mouse trapped in a chamber in the open center field of an arena. The Damsel-in-Distress paradigm provides an opportunity for the mouse to socially respond to the trapped female and allows for both prosocial behavior and empathy (in the form of investigation and digging near the trapped conspecific). It can also be used to assess rodent locomotor activity and behavior in a novel arena. Both the Barnes maze and the Damsel-in-Distress protocols require minimal financial investment and most aspects of the tests can be constructed from common lab supplies. These flexible and accessible tools can also be used to detect behavioral changes over the course of development.

Title: Auditory discrimination learning in a rodent model of human targeted cognitive training

Authors: *B. Z. ROBERTS[1], N. R. SWERDLOW[2], R. F. SHARP[1], J. W. YOUNG[1]
[1]Dept Psychiatry, UCSD, La Jolla, CA; [2]UCSD Sch. of Medicine, Dept of Psychiatry, La Jolla, CA

Abstract: Introduction: After 50 hours of Targeted Cognitive Training (TCT) schizophrenia patients show large gains in neurocognition. However, durable changes may require extended training, functional gains are modest, and individual responses are variable. We describe a novel paradigm for studying mechanisms of learning in TCT, in advance of testing interventions to enhance its clinical impact.
Methods: Male Long Evans rats (n=15) were trained to respond for reward in 3 distinct auditory discrimination tasks (ADT). Auditory stimuli were either a 500 ms pure tone of high (7 kHz) or low frequency (4 kHz) (ADT#1); a 200 ms sound sweep ranging from low to high frequency

("upsweep") or high to low frequency ("downsweep") (ADT#2); or a 500 ms upsweep or downsweep (ADT#3). The primary outcome variable was accuracy in choosing the lit aperture associated with the stimulus.
Results: Learning was reflected in a main effect of session on accuracy ($F_{(16,160)}$=3.467, $p<0.05$). A session x group interaction ($F_{(32,160)}$=1.522, $p<0.05$) revealed that the 500 ms sweeps group (ADT#3) learned faster than the other two groups. By training day 6 of 17, rats in ADT#3 exhibited greater accuracy vs. day 1. Performance superior to day 1 was never achieved in ADT#1, and required 13 days in ADT#2.
Conclusions: Long Evans rats: 1) can discriminate auditory frequency upsweeps vs. downsweeps; 2) learn faster from sweeps than pure tones; and 3) learn faster from long (500 ms) vs. short (200 ms) sweep duration. Studies will now assess the impact of pharmacologic agents on this model of TCT learning.

Title: Highly multiplexed concerted monitoring of deep-brain hypothalamic neuronal dynamics, gene expression, and behavior reveals cell type ensembles setting behavioral state

Authors: *S. XU, H. YANG, F. E. HENRY, V. MENON, A. LEMIRE, S. M. STERNSON
Janelia Res. Campus, HHMI, Ashburn, VA

Abstract: Brain function depends on a complex interplay of gene expression, neuronal dynamics, and behavior. Deep-brain areas are important for setting behavioral states and they are comprised of multiple molecularly defined neuron populations that are thought to influence distinct behaviors, however little is known about neuronal dynamics in these structures. Moreover, single cell transcriptomics comprehensively predicts neuronal identity, but it requires considerable effort and expense to examine the dynamics of each of these specific neuron populations using existing tools, such as Cre-lox technologies. To address these opportunities and technical challenges, we developed a new functional imaging platform that can simultaneously investigate neuronal dynamics of multiple molecularly defined cell types in a deep-brain structure. GCaMP was pan-neuronally expressed in a deep-brain region. Neuronal calcium activity was recorded through a GRIN lens by two photon volumetric imaging in awake behaving animals under multiple behavioral states. After in vivo imaging, the brain was

sectioned and molecular identity was assigned to the previously imaged cells by 12-plex fluorescence in situ hybridization. Using this new imaging platform, we simultaneously recorded neuronal ensemble dynamics of multiple molecularly cell types in the paraventricular hypothalamus (PVH), which plays a major role in controlling behavioral states associated with animal survival. This platform links traditional system neuroscience ensemble activity measurements with detailed molecular identity of individual neurons and behavior within a single experiment, thus it bridges the gap from gene expression to neural dynamics and behavior.

Title: *In vivo* adduction of photolabel anesthetic in mouse rostral pons profoundly extends drug behavioral effects

Authors: *A. R. MCKINSTRY-WU[1], A. WASILCZUK[1], W. P. DAILEY[2], M. B. KELZ[3]
[1]Anesthesiol., [2]Chem., Univ. of Pennsylvania, Philadelphia, PA; [3]Anesthesiol & Critical Care, Univ. Pennsylvania, Philadelphia, PA

Abstract: Introduction:Many drugs that act to modify complex behaviors, including antidepressants, sedative-hypnotics, and antipsychotics, produce their effects through multiple molecular mechanisms on interconnected neuronal populations. The resulting behavioral phenotype may not be entirely separable from the cumulative effects on a relevant circuit. To study such circuit-level effects, we use a photolabel-derivative of the common hypnotic agent propofol, m-azipropofol (aziPm), systemically with near UV light directed to a small region of the rostral pons centered about the locus coeruleus (LC) to covalently bind drug in vivo, testing whether behavioral-level effects can be prolonged when drug is trapped in a tightly circumscribed region.
Methods:C57/B6 male mice (n=30) implanted with EEG, EMG, and bilateral cannulae stereotaxically directed at the rostral pons (the LC.) During EEG/EMG recording, intravenous 100 mg/kg aziPm given over 5 minutes + or - 375 nm fiber-optic-delivered laser light. A sticker was placed on the mouse's nose and time to remove noted. Cannulae localized postmortem.Mice

with cannula were given IV 1 mg/kg [^{3}H]-aziPm with 375 nm light via cannula. Mice were perfused 1 hour after exposure, and 50 um thick brain sections placed on a phosphor imaging plate for 1 week before images were developed.Slice electrophysiology performed as described previously (Moore 2012). Neurons of the LC were patched in current clamp, and after characterization, baseline established and 10 uM aziPm given with and without 375 nm light.Analyses performed using custom code in Matlab 2016a and with Prism 7.0.
Results:Mice with cannula targeting the rostral pons (centered on the LC) that received UV and aziPm had time to behavioral recovery compared to mice with cannula >300 um off-target or those given drug alone increased by a factor of 10 ($p<0.01$.) Spectral estimates of frontal EEG show extended increases in delta and decreases in gamma and theta power in drug+UV, suggesting prolonged hypnosis, while EMG tone did not differ between groups and heart rate and respiratory rates were not different after drug bolus. Radiolabeled aziPm binding confirmed with a similar exposure, drug photoadduction occurs within a ~300 um sphere. Slice recordings of LC neurons showed a profound prolonged decrease in firing after being given aziPm and UV light vs drug alone ($p<0.001$.)
Conclusion:m-Azipropofol, when photoadducted in the rostral pons in the region of the LC, profoundly extends the hypnotic state. Recordings show some neuronal populations within the relevant area are silenced.

Title: Micro-TMS technology for ultra-focal brain stimulation

Authors: *R. LAHER[1,2], D. Z. PRESS[1], C. E. MCILDUFF[1], S. B. RUTKOVE[1], G. BONMASSAR[2], A. PASCUAL-LEONE[1]
[1]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Massachusetts Gen. Hosp., Boston, MA

Abstract: Transcranial Magnetic Stimulation (TMS) is a non-invasive brain stimulation technique widely utilized in both research and clinical settings. However, the relatively large size of the conventional 70 mm figure-of-eight coil limits spatial resolution and prevents

simultaneous network stimulation at multiple sites. With a goal of increasing stimulation focality, we have engineered a 13 mm Microcoil (μTMS) with a focality of 1-5mm as compared to the conventional 10-30 mm. The system utilizes two stereo, high powered audio amplifiers connected at the input to a pulse generator and at the output to an oscilloscope for monitoring. Miniaturization was achieved via a Flex design consisting of four copper traces, each a width of 711μm, selected to create a 2Ω resistance on 1oz of copper. The amount of amperage needed for the μTMS to induce a magnetic field of similar intensity to Magstim in tissue was determined using modeling and the Biot-Savart law. Aerogel, a material with extraordinary thermal insulation properties, was used for insulation between the skin and the coil. We plan to test the efficacy, safety, and focality of μTMS in peripheral nerves in the upper extremity that are commonly assessed with nerve conduction studies. First, an electrical stimulator will be used to perform standard motor and sensory nerve conduction studies of the median and ulnar nerves. The procedure will then be repeated using the standard figure-of-eight coil as the stimulator to demonstrate activation of evoked potentials by conventional TMS methods. Finally, the process will be repeated using μTMS. A focality map of sensory and motor responses relative to the stimulated peripheral nerve will be generated. This proof-of-concept investigation could provide support for the use of a new μTMS coil capable of stimulating the central nervous system at multiple nodes with greater focality than is available today.

Title: On demand control of hormone release from adrenal gland using magnetothermal stimulation

Authors: *D. ROSENFELD[1], A. SENKO[1], J. MOON[1], D. GREGUREC[1], A. S. WIDGE[3], P. ANIKEEVA[2]
[2]Materials Sci. and Engin., [1]MIT, Cambridge, MA; [3]Psychiatry, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: The adrenal glands play a central role in the regulation of stress responses in patients suffering from psychiatric and behavioral disorders. The glands are responsible for secretion of hormones such as cortisol and (nor)epinephrine, known also as the “fight or flight” hormones. Abnormal production of adrenal hormones has been linked to altered stress responses in mental disorders, including major depressive disorder and post-traumatic stress disorder affecting about 10% of the US population. The adrenal gland is therefore a high-value target for peripheral neuromodulation and control of hormones. Magnetic nanoparticles (MNPs) dissipate heat upon exposure to alternating magnetic fields (AMFs), which then can trigger thermally-sensitive ion channels in electro-active cells. Local heating from MNPs can be converted into an electrochemical gradient across the cell membranes, leading to depolarization in response to the externally applied AMF. The use of MNPs eliminates the need for invasive and tissue-damaging electrodes. Moreover, AMF has higher penetration depth (>10cm) compared to other fields and therefore is more suitable for deep tissue stimulation. It has been shown that heat sensitive ion channels, such as TRPV1, exist in various tissues, including the adrenal glands. Here, hysteretic heating of MNP in the presence of AMF was used to trigger hormone release from adrenal glands. The size, concentration, saturation magnetization, and specific loss power of the MNPs were examined and tailored to the applied AMF. We established a mixed primary adrenal cell culture from adult rat. Adrenal cells were shown to respond robustly to magnetothermal stimulation using calcium imaging. The effects of magnetothermal adrenal stimulation were then assessed in live rats. We developed a surgical procedure to directly inject MNPs to the adrenal gland. One week post-surgery AMF was applied using a custom apparatus. We found that both corticosterone, produced in zona fasciculata of adrenal cortex, and (nor)epinephrine, produced in chromaffin cells of adrenal medulla, can be released on demand with second precision in response to AMF. These results indicate the utility of magnetothermal approach for control and regulation of peripheral organ function.

Title: Non-invasive whole body imaging using magnetography

Authors: R. R. LLINÁS[1], M. USTININ[2], S. D. RYKUNOV[2], *K. D. WALTON[1], G. M. RABELLO[1], J. GARCIA[1], A. I. BOYKO[2], V. V. SYCHEV[2]

[1]Dept Neurosci and Physiol, New York Univ. Sch. of Med., New York, NY; [2]Keldysh Inst. of Appied Mathematics, Russian Acad. of Sci., Moscow, Russian Federation

Abstract: A novel spectroscopic paradigm has been developed that allows the magnetic field emissions generated by the electrical activity in the human body to be imaged in real time. The growing significance of imaging modalities in biology is evident by the almost exponential increase of their use in research, from the molecular to the ecological level. The method of analysis described here allows totally non-invasive imaging of muscular activity (heart, somatic musculature) and the imaging of real-time pathway conduction and the localization of activity in peripheral nerve, spinal cord, brain stem, deep mesencephalic structures, and thalamo-cortical activity. Such imaging can be obtained without additional methodological steps such as the use of contrast media. An unexpected finding in this study was the ability to image activity associated with muscle pain. Thus, this method offers a non-invasive biomarker for muscular pain, and significantly of the very prevalent neck and back pain, which now relies mainly on the patient's report of signs and symptoms.

Title: Brain MRI at ultra-low field: New multifunction instrument

Authors: *K. C. ZEVENHOVEN, A. J. MÄKINEN, I. LEHTO, M. HAVU, R. J. ILMONIEMI Aalto Univ., Helsinki, Finland

Abstract: While conventional MRI has evolved towards increasingly high magnetic fields of several teslas, another approach has emerged, where the signal is detected in an ultra-low field (ULF) on the order of Earth's field. Despite many similarities, ULF-MRI differs from high-field MRI in several interesting ways. Using such low fields, the pulsed magnetic fields can be applied silently and with an open-geometry coil system. The detected kHz-range signal can be modeled from theory with high accuracy. The unique possibilities of ULF-MRI also include the combination of MRI and magnetoencephalography (MEG), the measurement of the weak magnetic fields generated by the electrical activity of the brain. ULF-MRI and associated methods such as current-density imaging (CDI) can significantly improve the localization of

brain activity.
To make ULF-MRI ready for commercial devices for research and clinical applications, we have put significant effort in improving the image quality. Furthermore, the spatial calibration of the system provides vital information for localizing brain activity and submillimeter registration for MEG-MRI. Our aim is to, one by one, solve the problems that limit the possibilities of ULF-MRI. The long-term goal is to bring imaging of electrophysiology to the next level.
Superconducting quantum-interference devices (SQUIDs) configured as pulse-tolerant magnetic-field sensors for ULF-MRI can also be used for MEG. Compared to our first hybrid prototype, our current-generation system uses more robust techniques and a new software platform. With dedicated ultra-low-noise amplifiers, it is possible to switch off even B0 during an imaging sequence. This enables encoding three-dimensional information for current-density imaging (CDI) using novel techniques. We also describe Dynamical Coupling for Additional dimensioNs (DynaCAN), a method using specifically designed pulse waveforms to couple to complex dynamics that have memory of their past. In ULF MRI, DynaCAN-based techniques are useful for solving various problems.
We demonstrate the state of the art of ULF-MRI technology and evaluate the techniques that have led to the dramatic improvements compared to the previous-generation prototypes.

Title: Effects of iTBS on dorsolateral prefrontal cortex, posterior parietal cortex, and primary motor cortex in older healthy adults: A TMS-EEG study

Authors: *A. JANNATI, P. J. FRIED, A. MENARDI, A. PASCUAL-LEONE, M. M. SHAFI
BIDMC, Harvard Med. Sch., Boston, MA

Abstract: Background. Transcranial magnetic stimulation (TMS) techniques such as intermittent theta-burst stimulation (iTBS) enable the modulation of cortical and cortico-motor reactivity in humans. Concurrent TMS and electroencephalography (EEG) allow for the recording of TMS-evoked EEG potentials (TEPs). While the effects of iTBS over the primary motor cortex (M1) have been investigated in previous studies, the effects of iTBS on the reactivity of other brain regions, including dorsolateral prefrontal cortex (DLFPC) and inferior parietal lobule (IPL), remain poorly understood.
Methods. We examined the correlation between early TEPs from single TMS pulses before and after iTBS to the left DLPFC, the left M1, and the left IPL in 3 sessions in 14 older adults (age range: 50-80). Neuronavigated TMS was performed using the MRI-guided Nexstim eXimia system and a figure-of-eight biphasic coil. MEPs were recorded from the right first dorsal interosseous muscle. Single TMS pulses before and after iTBS were delivered at 120% of individual resting motor threshold. EEG was recorded with a 60-channel TMS-compatible EEG device. A passive-cooled figure-of-eight coil attached to a MagPro X100 stimulator was used to deliver iTBS (total of 600 pulses) at 80% of individual active motor threshold. Before and after iTBS, 3 blocks of 30 single TMS pulses were administered. Cortical reactivity was reassessed at 5, 10, and 20 minutes post-iTBS in each visit. For pre- and post-iTBS conditions, peak-to-trough amplitudes of N15-P30 TEPs (averaged over all post-iTBS trials) were determined. Average TEP amplitudes were calculated at all channels and separately at the region of interest (ROI). ROIs were defined bilaterally for M1 (FC3, FC1, FCZ, FC2, and FC4), DLPFC (F5, F1, FZ, F2, and F6), and IPL (CP5, CP3, CP1, CPZ, CP2, and CP4). Changes in the N15-P30 TEP amplitude were calculated as log(post-iTBS/pre-iTBS) in each ROI for each subject.
Results. Changes in M1 TEPs showed a moderate (and marginally significant) negative association with changes in DLPFC TEPs (r=-.56, p=.058) and a moderate (but non-significant) positive association with changes in IPL TEPs (r=.48, p=.13). Changes in IPL and DLPFC TEPs (r=0.34, p=0.30) were not significantly correlated with each other.
Conclusions. Overall, the impact of iTBS on TEPs was only modestly correlated across brain regions within individual subjects, suggesting that inferences about the effects of TMS neuromodulatory protocols on cortical reactivity across brain regions cannot be based solely on effects in primary motor cortex. The negative correlation between DLPFC and M1 TEPs might reflect the inhibitory motor control of the prefrontal cortex.

Autónoma de Barcelona, Barcelona, Spain

Abstract: We tested the utility of cortical plasticity measures by transcranial magnetic stimulation (TMS) delivered in a continuous theta-burst stimulation (cTBS) pattern as a physiologic biomarker in adults with autism spectrum disorder (ASD). Twelve high-functioning adults with ASD (11 males, age mean ± SD, 36.3 ± 12.0), and 23 neurotypical (NT) adults (22 males, age mean ± SD, 36.4 ± 14.3) underwent neuronavigated cTBS of the left primary motor cortex (M1). Stimulation was delivered by a figure-of-eight hand-held TMS coil. Each stimulation train consisted of 50 Hz bursts of three biphasic pulses repeated at 5 Hz for 40 seconds (for a total of 600 pulses), at an intensity of 80% of the individual active motor threshold

(AMT). Cortico-motor reactivity was assessed before and after cTBS by applying single biphasic TMS pulses to M1 at 120% of the individual resting motor threshold. Peak-to-peak amplitudes of motor evoked potentials (MEPs) were recorded from the right first dorsal interosseous muscle. Log-transformed, baseline-corrected MEP amplitudes (LnMEPs) were calculated at 5-, 10-, or 15-minute intervals between 5 and 60 minutes post-cTBS (*T5*-*T60*). Saliva samples were assessed for the Val66Met single-nucleotide polymorphism in the brain-derived neurotrophic factor (*BDNF*) gene. Logistic regression analyses found that, after controlling for AMT, cTBS aftereffects at T30 and T60 together significantly predicted whether a participant belonged to the ASD or the NT group: the model had 83.3% sensitivity and 85.7% specificity among *BDNF* Val66Val participants (n=20), whereas it had 100% sensitivity and 100% specificity among *BDNF* Val66Met participants (n=15). These results support the utility of cTBS as a physiologic biomarker for adults with ASD and emphasize the importance of considering *BDNF* genotypes in the analysis of the neurophysiologic results.

Title: Towards a neurophysiological reactivity monitor (NERMO) to assess coma severity in stroke patients

Authors: *C. A. SERBAN[1,2,3], A. BARBORICA[1,2,3], C.-A. PISTOL[1,2], A. ROCEANU[4], I. MINDRUTA[4], J. CIUREA[5], A.-M. ZAGREAN[6], L. ZAGREAN[6], M. MOLDOVAN[7,6,2]
[1]Fac. of Physics, Univ. of Bucharest, MAGURELE, Romania; [2]Termobit Prod SRL, Bucharest, Romania; [3]FHC, Inc., Bowdoin, ME; [4]Neurol. Dept., Univ. Emergency Hosp., Bucharest, Romania; [5]Dept. of Neurosurg., Bagdasar-Arseni Emergency Hosp., Bucharest, Romania; [6]"Carol Davila" Univ. of Med. and Pharm., Bucharest, Romania; [7]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Background Our previous research (Nita et al. 2016) showed that during deep unconsciousness with burst-suppression EEG, the decrease in EEG suppression probability during photic stimulation, referred to as burst-suppression reactivity, correlates with coma

severity as measured by the Glasgow Coma Scale (GCS). **Hypothesis** We hypothesize that a binary reactivity measure can be used to assess post-stroke coma severity in patients with continuous EEG. **Objective** To develop and validate a novel analysis technique, the default EEG reactivity (DERI). **Methods** We recorded multi-channel EEG from comatose patients with strokes of different localizations and etiologies. A group of healthy volunteers served as controls. From each subject we recorded at least 6 EEG trials lasting 3 minute each. Each trial comprised of a 1-minute stimulation (STIM) epoch preceded by a 1-minute baseline (PRE). During STIM, repeated stimuli were delivered with a frequency of 1 Hz either as binocular flashes or electrical stimuli to the median nerve at wrist. To distinguish changes in arousal we recorded heart rate variability (HRV). To further identify changes in awareness we conducted an additional series of measurements using auditory subject's own name (SON) stimuli. The STIM epoch consisted of repeated SONs generated by a native language voice synthesizer. The SON trials were alternated with trials where the SON was played in reverse (rSON). For each trial we calculated the default EEG reactivity index (DERI) by segmenting the EEG into consecutive classes with similar topographic frequency distribution and then identifying the default class with the largest decrease in occurrence probability from PRE to STIM. DERI was quantified from the binary default class as the relative decrease in probability (PRE-STIM)/PRE. Given the relatively short recording duration, HRV was quantified by the standard deviation of normal-to-normal intervals (SDNN). An awareness index was defined as mean DERI(SON) - mean DERI(rSON). **Results** We found that a mean DERI lower than 40% could discriminate comatose patients from controls irrespective of stimulation modality. The reduction in DERI appeared independent of arousal measures derived from SDNN. The AI was 24.1 % in controls and only -0.3 % in unconscious patients. **Discussion** Our data suggest that DERI (patent pending) and its derivate measures such as AI in conjunction with autonomic nervous system reactivity measures provide a valid neurophysiological measure of coma severity. We therefore feel encouraged to develop a hardware neurophysiological EEG reactivity monitor (NERMO) to facilitate long term DERI tracking to assess coma severity.

Title: Simultaneous monitoring of intact respiratory signals and membrane potentials of CA1 pyramidal neurons in mice

Authors: *M. SATO, A. NOGUCHI, T. OKONOGI, N. MATSUMOTO, T. SASAKI, Y. IKEGAYA
Grad. Sch. of Pharmaceut. Sciences, The Univ. of Tokyo, Lab. of Chem. Pharmacol., Bunkyo-ku, Japan

Abstract: Respiratory function is essential for survival. Besides, information processing related to respiration in the brain is also crucial. However, it has been controversial whether hippocampal neuronal activity is correlated with respiration. To fully understand the relationship between them, it is necessary to monitor intact and accurate respiratory signals. Conventionally, a thermal / CO_2 sensor is put into the nasal cavity to measure respiratory rhythm, but it obstructs nasal airway and affects respiratory rate itself. Thus, this method does not provide intact respiratory information. To work on this issue, we devised a method to monitor intact respiratory rhythms, which does not obstruct nasal airway. Based on the idea that respiration is likely to drift thoracic impedance, we implanted an electrode into pectoral muscles of anesthetized mice, thereby recorded electrocardiograms (ECGs). Then, we derived low frequency components from ECGs using the fast Fourier transform (FFT), and demonstrated that the low frequency oscillations corresponded to the respiratory rhythms. We confirmed that the low frequency was identical to the frequency of the side abdominal movement and the local field potentials (LFPs) of the olfactory bulb, which were regarded as respiratory indicators. In addition, even when the respiration was manipulated by the injection of respiratory stimulant (acetazolamide) or depressant (diazepam), we confirmed that all the three bio-signals shifted in parallel. Furthermore, even in awake (but immobile) mice, the respiratory signals were isolated from ECGs. Finally, we simultaneously performed ECG recordings and *in vivo* whole-cell patch-clamp recordings from hippocampal CA1 neurons of anesthetized mice. Interestingly, on the membrane potential level, some (but not all) CA1 neurons oscillated intermittently coherent with respiratory rhythm. In conclusion, we provided a simple and less-invasive technique to obtain the respiratory signals, which is co-applicable to various physiological and pharmacological experiments. This respiration-deriving algorithm is so simple that it can feed back the respiratory information to animals in real-time, which will disclose the causal relationship between the neural system and respiration.

Title: Development of three-dimensional (3D) cell culture models of the human brain

Authors: *U. ENGLUND JOHANSSON[1], M. CASTRO ZALIS[2], A. BRUZELIUS[2], S. JOHANSSON[2], F. JOHANSSON[3]

Abstract: Studying the human brain require sophisticated models to reconstitute the complex architecture and functions of brain cells. *In vitro* models are essential for precise measurements in controlled conditions. However, existing models are limited in their capacity to replicate the three-dimensional (3D) environment, complex interactions between brain cells and physiology. Therefore, we here study novel 3D human neural cell culture systems, using engineered bioscaffolds and validation against corresponding 2D cell cultures and later relevant animal models for advancing brain research. We fabricated polycaprolactone (PCL) fibrous substrates using electrospinning, consisting of either randomly-- and aligned oriented fibers (thickness: 6 μm, fiber diameter: 550--700 nm). Human neural progenitor cells (HNPC), were cultured for 10- to 20 days on 3D scaffolds or 2D (flat) glass surfaces. Immuno- and biochemical assays and microarrays were used to study gene expression profiles, viability, neurogenic potential and morphometry. PCL scaffolds were found very permissive for survival and attachment of the HNPC. Morphological formation was strongly influenced by culture substrates, with significantly more multipolar morphologies found at random fibers and flat controls. In addition, focal adhesion points formed varied between 2D and 3D substrates, as well as nuclear shape. Preliminary data reveals a significant increase in neuronal differentiation, and decrease in neural stem cells on 3D scaffolds compared to flat surfaces. On-going analysis demonstrates a trend towards different gene expression profiles after culture at 2D and 3D surfaces respectively. Our results demonstrate that the topography indeed matters for the cell fate of cultured human neural progenitor cells, i.e. 3D artificial scaffolds shows great promise for the development of novel and more in-vivo like models of the human brain. Such 3D biomimetic cell culture models of the human brain may indeed serve as an important i*n vitro* screening tool in future drug discovery.

Title: 3D cultures from rat and human IPSC derived neurons exhibit epileptic seizure-like activity

Authors: *M. HASAN[1], S. GHIASVAND[2], Y. BERDICHEVSKY[1,2]
[1]Dept. of Electrical and Computer Engin., [2]Dept. of Bioengineering, Lehigh Univ., Bethlehem, PA

Abstract: Most of the current in vitro epilepsy models use brain slices, which limits these models' experimental throughput.. Here, we present a simple yet novel and high-yield method to create Polydimethylsiloxane (PDMS) confined scaffold-free 3D neuronal cultures from dissociated rat cortex that show spontaneous culture-wide synchronized seizure-like activity without the application of any convulsant agent. These 3D cultures are far more amenable to high-throughput studies than slices. Genetically encoded Ca^{2+} indicator R-GECO1(1) and Micro-electrode array was used to optically and electrically observe the neuronal activity from these cultures. Spontaneous bursts were significantly longer than those observed in 2D dissociated neuronal cultures, but similar to epileptiform activity in hippocampal slices. Application of Tetrodotoxin and Kynurenic acid abolished all burst activity, indicating the key role of neuronal firing and glutamatergic network behind seizure-like activity. Application of anti-epileptic drug (AED) Phenytoin resulted in concentration-dependent modulation of total activity duration. 3D cultures from human induced pluripotent stem cell (hIPSC) derived neurons also exhibited similar seizure-like activity. This method can potentially provide a new and better way for high-throughput anti-epileptic drug (AED) screening. A patient-specific drug development system also becomes feasible with the integration of hIPSC with this technique.

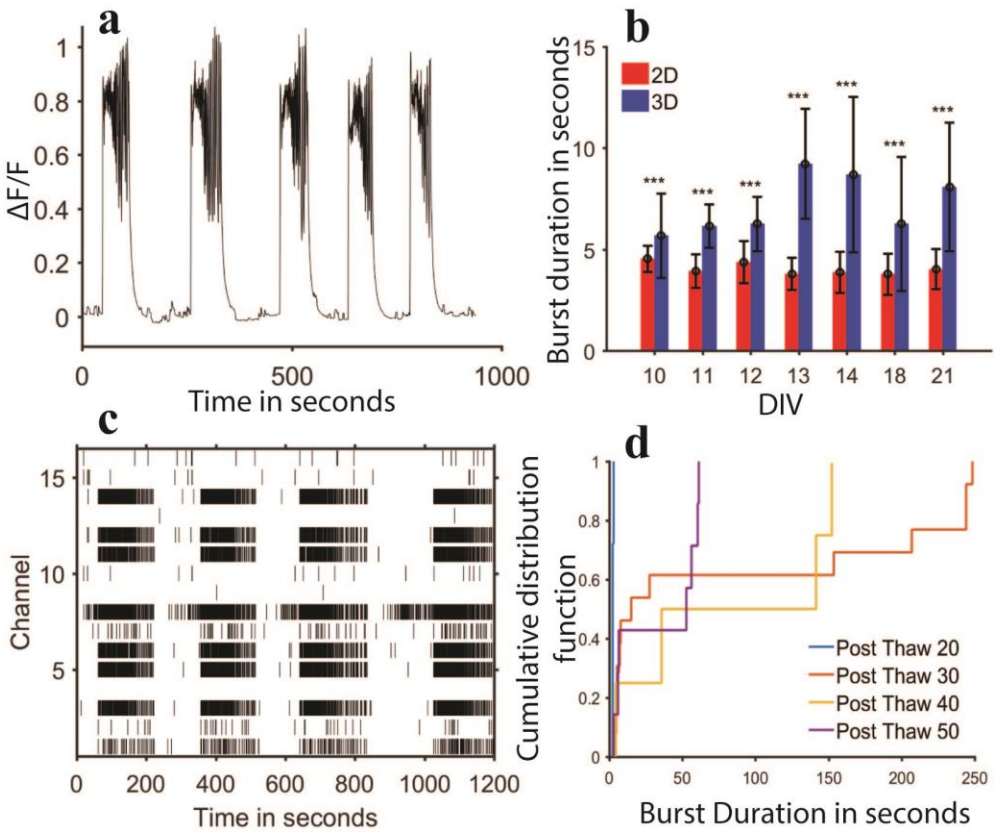

Figure 1: a) Fluorescence changes and c) raster plot of 16 channel MEA recorded extracellular field potential of rat 3D culture on DIV 14, b) Mean with standard deviation of burst duration of rat 2D and 3D cultures on different DIVs. (n=15, 19, 16, 16, 19, 140, 55 and n=21, 28, 18, 19, 39, 116, 32 for 3D and 2D cultures respectively, ***= P<=0.001 for t-test)) d) CDF of burst duration across different post-thaw days for 3D cultures created with hIPSC derived neurons.

Title: Highly homogeneous and highly functional 3-dimensional human cortical spheroids applied to high throughput and high content screening platform in drug discovery

Authors: *C. CARROMEU, S. DEA, S. BIESMANS, S. MORA-CASTILLA, S. ROMERO, A. SALEH, F. ZANELLA
Stemonix, San Diego, CA

Abstract: The human cerebral cortex is organized in a complex 3-dimensional (3D) structure comprising different neural cell types. The coordinated work of these different cell types is key for brain function and homeostasis. Recently, much work has been focused on obtaining 3D brain organoids in an attempt to better recapitulate the brain development/function *in vitro*. However, current protocols may lead to variable organoid size and function, making the use of these powerful tools impractical in an investigative toxicology setting. Here we describe the development of a highly homogenous human induced Pluripotent Stem Cell (hiPSC)-derived cortical spheroid screening platform in 384 well format, composed of neurons and astrocytes. Immunofluorescence analysis confirmed the cortical identity of the cells. Viability assays carried out with compounds with known mechanism of action indicated scalability and feasibility of the assays, with results comparable to a standard 2D model employing the same culture composition. High trhoughput calcium flux analysis performed in a Fluorometric Imaging Plate Reader (FLIPR) highlighted that the spheroids present quantifiable, robust and uniform spontaneous calcium oscillations. The calcium signal was modified with excitatory and inhibitory modulators coherently and in a highly reproducible fashion. High speed confocal imaging confirmed homogenous calcium oscillations at the cellular level, whereas multielectrode array (MEA) analysis demonstrated robust synchronous neurophysiological activity at the network level. Altogether, the developed 3D cortical spheroid platform can be easily implemented as a reliable high throughput screening platform to investigate complex cortical phenotypes *in vitro*, as a reliable high-throughput screening platform for toxicology studies, disease modeling and drug testing.

Abstract: Three-dimensional (3D) neuronal cultures present an opportunity to more accurately model the nervous system and allow for more applicable pharmacology, toxicity, and developmental studies. Magnetic 3D cell culture enables these cultures to be combined with somatic target cells to create functional units that can be manipulated in vitro. Toward this goal, we were able to successfully magnetize and create 3D cultures with iPSC-derived human motor neurons (MNs) from BrainXell using the standard protocol for suspension cells combined with the neuron protocol. We also generated co-cultures with tracheal smooth muscle cells (SMCs) using equal numbers of cells of each type and equal amounts of each media. Cells magnetically levitated in a 24 well plate displayed a normal morphology. MN cultures magnetically bioprinted into rings and spheroids in a 384-well plate did not show significantly significant mobility but did become cohesive structures. Bioprinted co-cultures with SMCs did show considerable movement in the first 24 hours and retained their cohesive shape in the following days. The numbers of MNs and SMCs and their ratio were optimized in 384-well format for both ring and spheroid patterns. Our results demonstrate the feasibility of this approach to produce three-dimensional neuronal and neuronal-smooth muscle systems with more physiologically relevant structures.

Title: Application of atmospheric pressure and hypoxia during culture promotes neural induction of iPSCs and subsequent differentiation into motor and CNS-type neurons

Authors: Z. PAPPALARDO[1], *B. A. ADAMS[2]
[1]R&D, [2]Xcell Biosci., San Francisco, CA

Abstract: Induced pluripotent stem cells (iPSCs) can be used for autologous regenerative medicine to treat a multitude of health conditions, including spinal cord injuries and neuropathology-associated genetic disease. iPSCs can successfully differentiate to neural progenitor cells (NPCs), a multipotent stem cell population that can give rise to all lineages of adult neuronal cells. However, a confounding limitation of differentiated neurons from iPSC-derived NPCs is that they are not genetically and functionally equivalent to adult neurons in vivo, thus rendering them sub-optimal for studying pharmaceutical or environmental responses in the dish. Recent studies highlight the significance of micro-environmental factors such as hypoxia and mechanical force / pressure on stem cell maintenance and directed-differentiation to specific cell lineages, yet none have evaluated the combined contribution of these factors towards differentiation of iPSCs to NPCs or on the differentiation of NPCs into adult neurons. Here we demonstrate the biological impact of oxygen and atmospheric pressure on differentiation of human iPSCs to NPCs as well as on differentiation of both motor and central nervous system-type neurons using the AVATAR™ cell control system. For this study, we demonstrate that combinatorial oxygen and pressure are significant drivers of neural ectoderm differentiation from multiple human iPSC lines. We compared either 5% versus 15% oxygen and increased pressure (+2 PSI) versus atmospheric pressure during culture of human iPSCs and show an induction of neural ectoderm by PAX6 and NESTIN staining specifically in cultures exposed to higher atmospheric pressure. We further show that low oxygen and increased pressure promotes the differentiation and survival of central nervous system-type neurons and motor neurons as determined by the enhanced and pro-longed expression of mature neuronal markers using immunofluorescence microscopy. Our findings suggest that physiologically relevant oxygen and pressure are important drivers of neural differentiation from human iPSCs, and that these micro-environmental factors have the potential to induce maturation of neurons such that they are better suited for translational studies in vitro and in the clinic.

Abstract: The biomechanical dissimilarity between rigid electrodes and soft neural tissues is a recurring problem in recording neural activity from the live brain, yet the development of stable neural interface that enables a complete biointegration remains a challenge. Self-assembling peptide has great advantages in developing a new biomaterial because along with its inherent biocompatibility, chemical and physical properties in macroscopic level can be controlled by sequence modulation. However, unwanted proteolytic degradation of α-peptide based material imposes challenges on chronic utilization. Here, we presented a conductive, biocompatible, and biostable neural interface with a peptidomimetic foldamer-based biopolymer hydrogel which forms a complex with carbon nanotubes (CNTs). To endow conductivity into β-peptide based hydrogel with controlled features of excellent structural and proteolytic stability, hierarchical assembly of β-peptide was designed to self-assemble into nanofiber that associate with carbon nanotubes (CNTs). Transmittance electron microscopy images revealed the end-to-end assembling of β-peptide nanofibers and tight wrapping of the nanofibers around CNTs. The intercortical and epidural neural signal recorded with the conductive hydrogel were founded to be augmented, especially in high frequency range, due to increased contact area and tight coupling with neural tissues. The soft hydrogel-based neural interface suggests many possibilities for developing advanced neural implants with secured signal reliability.

Abstract: What are the neuronal mechanisms underlying decision making? A general approach to studying this problem is to postulate that the information from different noisy sensory signals is integrated and temporarily stored to guide decisions (Gold & Shadlen, 2007, Annual review of neuroscience, 30). For motor decisions, this integration process can lead to long and variable delays between sensory activation and the first motor response. Where does this accumulation occur? Using computational modelling, we explore how multiple sensory signals activation lead to the decision to swim in hatchling Xenopus tadpoles. This animal provides a good system to study decision making because the repertoire of sensory signals is small, and many biological details are known. Recordings from brainstem reticulospinal neurons driving swimming show they receive slow, variable synaptic excitation which would allow integration of sensory inputs and explain the long, variable delays to swimming. There are at least four different sensory pathways whose stimulation can lead to starting or stopping. Swimming can be reliably started by trunk skin stimulation (TS), head touch (HT) or by activation of photoreceptors in the pineal eye by light dimming (LD). It can be reliably stopped by head skin pressure (HP). In each of these pathways distinct neuronal populations process the sensory signal which can start/stop locomotion. Previously we developed a model of the TS sensory pathway and a central pattern generator network which mimics swimming initiation following skin touch. Led by new experimental findings, we improve this model by adding new neuron populations which relay the sensory signals initiating swimming. Additionally, we include new populations for the other sensory pathways. We use the Hodgkin-Huxley formalism to describe neuronal and synaptic properties, based on previous experimental and computational data. Our model represents a biologically realistic reconstruction of the known tadpole's swimming neuronal network and it can reproduce the initiation, stopping and maintenance of the animal's swimming behavior. In agreement with experiments, the model suggests two distinct mechanisms for decision-making: (1) the TS and LD pathways generate slow and variable summation of excitation to threshold, and provide a simple mechanism of working memory. (2) The HP and HT pathways can provide much faster and less variable decisions, more comparable to reflex response times. Our computational model provides a framework for exploring multi-sensory integration and simple motor decision making, to generate new ideas and hypotheses for experimental testing.

Title: Convergent evolution of artificial and biological neural networks performing heat gradient navigation

Authors: *M. HAESEMEYER[1], A. SCHIER[1,2], F. ENGERT[1]
[1]Harvard Univ. Biolabs, Harvard Univ., Cambridge, MA; [2]Univ. of Basel, Biozentrum, Basel, Switzerland

Abstract: Brains represent the external world in form of concerted neuronal activity. While the neural encoding of stimuli could be arbitrary, it is expected that stimuli are represented in a way that facilitates important tasks such as categorization or the generation of adaptive behaviors. This view is well supported by neuroscience studies that uncovered preferential representations of stimulus features important for behavior generation. However, in animals it is very difficult to ascertain a causal relationship between goals and behavioral repertoire on the one hand and neural stimulus representation on the other. Here, we train deep convolutional neural networks that are constrained to predict the consequences of behavioral actions within a heat gradient using either a zebrafish or *C. elegans* behavioral repertoire. This allowed us to test whether these constraints alone lead to a neural representation of temperature observed in the animals themselves. Indeed, we find striking similarities between representation of temperature in the artificial networks and true neural representations. Interestingly, in spite of the same underlying network structure, representations differ when constrained by zebrafish versus *C. elegans* behavioral output. The networks furthermore allow to generate regressors for and identify previously missed response types in the zebrafish brain. At the same time, ablating cell types corresponding to real zebrafish neurons severely impacts gradient navigation performance of the networks while they are robust to deletions of other types. Importantly, retraining networks after ablations was only successful if they were allowed to recover fish-like neuron types. These results strongly suggest that neural stimulus representations can be seen as an optimal consequence of behavioral goals and motor repertoires.

Title: Analysis and modeling of low frequency local field oscillations in a hippocampus circuit under osmotic stimuli

Authors: *H. BARRIO[1], A. MOLINA[1], V. S. HERNANDEZ[1], T. GOVEZENSKY[2], R. A. BARRIO[3], L. ZHANG[1]

Abstract: Time series analysis is known to be a useful tool in the study of the dynamics and characteristics of complex systems, such as neural interactions. This study explores the behavior of different analytical methods for measurements made inside of two regions of interest of the

hippocampus, dorsal and ventral CA2 regions, of adult male Wistar rats. A 2% body weight volume of a 900 mM NaCl (hyperosmotic) solution, was intraperitoneally injected to perturbate the hypothalamus activity and measurements were obtained using electrodes inserted in the hippocampus to observe the local field potential (LFP). The resulting data was analyzed using Fourier Transformations and Wavelet Analysis. In all the methods it was observed that there was a modification in the delta (0.1 - 4.0 Hz) and an increase theta (4.0 -8.0 Hz) oscillations after the solution injection into the rat. A comparison between the signals was then done to determine the quality of the data and correlation methods were used to determine if there was any coherence between the signals due to the perturbation, under the hypothesis that the strength of the functional connections between the vasopressinergic hypothalamic magnocellular neurons and their target in the hippocampus is affected by the hyperosmotic solution. Results showed an increased coherence for these regions which would suggest that increased activity in the hypothalamus provides neuromodulatory input to the hippocampus, as well as enhancing functional coupling between the theta oscillations. Based on the hypothesis of these connections, a model is then developed to emulate the behavior of the signals observed. On the figure provided for this abstract we can see an example of the experimental and theoretical results obtained in this work: Shows comparison of (A) Analysis of the Fourier transform, (B) the correlation analysis and (C) the Wavelet analysis. The results of the theoretical model and those of the experiment show a similar behavior which reinforce the hypothesis of the connections between the hypothalamus and the hippocampus proposed in this study.

Title: Development of bidirectional 'mini-Brain' computer interface (mBCI) to modulate functional neural circuits - stimulation and recording from a cerebral organoid

Authors: M. BHATTACHAR[1], *A. DUTTA[3], D. FREEDMAN[2], E. K. STACHOWIAK[4], M. K. STACHOWIAK[5]
[1]Biomed. Engin., [2]Anatom. Sci., Univ. at Buffalo SUNY, Buffalo, NY; [3]Biomed. Engin., Univ. At Buffalo SUNY, Buffalo, NY; [4]SUNY, Buffalo, Buffalo, NY; [5]State Univ. New York Buffalo, Buffalo, NY

Abstract: INTRODUCTION Electrophysiology can be a powerful technique in deciphering functional microcircuits based on the evoked responses. In this exploratory work, we developed a bidirectional stimulation and recording system using tetrodes and Intan RHD2132 amplifier board for cerebral organoids. We hypothesized that evoked responses generated by multi-neuronal activation in the vicinity of the stimulating electrode would reveal the maturity of the neuronal circuit. METHODS Cerebral organoids were generated using a modified protocol published earlier [1]. We stimulated a 48-day old cerebral organoid using a platinum/iridium wire (dia: 25 µm) and recorded using a polyimide-coated nickel-chrome tetrode wire (dia: 50µm). We conducted spike detection and computational analysis of the tetrode data using custom code in Matlab. RESULTS Spontaneous neuronal activity was not detected in the 48-day old cerebral organoid, however, multi-neuronal activity could be evoked with electrical stimulation. Computational analysis of the evoked responses (see Figure: boxplot of the spikes) revealed correlated tetrode data. We found that our mBCI setup is capable of stimulation, multi-unit recording and online spike sorting. DISCUSSION We showed that continuous online monitoring of the tetrode data is feasible to detect evoked multi-neuronal activity, however, correlated data indicated weak connections and lack of circuit maturation. To detect spontaneous activity, longer cultured organoids are being examined and electrophysiology data compared with two-photon calcium imaging based on prior work in adult fly brain [2]. Furthermore, spontaneous activity triggered stimulation is possible with our mBCI to guide "Hebbian" learning and microcircuit maturation which will be a useful tool for the electrophysiology-based research in cerebral organoids. Title: Acetylcholine regulates redistribution of synaptic efficacy in neocortical microcircuitry

Authors: *C. COLANGELO[1], A. KHUBIEH[2], H. MARKRAM[3], S. RAMASWAMY[4]
[1]EPFL Blue Brain Project, Geneva, Switzerland; [2]EPFL, Lausanne, Switzerland; [3]EPFL, Blue Brain Project, Lausanne, Switzerland; [4]EPFL - Blue Brain Project, Geneva, Switzerland

Abstract: Acetylcholine is one of the most widely characterized neuromodulatory systems involved in the regulation of cortical activity. Cholinergic release from the basal forebrain controls neocortical network activity and shapes behavioral states such as learning and memory. However, a precise understanding of how acetylcholine regulates local synaptic transmission that reconfigures global brain states remains poorly understood. To fill this knowledge gap, we analyzed whole-cell patch-clamp recordings from connected pairs of neocortical neurons to investigate how acetylcholine release modulates synaptic transmission. We found that bath-application of 10 µM carbachol differentially redistributes the available synaptic efficacy and the short-term dynamics of excitatory and inhibitory connections. We propose that redistribution of synaptic efficacy by acetylcholine is a potential means to alter content, rather than the gain of information transfer of synaptic connections between specific cell-types in the neocortex.

Title: Recurrent neocortical circuitry supports spike-time reliability amidst cellular noise and chaos

Authors: *M. NOLTE, M. W. REIMANN, J. G. KING, H. MARKRAM, E. B. MULLER
Blue Brain Project, EPFL, Geneva, Switzerland

Abstract: Electrical activity of neocortical neurons *in vivo* is highly variable. The reliability of spike times in response to sensory stimuli is constrained by the amount of variability that arises directly from noise sources within local cortical circuitry, as opposed to encoding unobserved external signals. High internally generated variability would imply that the precise time of a spike cannot matter for coding, as is often suggested. However, the internally generated variability has been impossible to measure *in vitro* or *in vivo*. Here, we estimated this variability during spontaneous and evoked activity using the Blue Brain Project's digital reconstruction of neocortical microcircuitry. The reconstruction contains biological noise sources, such as synaptic noise and ion-channel noise, and detailed synaptic connectivity. We found that the variable neurotransmitter release due to synaptic noise is amplified by recurrent connectivity to cause highly variable, chaotic *spontaneous* activity. However, we found that relatively weak thalamocortical stimuli can *evoke* reliable packets of activity with millisecond spike-timing precision amidst the noise and chaos. These reliable events require the recurrent neocortical connectivity and are not a mere result of feed-forward thalamocortical input. We conclude that cortical circuitry supports millisecond-precision spike-time reliability amid highly variable, chaotic network activity. This resolves a vast body of conflicting previous studies.

Title: Stability of synaptic weights in a biophysical model of plasticity in the neocortical microcircuit without explicit homeostatic mechanisms

Authors: *M. W. REIMANN[1], G. CHINDEMI[2], E. B. MULLER[3], H. MARKRAM[4]
[1]Blue Brain Project, Geneve, Switzerland; [2]BBP, EPFL, Geneva, Switzerland; [3]EPFL - Blue Brain Project, Geneva, Switzerland; [4]EPFL, Blue Brain Project, Lausanne, Switzerland

Abstract: Spike-timing dependent synaptic plasticity has been characterized on a pairwise level in vitro. However, many of the identified forms of plasticity are inherently unstable in recurrent networks. For example, for hebbian-style plasticity the strengthening of a connection increases the likelihood that it will be strengthened further, leading to runaway potentiation. Homeostatic mechanisms have been proposed to stabilize the system, but physiological evidence for them remains indirect and inconclusive. For a morphologically detailed model of a cortical microcircuit in conjunction with a biologically constrained, calcium-based model of plasticity we characterized the stability of plastic connectivity in a population of neurons in the absence of an explicitly homeostatic mechanism. We explored the evolution of the strengths of 24 million recurrent glutamatergic synapses and their stability under in-vivo-like conditions with simulated external input. We found that while individual synapse weights evolved significantly, there was a remarkable degree of stability in terms of average synaptic strength both on the single cell and

population level. We then further characterized how the observed shift of synaptic strength between individual synapses affected the response properties of neurons, such as their average firing rates or their selectivity for individual stimuli and observed an increase in both for neurons in cortical layer 5.

Title: Improved memory efficient software workflow for data driven model building and simulation

Authors: *J. G. KING[1], P. S. KUMBHAR[1], J. FOURIAUX[1], G. CHINDEMI[1], F. PEREIRA[1], M. L. HINES[2], F. DELALONDRE[1], F. SCHUERMANN[1], H. MARKRAM[1]

Abstract: The Blue Brain Project (BBP) is a data driven platform for developing biologically detailed neuronal models. We have worked on advancing software tools to enable *in silico* scientists to build tissue models of different brain regions and execute simulations on a variety of computational hardware. Our circuit building toolchain now uses Spark technology to handle

large-scale analysis necessary to process touches between neuronal branches in order to create the final set of functional, parameterized synapses. On the simulation side, close collaboration with the developers of simulation software NEURON has led to further development of CoreNEURON. CoreNEURON started as a stand alone application to extract the core capabilities of NEURON in order to facilitate code changes necessary to leverage better memory layout and new computing technologies. Early users had to apply a two-stage process to first initialize a model with NEURON before proceeding to evaluation with CoreNEURON. Recently, this has been simplified for users such that NEURON model constructing capabilities and CoreNERUON optimized execution can be built into a single executable. Members of BBP have started to integrate CoreNEURON into their workflows on various hardware platforms such as BlueGene/Q, Intel Skylake and KNL, and GPUs. This has especially been necessary for work with Structural Plasticity done as part of Argonne INCITE grant. This use case has substantially increased the size and feature set of the simulated model and thus higher memory and computational demands. Using CoreNEURON, the same hardware can support models 6-7 times larger. These improvements are accessible as well to users of smaller systems to better utilize limited resources.

Title: Computational synthesis of cortical dendrites from their branching topology

Authors: *L. KANARI[1], A. CHALIMOURDA[1], G. ATENEKENG[1], J. W. GRAHAM[2], J. SHILLCOCK[1], K. HESS[3], H. MARKRAM[1]
[1]EPFL, Blue Brain Project, Geneve, Switzerland; [2]Neurosim Lab. @ SUNY Downstate, Phoenix, AZ; [3]EPFL, Lausanne, Switzerland

Abstract: The dynamical properties of neuronal networks depend on the branching of their neuronal morphologies, which is involved in both the functionality and the connectivity of neurons. Thus, it is essential for the accurate reconstruction and simulation of detailed brain networks to reproduce the anatomical properties of neurons. The digital reconstruction of a

physiologically realistic network, such as the Blue Brain Project (Markram et al. 2015), requires a large number of detailed neuronal morphologies that are difficult to acquire experimentally. Therefore, the digital generation of neurons that respect the branching properties of the biological cells is required.
The principles that control the final shape of dendritic and axonal arbors are still largely unknown. For this reason, there is a plethora of synthesis methods for the artificial generation of neuronal morphologies that range from biologically detailed methods (Ascoli et al. 2001, Koene et al. 2009) to minimally-constrained ones, which are based on fundamental mathematical principles (Cuntz et al. 2010). Each of these techniques contributes to our comprehension of neuronal growth, but no algorithm has managed to reproduce a large variety of neuronal shapes without manual selection of the appropriate input parameters.
A topological method that quantitatively captures the branching shapes of neurons, (Kanari et al, 2017) has previously been used to establish an objective classification scheme for cortical pyramidal cells. Here we use this topological descriptor, in combination with a small set of morphometrics, to synthesize dendritic morphologies. Each morphology is validated against a set of biological ones, based on a set of morphological features that have not been directly used as input. This topologically driven synthesis algorithm generates realistic morphologies for a large number of distinct dendritic cortical cell types as it implicitly captures correlations between the features inherent in a neuronal shape without manual identification of these inter-dependencies. Because the topologically-driven synthesis scheme is generalizable to a large number of different dendritic shapes it can be used to create the large number of morphological shapes needed for digital reconstructions of large-scale physiologically realistic networks.

Abstract: Structural and functional synaptic plasticity are constantly remodeling neural circuits, shaping them in response to stimuli coming from the external world and to the internal dynamics. This capability is thought to be the foundation of learning and memory in the brain. While plasticity mechanisms of few excitatory connection types have been extensively studied in vitro and in vivo, plasticity properties remain elusive for most of them. Furthermore, it is not clear how different plastic mechanisms, such as long-term potentiation (LTP) or synaptogenesis, would interact together on different time scales and how they could eventually enable learning and memory. In this work we presented a model of a plastic excitatory synapse, devised by integrating widely accepted theories and data on synaptic plasticity. In brief, synapses are located on spines; vesicle release is a stochastic process; functional changes are postsynaptic calcium dependent; N-methyl-D-aspartate receptors (NMDARs) and voltage-gated calcium channels (VGCCs) are the main source of postsynaptic calcium; synapse formation and elimination are stochastic process and the latter is assumed to depend on synaptic strength. The synapse model was parameterized using only a small set of experimental observations on synaptic plasticity, i.e. spike-timing dependent plasticity (STDP) in layer 5 thick-tufted pyramidal cell (TTPC) connections [Markram et al. 1997], and successfully validated against independent in vitro datasets from literature [Egger, Feldmeyer, and Sakmann 1999; Sjöström and Häusser 2006]. This approach allowed us to produce a first predictive map of connection type-specific plastic dynamics in the neocortex. We then analyzed the impact of synaptic plasticity on a large-scale reconstruction of neocortical microcircuitry. Our goal was to assess whether specific connectivity patterns emerge due to plasticity and, if so, how they influence network activity. We exposed a reconstruction of a neocortical network to a set of structured stimuli and monitored the evolution of excitatory synapses over one hour of biological time. Our preliminary results show

that synaptic plasticity can selectively alter the strength of specific connections, while preserving the overall firing activity.

Title: Revealing the information content of voltage-sensitive dye imaging-derived spatiotemporal patterns in cortex

Authors: *T. H. NEWTON, S. EILEMANN, E. MULLER, M. NOLTE, M. REIMANN, J. VILLAFRANCA DÍAZ, H. MARKRAM
EPFL BBP, Geneva, Switzerland

Abstract: Voltage-sensitive dye imaging (VSDI) is a commonly used method for imaging mescosale activity patterns in the cortex of awake and anesthetized animals. However, given that VSDI reflects a highly aggregate mix of cellular and synaptic signals, its precise interpretation can be challenging. Here, we present a study of the information content of the spatiotemporal patterns revealed by VSDI using a biophysically detailed digital reconstruction of rodent neocortical microcircuitry (Markram et al., 2015) to model VSDI signals and isolate the sources of the various signals. In particular, we demonstrate that the principal contributions to the VSD signal are both activity-dependent and layer- and cell-type-specific. Furthermore, by stimulating our microcircuit at varying locations and at varying time lags with in vivo-like injections of

current, we derive a theoretical upper bound to the spatial and temporal resolving power of VSDI. Finally, by performing in silico VSDI recordings of multiple trials of spontaneous and evoked activity that differ only in terms of local intracortical synaptic noise, we calculate the magnitude and timescale of divergence for VSDI signals under ideal conditions. These data suggest fundamental constraints for the interpretation of VSDI signals as meaningful reflections of cortical activity.

Title: Estimating the readily releasable vesicle pool size at layer 5 pyramidal connections in the neocortex

Authors: *N. BARROS-ZULAICA, J. RAHMON, G. CHINDEMI, R. PERIN, H. MARKRAM, S. RAMASWAMY, E. MULLER
Cells and Circuits Team BBP, EPFL, Lausanne, Switzerland

Abstract: Previous studies based on the 'Quantal Model' for synaptic transmission suggested that neurotransmitter release is mediate by a single release site at individual synaptic contacts in the neocortex (Del Castillo, 1954; Silver RA, 2003 & Markram H, 1997). However, recent studies seem to contradict this hypothesis (Rudolph S, 2015) and indicate that multi-vesicular release (MVR) could better explain the synaptic response variability observed in vitro (Wang Y, 2006).
In this study we present a novel method to estimate the number of release sites per synapse, also known as the size of the readily-releasable pool (NRRP), from paired whole-cell recordings of layer 5 thick tufted pyramidal cell (L5-TTPC) connections in the somatosensory neocortex. Our approach extends the work of Loebel and colleges (Loebel A, 2009) to take advantage of a recently reported data-driven biophysical model of neocortical tissue (Markram H,et al. 2015). From a collection of 33 paired whole cell patch-clamp recordings of L5-TTPC in the P14 rat

somatosensory cortex, we extracted the synaptic parameters for the Tsodyks-Markram model of synapse dynamics (TM-model) and estimated the maximal synaptic conductance through matching experimental EPSPs values with equivalently sampled pairs simulated in the neocortical tissue model *in silico*. Finally, the size of the readily releasable pool, NRRP, was adjusted to obtain the best match between the coefficient of variation (CV) profile of the EPSPs for the in vitro data and in silico simulations. Using this approach, we estimated NRRP to be between 2 to 3 for connections between layer 5 thick tufted pyramidal cells. To constrain NRRP values for other connections in the microcircuit, we developed and validated a generalization approach using data on EPSP CVs from literature and matching to in silico experiments.
Our study shows that synaptic connections in the neocortex generally are mediated by MVR and provides a data-driven approach to constrain the MVR model parameters of the microcircuit. These findings have important implications for synaptic transmission, biophysical models of synaptic plasticity, and when considering synaptic noise sources for information processing in the neocortex.

Title: Spatially-informed voxelwise modeling (SPIN-VM) for naturalistic fMRI experiments

Authors: E. CELIK, *T. CUKUR
Bilkent Univ., Ankara, Turkey

Abstract: Voxelwise modeling (VM) has been shown to be powerful in the analysis of fMRI data acquired under naturalistic conditions (Cukur et al., Nat Neuro, 2013; Huth et al., Nature, 2016). VM accurately predicts single-voxel responses evoked by a rich set of stimulus features present in complex natural stimuli in various modalities such as vision (e.g., movies) or language (e.g., stories). A potential drawback of VM is that it disregards response correlations known to exist across neighboring voxels (Zarahn et al., Neuroimage, 1997). Here, we introduce spatially-informed voxelwise modeling (SPIN-VM) to leverage response correlations in spatial neighborhoods of voxels. To optimally utilize shared information, SPIN-VM employs a graph Laplacian matrix representing inter-voxel spatial distances and performs regularization across spatial neighborhoods in addition to stimulus features. Therefore, SPIN-VM can offer improved sensitivity in model estimation while still predicting single-voxel responses.
We demonstrated SPIN-VM in a natural vision experiment, where 3600 time samples of whole-brain BOLD responses were recorded while human subjects passively viewed natural movies. Two separate models were considered based on 1705 distinct object and action categories (category model; Huth et al., Neuron 2012), and 2139 spatiotemporal Gabor filters (motion-energy model; Nishimoto et al., Curr Biol, 2011). To comparatively examine the performance of VM and SPIN-VM, separate voxelwise models were trained using the full set (3600 samples), a half set (1800), and a quarter set (900) of the experimental data. Prediction scores were calculated as Pearson's correlation between measured and predicted BOLD responses. To quantify the local coherence of the resulting models, we calculated the standard deviation across model weights of voxels in a neighborhood of 3×3×3 voxels.
SPIN-VM yields significantly higher prediction scores across cortex compared to VM (p<0.05). Improvements up to 17% are observed in high-level visual areas such as FFA, EBA and LOC for the category model; and improvements up to 11% are observed in low-level retinotopic visual areas for the motion-energy model. We also find that SPIN-VM better captures local coherence of information representations across cortex. Compared to VM, SPIN-VM yields 13% higher local coherence for the category model, and 11% higher local coherence for the motion-energy model (p<0.05). These results suggest that, by leveraging spatially correlated information in BOLD responses, SPIN-VM enhances sensitivity in single-voxel estimates of functional selectivity.

Title: Grey matter detection study using magnetic resonance imaging

Authors: *G. COVER[1], R. FARIVAR-MOHSENI[2]
[2]Ophthalmology, [1]McGill Univ., Montreal, QC, Canada

Abstract: Brain tissue loss, such as the gray matter (GM) thickness, is a potentially-reliable marker of injury and equally important, its reversal could serve as a powerful sign of recovery. GM thickness *in vivo* is detected using magnetic resonance imaging (MRI). MRI quality is tightly related to thermal noise, which is dependent on resolution and acquisition time. Recent developments have made it possible to acquire images that are substantially higher in resolution (i.e., 0.5mm isotropic), but such images suffer from high noise and require multiple acquisitions and averaging in order to yield suitable quality for analysis. Given that the only relevant information to GM thickness measurement is the boundary of white-gray-CSF, it may be possible to denoise high-resolution MRI. The objective of this work was exactly this: to improve the sensitivity of surface-based GM estimation from 0.5mm resolution MRI acquired over a clinically-normal time (~8min). We evaluated four denoising image filters: Optimized Nonlocal Means, Oracle-based, Adaptive Optimized Nonlocal Means, and Prefiltered Rotationally Invariant Nonlocal Means filter. The Adaptive Optimized Nonlocal Means filter exhibited the best segregation of white and GM based on an analysis of the voxel histograms. The GM thickness difference between the denoised image and a gold-standard (mean of 6 acquisitions with no denoising) were visualized as an overlay on the cortical surface (Fig. 1). Overall, GM thickness did not differ between the denoised image and the gold-standard, but there were regions were the denoised image yielded different GM thickness as compared to the gold-standard, suggesting further optimization is needed. As a bonus, the denoised images were preprocessed faster. This work showed that it is possible to reduce MRI acquisition time and maintain relevant image features for the GM thickness, plus the feasibility of 0.5mm isotropic anatomical imaging in clinically-relevant duration using software denoising to emphasize the crucial image features for extracting GM thickness estimates.

Title: Intracranial positioning of brain changes following long-duration spaceflight with implications for longitudinal neuroimaging studies

Authors: *D. ASEMANI[1], M. A. ECKERT[2], T. R. BROWN[3], D. R. ROBERTS[4]
[1]Dept. of Radiology, [2]Otolaryngology - Head and Neck Surgery, [3]Radiology and Radiological Sci., [4]Radiology, Med. Univ. of South Carolina, Charleston, SC

Abstract: Objectives
When assessing longitudinal changes in brain structure, neuroimaging studies conventionally neglect changes in brain positioning within the cranium as processing algorithms begin with skull stripping. Neglecting this global change in brain structure can be a source of error in the estimation of atrophy/growth of brain regions over time. Here we evaluated longitudinal changes in brain structure in a novel population: International Space Station astronauts. We demonstrate that the assumption of a fixed brain position over time is incorrect.
Methodology
Following IRB approval from NASA and our local institution, we analyzed brain MRI scans of 12 NASA astronauts obtained prior to spaceflight and soon after return to Earth. We developed a novel image analysis pipeline that began with the skull-based alignment between pre- and post-flight MRI scans. We used the skull as a reference as the skull does not undergo bone loss during spaceflight[1]. Our algorithm used a multi-objective optimization approach by preferentially weighting the calvarium over the skull-base. Next, the pre-flight brain was affine transformed to the post-flight brain to obtain a 12 degrees of freedom matrix representing shift, rotation, stretch and skewing across three axes. This global transformation matrix from the pre- to post-flight brain was then mapped to a common 3D space (MNI152) for statistical analysis.
Results
Comparing the pre- to post-flight MRIs, there was an obvious change in brain positioning in reference to the skull. Following spaceflight, there was a significant upward brain shift (+0.6mm, $p = 0.03$) and stretching (+0.8%, $p = 0.002$) superiorly along with a transverse compression (-0.4%, $p = 0.002$). These findings were confirmed by independent radiological reading by neuroradiologists[2].
Conclusion

Long-term microgravity exposure results in a significant change in global brain position. Previously, we have shown similar changes in brain structure in subjects undergoing long-term bedrest[3]. We hypothesize brain position within the cranium may also be altered by factors such as aging and various pathologies. We suggest that longitudinal neuroimaging studies consider global as well as local changes in brain structure.

Title: Regional fractal dimension analysis as qualitative and quantitative imaging markers in traumatic brain injury

Authors: L. ZHANG[1], G. R. WYLIE[2], *G. H. YUE[3]
[1]LZ Biomed. LLC, Broomfield, CO; [2]Rocco Ortenzio Neuroimaging Ctr., Kessler Fndn., West Orange, NJ; [3]Human Performance and Engin., Kessler Fndn. Res. Ctr., West Orange, NJ

Abstract: Traumatic brain injury (TBI) is one of the leading causes of mortality and disability worldwide. Due to the heterogeneous nature of the disease, it is challenging to accurately characterize the injury and predict clinical outcome. The purpose of this study was to investigate the potential of regional fractal dimension (FD) assessment as imaging markers to aid for TBI diagnosis and recovery prognosis. A framework was developed to perform qualitative and quantitative analyses of the brain structure based on standard T1-weighted anatomical MRI. The system computes regional FD, a complexity index, of cortical and subcortical structures (113 regions of interest) segmented from MR images and performs correlation analysis between FD values and cognitive function scores. The regional FD values are mapped onto the 3D brain to show structural complexity patterns in TBI. Correlation maps are generated to show the

relationship between local structural complexity and cognitive function scores. T1-weighted MR images of 13 moderate to severe TBI patients (6 left-sided and 7 right-sided injuries) were analyzed using the system. Processing speed, a standard neuropyschological test sensitive to detect cognitive impairment in TBI, was used for correlation analysis. Significant positive and negative correlations were observed between processing speed and FD values of various cortical and subcortical structures. However, these correlations differed between patients with left and right hemisphere injuries. For example in patients with left-sided injuries in frontal, temporal and parietal lobes, positive correlations were found in the thalamus proper, anterior part of the right middle frontal gyrus, right superior temporal gyrus and left posterior cingulate gyrus. In contrast patients with injuries in right frontal, temporal and occipital lobes had positive correlations in the left cerebellar cortex, right lateral ventricle, right lateral occipital gyrus, and right middle temporal gyrus. These findings suggest that regional FD, as an imaging marker may potentially serve as an injury classifier to aid clinicians in performing TBI diagnosis and to predict cognitive outcome. Future work will focus on understanding if regional FD is a more sensitive index than global FD in TBI classification and/or if FD of a given region is related to a specific domain of cognitive function.

Title: Searchlight analysis over functional rather than anatomical space reveals higher representational similarity with deep learning models

Authors: *S. KUMAR, C. ELLIS, T. O'CONNELL, Z. TANG, M. M. CHUN, N. B. TURK-BROWNE
Yale Univ., New Haven, CT

Abstract: Perceptual and cognitive representations are expressed in patterns of activity widely distributed throughout the brain. Despite being distributed, these representations can be localized in fMRI using a searchlight analysis. This involves passing a small, contiguous cube or sphere of voxels over the brain, extracting the pattern of activity from those voxels, performing some (typically multivariate) operation on the pattern, and assigning the result to the center voxel. This can reveal, for example, which local anatomical regions discriminate between stimuli or tasks. Although local information is expected from the gross functional organization of the brain, the assumption inherent to searchlight analyses that function is determined by anatomical proximity makes this approach blind to longer-range interactions that can contribute to whole-brain

analyses. Such interactions are widespread in the brain, including across sensory hierarchies, between homologous regions across hemispheres, and as a result of control or modulatory signals. Here we eliminate the anatomical constraint on searchlight analyses by remapping voxels from their original 3-D anatomical brain space into a 3-D functional space in which the proximity of voxels is determined by the similarity of their function. Specifically, we use shared response modeling (SRM) to find a lower-dimensional space of three orthogonal features in fMRI activity that are shared across participants while they view a common stimulus and then use the weights describing how voxels load onto these features as coordinates that place the voxels in functional space. To validate this method, we performed a representational similarity analysis on held-out data, comparing brain responses while participants watched an episode of Sherlock (Chen, et al., 2017) to the final layer of the deep learning vision model AlexNet while it "watched" the same movie frames. In 16/17 participants, the distribution of representational similarities across the brain was higher when brain activity patterns were obtained from searchlights passed over voxels arranged in functional compared to anatomical space. In other words, by removing the assumption that information is anatomically focal, we found that searchlights are consistently more correlated with model representations. These findings show that anatomically distant voxels carry information that may not exist in adjacent voxels. Using anatomical searchlights to localize multivariate effects seen at larger scale may thus miss important information.

Title: Brainiak education: User-friendly tutorials for advanced, computationally-intensive fmri analysis

Authors: *M. KUMAR[1], C. ELLIS[2], P. J. RAMADAGE[1], K. A. NORMAN[1], N. B. TURK-BROWNE[2]
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Psychology, Yale Univ., New Haven, CT

Abstract: Advanced brain imaging analysis methods, including multivariate pattern analysis (MVPA), functional connectivity, and functional alignment, have become powerful tools in

cognitive neuroscience over the past decade. There now exist multiple software packages that implement some of these techniques. Although these packages are useful for expert practitioners, novice users face a steep learning curve. These difficulties stem from: the need to learn a new programming language (e.g., Python); figuring out how to apply machine-learning methods to data-starved and high-dimensional fMRI studies; and inadequate documentation and training materials. Furthermore, most standard fMRI analysis packages (e.g., AFNI, FSL, SPM) focus primarily on preprocessing and univariate analyses, leaving a gap in how to integrate with advanced tools. BrainIAK (brainiak.org) is a new, open-source Python software package that seamlessly integrates several cutting-edge, computationally efficient techniques with other Python packages for file handling, visualization, and machine learning, picking up where standard packages leave off. As part of efforts to disseminate this package, we have developed user-friendly tutorials and exercises for learning BrainIAK and advanced fMRI in Python more generally. These materials cover cutting-edge techniques including: MVPA (Norman et al., 2006); representational similarity analysis (Kriegeskorte et al., 2008); background connectivity (Al-Aidroos et al., 2012); full correlation matrix analysis (Wang et al., 2015); inter-subject correlation (Hasson et al., 2004); inter-subject functional connectivity (Simony et al., 2016); shared response modeling (Chen et al., 2015); and real-time fMRI (deBettencourt et al., 2015). The learning materials were built using Jupyter notebooks and each notebook has an associated public dataset on which the code can be run. These notebooks were successfully deployed using GitHub Classroom for an advanced fMRI analysis class at Yale University. Students were able to perform analyses previously available only to experts in a simple, step-by-step manner by ssh tunneling into Jupyter on a high-performance compute cluster. We will be freely sharing these materials for public use, with the hope that they become part of a growing pool of open-source software and educational materials for large-scale, reproducible fMRI analysis.

Title: Identifying functional boundaries in the human cerebellum

Authors: *M. KING[1], R. IVRY[2], J. DIEDRICHSEN[3]
[1]Univ. of California, Berkeley, Oakland, CA; [2]Univ. of California, Berkeley, Berkeley, CA; [3]Brain and Mind Inst., Western Univ., London, ON, Canada

Abstract: While in-vivo functional parcellations of the human cerebral cortex have advanced progressively in recent years (Glasser et al. 2016; Huth et al. 2016; Yeo et al. 2011), such detailed characterisation of cerebellar functional organisation is absent. We believe this is because previous fMRI studies have focused on a restricted number of task domains making it difficult to provide a comprehensive mapping of functional organisation on the same set of subjects. To address this problem, we developed a large task battery that allowed us to derive and evaluate a task-based functional parcellation of the human cerebellum on individual subjects. We developed a battery of 26 tasks, selected to engage a broad range of sensorimotor and cognitive processes and we scanned participants on this task battery over the course of four independent fMRI sessions (totaling 5.5 hours per subject). To derive a task-based parcellation, we used semi nonnegative matrix factorisation, which identified latent dimensions of the task-evoked activity patterns elicited by our multi-task dataset. This approach expressed the activation profile of each voxel across task conditions as a (non-negative) weighted sum of latent functional components. We then leveraged our diverse data set to develop a spatially unbiased criterion to evaluate the existence of functional boundaries in the human cerebellum. The spatial criterion that we have devised is predicated on the idea that if a boundary between two distinct regions is dividing two functionally heterogeneous regions, then two voxels that lie within the same region should be more functionally homogenous than two voxels that are separated by a boundary. Integral to the evaluation criterion was the requirement that the boundaries should generalise beyond the dataset upon which they were established. Our task battery was sufficiently large and diverse such that boundaries could be established on one dataset and then evaluated on an entirely novel set of tasks.
We found that the functional boundaries derived on our multi-task data set could predict functional boundaries on a novel set of tasks. However, a lobular parcellation, which is the current nomenclature for assigning functional activations in the cerebellum failed to identify functional boundaries. While parcellations derived on resting state data (Buckner et al. 2011; Cole et al. 2018) performed substantially better than a lobular parcellation, a task-based parcellation yielded the best results. Based on these findings, we advocate for a revision of the existing lobular nomenclature to incorporate functional subdivisions of the cerebellar cortex.

Hosp., Boston, MA; [7]Dept. of Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [8]Dept. of Psychiatry, Columbia Univ. Col. of Physicians & Surgeons, New York, NY

Abstract: Background: Acquiring resting-state functional magnetic resonance imaging (fMRI) datasets on more than one MRI scanner and at multiple clinical sites can increase the overall sample size, which may improve statistical power and generalizability of the results. However, multi-site neuroimaging studies have reported considerable non-biological variability in fMRI measurements due to different scanner manufacturers and acquisition protocols. Ultimately, these extra, undesirable sources of variability may limit the statistical power to detect neurobiological and clinical associations of interest and may even result in erroneous findings. Until now, there has not been an approach to harmonization that entirely removes unwanted site or scanner effects in fMRI measurements.
Objective: We aimed to estimate the site effects on fMRI-based functional connectivity and network measures, and eliminate the identified site effects without affecting the true biological signal.
Methods: In this study, using a relatively large multi-site (4 sites) fMRI dataset consisting of 189 patients with major depressive disorder and 39 healthy controls, we investigated the impact of site effects on functional connectivity and network measures estimated by two widely used connectivity metrics (Pearson correlation and wavelet coherence) and three brain parcellations or atlases (anatomical: AAL; functional: Power and Gordon). To remove site effects, we applied ComBat, a harmonization technique that has previously been shown to eliminate site effects in multi-site diffusion tensor imaging (DTI) and cortical thickness studies.
Results: We found that ComBat successfully removed site effects identified in connectivity and network measures and increased the power to detect age associations when using optimal combinations of connectivity metrics and brain atlases. Moreover, the magnitude of site effects was influenced by the choice of connectivity metric and brain atlas. Particularly, we found that using wavelet coherence with the Power atlas resulted in the best power to detect anti-correlations between age and DMN functional connectivity as well as network efficiency measures following ComBat harmonization, suggesting the best preservation of underlying biological signal with this combination.
Conclusion: ComBat harmonization is a powerful technique for removing site effects in fMRI measurements, and simultaneously preserving biological variability. Our proposed ComBat harmonization approach for fMRI-derived connectivity measures facilitates reliable and efficient analysis of retrospective and prospective multi-site fMRI neuroimaging studies.

Title: Addressing the atlas concordance problem in fMRI

Authors: *M. FINNEGAN[1], S. KERN[1], D. NEWBERRY[2], W. HELLER[1], H. LAURENT[1]
[1]Univ. of Illinois at Urbana-Champaign, Champaign, IL; [2]Unaffiliated, Catheys Valley, CA

Abstract: Reliable identification of brain regions involved in cognitive phenomena is essential for developing a coherent picture of the functional localization of cognition. A serious impediment to this is the misidentification of cognitive function due to the atlas concordance problem (also called the neuroanatomical nomenclature problem). This is summarized by the fact that the same anatomical coordinate may be labelled differently across atlases. We have developed a tool called Neurosift that leverages the Neurosynth fMRI database to assist in identifying common brain regions reported across studies agnostic to anatomical labelling. This provides an easy-to-use alternative to label-based searches. It also addresses a problem in which fine-grained functional specialization is obscured by attribution to the large anatomical ROIs frequently reported in the literature. This is particularly salient for emerging areas of neuroscience with an insufficient publication base to support systematic meta-analyses. We illustrate this in the emerging area of mothers' neural responsiveness to infant emotional cues. Using functional MRI, twenty-five mothers at 3 months postnatal were scanned while observing video presentations of their own or an unfamiliar infant in positive or negative emotional contexts. They also underwent either passive viewing or labelling of emotionally salient faces from the NimStim database to assess emotional regulation in a well-studied paradigm. Peak voxels extracted from exploratory analysis of these runs are surveyed across several commonly used atlases. While there is considerable overlap, consistent with the concordance problem, there is notable divergence, such as a peak in a preliminary contrast of Emotional Labelling > Passive Viewing identified as the post-central gyrus in the AAL and the central opercular cortex in the Harvard-Oxford atlases.
Using a pre-defined protocol of study selection, we illustrate diverging narratives when literature reviews are based on a search driven by different anatomical labels and a search using Neurosift

that identifies analyses reporting peak voxels within the smoothing kernel radius. We identify statistical limitations to this approach such as applicability only to studies using voxel-level correction, and discuss future expansion of this work, such as accommodation of cluster-based correction and potential methods to address the spatial conservativeness of this new type of literature search technology.

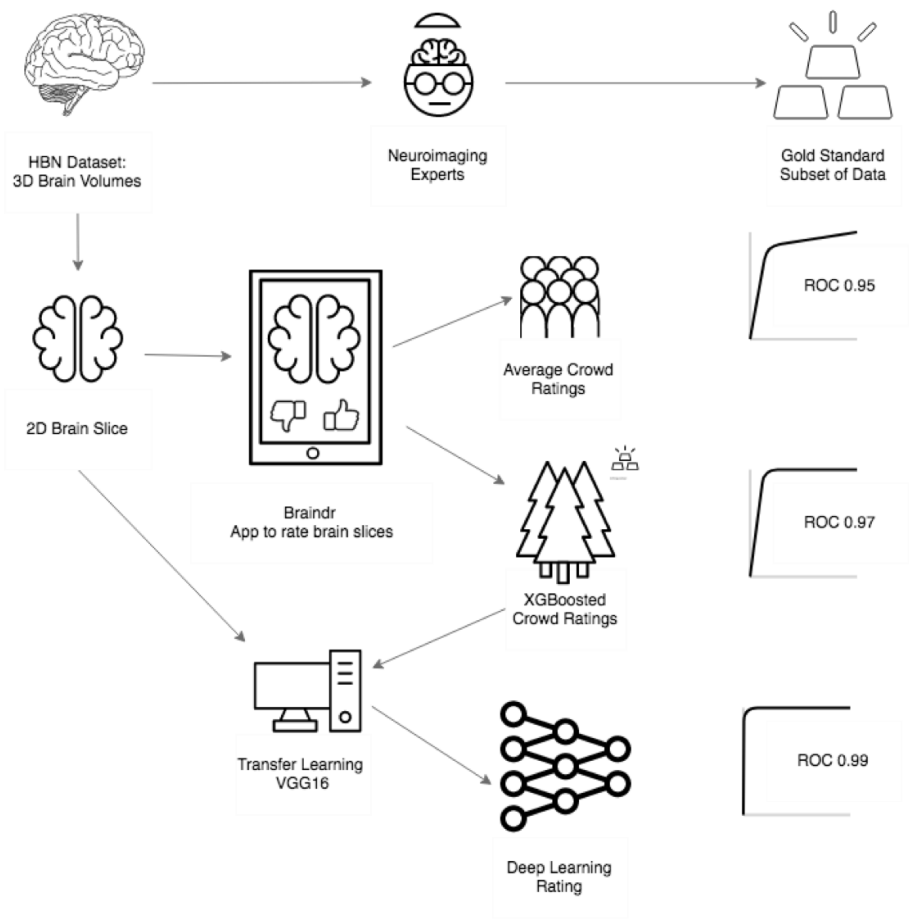
Title: Combining citizen science and deep learning to amplify expertise in neuroimaging

Authors: *A. KESHAVAN[1], J. D. YEATMAN[2], A. S. ROKEM[3]
[2]Speech and Hearing Sci., [1]Univ. of Washington, Seattle, WA; [3]eScience Inst., The Univ. of Washington, Seattle, WA

Abstract: Big data in neuroimaging holds the promise to answer important questions about the brain. However, many standard lab protocols that rely on experts examining each one of the samples is not feasible with large-scale datasets, because they are difficult to scale, and because automated approaches lack the accuracy of highly trained scientists. Our proposed solution is to 1) start with a small, expertly labelled dataset, 2) amplify labels through citizen science via web-based tools, and 3) train machine learning on amplified labels to emulate expert decision making. As a proof of concept, we developed a system to quality control over 700 T1-weighted images from the Healthy Brain Network dataset (Alexander, 2017). An initial expertly labelled dataset (of 200 images) was amplified by citizen scientists to the entire dataset (724) with over 80,000 ratings through a simple web interface called braindr (brain data review, https://braindr.us). A deep learning algorithm was trained to predict data quality with the aggregate citizen scientist labels in a subset of the data. In an ROC analysis on left out test data, the deep learning network performed as well as a state-of-the-art, specialized algorithm (MRIQC) for T1-weighted images (Esteban, 2017), each with an area under the curve of 0.99. Therefore, we assert that combining citizen science and deep learning can generalize and scale neuroimaging expert decision making; this is particularly important in the cases where specialized, automated tools do not already exist. Finally, as a specific practical application of the method, we explore how brain image quality

relates to the replicability of a well established relationship between brain volumes and age over development (Lebel, 2011).



Overview and results of our procedure: First, the HBN data set was rated by 4 neuroimaging experts to create a "gold standard" subset of data. Next, the 3D MRI scans were converted into 2D axial brain slices, which were loaded onto braindr (https://braindr.us), a web application to crowdsource the quality ratings. Area under the curve of the Receiver Operating Characteristic curve (AUC) was calculated for the average citizen scientist quality rating for each slice. Compared to an expert-labeled test set, this resulted in an AUC of 0.95. In an effort to remove unreliable raters, the ratings were aggregated by fitting a model (XGBoost) that weights each citizen scientist contribution to the slice score by how much that individual's scores match those of the experts. The resulting AUC was 0.97. Finally, the 2D brain slices together with the weighted citizen scientist ratings were used to train a neural network. In an ROC analysis on left out data, the AUC of these predictions was 0.99.

Title: Use of high frequency rhythmic SSVEP visual stimuli patterns for better trade-off between fatigue rate and accuracy rate in normal subjects

Authors: A. KEIHANI[1], Z. SHIRZHIYAN[1], M. FARAHI[1], E. SHAMSI[1], A. MAHNAM[2], B. MAKKIABADI[1], A. JAFARI[1], *M. RAZA[3]

Abstract: Steady state visual evoked potentials (SSVEP) are EEG responses generated due to periodic visual stimulation. These are commonly used to control brain computer interfaces (BCIs). LED screen can display high-frequency (26-90 Hz) visual stimuli that can reduce subjective fatigue while low (1-12 Hz) and medium (12-25 Hz) frequency visual stimuli lead to higher subjective fatigue. In this study we investigated the efficiency of the high frequency rhythmic visual stimuli patterns for using SSVEP-BCIs in normal subjects.
Twenty-two normal subjects (11 males and 11 females, aged 23-30 (25 ± 2.1) yrs) were enrolled in the study. Nine visual stimuli of 25, 30 and 35 Hz frequencies (three simple single high frequencies that used only one frequency in sequence e.g. S25-25-25, S30-30-30 and S35-35-35 and six rhythmic high frequency visual stimuli that used all three frequencies in different sequences e.g. R25-30-35, R25-35-30, R30-25-35, R30-35-25, R35-25-30 and R35-30-25) were presented on LED screen. Visual Analogue Scale (0-10) was used for the evaluation of fatigue rate. Fatigue and accuracy rates between simple single high frequency and rhythmic visual stimuli groups were compared.
Overall, rhythmic visual stimuli patterns showed reliable SSVEP responses and high accuracy rate (>90%), results showed lower within group fatigue rate for rhythmic group compared to simple single frequency group. VAS results showed maximum fatigue rate for S25-25-25 (4.95 ± 2.57) and minimum for S35-35-35 (2.95 ± 2.45) in simple stimuli group. Rhythmic group had

lower within group VAS variation (min=P25-30-35 [2.90 ± 2.45], max=P35-25-30 [4.81 ± 2.65]) as well as least individual pattern VAS (P25-30-35).
SSVEP were evoked robustly with high accuracy rate for rhythmic visual stimuli patterns. We conlcude that the lower within group fatigue rate in rhythmic high frequency visual stimuli group can increase user comfort and suggests further research for future application on SSVEP-BCI studies.

Universitario del Norte, Guadalajara, Mexico; [3]Mecatronica, Ctr. de Enseñanza Tecnica Industrial, Guadalajara, Mexico; [4]Medicina Interna, Inst. Mexicano de Seguro Social, Guadalajara, Mexico

Abstract: The study of neuroscience is complex from the point of view of the research since in most cases it is necessary to learn the neuroanatomy and neurophysiology of small species such as rats and mice for experimentation. However, there is a lack of technological tools that facilitate this learning as well as the research protocols in each case. It is necessary to innovate and implement new tools for assisted and practical learning of neurosciences.
By implementing tools for learning and developing the protocols of experimentation in the area of neuroscience, better results can be obtained, since the times and processes will be more efficient, counting with trained personnel in less time, as well as saving material in each case.
Experiment case.
An automated system for the development of deep electrodes in small species was developed with the intention of improving the precision at the moment of the acquisition of

electrophysiological signals. which is controlled by software in an intelligent device that allows the manipulation of the system in an efficient and easy way for the user. which was tested in a model of epilepsy by the supply of 4 Amino Pyridine in Wistar rats and using deep copper electrodes for electroencephalographic recording.

Material and methods

Wistar rats (200-250g) kept under the conditions of a bioterium, 12 hours light / dark, were used to later divide them into two groups, controls and experimental. The rats were anesthetized with isofluorane in O2 and placed in a stereotaxic frame with the incisor rod positioned at -3.3 mm. The rats were implanted with a guide cannula (internal diameter 0.5 mm) in the right entorhinal cortex (AP = -8mm, ML = 4.6mm and DV = 4mm) in order to place an injection needle in that region (DV = 5mm). A deep recording electrode placed in the mobile device was placed in the right hippocampus region (AP = -3.5mm and ML = 2.5mm, DV = 3), a surface electrode that functioned as a reference electrode (ahead of bregma).) and another electrode will be used as ground (below lambda). Subsequently, the mobile device was fixed on the skull of the animal with acrylic to finally allow the animals to recover for a period of 2 hours.

Title: Can the presence of neural probes be neglected in computational modeling of extracellular potentials?

Authors: *A. P. BUCCINO[1,4], M. KUCHTA[2], K. H. JÆGER[5], T. V. NESS[6], G. CAUWENBERGHS[4], K.-A. MARDAL[3], A. TVEITO[5]

Abstract: In mechanistic modeling of neurons the conventional approach to simulation of neural recordings consists of two steps: first, transmembrane currents are computed using the Cable equation and second, their contribution is summed to compute the extracellular potential. This two-step approach, assumes an infinite and homogeneous extracellular space, without considering the presence of neural probes in the vicinity of neurons. In this work, our main purpose is to investigate how the presence of the neural probes affects the extracellular field. Our methods include a detailed modeling framework that allows an explicit representation of the neuron and the probe to evaluate the effect of the probes and thereby estimate the effect of ignoring them. We use meshes with simplified neurons and different types of probe and compare the extracellular action potentials with and without the probe in the extracellular space. We show that small probes (such as microwires/tetrodes) do not significantly affect the extracellular electric field and their presence can typically be ignored. However, larger probes (such as Multi-Electrode Arrays, MEAs) strongly affect the extracellular field by increasing the action potential amplitude up to a factor of 1.9. This amplitude modulation, however, depends on the neuron-probe alignment and on the probe orientation. The *probe effect* that we describe here should not be ignored in certain applications such as neural localization from extracellular action potentials and parametrization of neural models from extracellular recordings. In addition, including the presence of the probe in the modeling framework could improve the interpretation of extracellular recordings, by providing a more accurate estimation of the extracellular potential generated by neuronal models.

Title: Optimization of seizure detection using machine learning

Authors: Z. HUANG[1], *Y. YING[2,1]
[1]Mathematics and Statistics, The State Univ. of New York at Albany, Albany, NY; [2]SUNY Albany, Albany, NY

Abstract: Epilepsy is a very common and devastating neurological disorder that affects 65 million people globally. Electroencephalography (EEG) recording is an essential tool in evaluating seizure activity, critical for epilepsy drug development and patient care. However, due to the random and low frequency of seizures, seizure evaluation requires continuous, long-term

EEG monitoring for weeks and months, producing huge volumes of data. This creates a formidable challenge for real-time tracking of seizures using wearable devices which have low computational power. Current algorithms for automating EEG seizure classification use computationally expensive methods to analyze minute features within small fragments of seizure events. However, despite this complexity, current algorithms still underperform, and laboratory technicians and clinical physicians alike still do not fully rely on these algorithms, opting to manually sift through thousands of hours of EEG data. Human visual analysis still drastically outperforms computer analysis. The proposed method in this study attempts to mimic the simplistic analysis of human vision for EEG seizure classification by focusing on broad, global trends in condensed EEG seizure data. EEG seizure clips were normalized and processed through a rolling mean function, producing smoothed EEG clips that represent the global shape of each clip. These signals were then directly inputted for machine training. This method achieved an accuracy rate of approximately 98.51%. Our approach provides a unique advantage in patient epilepsy management using wearables, where accuracy, computational cost, and speed are all critical to improving patient care.

Title: Time-varying approaches to recover the M/EEG recorded during tACS

Authors: *N. S. BLAND[1], J. B. MATTINGLEY[1,2], M. V. SALE[1,3]
[1]Queensland Brain Inst., St Lucia, Australia; [2]Sch. of Psychology, [3]Sch. of Hlth. and Rehabil. Sci., The Univ. of Queensland, St Lucia, Australia

Abstract: Pairing techniques of rhythmic non-invasive brain stimulation with neuroimaging is scientifically valuable (e.g., to observe neural entrainment), but the recovery of this information *during* stimulation ("online") can be very challenging. For example, artefacts of transcranial alternating current stimulation (tACS)—where a low-intensity AC is delivered via scalp electrodes—contaminate spectral analyses of neural oscillations observable in the magneto- and electro-encephalogram (M/EEG). While there have been many attempts to salvage M/EEG data

recorded during tACS, most (if not all) methods have assumed linear (time-invariant) stimulation artefacts—an assumption that has been recently challenged. Rhythmic changes in body impedance (and position) by heartbeat and respiration can nonlinearly modulate the amplitude (Noury, Hipp, & Siegel, 2016) and phase (Noury and Siegel, 2017) of tACS artefacts, resulting in spectral symmetry around the frequency of tACS. We outline two time-varying template approaches that aim to capture these physiologically derived modulations, exploiting either the concurrent measurement of tACS voltage output, or heartbeat and respiration traces. Using both simulated and real data, we demonstrate these approaches dampen the spectral symmetry observed in artefactual M/EEG. Key advantages of these approaches are their computational efficiency and sensor-specificity (not requiring dense sensor arrays). Our analytic approach will be useful for those wishing to recover M/EEG from artefacts of tACS. We thank Nima Noury, Joerg Hipp, and Markus Siegel for providing data used in their previous works.

Title: Decomposing hippocampal-prefrontal functional interactions via bivariate phase amplitude coupling

Authors: *B. NANDI[1], B. KOCSIS[2], M. DING[3]
[1]Biomed. Engin., Univ. of Florida, Gainesville, Gainesville, FL; [2]Harvard Med. Sch., Boston, MA; [3]Univ. Florida, Gainesville, FL

Abstract: Both hippocampus and prefrontal cortex (PFC) play important roles in memory. Anatomically, hippocampal CA1 region is known to project to PFC directly. More recent work reports polysynaptic projections from CA1 to PFC via the nucleus reuniens (RE) of the thalamus. How to determine the proportion of CA1-to-PFC neural transmission along these different pathways? We addressed this question by applying a recently proposed method of assessing directional interactions in LFP data called bivariate phase amplitude coupling (BPAC). In this method, broad-band high gamma activities are assumed to reflect population spiking, therefore the output activity of a neuronal ensemble, and the low frequency oscillations (e.g., theta) are assumed to reflect dendritic processing, therefore the input activity of a neuronal ensemble. For neuronal ensembles X and Y, significant X high gamma-Y theta coupling implies synaptic

transmission from X to Y (i.e., X->Y), and vice versa. Recording LFPs from CA1, PFC and RE in free-moving rats, and computing CA1 high gamma-PFC theta coupling (CA1->PFC), CA1 high gamma-RE theta coupling (CA1->RE) and RE high gamma-PFC theta coupling (RE->PFC) using BPAC, we found two results. First, CA1->PFC, CA1->RE, and RE->PFC were all significantly above 0 according to a permutation test. Second, a linear regression analysis with CA1->PFC as the dependent variable and CA1->RE and RE->PFC as independent variables yielded R^2=0.26. These findings suggest that in the present experiment, both CA1-PFC pathway and CA1-RE-PFC pathway are active, and theta-mediated synaptic transmission along the CA1-RE-PFC pathway explains 26% of the overall CA1->PFC theta activity transmission.

Title: Computational fluid dynamics (CFD) simulation of cerebrospinal fluid in the ventricular system

Authors: *T. WATAYA[1,2]
[1]Neurosurg., Shizuoka Children's Hosp., Shizuoka-shi, Japan; [2]Clin. research support center, Shizuoka Children's Hosp., Shizuoka, Japan

Abstract: <Introduction> Pediatric hydrocephalus is a challenging disease with high complication rate in the surgery, and development of new treatment is expected. It has been believed that human CSF flows from the choroid plexus to the arachnoid granulations. However, recent analysis has found many controversies in this classical theory, and better understanding of CSF dynamics is desired. Computational flow dynamics (CFD) analysis has been used in cardiovascular field for visualizing blood flow and its effects on the vessels, but little has done on CSF. We aim this study to visualize CSF flow and its effects on the ventricular walls by computer simulation with CFD analysis. **<Method>** The study was performed for the patients who were diagnosed with children with hydrocephalus and age-matched control. 1 mm slice, constructive interference steady state sequence (CISS) magnetic resonance images (MRI) were obtained by 1.5 tesla MRI. Image segmentation was achieved by medical imaging software, and then the 3D ventricular model was reconstructed. Volume data is meshed with 3 sublayers on the

wall boundary, and flow simulation was performed with CFD software (Ansys) (rigid wall, inlet velocity: 10 cm/second, bidirectional flow between inferior horns of the lateral ventricles and the foramen of Monro). Velocity, streamline, wall pressure and wall shear-stress (WSS) were calculated and visualized as 3D-color mapping. **<Results>**Site-specific pressure gradient was observed on both healthy and hydrocephalus ventricle walls, and larger gradient was found in the ventricles with significant dilatation. Surgical simulation of third ventriculostomy was performed on the imaging software, and decrease of wall pressure was confirmed. WSS mapping shows large site specificity in both healthy and pathological ventricles. CSF turbulence was visualized with streamlines. **<Discussion>** Simulation of CSF flow was successfully performed, and its clinical relevancy, at least partially, was confirmed. Computational simulations of biological phenomenon are done under limited condition in any cases, and the results have to be carefully interpreted. However, it also shows certain aspect that may not be able to observe. Addition of more factors will be considered for future studies to increase accuracy.

Title: The role of patient-specific volume conductor models in the simulation of local field potentials recorded from deep brain stimulation electrodes

Authors: N. MALING[1], B. HOWELL[2], T. J. STELWAGEN[2], H. S. MAYBERG[4], *C. C. MCINTYRE[3]
[1]Dept. of Biomed. Engin., [2]Case Western Reserve Univ., Cleveland, OH; [3]Case Western Reserve Univ., Lakewood, OH; [4]Neurology/Neurosurgery, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Emerging technological innovations in clinical deep brain stimulation (DBS) are enabling chronic recording of local field potentials (LFPs) from the implanted electrodes, with hopes that the signals could be useful as representative biomarkers of the patient-specific disease state. However, scientific details on the biophysical origin of these LFP signals remains elusive, and little is known about how the patient's unique brain anatomy and electrode placement impact the recording of such signals. To begin to address these questions, we developed a computational framework to theoretically analyze LFP recordings from clinical DBS electrodes that can be

customized to individual patients. To demonstrate our model system, we analyzed 6 subjects, suffering from treatment-resistant depression (TRD), who were implanted with the Medtronic Activa PC+S DBS system and had electrode contacts located in the subcallosal cingulate (SCC) region. For each subject, a patient-specific reconstruction of their head anatomy and DBS electrode implant location was generated using their clinical imaging data (MRI and CT). This patient-specific anatomical model was then used to define the parameters of a finite element volume conductor model, and to dictate the locations of thousands of multi-compartment cable model current sources relative to the implanted DBS electrode in an anatomically realistic way. We then used this model system to examine the impact of distributing subpopulations of highly synchronous neurons within the SCC region on the recorded LFP signal and compared those theoretical results to the experimentally measured LFPs. We found that incorporating patient-specific anatomical detail resulted in substantial changes to LFP signal compared to simplified models. Increasing the neuronal density near the electrode had a graded effect on LFP amplitude, while a more profound effect was generated by varying the synchrony of spatially discrete subpopulations of neurons.

Title: Methods for comparing models with eeg data using representational similarity analysis

Authors: *N. C. KONG[1], B. KANESHIRO[3], D. L. K. YAMINS[2], A. M. NORCIA[1]
[1]Dept. of Psychology, [2]Dept. of Psychology and Computer Sci., Stanford Univ., Stanford, CA; [3]Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: Assessing the quality of a neural model requires a method for comparing model predictions to data. For example, a model can be evaluated based on its ability to predict neural responses (Yamins and Hong et al., 2014) or on the similarity of representations of the stimuli in the model and in the brain (Kriegeskorte et al., 2008). We focus on the latter—representational similarity analysis. Because there are several ways to compute representational similarity, we

want to understand which measure of similarity (distance metric) is best.
We use a state-of-the-art convolutional neural network (CNN) model that performs object categorization when trained on a large image set (Russakovsky et al., 2014). EEG responses from human participants passively viewing 72 images were used, where each image came from one of six object categories (Kaneshiro et al., 2015).
In order to compute representational similarity of stimuli in the CNN, we compute the activations from each stimulus in each layer. The similarity of stimulus representations is measured by the correlation between each pair of activations for each pair of stimuli. For the neural measurements, we focus on three distance metrics: correlation, classifier accuracy and absolute voltage difference between EEG signals from different images. We then compared the representational dissimilarity matrices (RDMs) from each of these distance metrics to the model RDMs across layers using Spearman's R.
Comparing RDMs computed across time from EEG data and from the model, the best correlation between the model and brain RDMs was found using classifier accuracy as the distance metric ($r=0.35$ compared to $r=0.32$ and $r=0.27$ for absolute difference and correlation respectively). Qualitatively, the RDM computed using classifier accuracy had a block diagonal structure corresponding to the categorical nature of the stimuli. On the other hand, this categorical structure was not as clear if correlation or absolute difference were used as the distance metrics. Finally, the correlation between the classifier RDM and the CNN RDM was a smooth inverted U-shape function of time for each layer. However, these time structures were strongly oscillatory, with period approximately 80 ms, when correlation or absolute difference RDMs were used. This periodicity suggests an underlying temporal structure possibly due to alpha rhythms in the EEG data. This complicates the interpretation of these forms of RDMs because the CNN model class does not have this type of dynamics.
Taken together, RDMs based on classifier accuracy are the preferred method for comparing representational similarity between models and EEG data.

Title: Lobular electric field distribution during cerebellar transcranial direct current stimulation - Cognitive versus somatomotor sub-regions

Authors: *Z. REZAEE[1], A. DUTTA[2]
[1]Biomed. Engin., State Univ. of New York At Buffalo, Buffalo, NY; [2]Biomed. Engin., Univ. At Buffalo SUNY, Buffalo, NY

Abstract: INTRODUCTION We developed a computational pipeline to determine subject-specific lobular electric field (EF) distribution during cerebellar transcranial direct current stimulation (ctDCS). In this exploratory computational study, we investigated ctDCS-induced EF to understand its cognitive versus somatomotor effects. METHODS Head model was constructed from MR images of a healthy volunteer (female, age 31). Finite element analysis was conducted on the head model to find the ctDCS-induced EF. ctDCS was delivered via two 5cm×5cm electrodes at a direct current of 2mA based on two published 2-ch montages: anode over the right cerebellum 3 cm lateral to the inion, and 1) the cathode over the right buccinator muscle - Celnik montage [1], 2) the cathode on the contralateral supraorbital area - Manto montage [1]. Our pipeline isolated subject-specific cerebellar lobules using SUIT cerebellar atlas [2] and then computed average lobular EF distribution. We then optimized 8-ch high-definition (HD) ctDCS montage to target cognitive versus somatomotor sub-regions of the cerebellum. RESULTS Both 2-ch montages primarily affected the posterior and the inferior parts of the cerebellum (i.e., lobules VI-VIII) [1]. Multiple comparison post-hoc tests (see Figure) following ANOVA showed that Manto montage primarily targeted the somatomotor sub-regions (Lobules VIII, VII, IX) while Celnik montage targeted both motor (Lobules VIII, VII, IX) and cognitive (CrusI) sub-regions. Our software pipeline found novel 8ch HD-ctDCS montages for subject-specific focal targeting of cognitive versus somatomotor sub-regions. DISCUSSION To our knowledge, no previous study has optimized HD-ctDCS towards lobule-specific EF distribution [3].

Title: Unsupervised learning techniques for electromyography classification

Authors: *E. LASHGARI, U. MAOZ
Chapman Univ., Orange, CA

Abstract: Improving the accuracy of synthesized human motion is an ongoing challenge in various disciplines such as neuroscience, physiology, biomechanics, brain-computer interface, and robotics. Electromyography (EMG) measures muscular contraction, as part of neuromuscular activation. Complex, non-linear, high-dimensional data sets—such as neuromuscular activity—are hard to study in their original form. Therefore, we often strive to find meaningful low-dimensional representations of the data that maintain important aspects of and relationships between parts of the original, high-dimensional data. Linear dimensionality reduction algorithms have proved to be of limited use because they ignore the structure of the manifold in which the data is embedded and cannot well handle nonlinearities in EMG signals. Here we used a nonlinear dimensionality-reduction technique named Manifold Learning to analyze and visualize EMG of 5 upper limb muscles in a dataset of 12 human subjects. Our results demonstrate the advantages of non-linear over linear techniques as preprocessing stages before classification.

Abstract: Electrophysiological activities in the brain are often analyzed via spectral estimation of neural recordings, e.g. electroencephalogram (EEG) and local field potentials (LFP). The multitaper (MT) spectrogram is a statistically principled tool to analyze cerebral activities, including distinctive patterns characterized by short-duration band-limited high-amplitude power (bursts). Such burst patterns are associated with various neurological states and can be potentially used as informative markers to track brain states during anesthesia-induced unconsciousness. A computational method to automatically detect such bursts will allow for efficient, unbiased processing of data prior to any statistical analysis. With this motivation, we have developed a computational scheme to automatically detect the bursts using a Hidden Markov Model (HMM). In the current work, we consider neural time-series data, which contains bursts of band-limited activity lasting for and repeating at an interval of a few seconds, where this cyclic pattern is sustained over an extended duration. We employ a HMM with Gaussian observations to detect various neural states, one of which is associated to the bursts. The observation sequence is the fraction of MT power estimate in a narrow frequency band, which contains the bursts of interest, relative to a wider band that includes the narrow band but excludes other frequencies with simultaneous high power activity. Both these user-specified bands are currently chosen such that bursts are characterized by visibly distinct increase in observation relative to neighboring epochs. This discrepancy in the relative power during the burst epoch is leveraged by the HMM to associate one of the hidden states with a burst. We demonstrate our scheme using scalp human EEG under ketamine-anesthesia and macaque LFP under propofol-anesthesia. In our current implementations we consider that the relative power sequence contains periods of low, medium, and high (burst state) power in the narrow band. Therefore, we fit the data with a three-state HMM and generate the most probable sequence of states given the observations, thus yielding the time-points of each burst epoch. The burst sequences generated by the algorithm are compared against manually segmented (by visual inspection) data on relevant time segments. The current version of the algorithm achieves burst detection sensitivity of 81% across two ketamine human EEG datasets and 93% - 99% across three macaque LFP datasets.

Title: Admittance method for estimating local field potentials generated in a multi-scale model of the hippocampus

Authors: *C. S. BINGHAM[1], J. PAKNAHAD[2], J.-M. C. BOUTEILLER[1], D. SONG[1], G. LAZZI[3], T. W. BERGER[1]

Abstract: Significant progress has been made toward model-based prediction of hippocampal activation in response to extracellular electrical stimulation. While analytical methods provide a first order approximation suitable for model validation, efficient numerical methods are necessary to properly estimate fields arising from endogenous currents and to predict the influence that they have on nearby voltage-dependent mechanisms. Local field potential (LFP) estimation using a multi-scale model of the hippocampus may aid design of neural recording arrays by clarifying which features of tissue geometry or neuronal activity strongly contribute to the LFP. To achieve these goals, the authors have formulated an algorithm for bidirectional communication between an Admittance Method (AM) model volume conductor and a NEURON model hippocampal network. The approach is validated through the comparison of AM predicted evoked potentials with both analytically estimated and experimentally recorded signals. Closed-loop integration of the AM and NEURON models represents a step forward in the predictive power of multi-scale models of cortical tissue. These models may be used to deepen our understanding of hippocampal pathologies and the identification of efficacious treatment.

Title: State space oscillator models for isolating neural frequencies

Authors: *A. M. BECK[1], E. P. STEPHEN[2], P. L. PURDON[3]
[1]Electrical Engin. & Computer Sci., [2]MIT, Cambridge, MA; [3]Anesthesia, Critical Care, and Pain Mgmt., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Rhythmic or oscillatory neuronal spiking is an important avenue for information processing within the brain. Populations of these spiking neurons give rise to oscillatory electrical signals that can be recorded in the electroencephalogram (EEG). These oscillatory signals play a role in cognition, attention, sensory processing, and states of altered arousal or consciousness. A traditional approach for quantifying these neural oscillations is to examine signal power or amplitude within frequency bands of interest, using spectral analysis or linear bandpass filtering. A significant problem with the traditional method is that the power in the frequency band of interest is not evaluated with respect to the shape of the complete power spectrum. Thus, power in any band will include broadband “1/f” power, whether or not an oscillation is present. We propose a state space method to identify oscillations in the time domain that describes each oscillation with a low-order autoregressive model. We estimate the autoregressive and noise parameters with an Expectation Maximization (EM) algorithm and identify the presence of oscillatory components, distinct from 1/f noise, using AIC. This method also makes it possible to characterize more precisely the shape or bandwidth of oscillations when they exist, and can distinguish low-frequency (e.g., slow) oscillations from low-frequency drifts. We demonstrate this method on univariate EEG data during resting state and under propofol-induced unconsciousness, where prominent oscillations have been previously characterized.

Disorders and Stroke, Bethesda, MD

Abstract: Time-delays in communication between brain regions greatly impact brain function, which requires precise timing of the arrival of neural spikes and signals that propagate along axons. Our aim is to develop methods for measuring and estimating brain network latencies. Here, axon diameter distribution (AAD) measured via MRI are used to estimate conduction velocities, while transcranial magnetic stimulation (TMS) evoked potential (EP) via electroencephalography (EEG), as well as time-series analysis of the magnetoencephalography (MEG) and EEG recordings, provide complementary information with which to estimate latencies. The connectivities and latencies obtained from time-series analysis are typically inferred from time-shifted signals compared in a pairwise manner. Establishing connectivity usually relies on Wiener-Granger causality, which ascribes the improvement in linear prediction or information gain to the inclusion of the potential “causal” source time-series. Our approach is different, as we rely on unpredictable events in time-series and treat them as perturbations for which we try to infer the propagation of their influences. These events are defined as the time points where the time-series falls outside a very stringent confidence interval (e.g., z>5 or larger) for any prediction scheme that we use. Our latency estimation procedure has three steps: 1) identifying “trigger” times at which the onset of unpredictable event occurs; 2) using bi-variate analysis on the count data to determine significant pairs and temporal delays at which the “casual” propagation occurs; 3) using tri-variate mediation analysis to remove the “indirect causes”. We previously tested this procedure on simulated data (a non-linear network of neurons, using only auto-regressive linear prediction) and showed that very long recordings of activity

(many hours) can lead to the correct identification of the majority of the intrinsic latencies in the network. Here, we extend this analysis to a variety of machine learning prediction schemes and ultimately apply all these methods to 4-hour EEG recordings. In these pilot studies, we were able to identify significant latencies, but only in the range between 100 and 300 ms, and with the uncertainty that is larger than 10 ms. In trying to measure latencies, it is important to distinguish between the temporal differences in neural events and delays incurred solely by signal conduction, which we seek to infer. Our results further emphasize the need to supplement time-series analysis with the structural axon diameter and conduction velocity information and with TMS+EEG measurements.

Title: Eyes open or closed: Synchrony and complexity in a resting state brain network

Authors: *A. GHADERI[1,2], B. BALTARETU[3]
[1]Iranian Neurowave Lab., Najafabad, Iran, Islamic Republic of; [2]Ctr. for Vision Res., [3]Biol., York Univ., North York, ON, Canada

Abstract: Recently, there has been an increase in neuroimaging studies applying graph theoretical analysis (*GTA*) to resting state activity. In the resting state, no task is performed, yet brain activity is affected by visual information, which is why we would expect different brain activity patterns when the eyes are open or closed for example. GTA has been used to determine topological properties (statistical features) of functional brain networks; but, there is little knowledge about dynamical properties, such as synchrony and complexity, in these networks. Our aim here was to develop methodology to investigate these dynamical properties and to uncover them. To investigate the dynamics of the resting state network for eyes closed (*EC*) and eyes open (*EO*) conditions, we used the following measures for data obtained using electroencephalography (EEG): maximum eigenvalue (*ME*), graph energy (*E*) and Shannon entropy (*S*). For each participant (N=45; 8-45 years of age), coherence values from data obtained from 19 EEG channels were calculated. Then, dynamical measures (Laplacian matrices) were

compared by nonparametric permutation test, for each participant. A k-mean approach was used to separate data based on conditions. We did this for delta, theta, alpha, beta, and high beta frequencies. Our results indicate that there were significant differences in all three band frequencies tested. In the alpha band, higher value of *S* was observed in *EO* (p=0.00001), while *EC* exhibits higher *E* (p=0.00001) and *ME* (p=0.00002). In the alpha and beta bands, higher *E* (p=0.00000) and *ME* (p=0.00004) was observed in *EC*. In the high beta band, *EC* exhibits significantly higher *E* (p=0.0002) and lower *S* (p=0.0030) than *EO*. We also found a statistically significantly negative correlation between *E* and *S* (p=0.0195). The k-mean results in 83% accuracy for the *EC* clustering, when alpha measures were used as inputs. According to our results, dynamical properties of resting state network are changed based on whether the eyes are open or closed. Consistent with previous findings about alpha band activity, our findings of higher *ME* and *E* in *EC* can be viewed in terms of increased thalamo-cortical synchrony. This effect has been also observed in beta band, which in turn may be related to higher order cortical processing of visual inputs. The lower *S* in *EC* indicates decreased complexity and information processing in the resting state brain network. Lastly, the negative correlation between *S* and *E* suggests that synchrony predicts complexity in an inverse manner within the brain network. Overall, we have developed a method of analyzing dynamical properties of functional brain networks for resting state activity.

Ctr., Havana, Cuba

Abstract: An important goal of translational neuroscience is to characterize brain circuit dysfunctions leading to neuropsychiatric disorders. Such knowledge has potential for developing

non-invasive therapies based on brain-computer interfaces (BCI). However, most attempts to use BCI to rehabilitate impaired cognition fall short due to the use of suboptimal brain imaging technology with low spatiotemporal resolution and oversimplified assumptions of linearity and stationarity of brain interactions. In this work, we address these shortcomings by estimating EEG source time series using a recently developed, real-time, sparse Bayesian learning algorithm followed by the characterization of source functional connectivity using an estimator of local mutual information (LMI). We simulate ground truth functional connectivity patterns and EEG source activity using a biologically inspired large-scale dynamic causal model of the brain. Our simulations show that LMI can successfully track functionally relevant brain network states from the sparse nonlinear time series of online estimated EEG sources.

Title: Automatic elimination of EEG artifact using convolutional neural network, ICA features, and dipole source location

Authors: *G. KANG[1], D. KIM[2], S. KANG[3]
[1]Imedisyn, Seoul, Korea, Republic of; [2]iMediSyn, Seoul, Korea, Republic of; [3]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Electroencephalogram (EEG) signals can be distorted by unwanted noise sources such as eye blinks, horizontal eye movements, muscle activity, line noise and heart signal. Therefore, it is important to identify and remove them to avoid serious misinterpretation. Independent component analysis (ICA) is a statistical method, which is popular to separate the artifacts from EEG signals. Features extracted from ICA are topographic maps, power spectrum and dipole sources. Topographic mapping of the EEG often reflects source localization. Power spectrum can be specifically useful to identify EMG signals. Dipole source localization is used to estimate the location of sources of electrical activity in the brain. One major problem with ICA is that it needs visual inspection by EEG experts. In this study, a new method was developed for automatically classifying and eliminating EEG artifacts using image recognition of image patterns of ICA features using the convolutional neural network (CNN). The EEGs recorded from 841 healthy

subjects were used in this study. Subjects were between the ages of 4 and 80, with 6732 men and 884 women. The pipeline for EEG artifacts removal consists of pre-processing including filtering, common average referencing and ICA. Data for training and testing the CNN model were obtained from manual inspection of the ICA features by EEG experts. Since the volume of data was important for the CNN, generation of additional data was implemented as follows. The pre-processed signals were divided into several segments to extend data for the CNN. ICA was then applied to the segments and ICA features were generated. The CNN was then used to classify neural signal and 3 different artifacts including EMG, horizontal eye movements (eye blinks), and vertical eye movements. The CNN applied to the ICA features presented its effectiveness to automatically classify and remove the EEG artifacts. An accuracy rate of 93.01±2.09% was obtained and eye blinks were most effectively classified with a recognition rate of 98.29±4.76%. The error rates of missing neural signals and artifacts were 4.21±3.16% and 6.60±1.89% respectively. Finally, the execution time of the system was acquired for real-time applicability. In conclusion, a method of the CNN applied to ICA features has been presented to identify and remove EEG artifacts. The results demonstrate that the proposed method can effectively, automatically remove EEG artifacts in EEG signals. This study supports that the deep learning is capable of strong potential for removing EEG artifacts resulting high quality of EEG signal analysis without manual inspection by EEG experts.

Title: Cross-session transfer learning for brain-computer interfaces based on steady-state visual evoked potentials

Authors: *K.-J. CHIANG[1], C.-S. WEI[3], M. NAKANISHI[4], T.-P. JUNG[2]
[1]Univ. of California San Diego, La Jolla, CA; [2]Swartz Ctr. for Computat. Neuroscience, Inst. for Neural Computation, Univ. of California San Diego, LA Jolla, CA; [3]UCSD, La Jolla, CA; [4]UCSD, San Diego, CA

Abstract: Brain-computer interfaces (BCIs) based on steady-state visual-evoked potentials (SSVEPs) have been applied to high-speed spellers that allow typing without moving a finger or

speaking a voice. The high efficiency of SSVEP-based BCI speller is established upon the use of individualized training data and advanced detection methodology [1]. However, collecting training data could be time-consuming and laborious to ensure the accuracy of SSVEP detection. Cross-session transfer learning could be an effective way to reduce the need for collecting training data from a new session by leveraging the existing data from other sessions. Our previous study [2] has demonstrated the feasibility of transferring SSVEP templates across sessions to minimize the data-collection effort. We herein proposed a cross-session transferring framework that incorporates least-squares transformation (LST) to alleviate the session-to-session variability of SSVEP data within a subject. The experimental data consist of three sessions of 9-channel, 40-stimuli SSVEP recording from eight subjects [2]. The LST is applied to channel-wise SSVEP data from source (other) sessions to a target (new) session, and seeks the transformation across sessions to maximize the similarity between the transformed source SSVEPs and the target SSVEP templates. We then pooled the LST-SSVEP data and target SSVEP data together to expand the training data size for the new session, and performed the SSVEP detection with the state-of-the-art task-related component analysis (TRCA) technique [1]. The cross-validation results suggest that our cross-session LST-based transferring framework can achieve high performance with a small amount of training data from the new session. In sum, we showed that leveraging SSVEP data from other sessions could improve SSVEP detection and significantly reduce the training time without compromising performance. The proposed LST scheme can be further extended to cross-device or even cross-subject transferring in the future. Title: Skull conductivity and source location estimation (SCALE) to high-resolution EEG source imaging

Authors: *Z. AKALIN ACAR, S. MAKEIG
Inst. for Neural Computation, Univ. of California San Diego, La Jolla, CA

Abstract: We have published a novel iterative Skull Conductivity And source Location Estimation (SCALE) algorithm for simultaneously estimating head tissue conductivities and brain source locations (Akalin Acar et al., 2016). SCALE uses a realistic FEM head model and scalp maps of near-dipolar sources identified using independent component analysis (ICA) decomposition of sufficient high-density EEG data. Our simulations have shown that skull conductivity is the most important impediment to high-resolution EEG source imaging (Akalin Acar et al., 2013). Until now, there has been no widely accepted and used method for non-invasively measuring skull conductivity in individual subjects. We propose that using SCALE, functional EEG source imaging can become routine and accurate. Figure 1 shows scalp maps and estimated source distributions.

We applied SCALE to nine (9) subjects, ages 19-25 years. We collected 256-channel EEG data with 3-D digitization of electrodes while they performed either a video game-playing experiment, dart throwing, and/or an arrow flanker task. Table 1 shows the estimated brain-to-skull conductivity ratios (BSCR values) and (in parentheses) the number of ICs used for SCALE for these subjects' different experiments. For the 3 subjects with two experiment data sets (FR, JH, and SE), the estimated BSCR values for the two experiments were very close (mean within-subject difference <9% versus 33% between-subjects). These preliminary results indicate the robustness of the SCALE approach across experimental sessions and paradigms, and suggest this approach can make EEG a portable, low cost modality for accurately imaging EEG brain activity.

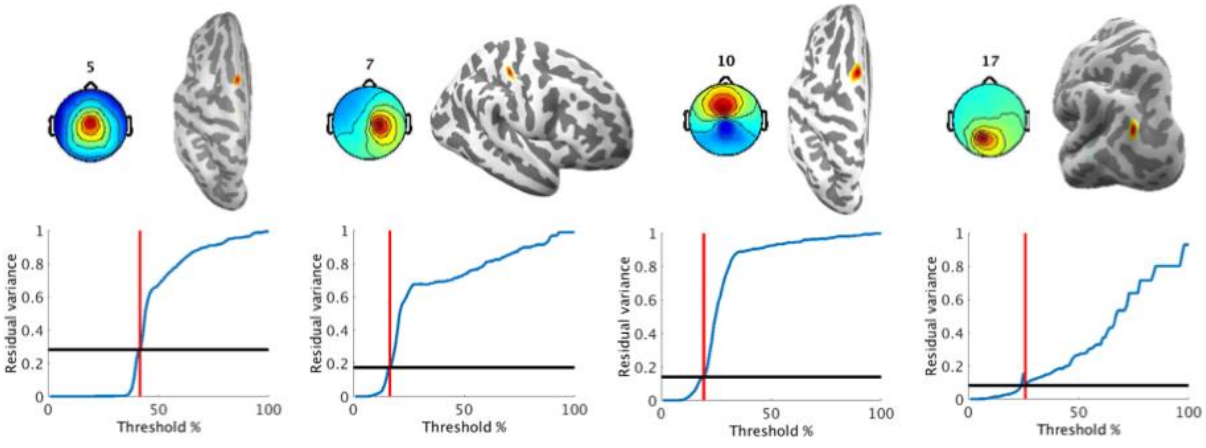

Figure 1 *(Top row): Scalp map, estimated source distribution (plotted on the subject's semi-inflated cortical surface) of 4 independent component sources dominating an Error-Related Negativity (ERN) feature of the event-related potential (ERP) time-locked to erroneous finger button responses in an Eriksen flanker task session recorded from 128 scalp channels. Bottom row: Residual scalp map variance of the percentage thresholded SCALE-converged best-fitting source distribution. The red line shows the threshold used for these source distributions.*

Table 1: BSCR values for 9 subjects									
	BD	FR	AV	RB	LH	GV	AS	JH	SE

Title: Calibrating the timing of neuroscientific apps on mobile devices

Authors: M. I. W. GRIVICH, 94704-1151, P. A. W. PEBLER, 94704-1151, *D. L. WOODS Neurobehavioral Systems, Inc., Berkeley, CA

Abstract: Neuroscientists wishing to use mobile apps in their research face two major obstacles: (1) High-precision mobile apps are challenging to program, and require different development environments for the iOS and Android operating systems (OSs); (2) App timing calibration is a challenge because mobile devices lack the hardware ports necessary to connect with traditional calibration systems. Here, we describe (1) Presentation® Mobile, which enables the rapid programming of mobile apps that execute on both iOS and Android devices; and (2) The LabStreamer, a device which enables paradigm timing calibration through wired connections or over wireless networks using the Lab Streaming Layer (LSL) network-timing protocol. METHODS. We measured timing delays of Presentation Mobile calibration tests on iOS and Android tablets and smartphones by comparing the time of stimulus occurrence reported by the mobile OS and the actual time of stimulus occurrence measured from photodiode and microphone inputs. Touch latencies were measured by stimulating touches with an electrode attached to the mobile-device screen. RESULTS: Figure 1 shows median latencies and 95% confidence intervals for different mobile devices (* = smartphone) and a Windows desktop computer. We found a range of OS- and device-specific latency delays for both auditory and visual stimulus delivery and touch-response registration. However, delays showed little temporal jitter (e.g., within-device standard deviations were less than 0.4 ms for auditory stimulus delivery and less than 0.8 ms for visual stimulus delivery). DISCUSSION: Accurate physiological and

behavioral data can be recorded from mobile devices connected over wireless networks if corrections are made for device-specific delays in stimulus delivery and response registration.

Abstract: Increasing computing power and availability of high-performance computing (HPC) resources have made it easier for neuroscientists to simulate and visualize large-scale brain network models. However, one bottleneck for building, simulating, and sharing large-scale networks is the lack of efficient data formats. A widespread practice is to represent models with simulator specific code such as hoc, SLI or python. XML based formats have been proposed as a solution. But the use of XML quickly becomes problematic when scaling up to large realistic networks.

Thus, an open specification is needed that is compact, computationally fast, yet also easy to read and edit. To meet these demands, the Allen Institute (AI) and the Blue Brain Project (BBP) have jointly developed the SONATA (Scalable Open Network Architecture TemplAte) Data Format - an open-source framework for representing neuronal circuits. The framework utilizes both organizations' expertise with large-scale HPC network simulation, visualization and analysis. It was designed for memory and computational efficiency, as well as to work across multiple platforms. We provide the specification documentation, open-source reference APIs, and model and simulation output examples with the intention of catalyzing support and adoption of the format in the modeling community.

In the SONATA format, properties of nodes (cells) and edges (synapses/junctions) of a network are stored in table-based data structures, hdf5 and csv, using indexing procedures for fast and parallelizable lookup. The use of hdf5 provides both efficiency in space and read-time. The format provides naming conventions for node and edge properties, but also allows for extensions to include additional properties.

Besides network representation, SONATA includes representation of simulation output, which is optimized for memory and read/write performance. This permits efficient storage of variables such as spike times, membrane potential, and Ca2+ concentration. Lastly, to bring together network models, simulation output, and various run-time conditions (duration, time step, temperature, etc.), SONATA includes a JSON-based file format for configuring simulations.

The rapid advancement in neuroscientific data generation, large-scale data-driven modeling, and simulation capabilities makes the development of standards for network simulations necessary. The SONATA Data Format and framework (https://github.com/AllenInstitute/sonata) are open to the community to use and build upon with the goal of achieving such a standard data format.

Title: The Neuroscience Gateway: Enabling large scale modeling and data processing in neuroscience

Authors: *N. T. CARNEVALE[1], S. SIVAGNANAM[2], K. YOSHIMOTO[2], A. MAJUMDAR[2]
[1]Neurosci., Yale Univ. Sch. Med., New Haven, CT; [2]San Diego Supercomputer Ctr., Univ. of California San Diego, La Jolla, CA

Abstract: We review the origin and evolution of the Neuroscience Gateway (NSG; http://www.nsgportal.org) as a high performance computing (HPC) resource for neuroscientists. When it first became available to users in 2013, NSG's design goal was to provide neuroscientists free and easy access to simulation software installed on HPC hardware for their increasingly complex models of biological neurons, neural circuits, and systems. More recently we have expanded it to also serve cognitive and experimental neuroscientists facing large scale data analysis problems (e.g. fMRI processing, connectome pipelines). It is also being used for educational purposes in neuroscience courses and workshops. The diverse and growing set of modeling and data analysis tools currently available via NSG includes BluePyOpt (from the European Human Brain Project), Brian, CARLsim, DynaSim, EEGLAB, Freesurfer, Human Neocortical Neurosolver (HNN), Large Scale Neural Modeling Simulator, MATLAB, MOOSE, NEST, NetPyNE, NEURON, Octave, PGENESIS, PyNN, Python, R, TensorFlow, and The Virtual Brain Personalized Multimodal Connectome Pipeline. These can be accessed either through a web portal or programmatically through a RESTful API. NSG allows a wide range of use cases: individual users with NSG accounts can work directly with individual tools, or with packaged pipelines, or configure their own pipelines; users of community projects that take advantage of NSG's RESTful API (e.g. OpenSourceBrain) can employ HPC resources via NSG without having to leave their familiar working environment or even obtain their own NSG accounts; software developers can use NSG for dissemination of their projects, e.g. BluePyOpt, CARLSim, DynaSim, EEGLAB, HNN. NSG is being used by neuroscience researchers, educators, and students at institutions and laboratories around the world, and its user base is currently >600 and still growing. Based on increasing demand and usage, we have successfully obtained progressively larger allocations of HPC resources through the competitive peer review process of the Extreme Science and Engineering Discovery Environment (XSEDE) program.

Developing and operating the NSG has given us a unique opportunity to understand the diverse HPC needs of neuroscientists and explore associated issues and needs for collaboration, data sharing/management and various forms of computing. Supported by NSF 1458495 (NTC) and NSF 1458840 (SS, KY, AM).

Title: Systematic statistical validation of data-driven models in neuroscience

Authors: *S. APPUKUTTAN[1], P. E. GARCIA-RODRIGUEZ[1], L. SHARMA[1], S. SÁRAY[2], S. KÁLI[2], A. P. DAVISON[1]
[1]Unité de neurosciences, information et complexité, Ctr. Nationale De La Recherche Scientifique, Gif-sur-Yvette, France; [2]Inst. of Exptl. Med., Hungarian Acad. of Sci., Budapest, Hungary

Abstract: The expansion of knowledge in neuroscience has resulted in a myriad of models to represent the multi-level complexity of the brain, from the subcellular scale, through multi-compartment neurons, microcircuits to network level models. An essential element of scientific modeling is validation of the model with respect to experimental data. Until recently this has most often been done in an ad hoc way, with most studies reporting only qualitative comparisons between simulation results and experimental findings, and different modeling studies using different datasets for validation, which makes comparison of models difficult.
Inspired by quality control methods from software engineering, SciUnit (Omar, Aldrich & Gerkin, ICSE 2014) is an attempt to remedy these problems by providing a software framework for quantitative validation testing that explicitly supports applying a given validation test to different models. By defining interfaces to which models must adhere, tests can be model agnostic and used to validate any compatible model despite differences in their internal structures, the language used and/or the simulator employed.
Building on the SciUnit framework, we have developed suites of validation tests for biophysically and morphologically detailed neuron models, and for circuit models of different brain regions. HippoUnit, CerebUnit and BasalUnit are validation suites catering to neuron activity models of hippocampus, cerebellum and basal ganglia, while MorphoUnit targets testing of neuronal reconstructions and network structures. Each test is implemented as a class in the

Python language, and comprises a specification of the required model capabilities, the location of the reference dataset, and data analysis code to transform the variables recorded from simulations (such as membrane potential, action potentials) into a format (for example a histogram) that allows the simulation results to be directly compared to the experimental data through a statistical test.
We have further developed a web services framework to support the management of models, tests, and validation results. It is accessible via web apps within the Human Brain Project Collaboratory and through a Python client. The framework enables tracking the evolution of models over time, as well as comparison against other models in the domain.
This work was performed as part of the Human Brain Project (HBP), in collaboration with colleagues modeling the brain regions mentioned above.

Abstract: Neuroscience is engaging at the forefront of science by dissolving disciplinary boundaries and promoting transdisciplinary research. This is a process that, in principle, can facilitate discovery by convergent efforts from theoretical, experimental and cognitive neuroscience, as well as computer science and engineering. To assure the success of this process the current lack of established mechanisms to guarantee reproducibility of scientific results must be overcome. Promoting open software development and data sharing have become paramount in the quest to achieve reproducibility. We present brainlife.io, a platform addressing challenges of neuroscience reproducibility by providing integrative mechanisms for publishing data, and algorithms while embedding them with computing resources to impact multiple scientific communities.We present three main technological results for widespread impact on neuroscience research and discovery. First, we demonstrate that platform can capture brain data, publish algorithms as reproducible applications, and perform data-intensive computing on Clouds. Second, we present novel algorithms for mapping brain networks using Clouds. The algorithms will enhance discovery by leveraging on the online platform for data-intensive processing of large datasets. Third, we publish test-retest brain datasets and derived data (processed), such as connectome matrices, multi-parameters tractography models, cortical segmentation and functional maps. These datasets can be used as a reference or to develop algorithms for functional mapping, anatomical computing, and optimization.The platform presents a unique method and technology for publishing the full set of scientific research assets in a study comprising data and analyses code as well as all provenance information, embedded in a series of reproducible, open cloud platform web-services that allow collaborative tracking of the scientific process. We demonstrate that the core platform functionally including software, data, and analyses to reproduce major published results in neuroscience. To promote a grassroots approach to open neuroscience, brainlife.io allows scientists to publish data and reproducible analyses with seamless access to national supercomputers. In sum, the brainlife.io platform provides access to algorithms, data and computing resources to trainees, and faculty nationally. The entire platform and all technologies developed with it are freely available and open-source to contribute to the wide community of users, and researchers in the neurosciences.

Title: Neuroglia: A Python library for analyzing large scale electrophysiology and calcium imaging with scikit-learn machine learning pipelines

Authors: *J. KIGGINS, M. D. OLIVER, S. MANAVI, C. MOCHIZUKI, N. CAIN, S. R. OLSEN
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Applying modern machine learning techniques to the analysis of neurophysiology data requires the researcher to extract relevant features from the continuous time-varying activity of populations of recorded neurons. For example, to apply supervised classification techniques to population activity for a decoding analysis, the researcher must create a population response vector for each stimulus to decode. Depending on the scientific question and recording modality, this response vector could be the mean calcium signal in a window during each stimulus or the time to first spike after the stimulus onset. We have developed an open source Python package, *neuroglia*, to aid neuroscientists in incorporating these common transformations into machine learning pipelines. In *neuroglia*, these transformations between these core data structures are defined as scikit-learn compatible transformers—Python objects utilizing a standardized fit, transform, and predict methods, allow them to be chained together into scikit-learn pipelines. Here, we illustrate the core design principles of the package and demonstrate how the package facilitates applying modern machine learning to population neurophysiology datasets. We demonstrate its use on both large scale Neuropixels recordings and 2-photon calcium imaging data.

Title: Nih funded NITRC's triad of services: Software, data, compute

Authors: *D. N. KENNEDY[1], N. PREUSS[2], C. HASSELGROVE[3]
[1]Psychiatry, U. Massachusetts Med., Worcester, MA; [2]TCG, Inc., Washington, DC; [3]Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Aim of Investigation: NeuroImaging Tools and Resources Collaboratory (NITRC) is a neuroinformatics knowledge environment for MR, PET/SPECT, CT, EEG/MEG, optical imaging, clinical neuroinformatics, computational neuroscience, and imaging genomics tools and resources.
Methods: Initiated in 2006 through the NIH Blueprint for Neuroscience Research, NITRC's mission is to foster a user-friendly knowledge environment for the neuroinformatics community. By continuing to identify existing software tools and resources valuable to this community, NITRC's goal is to support its researchers dedicated to enhancing, adopting, distributing, and contributing to the evolution of neuroinformatics analysis software, data, and compute resources.
Results: Located on the web at www.nitrc.org, the Resources Registry (NITRC-R) promotes software tools and resources, vocabularies, test data, and databases, thereby extending the impact of previously funded, neuroimaging informatics contributions to a broader community. NITRC-R gives researchers greater and more efficient access to the tools and resources they need, better categorizing and organizing existing tools and resources, facilitating interactions between researchers and developers, and promoting better use through enhanced documentation and tutorials—all while directing the most recent upgrades, forums, and updates. All services freely downloadable, NITRC-R offers 1,000 public resources; NITRC-Image Repository (NITRC-IR) offers 9,924 imaging sessions, and NITRC Computational Environment (NITRC-CE) provides cloud-based computation services downloadable to local machines or via commercial cloud providers such as Amazon Web Services and Microsoft Azure.
Conclusions: In summary, NITRC is now an established knowledge environment for the neuroimaging community where tools and resources are presented in a coherent and synergistic environment. NITRC is a trusted source for the identification of resources in this global community. With over 5,600 citations on Google Scholar, NITRC has supported over 23,900 registered users, served up 10.7 million total, and of that, 9.7 million data downloads, to over 1 million users generating 2.2 million sessions. We encourage the neuroinformatics community to continue providing valuable resources, design and content feedback and to utilize these resources in support of data sharing requirements, software dissemination and cost-effective computational performance.

Title: A volumetric brain data repository for neuroscience research

Authors: *A. J. ROPELEWSKI[1], A. W. WETZEL[1], G. P. HOOD[1], D. SIMMEL[1], K. BENNINGER[1], J. A. CZECH[1], A. M. WATSON[3], S. C. WATKINS[3], M. P. BRUCHEZ[2]
[1]Pittsburgh Supercomputing Ctr., [2]Mol. Biosensors and Imaging Ctr., Carnegie Mellon Univ., Pittsburgh, PA; [3]Ctr. for Biologic Imaging, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Capabilities to image the Brain in terms of both resolution and capture speed of optical microscope have pushed the boundaries of what was once thought possible. High resolution cameras, which easily generate gigabytes of data/second, have been integrated into multiple systems. There is also a growth in very fast resonant scanning confocal (ribbon scanning) and multiphoton microscopy. In each case these platforms generate very large data sets, generally multi-terabytes per specimen. While these acquired data can be immediately housed and processed using local storage systems, individual labs frequently must decide the value of data immediately after collection and its value for reuse and long-term storage.
The Brain Image Library is an NIH funded resource to store volumetric brain data, along with essential information about the experiment. BIL has direct connectivity to Internet2, multiple commodity internet providers and direct peering with other networking providers. This high-bandwidth connectivity makes BIL an ideal distribution site for imaging data compliant with FAIR (Findable, Accessible, Interoperable, and Reusable) standards. BIL provides citable identifiers for the submitted data to facilitate tracking of contributed data used by others in publications. BIL deposits serve as a backup function for high-value data that submitting sites desire to be preserved off-site. BIL also provides high performance computing resources that can be used to process staged data prior to submission and supports access control capabilities, including data embargoes until publication.
A unique feature of BIL is that it can provide assistance in moving multi-terabyte brain datasets to the library and help diagnose and resolve network issues related to file transfer speeds. A help desk (bil-support@psc.edu) is available to data submitters to access this service and provide other assistance to sites submitting data to the library.

Title: Cloud processing and web visualization of petabyte images

Authors: *W. SILVERSMITH, I. TARTAVULL, S. SEUNG
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: When image datasets fit on one machine, it's easy to see your data, compute metrics, and share entire copies. However, once datasets grow to hundreds of gigabytes, it becomes difficult to view them, and it takes powerful hardware to compute on them. Today, multi-terabyte and even petabyte electron microscopy datasets require storage and computation on a large number of machines. Some labs cannot even see their data, which is critical for analysis and quality assurance.

Within the next year, the iARPA MICrONS program plans to acquire a petavoxel image to study nanoscopic details of neural microcircuitry on the order of a cubic millimeter. The eventual ambition of the connectomics field is to analyze entire brains. This upward pressure has resulted in the development of increasingly sophisticated tools for viewing volumetric images (Saalfeld et al. 2009, Boergens et al., 2016, Knowles-Barley et al. 2016).

Recently, Neuroglancer (an unofficial Google product) has become a popular web app to view large volumetric datasets and associated 3D objects due to its responsive interface, simple and manipulable architecture, and hyperlinked interactive views. Neuroglancer provides interfaces to many server based backends (e.g. NDstore, DVID, Render), but it also defines the "Precomputed" format, a serverless chunk-based format suitable for local storage, Google Cloud Storage, and AWS S3. Precomputed obviates the need to deploy and manage potentially bottlenecking servers. However, Neuroglancer does not provide a client that can read or write Precomputed.

We introduce CloudVolume, a Python client that uses an array-like interface to access arbitrarily sized images in the cloud or locally as numpy arrays. It uses a configurable number of processes, doesn't touch disk unnecessarily, and discards downloaded image chunks after painting to keep a low memory profile. We've witnessed 1.8 Gbps read speeds of gzipped 1024x1024x1 8-bit images on a 16 core Google Compute Engine instance.

We also introduce Igneous, a Python/Numpy based task execution system that can generate image hierarchies, meshes, remap segmentations, and contrast correct images. Igneous pulls dependency free JSON specified tasks off Amazon Simple Queue Service, is based on Kubernetes and CloudVolume, and scales to at least 1600 cores. It has generated five levels of eight bit image hierarchies for a 59 teravoxel image in less than an hour.

Neuroglancer, CloudVolume, and Igneous comprise a system for visualizing and accessing petascale biomedical images collaboratively and are available to the community as open source tools. Used in combination, sharing, computing, and seeing your data are easy again.

Title: Anatomical variability of brain structures in the allen mouse brain common coordinate framework

Authors: *M. D. NAEEMI, N. S. GRADDIS, Q. WANG, S. MIHALAS, J. ROYALL, Y. LI, L. NG, J. A. HARRIS
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The Allen 3D Reference Atlas segments the adult mouse brain among 840 anatomical structures drawn natively within a 3D reference space, the Common Coordinate Framework (CCF). Using these segmentations, we analyzed the neuroantomical variation in 2859 male and female C57BL/6J mice. The dataset consisted of 2-photon image stacks registered to the CCF. Our aim was to find the variability in the volumes of each structure across our mouse population, identify the most variable structures, and analyze the contribution of gender and hemisphere asymmetry to that variability. The CCF is a symmetric 3D reference space generated by the registration and averaging of 1,675 brains imaged from male and female C57BL/6J mice at 2.5 months of age. Annotation of this average template was done by assigning each voxel in the reference space to a brain structure using multi-modality datasets registered to the template. To systematically investigate neuroanatomical variation in our mice, we first triangulated the voxel segmentations of brain structures within our CCF space to produce reference meshes describing the surface of each structure. We deformed these meshes to match the structures in individual subjects, and obtained a set of meshes characterizing the specific anatomy of each individual mouse. The deformed meshes could then be used to calculate surface areas and volumes of all structures in the brain of each individual mouse. Due to the range in the scale of structures in the brain, the coefficient of variation was used as a standardized metric for volume variability. To account for surface area effects, we modeled the coefficient of variation as a function of the surface area to volume ratio. This model was used to evaluate a standardized neuroanatomical variability, accounting for the effects of structure shape and size. We used a generalized linear model to evaluate the effects of gender and hemisphere asymmetry on this standardized variability and found no significant differences. We also measured the variability in the deformation of each voxel in each individual mouse brain when registered to the CCF. Our results show the neuroanatomical variability for each structure in CCF space, and compare it to the variability of voxel deformation from the registration process.

Title: Open online platform and functionalized anatomical models for computational modeling and integration of NIH SPARC initiative data and models

Authors: *N. KUSTER[1], E. NEUFELD[2], N. CHAVANNES[2], A. M. CASSARA[2], B. LLOYD[2], P. CRESPO[2], M. GUIDON[2], O. MAIZ[2], W. KAINZ[3]
[1]ETH Zurich & IT'IS Fndn., Zurich, Switzerland; [2]IT'IS Fndn., Zurich, Switzerland; [3]Ctr. for Device and Radiological Hlth., U.S. Food and Drug Admin., Silver Spring, MD

Abstract: Advances in neuro-engineering have opened up new avenues for 'electroceuticals' – devices that affect organ function through neuromodulation. For their rapid development, an improved understanding of neural dynamics, nerve mapping, organ electrophysiology, interaction mechanisms, and the design of safe and effective implantable devices is crucial. Computational life sciences (CLS) and *in silico* tools are the method of choice to study interaction mechanisms, targeting optimization, side-effect minimization, treatment personalization, and closed loop control of such devices. Recently, the NIH SPARC initiative was established, an important research endeavour which aims to "transform the understanding of nerve-organ interactions" and "advance the neuromodulation field towards precise disease treatment". A key component of SPARC is a freely accessible online platform (o^2S^2PARC) to support modeling-related activities. o^2S^2PARC will allow to study the interaction of physical stimuli with the human body and its physiology via multi-physics/-scale simulations.o^2S^2PARC is an open-source framework to create, host, connect, and execute computational models, as well as solvers for anatomical model-centred multi-physics simulations. At the core of o^2S^2PARC are detailed, human and animal models which are functionalized with dynamic nerve models and will serve as integration centres for computational (tissue/organs/⋯) models and measurement data and as context for physical modeling. The modeling/coupling originates from a mechanistic electrophysiology perspective. The platform will support image-based- and meta-modeling and quality assurance (chain of custody, traceability, reproducibility, V&V, certification). Prototypes of the o^2S^2PARC platform (front/back-end, communication, and compute services) were realized. Critical solvers (e.g., for electromagnetic and coupled neuronal dynamics modeling) were developed, verified against reference models, and successfully applied to study a range of

therapeutic applications. Anatomical models were functionalized with peripheral nerves (currently: cranial, sacral, brachial, lumbar plexi) based on high-resolution cryosection images (female & male human, monkey). First organ physiology models from SPARC teams could be executed within containerized services and the use of our CLS platform Sim4Life as a service was explored.The evaluated technologies demonstrate that the ambitious vision of o^2S^2PARC is feasible. The final software will be a crucial contribution towards open and extendable simulation platforms for electroceuticals/ neuroprosthetics research.

Title: Pair-wise interactions in gene expression determine a hierarchical transcription profile of the brain

Authors: *J. HUA, Z. YANG, T. JIANG, S. YU
Inst. of Automation, Chinese Acad. of Sci., Beijing City, China

Abstract: Expression of individual genes are not independent with each other, therefore characteristics of each gene and gene-gene interactions determine the transcription profile of the genome. Similarly, transcription profiles in different areas of the brain are not independent with each other, so transcription characteristics of each area combined with interactions among different areas determine the global transcription profile across the brain. Together, this is a hierarchical organization traversing from the level of individual genes to the entire brain, which governs how the brain is shaped by genes' transcription. In this study, we are aiming at revealing the quantitative nature of this organization. By studying gene transcription profiles across different areas of human brain in six individuals (the Allen Brain Transcription dataset), we found that such a two-level, hierarchical organization is mainly determined by pairwise interactions. Specifically, we found that the first- and second- order statistics of gene expression profile, corresponding to the likelihood of individual genes expressing and pairwise correlation

in the expression patterns between genes, respectively, could accurately predict the collective features of transcription of the whole genome. Meanwhile, the number of genes been expressed in individual areas, and pairwise correlation in the gene expression patterns between areas could be combined to accurately approximate the collective features of the transcription profile across the entire brain. Our results reveal how the pairwise interactions in gene expression determine the hierarchical transcription profile of the brain, providing a framework to better understand the mechanisms by which complex interactions among genes give rise to brain's structural and functional organizations.

Title: Large scale analysis of cell type specific changes in whole tissue expression profiles

Authors: *O. MANCARCI[1], L. TOKER[1], S. TRIPATHY[1], P. PAVLIDIS[2]
[1]Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychiatry, Univ. British Columbia, Vancouver, BC, Canada

Abstract: Analysis of gene expression in whole tissues remain an important tool for the study of neurological disorders. These types of analyses are complicated by the heterogeneity of brain tissues due to difficulties in differentiating cell type specific differences from global changes in gene expression. Recently, we published a method for summarizing expression of cell type markers using principal component analysis (marker gene profiles) and demonstrated that they reflect cell type proportion changes in select datasets. We now expand the scope of our analysis by examining ~400 manually curated, previously published whole tissue datasets to discover cell type specific changes not analyzed by the original studies. The data allows us to compare cell type compositions of mouse and human brains under a wide variety of conditions such as different developmental stages or various neurological diseases. Finally, to ensure the accuracy of our findings, we introduce quality metrics to our marker gene profiles. These quality metrics examine the effect size, the number of correlating cell type markers and how much variance is explained by the first principal component of marker gene expression. In select datasets, we show that quality metrics are useful in differentiating between true (whole tissue studies with

known differences in cell type proportions) and false positives (studies where no cell type proportion differences are expected)

Title: Realistic spatial modeling of vesicle trafficking in neurons

Authors: *A. R. GALLIMORE, I. HEPBURN, S. Y. NAGASAWA, E. DE SCHUTTER
Computat. Neurosci. Unit, Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: The trafficking of vesicles inside neurons plays a number of critical roles: the packaging and release of neurotransmitters on the presynaptic side and the trafficking and sorting of membrane receptors during plasticity on the opposite side of the synapse, for example. Complex subcellular networks coordinate the trafficking of vesicles and their cargo to and from the membrane, and through the cytosol and endosomal system. Despite its central importance in many aspects of neuronal function, and even though computational models of subcellular neuronal processes are becoming increasingly important in neuroscience research, realistic models of vesicular trafficking are almost non-existent. This is largely because the modeling tools for detailed spatial modeling of vesicles are not available. Although spatial modeling has advanced in recent years, with voxel-based molecular simulators such as STEPS incorporating spatial effects - diffusion and probabilistic interactions between molecules within realistic neuronal mesh structures[1] - there has been no explicit account of molecule size or excluded volume effects. Such a simplified approach has the advantage of computational performance and accuracy for small molecules and ions, but these assumptions break down for complex structures of large size such as vesicles and a new modeling approach is required. Extending the STEPS simulator, we have pioneered spherical ‘vesicle’ objects that occupy a unique excluded volume and sweep a path through the tetrahedral mesh as they diffuse through the cytosol. Our vesicles incorporate endocytosis, exocytosis, as well as fusion and budding to and from intracellular membranes, allowing us to model the complete vesicular cycle. In addition, interactions between vesicular proteins and cytosolic and plasma membrane proteins allow us to model vesicular processes, such as membrane docking and endosomal sorting events at an unprecedented level of spatially-realistic and biochemical detail. Our preliminary models using this technology have successfully replicated experimental studies revealing the role of specific Ras-family proteins in the expression of plasticity in the cerebellum[2,3]. In the future, we envisage that this new methodology will open up entirely new avenues of modeling research in all areas of

neuroscience and cell biology in which the regulation of vesicle trafficking and function plays a role. 1. Hepburn, I., Chen, W., Wils, S., De Schutter, E. **2012**, *BMC Syst. Biol.* 6, 36. 2. Title: Brain modeling toolkit (BMTK): An open-source package for multiscale modeling of brain circuits

Authors: *K. B. DAI, Y. N. BILLEH, S. L. GRATIY, M. BUICE, N. CAIN, F. BAFTIZADEH, D. FENG, N. W. GOUWENS, R. IYER, S. MIHALAS, C. KOCH, A. ARKHIPOV
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The field of neural circuit modeling currently utilizes a variety of different levels of resolution, from biophysically-detailed and point-neuron based networks to population-level and more abstract types of models. Each have their own benefits and drawbacks depending on the questions being investigated. And though it's sometime necessary to bridge these network models, the fact that different levels of resolution use different set of tools and formats can make doing so difficult. To this end the Allen Institute has developed the Brain Modeling Toolkit (BMTK), a open-source software framework for building, simulating and analyzing neural circuit models of various levels of resolution.
The BMTK provides a single and unified package for creating and simulating large-scale network for multiple simulators. Modelers can build a network once, or use an existing network, and run it across a range of different simulators without having to write converters or adaptors. The toolkit provides interfaces to the NEURON simulator for biophysically detailed network, NEST simulator for point-neuron network, DiPDE for populational statistical simulation, LGNModel for filter models, and TensorFlow for convolutional neural networks. The BMTK also uses the SONATA data format that has been jointly developed by the Allen Institute and Blue Brain project. SONATA, a open-format for representing circuit files, simulation parameters and simulation output, allows BMTK to work interchangeably with other software. Software that implements the SONATA standard can reuse networks/simulations built on the BMTK and vice-versa, thus providing a powerful platform for reproducibility and collaboration. And finally the BMTK can work on scales from circuits of a few cells up to circuits of millions of scales and

automatically handle parallelization for cluster computing.
The BMTK, using the SONATA data format, provides a way of integrating a diverse collection of tools and software into a single platform. By unifying different levels of resolution not only does it allow individual modelers to expand upon their own work, but also makes it easier for modelers working across levels to share and collaborate.

Title: Exploring nuclear connectivity and function within the primate amygdala using the neural engineering framework

Authors: *K. D. FISCHL[1], T. C. STEWART[2], K. M. GOTHARD[3], A. G. ANDREOU[1]
[1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. of Waterloo, Waterloo, ON, Canada; [3]Univ. Arizona, Col. Med., Tucson, AZ

Abstract: The Neural Engineering Framework (NEF) offers a structure and methodology to explore internal dynamics of ensembles of spiking neurons that perform specific computations. The NEF provides the equations that govern neural dynamics and is simulated using Nengo, a graphical and scripting-based Python simulation environment. In Nengo, neural populations are defined such that the collective activity of each population represents a vectored value to be decoded in later computations by way of connections to other populations within the model. The necessary connection weights to implement the desired functions are determined using least squares optimization. We employ Nengo to create a biologically realistic model of the amygdala i.e., a model that reproduces the stimulus-selectivity and the temporal spiking patterns (phasic or tonic responses to stimuli) of the component neurons. Existing models of the amygdala seldom consider biological plausibility due, in part, to the complexity of neuronal types and connections and also to the almost exclusive focus on associative learning (fear conditioning).
Our first attempt at the primate amygdala model focuses on the three main nuclei: lateral, basal/accessory basal, and central. To enable a direct comparison with neural data recorded from the primate amygdala, the model employs simplified abstractions for the experimental setup and

stimuli used to record the activity of small groups of single neurons. Neural data were classified using temporal features and a clustering algorithm. Neurons were categorized as: (1) responsive to the cue, (2) responsive to stimulus onset, (3) responsive to stimulus offset, and (4) tonically responsive during stimulus presentation. The firing patterns of the simulated and real-life neurons were then compared. Using these metrics, we found that the experimental and simulated data were highly correlated. The prevalence of the response patterns of the simulated neurons matched those of the real data for 98.8%, 81.5%, and 92.6% of the responses, respectively by nucleus. These results were obtained after varying model parameters and model size to observe effects on neural response patterns.
The results obtained with the NEF are encouraging and warrant further exploration of this modeling approach, specifically to develop more detailed models of connectivity and function for the main nuclei of the amygdala and of the amygdala as a whole. The results presented in this work come from simulations of our model with visual stimuli, but future work will include simulation with multi-sensory inputs.

Title: Dynamic worm: Moving model of *Caenorhabditis elegans* worm controlled by the nervous system

Authors: *J. KIM[1], E. SHLIZERMAN[2]
[1]Electrical Engin., [2]Univ. of Washington, Seattle, WA

Abstract: Neural circuits generate body movements using rhythmic signals, however, little is known about characteristics of these signals, and their transformation to behavior. Here, we implement the dynamic worm, an in-silico model for the nematode *Caenorhabditis elegans,* to understand how the nematode's nervous system transforms stimuli to behavior. The model emulates the response of the nervous system to stimuli, translates neural activity to muscle forces and muscle impulses to body movements, and implements feedback to account for environmental entrainment. We validate the dynamic worm in both signal propagation directions; back propagating external force applied to the body, and investigate touch response

behaviors by injection of current into sensory and inter neurons. We are able to generate locomotion behaviors typical to the nematode from external force waves and identify a set of stimuli that generate coherent locomotion. In particular, we show that only precise combinations of both sensory and inter neurons generate coherent movements, such as crawling forward, backward and turns. The characteristics of the movements resemble experimentally identified locomotion patterns. We show that neural dynamics associated with distinct movements can be mapped and classified using low dimensional space, but even more importantly, we show that the transformations between the layers of the model are dynamic and require full simulation for each stimulus. By exploring the effect of the environment on locomotion, we find that specific environmental parameters facilitate typical locomotion behavior, and environmental sensory feedback can entrain, sustain and switch between movements. Taken together, our results show that the nervous system encompasses mechanisms of movement initiation, activated by constant stimulation, and mechanisms of movement sustainment through entrainment by the environment.

Title: N2A: A language and software tool for large-scale modeling

Authors: *F. ROTHGANGER
Sandia Natl. Labs., Albuquerque, NM

Abstract: Sharing models and data is doubtless a prerequisite for progress toward a full understanding of brain function. The Neuroscience Information Framework (NIF) does this for many forms of descriptive data. Interchange languages such as NeuroML/LEMS provide a simulator-agnostic description of models, and repositories such as NeuroML-DB and ModelDB make them searchable and accessible.
However, exchanging models and data is not sufficient. It is also necessary to assemble those shared models into larger functional units, ultimately reaching the level of an entire nervous system. From all these details we hope to form abstract descriptions of function. The modeling system must be capable of crossing many scale levels, and component models should be expressed in a form suitable for automated analysis.
N2A is an effort toward these challenging goals. It treats models as data rather than code. This declarative approach describes a model as a set of attributes and equations, without specifying a step-by-step procedure for simulation. It emphasizes the relationships between values within a model and the relationships between models in a larger functional unit.
The declarative approach allows one model to directly extend and modify another, simply by referencing the parent model and declaring new values for specific attributes and equations. A model may also incorporate other models as components, allowing the assembly of arbitrarily deep systems. We will demonstrate an open-source implementation of N2A.

Title: Neuromorphic synapses with reconfigurable voltage-gated dynamics

Authors: J. WANG[1], A. AKININ[2], G. CAUWENBERGHS[3], *F. D. BROCCARD[3]
[1]Bioengineering, [3]Inst. Neural Computation, [2]UCSD, La Jolla, CA

Abstract: Synapses are fundamental elements for computation and information processing in neural systems. Although biological synapses express a large variety of receptors in the neuron's membrane, the current hardware implementation of neuromorphic synapses often rely on simple models ignoring the heterogeneity of synaptic transmission. Here we describe a biophysical model of a chemical synapse with reconfigurable pre-synaptic and post-synaptic voltage-gated dynamics implemented on a neuromorphic VLSI chip, and evaluate its versatility with measurements from the chip reproducing the response characteristics of five different ionotropic conductances for both excitatory (AMPA, NMDA) and inhibitory ($GABA_A$, $GABA_C$, glycine) receptors. A neuromorphic implementation of an electrical synapse is also presented. Finally, we discuss applications of the reconfigurable dynamic clamp capabilities of the neuromorphic synapses for the creation of biohybrid circuits between biological and silicon neurons.

Title: In-silico anatomical reconstruction of astrocytic microdomains

Authors: *E. ZISIS[1], D. KELLER[2], H. MARKRAM[3]
[1]Blue Brain Project, École polytechnique fédérale de Lausanne, Geneve, Switzerland; [2]Blue Brain Project, Brain Mind Institute, EPFL, Lausanne, Switzerland; [3]EPFL, Blue Brain Project, Lausanne, Switzerland

Abstract: Astrocytes in the brain form anatomically exclusive territories that minimally overlap with neighboring astrocytes. In these domains, each cell establishes connectivity with vasculature and neuronal synapses. In order to investigate the bidirectional dynamics in the neurovascular unit, an accurate anatomical model of such organization is essential. To create the structural geometry of astrocyte domains, we used a weighted tessellation model with volumetric constraints acquired from the literature. Use of a weighted model allowed for non-equidistant boundaries, allowing territories to be affected by the size of the cell.
We distributed astrocytic somata in a rectangular space to match the average cell densities in the rat neocortex as well as the nearest neighbor and radius distributions. Cell positions were co-localized with the reconstruction of the neocortical vasculature and neuronal somata. Next, we

used a Laguerre tessellation model to construct the domains and optimized to match the experimental volume distribution. Extended boundaries were then constructed in order to take into account the required expansion of the domain to account for the overlap with neighbors. Using the geometry of the domains, we extracted the pairwise connections between astrocytes and the vasculature and between astrocytes and neuronal synapses. Finally, the connectivity and the geometrical boundaries set the foundations for in-silico growth of the astrocytic morphologies into their predetermined space using space-filling algorithms.
The presented anatomical reconstruction pipeline forms the basis for future functional models of energy provision to the neuronal microcircuit. Furthermore, the indirect communication of neuronal synapses through the astrocytic syncytium could provide us with insights on the plasticity dynamics in the neuronal-vascular-glial ensemble. Finally, calcium induced intra-cellular and inter-cellular wave simulations require the geometry of domains, the morphologies and the overlap with their neighbors. The workflow generates the anatomical architecture that renders possible all of the above.

Abstract: There is a growing trend within the neuroscience community and the medical and health industries towards bioelectronics medicine: applying electrical modulation to the nervous system to control and modify physiological functions of the body. These so-called “electroceuticals” include numerous types of neurostimulation devices. While computational techniques to quantify electromagnetic exposure, power absorption, and thermal consequences are well established, predictive tools to study nerve electrophysiology within the complex human anatomical environment and estimate the risk of peripheral nerve stimulation (PNS) are lacking.

To this end, we are developing reference human and animal (rat, monkey) anatomical models, with unprecedented details in the peripheral nervous system and connectivity to organs and muscles, functionalized with compartmental nerve models to investigate interactions with neuronal electrophysiology.
Cryosection image data is being used as the basis for the new monkey and human male and female phantoms due to the unique resolution (i.e. 0.1 × 0.1 × 0.2 mm in the human female) and quality of these images. For the rat, high-resolution magnetic resonance images will be acquired.
To segment important peripheral nerves, a nerve tracing tool has been developed, which allows to semi-automatically extract smooth nerve trajectories by specifying sparse (start/end) points along a nerve in the cryosection image stack. Functionalization is achieved by assigning electrophysiological models of myelinated and unmyelinated axons to trajectories within nerve models based on histological investigations documented in the literature.
The computational phantoms will continue evolving, but already over 1000 different tissues and structures have been segmented in the human datasets, including more than 320 muscles. The following major nerves are or will soon be completed: the vagus nerve and other cranial nerves as well as the lumbar, brachial and sacral plexus. To ensure high quality standards, we follow an internal/external review approach similar to that of the Virtual Population models V3.x.
The NEUROMAN models are expected to significantly impact the scientific community and the field of PNS research and will enable multi-scale modeling studies with realistic anatomies and electrophysiology. The obtained neuro-functionalized models will provide experimental test-beds for new therapeutic approaches and devices, and allow studying safety aspects, providing a tool to facilitate regulatory submissions and standardization activities.

Title: Building, simulating, and visualizing reaction-diffusion models with NEURON's enhanced rxd module

Authors: *R. A. MCDOUGAL[1], A. NEWTON[1], M. L. HINES[1], W. W. LYTTON[2,3]
[1]Neurosci., Yale Univ., New Haven, CT; [2]SUNY Downstate, Brooklyn, NY; [3]Kings County Hosp., Brooklyn, NY

Abstract: Intracellular phenomena -- e.g. calcium waves, protein interactions, etc -- play key roles in modulating brain activity through their interactions with electro-chemical signaling between neurons. Quantitative models used as tools for pre- and post-dictive studies of neural functioning have incorporated these phenomenon using the mathematical formalism of reaction-diffusion kinetics. NEURON (neuron.yale.edu) has long provided a Python module -- *rxd* -- for these kinetics that provides a separation between model specification and numerical implementation. We describe recent developments that enhance the usability and performance of this module: just-in-time (JIT) compiled reactions accelerate simulation. A redesigned graphical reaction-diffusion builder allows modifying reaction schemes on the fly, parameter changes, and more numerical simulation options including 3D simulation. Graphical display enhancements allow selecting and visualizing reaction-diffusion states alongside electrophysiological ones. We describe the underlying methods and demonstrate the enhancements with a study of calcium wave entry (or non-entry) into the soma.

Abstract: Transforming experimental data into solid conclusions and theory requires integrating and interpreting disparate datasets at multiple scales. The BRAIN Initiative 2025 report highlights this requires rigorous theory and modeling. The widely used NEURON simulator allows researchers to develop biophysically realistic models of neurons and networks. However, building and running parallel simulations of complex brain networks usually requires years of highly technical training. Here we present NetPyNE (www.netpyne.org), a tool that extends NEURON's capabilities and makes it accessible to the wider scientific community. NetPyNE provides both a programmatic and graphical interface that facilitates the definition, parallel simulation and analysis of data-driven multiscale models. Users can provide specifications at a high level via its standardized declarative language, e.g. a probability of connection, instead of millions of explicit cell-to-cell connections. With a single command, NetPyNE can then generate the NEURON network model and run an efficiently parallelized simulation. The user can then select from a variety of built-in functions to visualize and analyse the results, including connectivity matrices, voltage traces, raster plot, local field potential spectra or information transfer measures. The graphical user interface was developed using state-of-the-art technology (www.geppetto.org) and allows users to more intuitively access all NetPyNE functionalities: specifying model parameters using drop-down lists or autocomplete forms, interactively visualizing the 3D network, running parallel simulations or plotting results. NetPyNE models can be imported/exported to NeuroML specifications, facilitating model sharing and simulator interoperability. As a case-study we present the development of a multiscale model of mouse primary motor cortex (M1) microcircuits. The model simulates a cylindrical volume of cortical tissue with over 10,000 biophysically detailed neurons and 30 million synaptic connections. Neuron densities, classes, morphology and biophysics, and connectivity at the long-range, local and dendritic scale were derived from published experimental data. NetPyNE enabled the integration of these complex experimental datasets and in silico exploration of the microcircuit neural dynamics, information flow and underlying biophysical mechanisms.

Title: Assessing goodness-of-fit of neural population models using marked point process time-rescaling

Authors: *K. ARAI[1], L. TAO[2], K. WEBER[2], U. EDEN[2]
[2]Mathematics & Statistics, [1]Boston Univ., Boston, MA

Abstract: The assessment of the goodness-of-fit to the observed data is a critical step of any statistical modeling procedure. For neural spike train models of individual neurons, many goodness-of-fit measures rely on the time-rescaling theorem to assess the statistical properties of rescaled spike times. Recent interest in building a single model for the population spiking activity has also necessitated a goodness-of-fit measure for the population model. Classically, such models have used spike sorted data to describe relationships between the identified neurons, but more recently single clusterless models have been used to describe the spiking activity of a population of neurons. Here we develop a generalization of the time-rescaling theorem that enables a comprehensive goodness-of-fit analysis for both traditional spike sorted and clusterless population models. We model the population spiking using the theory of marked point processes, and show that under the correct model, each spike can be rescaled individually to generate a uniformly distributed set of events in time and the space of spike marks. After rescaling, the assessment problem for complicated population spiking models can be simplified to the assessment of various properties of the rescaled spikes using multiple well-established statistical tests. We demonstrate applications of our assessment methods to models of sorted spikes and clusterless models of population spiking with and without history, of the same simulated spiking data. Further we illustrate our methods to real neural population spiking data from CA3 of a rat performing alternating spatial navigation task. All code is available via github.

Title: Improving the convergence of multiobjective optimization for morphologically realistic neuron models

Authors: *A. ABOUZEID[1], W. L. KATH[2]
[2]Applied Mathematics, [1]Northwestern Univ., Evanston, IL

Abstract: Evolutionary multiobjective optimization (EMO) techniques are receiving increasing interest in neuroscience, as technical advances are providing more detailed morphological and electrophysiological data that can be used to constrain large-scale neuron models. Although computing power has simultaneously grown, the problem of fitting large numbers of parameters to satisfy multiple simultaneous constraints has remained challenging. Here we present a method for improving the speed and convergence of the widely-used NSGA-II algorithm [Deb et al. 2002], and we illustrate the approach by fitting the parameters of a model CA1 pyramidal cell with full dendritic morphology.

EMO strategies are designed to maximally explore the Pareto-optimal front of solutions, which represents inherent trade-offs among the objectives being optimized. NSGA-II as originally developed by Deb et al. (2002) attempts to balance these trade-offs by computing a crowding distance among solutions in error space, preferentially emphasizing those from more sparse regions. This creates selection pressure that guides the solution set into regions where at least one of the objectives has large error values. Although such solutions satisfy the criterion for Pareto-optimality, they may not be the most useful in applications where small error values across all the objectives would be preferred. Moreover, we show that this biasing effect toward the extreme-valued fringes of the Pareto front occurs at the expense of solutions near the origin of the error space, where error values are small across all objectives.

By performing a projection of the error vectors prior to the crowding distance calculation, the "outward" pressure of the NSGA-II crowding distance operator can be counteracted while preserving its role in promoting solution diversity. Specifically, we perform stereographic projection of errors onto the n-dimensional unit sphere before calculating the crowding distance. This rescales the error space such that distances between points near the origin remain essentially unchanged, while distances between points with large error values become compressed, thus biasing the evolution "inward" toward the origin in error space.

Using a model CA1 pyramidal cell with full dendritic morphology as a case study, we show that the modified NSGA-II algorithm converges more rapidly than the standard algorithm as measured by the L1 norm on the original error space. Furthermore, solutions produced with the projection method "dominate," in the Pareto sense, those found using the unmodified algorithm, suggesting that the standard algorithm may become trapped by local minima of the objective function.

Title: A point-process approach for dendritic morphology generation

Authors: *Z. Z. CHOU, G. J. YU, T. W. BERGER
Dept. of Biomed. Engin., USC, Los Angeles, CA

Abstract: Biologically realistic dendritic morphologies are critical to developing meaningful simulations of neuronal activity. In particular, the length of dendritic branch segments and the overall arborization of the dendritic tree largely determine how a neuron integrates input signals. Here, we present a non-parametric approach that uses a point-process filter and Expectation-Maximization (EM) to estimate the branching rate of a rat dentate granule cell dendrites as it changes according to distance from the soma. We use the estimated branch rate to randomly generate morphologies that match several aspects of the branching behavior of real cells.
We model dendritic branching as a simple discretized Poisson generalized linear model with an exponential conditional intensity function. We use a point-process filter and smoother, combined with the EM algorithm to simultaneously solve for an estimate of the branching rate and the model parameters. These algorithms were run on a set of 42 histological reconstructions of rat dentate gyrus granule cell morphologies to provide an estimate for the branching rate. 50 randomly generated morphologies were created using by spike thinning a Poisson point-process at the maximum branch rate. The distributions of key metrics for branching behavior were quantified for both the real and the generated morphologies, namely the branch pathlength, total dendritic length, a Scholl analysis, and the total number of bifurcations.
The generated morphologies closely matched the distributions of all measured parameters, but there was a mild overestimation of shorter pathlengths and underestimation of early branching. The model is able to capture many of the important characteristics of granule cell dendritic branching dynamics, and shows significant advantages over stochastic generation algorithms. We can use these more biologically accurate morphologies in our existing large-scale model of the dentate gyrus to achieve more meaningful simulations. In future work, additional elements can be added to the state-space model to account for the history of branching events along neighboring processes.

Title: An evolutionary multi-objective optimization approach for constraining biophysical properties for neuron models in a large-scale neuronal network model of the hippocampus

Authors: *P. K. GUNALAN, G. J. YU, T. W. BERGER
Biomed. Engin., USC, Los Angeles, CA

Abstract: One of the major applications for the large-scale neuronal network model of hippocampus we are developing is to investigate biological and functional differences between healthy and diseased states and to explore electrical and pharmacological treatment therapies. Pathology-driven physiological changes may be modeled by changes in the biophysical properties, such as the distribution of ion channel conductances of neurons, which must therefore be constrained to simulate healthy and diseased networks. As direct measurements of all ion channel conductances that comprise a neuron are difficult to obtain, electrophysiological responses of neurons due to stimulation can be used to constrain parameters as certain stimulation paradigms reveal specific electrophysiological responses that can largely be mediated by certain subsets of ion channels. Here we provide a method for constraining the biophysical properties of granule cells using a multi-objective genetic optimization algorithm to increase the speed of optimizing such models.

A three-dimensional multi-compartmental model of a granule cell with representations of dendrites, soma, axon initial segment, and axon was implemented in the NEURON simulation environment using the Python interpreter [Hines and Carnevale 2001; Santhakumar 2004]. The conductances of sodium and multiple types of potassium and calcium ion channels were optimized. To decrease the number of parameters that are necessary to optimize for a model, we assumed that each ion channel conductance decreases linearly as a function of distance from the soma, so the total number of parameters optimized per granule cell was twenty-two. Defined objectives include the amplitude and duration of threshold, input resistance, resting membrane potential, spike frequency adaptation, and slow, medium and fast afterhyperpolarizations. An Evolutionary Multi-Objective Optimization (EMOO) algorithm was used to minimize error between the computational model's stimulation response values and experimental values found in literature and to determine parameter values [Bahl 2012]. Parallelization decreased the duration of runs.

We demonstrate the EMOO algorithm can be used to constrain model parameters to satisfy all the electrophysiological objectives. This general approach can be used to generate models for additional hippocampal cell types and additional objectives can also be added in future work.

Title: A generalized linear model to capture the nonlinear dynamics of neural ensembles within a large-scale neuronal network model of hippocampus

Authors: *G. J. YU[1], D. SONG[2], J.-M. C. BOUTEILLER[2], T. W. BERGER[2]
[2]Biomed. Engin., [1]USC, Los Angeles, CA

Abstract: We are developing a three-dimensional, large-scale neuronal network model of the hippocampus with multi-compartmental representations of each neuron and the goal of representing every neuron and synapse in a single hemisphere of the rat hippocampus. The current version of the large-scale model includes the entorhinal cortex, dentate gyrus, and CA3 and a majority of their cell types and offers a unique platform through which the propagation and transformation of spatio-temporal patterns can be investigated. As such, new techniques are necessary to describe and characterize the nonlinear transformations performed by these neural regions. Furthermore, given the scale, methods need to be developed to characterize a neural system at a physical scale beyond the neuronal level and towards a network/circuit level.
The generalized linear model (GLM) framework, in combination with Laguerre basis functions, has been used to capture the nonlinear input-output transformations performed by single neurons. The kernels that can be constructed from the GLM model capture the dynamics that result from direct and indirect synaptic activations that are caused by an input.
Using a GLM, an input-output model was created for neural ensembles that were organized into neural modules based on anatomy. In this work, the dentate gyrus was discretized into square spatial bins based on the septo-temporal and transverse axes with a size of 0.5 mm. The spatial bins were referred to as neural modules. The input and output signals were defined as the total number of spikes elicited by a cell population and discretized into 10 ms bins. An input to the neural module consisted of the sum of all unique presynaptic events received by the neurons within the neural module and was divided between the neurons of the medial and lateral entorhinal cortex. The output of the GLM consisted of the sum of all spike times elicited by the principal neurons of the subfield, i.e., dentate granule cells, within the neural module. A Poisson GLM with a log-link function was selected, and 4^{th} order Laguerre basis functions and 2^{nd} order self-kernels were used for the feedforward and feedback kernels. Cross validation was performed

using an 80:20 split with 32000 training samples and 8000 validation samples. The out-of-sample prediction achieved an NRMSE of 0.48.
The GLM of neural modules offers a method by which the nonlinear spatio-temporal transformation properties of neural ensembles can be quantified. Given that the GLM sufficiently predicts the output of the model, it could then be used as a generative model for simulating long periods of time after being initially trained using the large-scale neuronal network model.

Title: Multi-scale modeling of complex nonlinear synaptic dynamics using sparse laguerre-volterra network

Authors: E. HU, *J.-M. C. BOUTEILLER, G. YU, D. SONG, V. Z. MARMARELIS, T. W. BERGER
Biomed. Engin., USC, Los Angeles, CA

Abstract: Synapses constitute key specialized structures through which interneuronal communication takes place. They are also critical specialized structures in which long term potentiation, the cellular substrate of learning and memory occurs. This critical role is done through a large number of biochemical processes that result in complex nonlinear dynamics. Yet, computational models of large-scale neuronal systems often rely on highly simplified linear representations of synaptic dynamics. This is partly because the nonlinear complexity of synaptic dynamics leads to a prohibitively heavy computational load in network models comprised of a large number of neurons.
Here we present a solution for the multi-scale modeling of a glutamatergic CA3 to CA1 hippocampal synapse through the use of nonlinear dynamic system modeling. More specifically, we develop an “input-output” (IO) model using the Volterra functional series that is trained using the mechanistic (kinetic) models of the ionotropic receptors AMPAr and NMDAr.
We compare the input-output model to the original mechanistic models and demonstrate that the IO model replicates the nonlinear dynamics with a high degree of accuracy. Then, we further improve the computational efficiency of the IO model by adopting a Laguerre-Volterra Network (LVN) structure, and demonstrate improved performance in both runtime and memory usage in

large scale simulations. Finally, we measure the network activity obtained from large scale network simulations comprised of either linear (exponential) or nonlinear (IO model) synapse models subjected to the same patterns of stimulation; We compare the network spiking activities - outlining the effects of nonlinear synaptic connections on network-level response.
The methodology presented constitutes an efficient solution for bridging subcellular to network scales, enabling relevant information to be passed across levels while maintaining low computational load. Incorporation of such pertinent subcellular nonlinear dynamics will undoubtedly improve the validity of large-scale simulations. The methodology is general and may be adapted to other types of subcellular (physiological and pathological) processes, furthering our understanding of the large number of interdependent processes that take place in the brain, and how they shape brain function and dysfunctions.

Title: A computational study of the effects of muscarinic m1-mediated cholinergic modulation on ca1 pyramidal cell excitability

Authors: *A. MERGENTHAL, J.-M. C. BOUTEILLER, T. W. BERGER
Biomed. Engin., USC, Los Angeles, CA

Abstract: Projections from the basal forebrain provide extensive cholinergic modulation to the hippocampus. This modulation has been established to play an important role in attention, learning, and synaptic plasticity, while its disruption has been linked to various neural disorders (e.g. Alzheimer's Disease). The primary cell type of the CA1 region of the hippocampus, the pyramidal neuron, expresses M1 muscarinic receptors throughout their morphology. We have developed a computational model of these receptors and their downstream modulatory effects of ionic channels in the soma of the pyramidal cell. We verify that this computational model replicates CA1 pyramidal cell behavior observed after in vitro acetylcholine exposure. We then demonstrate how the increased excitability measured during acetylcholine exposure alters the way the cell model integrates synaptic inputs. Through these developments, we propose to use this simulation framework to investigate how cholinergic modulation alters cell function in

normal function, and in pathological situations (e.g. following a decrease in cholinergic modulation as reported in AD, or as a result of exposure to organophosphates), and identify potential ways to re-establish normal function. The model presented will also serve as essential building block for a large scale model network of the CA1 region to extend our investigations to network-level observables.

Title: Three-dimensional reconstructions of dorsal root ganglia morphometry and cell distribution

Authors: *Z. J. SPERRY[1,2], N. PECK-DIMIT[1,2], R. D. GRAHAM[1,2], S. F. LEMPKA[1,2], T. M. BRUNS[1,2]

Abstract: We created realistic quantitative computer models of dorsal root ganglia (DRG) anatomy using cross-sections taken from felines and non-human primates. DRG contain the cell bodies for primary sensory neurons in spinal nerve roots and hold significant potential as sites for neural interfacing. Existing commercial therapies deliver electrical stimulation near the DRG or spinal roots to provide targeted pain relief or improved bladder control. On-going animal research suggests that electrical recordings from DRG could be used as sensory feedback for neuroprosthetic devices. Devices for spinal cord injury patients, for instance, could utilize sensory feedback from limb proprioceptors or bladder mechanoreceptors below the level of their injury, accessed with electrodes in or on relevant DRG. Design of these therapies will benefit from a detailed and quantitative understanding of DRG anatomy. We have previously presented quantitative descriptions of cell body distribution in feline lumbosacral DRG at a single medial location. Here we extend this study to include multiple sections per DRG as well as non-human primate DRG as an alternative translational animal model. Following intracardiac perfusion with paraformaldehyde, lumbar and sacral spinal roots of either feline or rhesus macaque subjects

were exposed via spinal laminectomy, removed, and fixed in 10% formalin. The roots were bisected in the transverse plane and embedded in paraffin. Roots were sectioned at closely spaced intervals (4-50 µm) and the sections stained for neurofilament-heavy polypeptide and counterstained with hematoxylin. This stain allows for high contrast imaging of the pseudounipolar neurons of the DRG, both cell bodies and axons. A custom MATLAB GUI was developed to allow for semi-automated segmentation and alignment of the sections, as well as identification and quantification of cell component properties. By interpolating the profiles of the spinal root components in a CAD program, we reconstructed the 3D geometry of each DRG and ventral root within the overall spinal root. By combining these models with realistic tissue electrical properties, it may be possible to predict and improve experiment outcomes. We also quantified the distribution and location of different cell component sizes across the length of the DRG, utilizing a polar transformation to normalize for different spinal root profiles across samples. By combining these spatial soma/axon density maps across sides and levels, we produced a map showing the organization of cells within the DRG that could be useful for future device development.

Title: Bayesian inference of spontaneous neuronal assemblies

Authors: *G. DIANA[1], T. SAINSBURY[2], M. MEYER[1]
[2]Ctr. for Developmental Neurobio., [1]King's Col. London, London, United Kingdom

Abstract: Brain function emerges from the coordinated activation of neuronal populations. Descriptions of population dynamics will provide important insights into how brain computations are distributed across neural networks. The proliferation of experimental techniques for recording the activity of neuronal populations calls for a comprehensive statistical method to describe, analyze and characterize these high dimensional datasets. Here we develop a new Bayesian inference method based on a stochastic model of pattern activity to describe spontaneously active neural ensembles throughout the tectum of larval zebrafish. Unlike heuristic methodologies employed to detect neural assemblies, our framework provides rigorous statistical estimates of composition and dynamics of these neural populations. Furthermore, we

have derived a message-passing algorithm to boost computational performance, which extend the applicability of our method to the analysis of long recordings of thousands of neurons. Within our model we can show how data sufficiency is constrained by the balance between noise and neuronal activity, providing robust estimates of the recording time required to capture the ensemble structure of large neural populations. Our method allows to make statistical inference on the spatio-temporal organization of neuronal ensembles their composition and the logic of their interactions.

Abstract: The *Caenorhabditis elegans* embryo is a useful model for studying tissue morphogenesis and complex developmental events due to its small number of cells and experimental accessibility. Development is well characterized in pre-twitching embryos, but halfway through embryogenesis morphological changes and muscular motion combine to make data analysis difficult. To remedy this problem, we developed software that computationally untwists embryo images, allowing for detailed analysis of developmental time series in a common reference frame. We are applying our software to generate a developmental map of cell position in the *C. elegans* embryo, with an eventual goal of covering the position of all 558 embryonic nuclei from the beginning of twitching until hatching. Currently, the atlas covers 65 nuclei including 20 seam cells, 20 E lineage intestinal cells, and 11 neurons with each modeled position derived from cell positions in three individual embryos. We are also interested in mapping out major neuronal tracts and the outgrowth of neurites in the post-twitching regime, with the atlas currently incorporating neurite outgrowth from the ALA neuron. Finally, we

implement a re-twisting capability which allows the positions of cells from our model to be matched to the configuration of a specific embryo volume, potentially allowing for identification of unknown cells in embryo images. These tools should allow the generation of a computational map showing the position of all nuclei as well as neurite position and outgrowth in the *C. elegans* embryo from the beginning of twitching until hatching.

Abstract: Circuit-mapping experiments combining whole-cell electrophysiology with two-photon optical stimulation of potentially presynaptic neurons have produced rich data on cell type-specific monosynaptic connectivity of neural circuits. However, mapping large volumes of densely-packed neurons (e.g. cortical excitatory neurons) at cellular resolution with two-photon optogenetics has proven challenging because of two main problems: 1) stimulation sensitivity and resolution varies across cells due to differential opsin expression and intrinsic excitability, making the precise localization of connected neurons difficult, and 2) experimental time is severely limited compared to the number of potential connections to map. We present a method which overcomes these limitations using statistical modeling, online experimental design, and the combination of a fast, high-potency soma-targeted opsin (st-ChroME) with computer generated multi-target holography. To infer posterior distributions for connectivity parameters (e.g. probability of synaptic transmission or short-term dynamics) and per cell parameters for the

excitability of the local population (e.g. opsin expression level, spatial opsin distribution), we fit a generative model with three main components: a neural response model which predicts presynaptic spike rates given the power and location of stimulation targets, a connectivity model which filters presynaptic spike rates into a postsynaptic event rate, and a postsynaptic model which converts the postsynaptic event rate into a voltage-clamp observation. To improve mapping efficiency, we implement a closed-loop parallel computational system which designs batches of stimulation targets online based on fast stochastic variational inference of these posteriors. Specifically, stimulation design for each neuron automatically switches between coarser (multi-target) and finer (single-target) protocols depending on the posteriors. This approach allocates high-resolution single-target stimuli only at locations of evoked connections and ambiguous responses. Furthermore, our experimental system allows us to collect data at 20 trials per second for a large portion of experimental time while analyzing data in the background. We demonstrate the efficacy of our method by mapping excitation onto both excitatory and inhibitory cells in layer II/III of cortex in acute mouse brain slices.

Abstract: The combined single-cell resolution and brain-wide coverage of light-sheet microscopy calcium imaging has provided a spatiotemporally unmatched view into vertebrate and invertebrate brain activity. However, data generated using these imaging tools have thus far been little analyzed or modeled integratively at the level of the whole brain (Figure 1). Here, we developed population models of neuronal network dynamics that allowed us to characterize the activity of all cells in the brain or nervous system of vertebrate (larval zebrafish) and invertebrate (larval *Drosophila*) organisms. Our models describe individual cell activity in terms of correlations of each cell to its largest system (group of co-activated cells), and in terms of

average correlations of cells between system hierarchies (Figure 2). Numerical solutions for these constraints provide accurate and ultra-compact (order of magnitude smaller than current state of the art) representations of whole-brain single-cell resolution activity. We demonstrated the utility of these representations, by showing that the coarse system correlation structure distinguishes between global underpinnings of behavioral states, links these global changes to differences in activity of individual cells and predicts the effects of interrogating these systems with ablation and stimulation experiments. Our approach provides a bridge between big functional imaging data sets and empirically grounded mechanistic formulations of whole-brain activity.

Title: EXTRACT: Automated cell sorting for large-scale neural calcium imaging based on the framework of robust statistics

Authors: *H. INAN[1], C. SCHMUCKERMAIR[1], B. AHANONU[2], M. A. ERDOGDU[3], M. J. SCHNITZER[4]
[2]Dept. of Biol., [1]Stanford Univ., Stanford, CA; [3]Univ. of Toronto, Toronto, ON, Canada; [4]Depts. Biol. & Applied Physics, Stanford Univ. Dept. of Biol., Stanford, CA

Abstract: Fluorescence calcium imaging is a widely used methodology for tracking the simultaneous activity patterns of large numbers of neurons in awake behaving animals. High-fidelity computational extraction of individual neurons and their activity time traces from the raw calcium video datasets is important for attaining reproducible, high-quality biological results. However, most calcium imaging datasets acquired in behaving animals contain substantial sources of non-stationary noise and signal contamination, such as from brain motion, neuropil activation, or clustered patterns of neural activation. Although previous research has considered the effects of such contamination under limited circumstances, there has not been a general framework treating its effects on the statistical estimation of calcium signals. Here we propose a new cell sorting approach based on the statistical framework of robust estimation. Using approaches from the theory of statistical estimation, we find a statistically optimal objective function for estimating neurons' spatial locations and the time-dependent activity traces. This objective function leads to substantial improvements in estimation accuracy, even in cases with large-amplitude signal contamination caused by noise sources, including neuropil activation and spatiotemporal overlap with other background activity. The resulting algorithm for automated cell sorting, which we call EXTRACT, enables rapid estimation of cells' images and fluorescence dynamics. By implementing EXTRACT on graphical processing units (GPUs), we further decrease the required runtimes for cell extraction. Using simulated and real datasets, we showcase several advantages of our robust estimation approach as compared to other commonly used algorithms for cell sorting. EXTRACT also enables fast and accurate analyses of large-scale neural calcium imaging datasets acquired in freely behaving mice. To share EXTRACT with other labs in the neuroscience community, we have created a github repository enabling researchers to apply our software to datasets generated using a wide variety of calcium imaging techniques.

Title: An array tomography exploration tool: Exploring synapses from FMR1 knockout mice

Authors: *A. K. SIMHAL[1], K. D. MICHEVA[2], Y. ZUO[3], R. J. WEINBERG[4], S. J. SMITH[5], G. SAPIRO[1]
[1]Electrical Engin., Duke Univ., Durham, NC; [2]Molec Cell. Physiol, Stanford Univ. Sch. Med., Stanford, CA; [3]UC Santa Cruz, Santa Cruz, CA; [4]Cell Biol. & Physiol., Univ. North Carolina, Chapel Hill, NC; [5]Synapse Biol., Allen Inst. for Brain Sci., Seattle, WA

Abstract: Array tomography is a powerful imaging tool that can address a variety of important but hitherto-intractable biological questions. Array tomographic study of the brain can generate high-dimensional data sets containing markers for different cell types (neurons, glia), neuronal compartments (dendrites, axons) and subcellular structures (synapses, mitochondria, myelin), but the power of this tool presents unique challenges for understanding and quantifying the produced data. The output of array tomography is three-dimensional multi-channel immunofluorescence (IF) images, where the number of channels range from four to thirty or more. Manually identifying brain substructures and their relationships with each other by visually inspecting thirty channels is a daunting task. Recent work in this area focusing on computational synapse detection represents one step toward a general approach to comprehensive analysis of the complex and diverse elements of neuropil.
We developed a framework comprising a suite of computer vision methods designed to facilitate the exploration of array tomography data, the Array Tomography Exploration Tool (ATET). The goal of this framework is to use computer vision methods to segment and quantify various properties such as size and shape of subcellular structures, and the relationship between them. For example, the tool, detects traditional synapses with specific subtype accuracy, as well as "tripartite" synapses—defined by the presence of an astrocytic process in close apposition to the synapse. By extracting morphology from the AT data, ATET can identify which axon a synapse

originates from, and which dendrite it terminates upon, whether a synapse contains mitochondria, or an axon is ensheathed in myelin.
To illustrate the value of this tool, we imaged the somatosensory cortex from FMR1 (a gene associated with Fragile X Syndrome) knockout mice and from wild-type mice. Each was processed using standard array tomography techniques and imaged with a variety of synaptic and nonsynaptic neuropil markers. We used this data to validate the tool by comparing the output to the results of previous studies, as well as to discover previously unreported features of this Fragile X Syndrome mouse model.
Developing the ATET to explore the relationship between brain substructures will allow for holistic analysis of array tomography at scale. The tool is developed in Python and will be open sourced upon publication.

Title: Improved deconvolution and image processing for oblique light sheet tomography

Authors: *J. MIZRACHI[1,5], A. NARASIMHAN[2], K. UMADEVI VENKATARAJU[3], P. OSTEN[4]
[1]Neurosci., Cold Spring Harbor Lab., Great Neck, NY; [2]Neurosci., [3]Osten Lab., [4]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [5]Biomed. Engin., Stony Brook Univ., Stony Brook, NY

Abstract: Oblique Light Sheet Tomography (OLST) is a light-sheet fluorescence microscopy (LSFM) method designed for volumetric imaging of larger specimens at a high-spatial resolution, high imaging speed and dynamic range with low photobleaching and noise. OLST utilizes XYZ translation stages and vibratome tissue sectioning to achieve high speed and consistently high resolution throughout large specimen volumes. The current OLST setup produces whole mouse brain imaging at 0.4 micron XY resolution and 2.5 micron Z-spacing between oblique planes in approximately 14 hours. The Z-resolution is restricted by the thickness of the light sheet, but Gaussian blur also occurs in the X-Y plane. This blur results from the

optical transfer function (OTF), and causes fluorescently labelled point-sourced objects to appear larger than they are. The OTF's blur is from several inevitable factors, including Abbe's diffraction limit, the collection objective's NA, and camera properties. To reduce this blur, deconvolution is implemented before image volume reconstruction. Signal to noise is improved as deconvolution reduces the effects of stray fluorescence (from source autofluorescence, camera artifact, and photon scattering) in the illumination plane. We modeled a custom 3D Gaussian point spread function (PSF) specifically suited to counter the PSF of detected blur. This was calculated from experimental beam parameters, 5 microns at the center and 20 microns near the edges. The modeled PSF is used for pixel-wise deconvolution. This addition results in significant noise reduction and narrower pixel PSFs. In this manner, the new software employs Lucy-Richardson Deconvolution to decrease background, improve resolution, and create sharper halo-reduced images. In addition to image processing, it was also necessary to develop and implement an image transformation model to produce the coronal section series. A shear transform is used to permute and shear the oblique image stacks. Custom software for OLST image stitching, better suited than previous techniques, was also developed. These additions and their optimizations, including reconstruction, deconvolution, shearing, permuting, and stitching, reduce processing time and produce superior image quality.

Abstract: The transmission of information between neurons occurs at specialized contact zones called synapses. Synapses are complex structures comprised of a dense network of several hundred different protein types, which can exhibit functionally important variation between distinct synapses and within single synapses over time. Fluorescence imaging is the principal means of measuring protein localization within intact developing neuronal circuits, but is limited by the spectral overlap of fluorophores in conventional microscopy to assaying three to four protein targets within a given sample. To facilitate high-content confocal imaging of neurons without the limitation imposed by this spectral limit, we turned to modified antibodies and developed an imaging platform (PRISM: **Pr**obe-based **I**maging for **S**equential **M**ultiplexing) that sequentially utilizes high affinity Locked Nucleic Acid (LNA) probes to enable highly multiplexed and high throughput confocal imaging compatible with 384-well plate imaging formats. Using this approach, we can stain for over a dozen protein targets to create detailed profiles of cellular and synaptic features, characterizing individual synapses and different neuronal subtypes. Here, we apply this method to examine synaptic protein expression in rat neuronal cultures before and after chemical induction of long-term potentiation (cLTP), classifying subclasses of neuronal synapses and examining changes in synaptic protein expression and localization. To accomplish this, we apply a neural network approach for synapse identification, using supervised learning trained on user annotated synapses and applying these results to improve synapse segmentation and feature extraction. Further, with recent developments in human stem cell derived neural cultures that can recapitulate neurodevelopmental conditions *in* vitro, we have also developed a panel of markers that characterize neural stem cell differentiation in 3D cultures *in vitro,* highlighting PRISM's promise as a high content assay platform for drug discovery and developmental studies.

Title: Robust identification and removal of false transients in calcium fluorescence imaging data

Authors: *J. L. GAUTHIER, A. S. CHARLES, J. W. PILLOW, D. W. TANK
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Two-photon calcium imaging has become an important source of insight into neural circuit function, and advances in large scale imaging have created the need for high throughput analysis methods. These consist largely of algorithms designed to isolate the activity of individual neurons within a large field of densely-stained tissue. However, automated inference methods can be susceptible to misattribution of fluorescence activity. For example, if two neurons overlap, but only one is known to the algorithm, or even if a part of one cell's spatial extent is not fully included in the model, activity from the "missed" cell can contaminate the found cell. Such cross-talk has the potential to affect scientific conclusions about population activity. To address these cases of misattribution, we have developed a generative model that explicitly describes the interfering activity. In our framework, missed cells are modeled as the sum of small Gaussian-shaped kernels, allowing the activity of found cells to be estimated through likelihood maximization. This effectively prevents the contamination of found cells by accounting for the spatial structure of missed cells. In its basic form, our method may be run independently on a frame-by-frame basis, allowing for efficient parallel computation. To further improve the estimation quality, we also expand our model to incorporate the expectation of temporal continuity, a key feature for helping to discriminate cellular activity from photon shot noise. The augmented model includes temporal consistency information via sparsity-aware dynamical filtering techniques from the signal processing literature. These techniques modify the base probabilistic model to include a dynamics function describing how activity changes over time, and incorporate this dynamic information into the likelihood estimation procedure, resulting in augmented LASSO and weighted LASSO procedures. In addition to this refined methodology for estimation procedures, we describe how Bayesian optimization techniques can

be used for efficient parameter fitting under the new probabilistic model. Together, these improvements enhance the ability to discriminate different sources of variability in calcium-imaging movies, providing a more veridical estimate of neural activity.

Title: A comparison of the avisoft (5.2) and ultravox (2.0) recording systems: Implications for early life communication and vocalization research in mouse models

Authors: *M. BINDER, C. HERNANDEZ-ZEGADA, C. POTTER, J. LUGO
Psychology & Neurosci., Baylor Univ., Waco, TX

Abstract: Alterations in early life communicative behaviors are a common feature of neurodevelopmental conditions such as autism and epilepsy. One way communication can be investigated in murine models is through analyzing ultrasonic vocalizations. These vocalizations are commonly recorded with either the Avisoft (5.2) or the Ultravox (2.0) recording programs. However, since no study has compared whether the systems are equally sensitive, the findings in one program may not be reproducible in the other. To directly compare the two programs, we elicited vocalizations from male and female 129SvEvTac and C57BL/6 mouse pups via the maternal isolation paradigm, recording vocalizations simultaneously with both systems. We held the detection parameters identical for each system and found that the Avisoft (5.2) program detected more calls emitted at 50, 60, and 70 kHz, than the Ultravox (2.0) program, $p < .05$. No statistically significant difference was present at 80 kHz. These findings demonstrate that different recording systems do not detect the same quantity of vocalizations as one another, even when detection parameters are congruent. Therefore, it may be useful to revisit previous negative results obtained with Ultravox (2.0) and repeat the experiments using the Avisoft (5.2) system. Ultimately, ultrasonic vocalizations are a valuable tool capable of examining early life phenotypes, however, a more thorough understanding of the relationships between recording systems is necessary in order to achieve a more comprehensive, reproducible, assessment of vocalizing behaviors.

Abstract: The design of microelectrodes for electrical stimulation or recording of neuronal activity increasingly focuses on biocompatibility. Still, implantation of a cortical probe evokes a sustained sterile inflammatory response (SIR) within brain tissue. This manifests in activation of microglia, astrocytic scarring, neurodegeneration, and other molecular and morphological changes that may ultimately lead to failure of the device.
To visualize the extent of the spatially limited tissue response, immunohistochemistry (IHC) is the well-established method of choice. But while qualitative assessment of resulting microscopic images can be easily accomplished, quantitative analysis poses a larger challenge to the investigator. This is partly due to the large number of images required to adequately represent the SIR, but also accounted for by high variability within and across tissue sections and animals. To this point there have been several publications that employed custom-built codes for quantification of IHC signals at the implantation sites of cortical electrodes. However, these differ greatly with respect to their evaluation methods and are not provided for open access. Hence, it is difficult to compare the extent of the SIR across different or even identical electrode types utilized by different groups. We therefore aimed at creating a semi-automated quantification method that allows fast and flexible delineation of the signal-intensity distribution from the site of lesion towards healthy brain tissue, based on the widely used software tools ImageJ and MATLAB.
In this study cortical implantation of lithographically fabricated, flexible polyimide probes (10µm thickness with iridium oxide electrodes) was performed on adult Sprague Dawley rats.

After different survival times transversal tissue sections were immunohistochemically stained and imaged with an epifluorescence microscope. Subsequent signal quantification was performed in concentric distance bins with flexibly adaptable size (the shape of the latter is determined by the respective cavity shape of the individual image). Processing artifacts can optionally be selected and excluded from the analysis. Apart from that normalization parameters can be modified towards the needs of the study design. This also yields the possibility of using differently processed and/or imaged tissue sections within one experimental population.
Our approach provides a novel, straightforward tool for quantification of IHC-images that is versatile and adaptable for various purposes.

Title: Blackfynn: Rapid multimodal data integration for the neurosciences

Authors: L. A. GUERCIO, M. HOLLENBECK, *J. B. WAGENAAR
Blackfynn Inc., Philadelphia, PA

Abstract: Neurological and mental disorders pose a significant public health concern, representing the leading cause of death and disability in the world today. Moreover, the burden of neurological disorders has increased substantially over the past 25 years. The significant human costs notwithstanding, these conditions also impose overwhelming costs on the global economic system. The current annual costs of neurological and mental health disorders are approximately $2.5 trillion USD, with a projected increase to over $6 trillion USD by 2030. In response to these rapidly expanding costs, there have been significant increases in public and private funding to support research into nervous system disorders. These global initiatives, such as the US BRAIN Initiative or the EU Human Brain Project, have led to expansive and diverse datasets generated through broad, multi-disciplinary research approaches. This underscores the need for sophisticated methods and tools for multi-modal data integration and analysis to enable scientists and clinicians to explore and analyze scientific and clinical data in context.
We have developed a HIPAA-compliant, cloud-based data management, visualization, and analytics platform for the Neurosciences to help accelerate research, foster collaborative efforts,

and ultimately improve clinical care for patients suffering from neurological disorders. The platform enables researchers to explore relationships that are typically difficult to extract from complex, multi-modal datasets. This removes friction in the scientific process, allowing individual investigators and teams to maximally leverage their data and capture their full value. The ability to integrate and analyze a wide variety of data modalities — including genomics data, time series data, imaging data, and behavioral data — in a single platform will significantly improve the ability of the research community to gain insight in the mechanisms of neurological and mental diseases, identify relevant biomarkers, and predict responses to therapy.
The platform is used by a growing number of investigators as part of the NIH Stimulating Peripheral Activity to Relieve Conditions (SPARC) program, the National Institute on Drug Abuse (NIH NIDA) and others. Here, we demonstrate the capabilities of the platform to rapidly provide novel insight into scientific data as well as novel methods to integrate complex meta-data using a graph-based approach to data management, and analysis.

Neuroimaging Technol., Seoul, Korea, Republic of; [4]Ctr. for Systems and Translation Brain Sciences, Inst. of Human Complexity and Syst. Science, Yonsei Univ., Seoul, Korea, Republic of; [5]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Preclinical neuroimaging study for animal plays an important role in that it links non-invasive imaging with invasive experiments that cannot be performed on human. As a brain network mining has recently come to the fore in recent science of the human brain, network analysis in the animal is also gaining a spotlight in both clinical and basic science research. It holds great promise for expanding our understanding of the animal brain in relation to principles of brain network organization and its organizational properties associated with pathology. This method of artificial network perturbation in animal brain, which is inapplicable to human, would allow testing and verification of alterations in connectivity through invasive experiments. Despite the importance of brain network analysis in the animal neuroimaging, we still lack simple and automatic pipelines to analyze brain networks using multimodal imaging data. Such pipelines will allow structural-functional integration and data mining. In order to utilize big graph networks, automated pipelines should include the followings: preprocessing steps of raw neuroimaging data, feature extraction and data mining using statistical evaluation or machine learning methods. For this purpose, we have developed a MATLAB-based multimodal network analysis toolbox for animal network analysis, aMNET. aMNET provides both optimal preprocessing modules of resting state functional MRI (rs-fMRI) and diffusion tensor images (DTI) for functional network and structural network, respectively, construction of various types of structural and functional connectivity matrixes with user configurable parameters, extraction of graph theoretical features of each network and structure-function relationships. The tool also includes statistical analysis for group level study and data mining using machine learning techniques such as deep neural network or support vector machine. With the help of its interactive and informative visualization techniques and the integration of invasive approaches and non-invasive imaging, we expect to translate animal experiment results to humans.

Title: Frequency-based separation of fast-scan cyclic voltammetry analytes

Authors: K. N. BAUSTERT[1], *E. RAMSSON[2]
[1]Dept. of Chem., [2]Biomed. Sci., Grand Valley State Univ., Allendale, MI

Abstract: With the flourishing use of Fast Scan Cyclic Voltammetry (FSCV) as an analytical technique, the potential for interfering analytes increases. Principle Component Regression (PCR) is a common method used to isolate multiple signals from a complex matrix, however, it

requires the a priori generation of a training set of all species of interest. Even with careful planning, though, it can be difficult to account for all interferents or generate a sufficient training set. While standard training sets can be utilized, this is currently debated within the field. Currently, frequency-based separation is not utilized in FSCV and provides separation of analytes such as dopamine, pH, serotonin, and background drift. This method does not require a training set and can thus prove useful in certain situations.

Title: Analyzing EEG data in EEGLAB: One useful approach

Authors: *R. MARTINEZ-CANCINO, S. MAKEIG, A. DELORME
Swartz Ctr. for Computat. Neurosciences, La Jolla, CA

Abstract: EEGLAB (sccn.ucsd/eeglab) is an open source signal processing environment for electrophysiological signals running on Matlab (Mathworks, Inc.). Despite the extensive documentation and current widespread use of EEGLAB, implementing reasoned preprocessing of EEG data remains challenging for many users because of the richness and variety of algorithms, plug-in toolboxes and data-specific approaches EEGLAB makes available. There are more than one ways to analyze EEG data; here, from our perspective as EEGLAB developers, we present a reasonable approach to assessing event-related dynamics of source-resolved multichannel EEG data using EEGLAB functions. For this demonstration, we use EEG data made available by Wakeman & Henson (https://openfmri.org/dataset/ds000117/) and apply ICA decomposition (Makeig et al., 1996) to study the dynamics of the effective brain sources following face image presentations and ensuing subject button presses. Preprocessing steps include data import, channel location specification, frequency domain filtering, and 'bad' data removal. We demonstrate decomposition of the preprocessed EEG data into brain and non-brain effective sources. Several visualizations of data measures at the single-subject and group analysis levels are shown. An attempt to interpret the results and conciliate them with previous findings using the same data is done from the effective brain sources perspective.

Title: Achieving reproducible data workflows: Lightweight tools for safe and efficient data management

Authors: C. GARBERS[1], M. SONNTAG[1], A. KOUTSOU[1], C. J. KELLNER[1], J. GREWE[2], *T. WACHTLER[1]
[1]G-Node, Dept. of Biol. II, Ludwig-Maximilians-Universität München, Planegg, Germany; [2]Eberhardt-Karls-Universität Tübingen, Tübingen, Germany

Abstract: Maintaining reproducible data workflows while keeping data in sync, backed up, and easily accessible from within and outside the lab is a key challenge in research. To minimize time and effort scientists have to spend on these tasks, we provide a suite of tools designed for comprehensive, reproducible and versioned management of scientific data.
Reproducibility and data re-usability require the presence of metadata also providing information about experimental conditions. The odML[1] metadata format is a simple and convenient format to flexibly collect and organize any kind of metadata. It enables comprehensive collection and automated processing of metadata[2], including conversion to other formats such as RDF to utilize semantic web technologies.
To keep data and metadata organized, the NIX[3] data format enables to effectively link data and corresponding analysis results as well as the associated metadata. It supports a wide range of data types, including electrophysiology and imaging data. NIX uses the odML metadata format and is integrated with the Neo[4] Python package for electrophysiology, enabling Neo users to store their data in a common open format.
The GIN[5] services provide versioned data management and collaborative data sharing. Using established versioning technology[6,7], GIN keeps track of changes and provides secure access, making it convenient to work from multiple workplaces while keeping all data available and in sync. Data can be managed from web and file browsers or a command line client, enabling integration into data acquisition or analysis procedures. The service works with any kind of directory structure and file types, keeping previous versions accessible when datasets are updated. It makes it straightforward to share data within a lab or with off-site collaborators and to work on it together.
The tools presented are easy to use, can be combined with other approaches supporting

reproducibility and data sharing[8,9,10], and enable efficient data management that supports the FAIR principles[11]. Combining them for data annotation, organization, and storage allows streamlining data workflows and efficiently sharing well-annotated datasets within the lab, among collaborators, or with the larger scientific community.

Title: ICLabel: An automated electroencephalographic independent component classifier, dataset, and website

Authors: *L. PION-TONACHINI, K. KREUTZ-DELGADO[1], S. MAKEIG[2]
[1]Electrical and Computer Engin., [2]Inst. for Neural Computation, UCSD, La Jolla, CA

Abstract: Human brain dynamics are now a focus of intense academic research and public interest. Consequently, there is growing interest in electroencephalography (EEG) as a non-invasive, highly time-resolved, and relatively cheap platform for imaging normal and abnormal brain dynamics.While blind source separation (BSS) methods, particularly independent component analysis (ICA), provide demixing estimates of the numerous source-signals summed in each EEG channel signal, they introduce two difficulties into EEG analysis: (1) vulnerability

to large-amplitude, non-stereotyped artifacts and (2) the unknown natures of the retrieved components. The former issue is largely resolvable through readily available signal processing methods; the latter requires expert skill and visual analysis. We present a tool for this problem through the public release of ICLabel, an automated EEG independent component (IC) classifier, as a plug-in for the EEGLAB analysis environment (sccn.ucsd.edu/eeglab) running on MATLAB.The ICLabel project comprises a MATLAB plug-in, an IC dataset, and a tutorial website. The dataset consists of multiple measures (IC scalp topographies, power spectral densities, equivalent dipole models, etc.) for roughly 250,000 ICs decomposed from about 16,000 EEG recordings. The ICLabel dataset also includes nearly 30,000 crowd-sourced labels for over 8,000 ICs contributed by over 240 volunteers through the ICLabel website (labeling.ucsd.edu/tutorial), which remains available for IC classification tutoring and further label contributions. The ICs and accompanying labels have been used to generate multiple candidate IC classifiers using semi-supervised generative adversarial networks. We analyze their efficacy and compare them to other available EEG IC classifiers.

Title: Sexrat male: A smartphone and tablet application to record sexual behavior in male rodents

Authors: *A. TAPIA DE JESUS
Univ. Iberoamericana, Ciudad de Mexico, Mexico

Abstract: In behavioral neuroscience studies, it is essential to accurately and easily record rodent sexual behavior either live or in a video. However, current systems are complex or require a computer that hinders their use in situ. The aim of this work is to validate SEXRAT MALE, new software for the recording and quantitative analysis of the sexual behavior of male rodents. It works on smartphones and tablets, both in the Google™, Android™ and in the Apple™ iOS™ operating systems. This software uses a simple algorithm based on chronometry and frequency counting of the behavioral states or events that the user taps on the screen. Its main advantage is that it can record and time a complex sequence of behavioral states by a human observer. SEXRAT MALE can record sexual behaviors such as genital exploration, mounting, intrusion, ejaculation, and also a behavioral event established by the user (i. e. grooming, rearings, etc.). The user can record events by pressing (or tapping) the corresponding keys. SEXRAT MALE is designed primarily for focal sampling with continuous or live recording (continuous recording

for a predetermined time). The value added of SEXRAT MALE is its ability to analyze events, since it could report the times, order, duration at which every event happened, and also the intervals between them, as statistics of all events in the session. This allows the observer to save multiple data from one or several recording sessions. SEXRAT MALE generates two data files in comma-separated values (CSV) format easily importable from any statistical analysis software such as R™, SPSS™, Graphpad™, or spreadsheets such as Excel™, OpenOffice™, Numbers™. To validate SEXRAT MALE, we observed video recordings of the sexual interaction of Wistar rats. Expert and naive observers participated in these recordings, and in turn registered the sexual behavior in the traditional way or with SEXRAT MALE. The groups were counterbalanced between the registration sessions to avoid bias. SEXRAT MALE showed greater precision among both expert and naive observers, decreasing the number of errors and the accurateness of timing data. Additionally, it processes and displays more information than the traditional recording such as order, time of occurrence, and duration of all behavioral events, intervals between them, statistics of all events in the recording session. It is of particular interest that the user can record an event that can be established by a wildcard button; this particular feature expands the options and personalization of the recording session.

Title: Video tracking module for the real-time experimental control with graphical user interface (rec-gui) framework

Authors: *B. KIM[1], H. LEE[2], H. X. CHAM[3], A. ROSENBERG[1]
[1]Neurosci., [2]Dept. of Mechanical Engin., Univ. of Wisconsin - Madison, Madison, WI;
[3]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The Real-Time Experimental Control with Graphical User Interface (REC-GUI) framework uses a modular design and network-based parallel processing to implement highly flexible and easily extendable neuroscience research (Kim et al., Society for Neuroscience 2017). Here we present a video tracking module for the REC-GUI framework that can track multiple

targets simultaneously. Video tracking systems are widely used to quantify behavioral measurements of head orientation, gait, spatial navigation, social interactions, etc. Specialized commercial systems with high frame capture rates are available on the market, but may be cost prohibitive or overpowered for certain needs. The REC-GUI video tracking module paired with a USB webcam or other lower-end camera provides a low-cost, practical alternative to such systems for experiments where lower capture rates (~ 60Hz) will suffice. The tracking algorithm consists of three simple stages that are applied to each frame in real-time, utilizing color information to isolate and track multiple targets simultaneously. First, the Red, Green, and Blue (RGB) components of every pixel in the frame are extracted. Second, the RGB triplet of every pixel in the frame is compared to pre-acquired distribution(s) of RGB values defining the tracking target(s). Pixels that match a target within a user-defined tolerance are isolated as part of the target. Third, the center of mass of isolated pixels within each frame is defined as the tracking result. In this way, multiple targets with different colors can be tracked in real-time. The module is coded in Python using the OpenCV library. Because Python is a cross-platform language, the module will run on different operating systems as well as small, single board computing environments like Raspberry Pi. The module includes a simple and intuitive user interface, and fully integrates with the REC-GUI framework using internet protocols to provide a simple and affordable video tracking system for neuroscience applications.

UC San Francisco, San Francisco, CA; [7]Neurosurg., UCSF, San Francisco, CA; [8]Univ. California, Helen Wills Neurosci Inst., Helen Wills Neurosci. Inst., Berkeley, CA; [9]HHMI / Janelia Farm Res. Campus, Ashburn, VA; [10]Biol. Systems and Engin., LBNL/UCB, Berkeley, CA

Abstract: Neurodata Without Borders: Neurophysiology (NWB:N) is an emerging unified data standard for neurophysiology data, focused primarily on the dynamics of groups of neurons measured under a large range of experimental conditions. Here we describe recent advances in the NWB:N data standardization ecosystem with a particular focus on data organization, advanced data input/output (I/O), schema extension, and community building. We have enhanced the NWB:N specification language and extension APIs via support for compound data types, enabling storage of complex data types, e.g., tables. In addition, object/region references provide advanced mechanisms for explicit cross-referencing of data. Together, these methods have enabled significant improvements in the organization of complex metadata in NWB:N, e.g., for describing electrodes and ROIs. To support advanced data I/O needs, we have extended the PyNWB Python API for NWB:N to support optimization of the layout of data arrays on disk via chunking and compression, enabling significantly reduced I/O and storage cost. PyNWB also enables the use and creation of external links, facilitating modular storage and enhanced organization of large data collections across files. Finally, we have extended PyNWB via novel, customizable interfaces for iterative data write with broad applications to data streaming, on-the-fly data generation, and progressive, out-of-core conversion of large data arrays. As part of our community engagement efforts, more than 65 users from more than 20 different laboratories have participated this year in NWB:N development and user training hackathon events organized by Lawrence Berkeley National Laboratory (LBNL), the Allen Institute for Brain Science, and Kitware. Here we demonstrate the application of our system to diverse neurophysiology use cases by the Frank Lab (USCF), Chang Lab (UCSF), Bouchard Lab (LBNL) and the Allen Institute for Brain Science among others. The NWB:N software ecosystem empowers users to easily access, use, and analyze NWB:N data, integrate NWB:N with user code bases, and develop new extensions for NWB:N. This work builds the critical foundation towards advanced methods for data management, provenance, query/discovery, and advanced, high-performance visualization and analysis.

Title: A method for the precise detection and validation of spindle timing in rodents

Authors: *B. HARPER[1], J.-M. FELLOUS[1,2,3]
[1]Dept. of Psychology, [2]Biomed. Engin., [3]Program in Applied Mathematics, Univ. of Arizona, Tucson, AZ

Abstract: The automatic and temporally precise detection of cortical sleep spindles is critical to basic research on memory consolidation in humans and rodents. Existing studies of algorithm performance have not included systematic parameter variations or validated detection accuracy in rodent data. We propose a method to systematically tune and validate algorithm parameters in automatic spindle detection algorithms using a small number of human raters. Tuning was based on a 2.5-hour recording from an adult male Brown Norway rat. Six human raters with basic training in spindle scoring extracted spindles from this recording, and a ground truth was constructed at 10-millisecond resolution using agreement between any three raters. The bandpass filter, extraction threshold, smoothing window, and rejection criterion of a Hilbert transform-based algorithm were varied in a parameter sweep for comparison to ground truth. This procedure identified a parameter set yielding 84% recall and 80% precision, falling within the range of human agreement with the ground truth. Both human and algorithm failures with respect to ground truth tended to arise from disagreement in spindle temporal boundaries rather than in spindle occurrence. We explore options for post-extraction artifact rejection. With no additional tuning, the algorithm performed similarly in recordings from different days or rats. We discuss measures of recording quality associated with detection performance. The tuned Hilbert transform algorithm in our study performed better than most algorithms in prior reports using human data. Overall, these results suggest that a systematic approach to algorithm parameter tuning can enhance detection reliability in studies relying on precise spindle timing in rats.

Title: InterLex: A community lexicon for crowd sourcing common data elements and terminologies in support of fair data

Authors: *J. S. GRETHE, T. H. GILLESPIE, T. M. SINCOMB, J. GO, M. E. MARTONE
Ctr. for Res. in Biol. Systems, Univ. of California San Diego, La Jolla, CA

Abstract: InterLex (interlex.org) is a dynamic lexicon, initially built on the foundation of NeuroLex, of biomedical terms and common data elements designed to help improve the way that biomedical scientists communicate about their data, so that information systems like the Neuroscience Information Framework (neuinfo.org), the Center for Reproducible Neuroimaging Computation (repronim.org), and the Open Data Commons for Spinal Cord Injury (odc-sci.org) can find data more easily and provide more powerful means of integrating data across distributed resources. One of the big roadblocks to data integration and making data FAIR - Findable, Accessible, Interoperable and Reusable - is the inconsistent use of terminology and data elements. InterLex allows for the association of data fields and data values to common data elements and terminologies enabling the crowdsourcing of data-terminology mappings within and across communities. A primary goal of InterLex is to provide a stable layer on top of the many other existing terminologies, lexicons, ontologies (i.e. provide a way to federate ontologies for data applications), and common data element collections and to provide a set of inter-lexical and inter-data-lexical mappings. As part of the ReproNim project, InterLex has been expanded to include the full NIMH Data Archive (NDA) CDE library. Through available RESTful web-services, InterLex is supporting alignment of data elements and terminology through PyNIDM which is meant to simplify creation, editing, and querying of NIDM documents. Within the ODC-SCI, InterLex is integrated into the portal platform allowing users to align their data elements to CDEs thereby improving the interoperability and reusability of the data in support of FAIR.

Abstract: The study of several temporal processes such as temperature, humidity and atmospheric pressure changes in meteorology, rhythmic fluctuations in physiological processes, and nonlinear vibrations in physics, generate time series that are non-linear in general, making difficult the detection of a trend or relationship between points. However, using such time series it is possible to define a map as fractal figure, where groups of points with a similar behavior can be observed. We developed a tool (pyTral) that generates a fractal figure based on time series. User can select just a subset of points on the fractal figure and then recovery the corresponding points of the original time series. In addition, this tool generates a Poincare plot of the time series, which is used as visual tests of chaos within time series. PyTral was developed on Python programming language with a graphical user interface programming in pyqtgraph, which allow portability of the tool.

Title: A framework for pipeline optimization and deployment for large neuroscience datasets

Authors: E. C. JOHNSON[1], M. WILT[1], R. NORMAN-TENAZAS[1], L. RODRIGUEZ[1], J. DOWNS[1], E. REILLY[1], M. HUGHES[1], J. MATELSKY[1], N. DRENKOW[1], C. RIVERA[1], B. WESTER[1], E. L. DYER[2], K. P. KORDING[3], *W. R. GRAY RONCAL[1]
[1]Applied Physics Lab., Johns Hopkins Univ., Laurel, MD; [2]Georgia Inst. of Technol., Atlanta, GA; [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: There is much excitement in the neuroscience community about new large-scale datasets and high-throughput imaging modalities. At nanoscale resolution, single synapse connectivity maps may radically improve our understanding of neuronal microcircuitry. Coarser resolution datasets provide complimentary approaches and aim to reveal whole-brain connectomes. Insights from these data, and fusion between them, promise to elucidate the

function of healthy brains and reveal the neural basis of disease.
Computational pipelines for working with these datasets are limited in scale, scope, and accessibility. For many pipelines developed to process neuroscience data, the approach does not scale to terabyte-sized datasets. Many tools are developed for specific datasets, and the results do not generalize to new datasets without extensive development. Finally, research groups often lack the computational expertise to deploy these pipelines for their datasets. We need reproducible tools to simplify and streamline the discovery process.
Our framework abstracts many of the computer science challenges that are commonly associated with testing neuroscience hypotheses on modern datasets. The framework consists of: 1) canonical tools and pipelines for processing data and benchmarking performance, 2) workflow execution engines for deployment on datasets of varying sizes, and 3) optimization routines to facilitate the application of pipelines to new datasets. We have incorporated ideas and code from open source solutions such as Common Workflow Language, the Galaxy Project, and Apache Airflow. We have developed a robust, reproducible framework for science, specifically for large neuroimaging datasets (e.g., Electron Microscopy, X-ray Microtomography, optical microscopy). We apply this framework to extract connectivity graphs from Electron Microscopy data and cellular densities from 3D volumes of X-ray Microtomography data. We demonstrate how this framework can be easily configured, how a pipeline can be optimized on a small training dataset, and how the resulting pipeline can be deployed at the scale of hundreds of gigabytes or terabytes. To improve the optimization process, we also present results on parameter optimization and reusing methods for new datasets. Overall, this framework aims to provide accessible, reproducible computational neuroscience for a wide range of problems, with an initial focus on large, neuroanatomical datasets.

Title: Make electrophysiology great again (MEGA)

Authors: *K. NASIOTIS[1], M. COUSINEAU[2], F. TADEL[3], A. PEYRACHE[1], C. PACK[1], S. BAILLET[1]
[1]Montreal Neurolog. Hosp., [2]Montreal Neurolog. Inst., Montreal, QC, Canada; [3]INSERM, Grenoble, France

Abstract: The methods for electrophysiology in neuroscience have evolved tremendously over the recent years, with a growing emphasis on dense-array signal recordings, often at multiple sites simultaneously.Our goal was to implement a software that is oriented for basic electrophysiology, with a user-friendly graphical interface that allows a user experience that interacts as little as possible with “what is under the hood” unless it is explicitly needed. We introduce a free, open-source software application for integrated and advanced data analytics and visualization in basic e-phys. This tool responds to an unmet need of the large neuroscience community relying on diverse recording techniques, ranging from in vitro slices to free-behaving models. The core notion is that researchers (even without any programming skills) shall rely on a tool in which they can import a raw version of their experimental data and then perform all data analytics (spike sorting, spike analysis, LFP analysis etc.) in a traceable (logged) and reproducible manner.

Title: Introducing "RAVE" (R Analysis and Visualization of intracranial Electroencephalography), a free, open source software package

Authors: *J. F. MAGNOTTI[1], P. J. KARAS[1], Z. WANG[2], M. LI[2], M. S. BEAUCHAMP[1]
[1]Baylor Col. of Med., Houston, TX; [2]Rice Univ., Houston, TX

Abstract: A fast-growing technique in human neuroscience is intracranial electroencephalography (iEEG), the only technique that allows for direct recording of the activity of small population of neurons in the human brain. iEEG includes a range of invasive recording techniques (from subdural strips and grids to penetrating electrodes) that share the common attribute of recording neural activity from the human brain with high spatial and

temporal resolution. While this ability has resulted in many advances in understanding fundamental mechanisms of brain function in health and disease, it generates staggering amounts of data as a single patient can be implanted with hundreds of electrodes, each sampled thousands of times a second for hours or even days. The difficulty of exploring these vast datasets is the rate-limiting step in using them to improve human health. We are overcoming this obstacle by developing an easy-to-use, powerful platform designed from the ground up for the unique properties of iEEG, named RAVE: R Analysis and Visualization of intracranial Electroencephalography. The design philosophy of RAVE is driven by three imperatives. The first is to keep users "close to the data" so that users may make discoveries about the brain without being misled by artifacts. The second imperative is rigorous statistical methodology, with a focus on transparency and reproducibility of analyses. The final imperative is "play well with others", allowing easy integration of new or pre-existing code written in languages other than R (e.g., python, Matlab). We describe the data pre-processing and analysis pipeline we have developed and emphasize how our platform enables both confirmatory and exploratory data analysis. The modular design of RAVE allows for seamless incorporation of new and existing analysis tools, providing non-technical users with GUI-based access to state of the art tools. Users comfortable writing their own software can easily plug-in to the RAVE environment to access the optimized computational routines and data management facilities. By distributing software as a RAVE module, developers gain access to a broader audience for their tools, facilitating dissemination of best practices. Abstract: As light induced cation influx through channelrhodopsin-2 (ChR2) is able to generate action potentials (APs) at genetically manipulated neurons, ChR2 has become a very important tool in neuroscience study, particularly in the functional study of neuronal circuits both in vivo and in vitro. However, the question how much extent the optogetical stimulation can be equivalent to electrical stimulation in regulating neuronal encoding has never been thoroughly addressed. We studied the synaptic responses under various electrical stimulations and optogenetic stimulations at the Calyx of Held synapses and the Parabrachial neucleus - central amygdala (PB-CeAL) synapses. It was found that electrical presynaptic neural fiber stimulation induced postsynaptic excitatory currents (EPSCs) were significantly smaller than the EPSCs induced by optical stimulation upon the presynaptic nerve terminal. Moreover, we found same intensity of optical stimulation induced different ChR2 channel currents at different extracellular Ca^{2+} concentration. The results suggest that light-evoked action potentials at nerve terminal induce additional calcium influx which may cause the significant change in synaptic transmission and short term plasticity. Our study reveals that direct optical stimulation upon the optogenetically manipulated nerve terminal causes non-physiological change in synaptic transmission and thus calls for further evaluating the scope of application and limitation of optogenetic approach in the study of synaptic transmission as well as neuronal signaling

Title: Adapting the ‘Patch-seq’ protocol to scaled morphological, electrophysiological, and transcriptomic data generation: Keys to maximizing triple modality data

Authors: *B. R. LEE, K. HADLEY, A. BUDZILLO, T. JARSKY, T. BRAUN, D. HILL, L. KIM, R. MANN, L. NG, A. OLDRE, R. RAJANBABU, R. DALLEY, N. GOUWENS, T. KIM, O. PENN, K. SMITH, S. SORENSEN, B. TASIC, J. TING, Z. YAO, C. FARRELL, J. BERG, G. MURPHY, H. ZENG
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The Patch-seq approach (Cadwell et al. and Fuzik et al., Nature Biotechnology 2016) is a powerful variation of the standard patch clamp technique that allows us to characterize the electrophysiological, morphological, and transcriptomic diversity of individual mouse and human neurons. To bridge existing large scale, publicly accessible datasets of morpho-electric (ME) and transcriptional (T) cell types in the Allen Cell Types Database, we have adapted this

protocol to generate high quality 'MET' data from cortical and subcortical neurons. Through this development process, we have identified key factors that together maximize the chance of generating high quality triple modality data. First, we utilize an adaptive extraction technique, varying extraction and retraction pressures and retraction speed to the individual cell to bias toward nucleated patches, as we have determined that to be the ideal post-patch outcome for obtaining high quality transcriptomic data while maintaining morphological integrity. Second, we built custom modules in an automated electrophysiology acquisition software package that allow us to quickly and efficiently acquire the electrophysiological measurements needed to characterize cell types. These modules include online analysis to abort acquisition when QC criteria are not met, as well as stimuli that automatically adjust to a neuron's intrinsic properties. To accurately track the multiple experimental variables we test, we created the JSON Electrophysiology Metadata (JEM) HTML form for efficient and standardized metadata reporting. Although these adaptations were made for large-scale data generation, the techniques and tools described here can be used in any number of settings to improve data quality and throughput.

Title: Do neurons in the vicinity of chronic neural implants experience mitochondrial dysfunction?

Authors: *V. VOZIYANOV, A. SRIDHARAN, J. MUTHUSWAMY
Bioengineering, Arizona State Univ., Tempe, AZ

Abstract: The goal of this study is to assess any disruption in mitochondria function in the neurons surrounding a brain implant. Mitochondrial activity is an important determinant of neuronal viability and function. Brain tissue in the immediate vicinity of chronic neural implants undergo micromotion induced cyclical mechanical stresses that can potentially induce mitochondrial dysfunction. In these exploratory experiments, we assessed the metabolic activity

of the mitochondria both *in vivo* and *in vitro* using MitoTracker™ Red CMXRos. In the *in vitro* experiments, neuronal cells were cultured on either a hard PDMS (poly-dimethyl siloxane) surface with a hardness similar to that of an electrode implant (elastic modulus of 1-3 MPa) or a novel soft PDMS coating that is designed to match the viscoleastic properties of the brain tissue (elastic modulus of 5-10 kPa). These cell cultures were then cyclically stretched for several hours with a maximum strain rate of 3%. At the end of the stretching, the cells were stained with MitoTracker™ Red CMXRos to assess mitochondrial function. In the *in vivo* experiments, several male Sprague-Dawley rats were implanted with tungsten wires, some of which were coated with the novel soft PDMS coating. After two and four weeks, the animals were sacrificed and the brains sliced for staining with MitoTracker™ Red CMXRos to assess mitochondrial activity. The data gathered from the experiments showed that *in vitro*, the cells on the hard substrate showed an elevation in mitochondrial activity that was proportional to the level of cyclical strain rate whereas cells on the soft PDMS surfaces showed similar levels of mitochondrial activity across all levels of deformation. Assessment of data from our in vivo experiments are still in progress. Preliminary data therefore suggest that the function of the mitochondria is disrupted around neural implants as a potential precursor to neuronal migration or necrosis or other forms of neuronal remodeling around such implants. The data also suggests that the soft PDMS coating could be helpful in mitigating any mitochondrial dysfunction around chronic neural interfaces.

Title: Electrophysiological properties of SF1 neurons in ventromedial hypothalamus

Authors: *J. SHAO, Y. LIU[1,2], S. CHEN[1,2], D. GAO[1], L. ZHANG[1,3], X. ZHOU[1,2], Q. XIAO[1,2], N. HU[4], X. ZHANG[4], J. TU[1], F. YANG[1]

Abstract: Ventromedial Hypothalamus (VMH) plays important roles in the regulation of feeding, energy homeostasis, emotional state and social behaviors. The major neuron type in dorsal medial/central VMH (dm/c VMH) is steroidogenic factor 1 (SF1) expressing neurons, these neurons are involved in the control of glucose metabolism, bone metabolism and defensive state. Previous studies have demonstrated these diversified functions are mediated by anatomically distinct and/or genetically specified ensembles of SF1 neurons in dm/c VMH. However up to now little is known about the diversity of the electrophysiological properties of these SF1 neurons, which is fundamental to understand the important functions of distinct neural ensembles. In the present study, we performed a classification study of dm/c VMH neurons in C57BL 6J mice (3-4 months, male) using whole cell patch-clamp recordings. We found that these neurons vary in electrophysiological properties, and could be divided into three types: small input resistance and low resting membrane potential(rheobase>20pA), or Type I; high resting membrane potential and spontaneous firing, or Type II; large input resistance and low resting membrane potential (rheobase<10pA), or Type III. Obvious potential sag, induced by HCN-mediated Hyperpolarization current, was detected in many Type III neurons when injecting current at -100pA. Interestingly, low threshold response (LTR) had been found in some Type II neurons after hyperpolarization. LTR has been considered to be mediated by pacemaker channels which are important ionic components involved in burst firing. Our study is the first to dissect the diversity of the electrophysiological properties of VMH dm/c SF1 neurons using patch-clamp recording; this information is helpful to the classification of subtypes of SF1 neurons, understanding their electrophysiological mechanisms, and dissecting the important functions of the Ventromedial Hypothalamus.

Title: Increasing FSCV dopamine microelectrode sensitivity with NCAM

Authors: *D. P. DABERKOW, D. GINDER, N. SCHERR, J. SEIER
Biol., Eastern Washington Univ., Cheney, WA

Abstract: Chronic fast-scan cyclic voltammetry (FSCV) dopamine (DA) microelectrodes can potentially monitor DA signaling in the brain for several months. After surgical implantation of chronic FSCV DA microelectrodes, a one-month recovery period is usually required for the microelectrode surface to stabilize and accurately detect DA signals. Signal loss during this recovery period is thought to be due to, at least in part, an immune response around the microelectrode sensor (carbon fiber). Neural cell adhesion molecule (NCAM) has been implicated as a means to reduce gliosis around electrodes implanted in the brain. Therefore, chronic FSCV DA microelectrodes were coated with NCAM to investigate potential ability to improve FSCV microelectrode recovery post-surgery. FSCV microelectrodes (n=6) were first sterilized with 70% alcohol and then exposed to 8M nitric acid, dry toluene (100-98%), 2% solution of (3-mercaptopropyl) trimethoxysilane, 2mM 4-maleimidobutyric acid N-hydroxysuccinimide ester, 100 µg/ml NCAM, and 100µM Poly (ethylene glycol)-NH2. Prior to surgical implantation, FSCV microelectrode sensitivity to DA was assessed *in vitro* (i.e., 1 µM DA flow-injection apparatus) before and after NCAM coating. Interestingly, NCAM treatment of FSCV microelectrodes significantly increased the electrode response to DA *in vitro* (51% increase in current response to 1 µM DA in buffer). Future directions include investigating the impact of NCAM coating on FSCV microelectrode recovery and sensitivity to DA *in vivo*.

Title: Pipette cleaning enables one hundred whole cell recordings with a single pipette

Authors: C. LANDRY[1], I. KOLB[1], W. STOY[1], M. YIP[2], C. LEWALLEN[2], *C. FOREST[3]
[1]Wallace H. Coulter Dept. of Biomed. Engin., [2]Georgia Inst. of Technol., Atlanta, GA; [3]Georgia Tech., Atlanta, GA

Abstract: The late 1970s saw the birth of patch clamp electrophysiology, and despite being a “gold standard” technique across neuroscience, patch clamping has remained a high-skill manual technique, which limits throughput to approximately five cells per hour (for sufficiently short recordings with a single pipette). While significant advances in patch clamp automation (i.e., closed loop image guidance) and multiplexing (i.e., simultaneous recordings with up to 12

electrodes) have occurred, all patch clamp experiments require replacement of pipettes, fundamentally limiting throughput and scalability. We have previously demonstrated a technique that enabled pipettes to be successfully cleaned and reused up to 10 times, enabling unattended operation of patch clamp experiments for 1-2 hours. Here, we present a new method for cleaning pipettes that enables a practically infinite number of reuses with no measurable change in yield or recording quality at a rate greater than trained humans (12-15 cells per hour) for 4 hours with no human intervention. We will demonstrate this new technology by performing 3 experiments: **1)** show efficacy of cleaning by patching >100 cultured HEK 293 cells with a single pipette, **2)** increase throughput by using cleaning for simultaneous dual-pipette patching experiments (25-30 whole cell recordings per hour), and **3)** demonstrate scalability by a single experimenter operating two electrophysiology rigs simultaneously (estimated 50-60 cells per hour). This technology development will bring new levels of scale to patch clamp electrophysiology, enabling repeatable high throughput experiments across neuroscience that can be readily adapted to fields ranging from *in vitro* phenotypic screening to connectomics.

Title: Transmission electron microscope study of the foreign body response to implanted polyimide-based gold microelectrode platform under *in vivo* conditions

Authors: *H. EREZ[1,2], N. SHMOEL[1,3], S.-H. HUANG[1,3], M. M. JANKOWSKI[1,4], I. NELKEN[1,4], M. E. SPIRA[1,2,3]

Abstract: Electrode platform implanted to vertebrate central nervous system elicit a cascade of cell biological events that culminate in a characteristic foreign body response (FBR). The severity of the FBR is classically characterized by confocal microscope imaging of immuno-labeled sections prepared from paraformaldehyde fixed brains after the removal of the electrodes-platform. Whereas this method is sufficient to describe the overall distribution of the cells around the implant at a resolution of tens to hundreds micrometers, detailed information as

to the cell types that in fact adhere to the implant surface and the nature of the contact formed cannot be extracted. Here we developed a protocol that enable to prepare thin section from a polyimide-based (PI) gold electrode-platform together with the surrounding rat cortex tissue for transmission electron microscopic (TEM) analysis. Immunohistological examination of two weeks implanted PI perforated MEA and the surrounding tissue revealed that the platform generated a minimal overall FBR. Nonetheless, both activated microglia and astrocytes are detected in the vicinity of the PI-MEA. These cells and occasionally neurites extend branches into the perforations. Established ultrastructural features were used to differentiate among the different cell types in the TEM images. We found that the PI platform and the surfaces of the gold electrodes were occupied by adhering microglia with a PI/microglia extracellular cleft that ranges between 0 to 50 nm. Although this narrow extracellular cleft could represent tissue shrinking artifact in the order of 5-15% due to the processing, this implies very tight adhesion of the microglia to the implant surface. Interestingly, whereas astrocyte adheres to the microglia in vicinity to the platform they don't form direct contact with the PI surface. Neurites were detected at distances as small as approximately 1 µm from the PI-MEA surface but were separated from the platform by microglia. The dominant adhesion of microglia to the PI platform and gold electrodes mechanically isolate the platform from the astrocytes and neurons and probability electrically insulate the electrode.

Title: Multi-modal *in vivo* electrophysiology with integrated glass microelectrodes

Authors: *M. BARBIC[1], D. L. HUNT[2]
[1]jET, HHMI, Ashburn, VA; [2]HHMI-Janelia, Ashburn, VA

Abstract: Progress in neurobiology has driven increasing demand for diverse modalities of information to gain a cohesive understanding of neural function. Electrophysiology is the most ubiquitous form of functional data collected for basic and clinical neuroscience research, typically limited to a single-mode, intracellular or extracellular recording. The integration of multiple physiological modalities for routine acquisition of multi-modal data would be advantageous for numerous biomedical applications but has been challenging due to the incompatibility of their fabrication methods. Here we present a flexible suite of devices with integrated glass pipette microelectrodes, engineered to simultaneously obtain multi-modal

information (intracellular + extracellular) *in vivo*. Moreover, we extend this platform to include electrochemistry, and capabilities for optogenetic perturbations of neural activity. Utilizing our toolkit of integrated devices to acquire multi-modal signals from the CA1 region of the hippocampus in vivo, we demonstrate how such data can serve as ground-truth validation for the performance of spike-sorting algorithms. Thus, our technologies are applicable for basic neurobiological and clinical discovery, as well as for developing next-generation brain-machine interfaces.

Title: All in one go: Expression, electrophysiology and imaging within 24 hours using Semliki Forest virus *in vivo* and *in vitro*

Authors: *S. DOMINIAK, J. MÜLLER-PESTER, T. A. ZOLNIK, R. N. SACHDEV, M. E. LARKUM, A. GIDON
Humboldt-Universität zu Berlin, Berlin, Germany

Abstract: During the last two decades, the field of neuroscience has been transformed by our ability to express a wide range of proteins in neurons, often by injecting viral vectors into the living brain. Typically, expression is slow, reaching optimal levels in days to weeks following viral transfection. Consequently, state-of-the-art approaches using opsins or other genetically encoded indicators are intractable for experiments constrained in time e.g. in acute brain slices obtained ex vivo from human patients. Here we used a strategy whereby transfection, expression, recording and/or imaging are achievable within hours using Semliki Forest Virus (SFV), a positively stranded RNA viral vector capable of driving rapid protein expression. We describe a simple technique for delivering SFV *in vitro*, using micro-droplets and/or micro-injection of the virus suspension directly onto acute brain slice preparations. Using this technique *in vitro* as well as standard *in vivo* viral injections, we systematically characterized the viability and function of mouse cortical neurons expressing GFP, channel-rhodopsin, CaMPARI or RCaMP. We found that transfecting with viral particles at low concentrations ($<10^8$ particles/ml) resulted in sparse yet strong expression. Importantly, initial expression began as early as 4 hours after viral transfection and the infected cells had viable electrophysiological behavior at least up to 24 hours

post transfection. In summary, we present “all in one go” strategy providing an easy, fast and efficient way to go from transfection to imaging and electrophysiology.

Title: Application of high-throughput automated patch-clamp techniques to the study of neurotransmitter receptor function: From engineered cell lines to cultured cortical neurons

Authors: *M. TOH[1], J. M. BROOKS[1], T. STRASSMAIER[2], S. S. PIN[1]
[1]Alkermes Inc, Waltham, MA; [2]Nanion, Livingston, NJ

Abstract: Drugs that target neurotransmitter systems are immensely important as therapeutic agents and as research tools for neuroscientists seeking to unravel the complexities of neuronal signaling. While there are numerous examples of such drugs there is much room for improvement in terms of potency, selectivity, and efficacy. Automated high-throughput systems that directly measure the activity of ionotropic neurotransmitter receptors will help to enable the discovery of the next generation of drugs and research tools. Traditional approaches rely on the use of engineered cell lines that over-express defined receptor types, but these artificial systems may not always faithfully reproduce the function of all neurotransmitter receptors in their native environment, the neuron. For this reason, we sought to bridge the gap between cell line and neuron using a high-throughput planar patch clamp recording system. We started by studying the effects of reference compounds on recombinant NMDA receptors (NR1/NR2B) expressed in an HEK cell line. NMDAR activity was elicited by application of glutamate/glycine both before and after the application of compounds. The NMDAR activity remained stable over repeated applications of glutamate/glycine (average of 7.5% signal decrease over 5 additions) and was inhibited by CP-101,606 with an IC_{50} of 235 nM and Ro-25,6981 with an IC_{50} of 190 nM. As expected, TCN 213, a selective antagonist of NMDA-NR1/NR2A, had no effect up to 30 μM. We also examined the activity of positive allosteric modulators on responses to glutamate alone; the EC_{50} for glycine was 100 nM and the EC_{50} for D-serine was 160 nM. While spermine also potentiated the glutamate activity the response did not saturate at the highest concentration tested. Finally, we applied the same automated patch clamp technology to acutely-dissociated neurons derived from rat cortex. These neurons display a range of voltage-gated conductances. In addition, preliminary pharmacological studies show that a sub-population of the rat cortical neurons express receptors for GABA.

Title: Accelerating pain research via human dorsal root ganglia analysis

Authors: *M. W. VONDRAN[1], S. SHAD[1], G. KOPEN[1], T. J. BELL[1], S. G. WAXMAN[2,3], S. DIB-HAJJ[2,3]
[1]Natl. Dis. Res. Interchange, Philadelphia, PA; [2]Yale Sch. of Med., New Haven, CT; [3]Ctr. for Restoration of Nervous Syst. Functions, Veterans Affairs Connecticut Healthcare Syst., West Haven, CT

Abstract: Species-specific differences in genomic, transcriptomic, and proteomic profiles are emerging as major hindrances for investigators pursuing basic and translational neuroscience research. Analysis on primary human tissues and cells provides an alternative method to overcome this challenge. However due to the experimental and logistical challenges of studying human neurons, this approach is substantially underutilized by investigators. Recent advances in experimental methodologies and procurement practices have ameliorated several key issues. Here we report our advances to provide suitable tissue for state-of-the-art experimental methods. The National Disease Research Interchange (NDRI) is a non-profit organization that serves as the critical link between individuals wishing to donate organs and tissues for research and biomedical investigators. NDRI specializes in using a project-specific approach to design recovery protocols for donor eligibility and tissue collection and preservation procedures. In doing so, the scientist obtains experimental-specific human tissues for their studies. For example, NDRI provides human DRG for pain research that specifically meets the needs of the physiologist. DRGs from NDRI have been utilized to show that the membrane and firing properties of human DRG neurons have several distinct physiological properties compared to rat DRG neurons (Han et el., 2015). Our approach to providing human DRGs and other tissues for rigorous experimental methods such as electrophysiology and RNAseq is presented. For example, as the lead organization for the NIH's Geneotype Tissue Expression project, NDRI applied their project-specific approach to obtain multiple tissues (n=5 to 32) per donor for RNAseq analysis. Due to the escalating nature of experimental questions and techniques that investigators are addressing and pursuing, suitable tissues are needed to enable experimental

success and accurate data. Optimizing tissue collection and preservation methods to the experimental procedures for each scientific study will play a key role in accelerating the development of new pain and other clinical therapies and treatments.

Title: A novel virtual reality based platform for understanding the mechanism of visually evoked anxiety and habituation in healthy and anxious subjects

Authors: *M. YILMAZ BALBAN[1], A. D. HUBERMAN[1,2,3,4]
[1]Dept. of Neurobio., [2]Dept. of Ophthalmology, [3]Stanford Neurosciences Inst., [4]BioX, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Our ability to respond adaptively to different stimuli in our environment is a critical skill for ongoing mental health and overall life progression. Humans rely heavily on vision more than other senses to carry out their daily life functions as well as survival. Habituation to repetitive, inconsequential stimuli, is one mechanism by which the visual system eliminates irrelevant stimuli and therefore responds selectively to salient features in our environment. Defects in habituating to visual stimuli have been to linked a variety of neuro-psychiatric disorders; however, how behaviors and internal states habituate to the repeated presentation of visual stimuli remains poorly understood. The two main goals of this research are (1) to understand how healthy humans respond to repeated and anxiety producing visual stimuli, (2) to understand how these processes are affected in individuals with generalized anxiety disorder. To reach these goals, we built a state-of-the-art Virtual Reality (VR) platform that enables the delivery of realistic and emotionally salient visual environments to humans in the laboratory, while simultaneously measuring their behavioral, physiological and subjective responses. Subjects repeatedly experienced a suite of anxiety-inducing visual stimuli in VR. Peripheral physiology of each subject was continuously recorded by electrocardiogram, electro-dermal activity, respiration and pupil size. Their behaviors were automatically scored in real-time using custom written software. The survey ratings for each stimulus were analyzed as a way to assess subjective perception. Changes in all of the collected responses during consecutive exposures

were evaluated as a measure of habituation.
We discovered that in healthy subjects, there is a pronounced reduction in the number of autonomic and behavioral responses during the second exposure to a stimulus. This finding suggests that changes in baseline reactivity is a robust signature of habituation in this population. By contrast, preliminary data from patients with anxiety show that this population increases their responsiveness to the stimuli (i.e. sensitization) instead of habituating to them. These results suggest that relative sensitization/habituation to repeated exposure to visual stimuli may represent a powerful biomarker for diagnosis of generalized anxiety disorder and a means to reliably measure the efficacy of various treatments. Our VR-based platform enables **objective measurements of the human internal state:** a methodological advance in the field of affective neuroscience, which will lead to a mechanistic understanding of anxiety and other affective disorders.

Title: A surface design of polystyrene sheet by an inkjet printer for network architecture of cultured neurons

Authors: *S. ISHIDA[1], K. UMETA[2], N. TESHIMA[2], Y. YOSHIMI[3]
[1]Shibaura-Institute-of-Technology, Tokyo, Japan; [3]Dept. Applied Chem., [2]Shibaura Inst. Technol., Tokyo, Japan

Abstract: Simulating neural network by neurons cultured on the pattered substrate is important for basic study or screening of neurotoxicity of drugs under development.
The purpose of this study is simulating nervous system by patterned culture of neurons on a substrate whose surface is designed by a widely commercialized ink-jet printer. The ink-jet printing can be done economically and flexibly then conventional photolithography.
Firstly, 0.96 wt% cationic polyethylene imine aqueous solution was printed on a polystyrene sheet as the substrate by using a portable inkjet printer (iP100, Canon, Tokyo). The printed area was positively charged and attaches neurons. However, axons grew randomly and extended to the non-printed area.
The results indicate that the axon growth factor would be adsorbed on the polystyrene surface, then the charge patterning is not sufficient for control of the axon growth. Then, we designed a

method to make bulged pattern of the polystyrene surface with the inkjet printer as well by using limonene which is eco-friendly solvent of polystyrene. A mixture of 2: 3 (wt) ethanol-limonene with 0.8 wt% rose bengal was printed on the polystyrene sheet. The polyethylene imine was printed on the interval again. Aplysia neurons were allowed to attach on the interval and were cultured in a mixed medium of SL-15 and Aplysia bodily fluid (1:1 in volume).
As the results the axon of the all neurons extended along the edge of the bulged area.
In addition, 30% of the neurons formed synapse each other.
As a conclusion, a commercialized ink jet printer is a potential tool to create neural networks among the neurons adsorbed on the substrate printed pattern of bulge and charge.
