Title: Neural mechaisms of chromatin remodeling: The role of cohesin complex proteins in memory and learning using *Drosophila melanogaster*

Authors: *K. A. EDWARDS, B. Z. KACSOH, G. BOSCO
Mol. and Systems Biol., Dartmouth Col., Hanover, NH

Abstract: Mutations in proteins that organize chromatin are implicated in neurodevelopmental disorders, such as Cornelia de Lange Syndrome (CdLS). CdLS patients present with microcephaly, intellectual disability, and autism spectrum disorder caused by heterozygous loss-of-function mutations in genes encoding the cohesin complex proteins and the cohesin-loading factor, Nipped-B (NipB). These proteins function together in regulating chromatin structure and gene transcription. Our objective is to determine how cohesin and cohesin-related proteins regulate memory and social learning in the fruit fly *Drosophila melanogaster*. In the presence of a larval endoparasitoid wasp, adult flies perform two behaviors: either decrease egg laying or lay their eggs on ethanol-laden food. Flies will remember this exposure following wasp removal. Our lab has shown that known long-term memory genes and a functional mushroom body (MB) are necessary for this memory. Adult flies (10 replicates 5 female and 1 male 3-5 days past eclosion (dpe)) are allowed to lay eggs on their choice of food made with water or 6% ethanol in the presence or absence of 3 female wasps. After 24 hours, wasps are removed and flies are moved to new enclosures each day with fresh food while the proprtion of eggs laid of ethanol-laden food is reported.
Flies that have been exposed to wasps will also communicate their exposure to naïve fruit flies which subsequently decrease egg laying. We use this behavior to assay social learning by placing wildtype *Canton-S* flies (12 replicates 10 female and 2 male 3-5 dpe) in one section of a two-part enclosure with or without 20 female wasps in the neighboring chamber for 24 hours. After measuring the egg depression of these “teachers”, each replicate is paired with naïve “student” flies (12 replicates 10 female and 2 male 3-5 dpe) in new enclosures with fresh food. The egg depression of students is recorded as a measure of learning. Using these assays, we have measured how flies with mutations in cohesin or NipB are able to remember and learn. We found that mutations in SMC1, a cohesin protein, impaired memory formation while flies with mutations in NipB have impaired memory retention. Additionally, flies with mutations in Rad21, another cohesin protein, are unable to learn while flies with mutations in SMC1 and NipB have

an impaired ability to learn. Because flies with NipB mutations have been observed to have abnormal MB structures while loss of SMC1 and Rad21 cause dendrite and pruning defects in the MB, we have evaluated MB structure of mutants across their development. We are investigating these phenotypes to evaluate influences of cohesin and cohesin-related proteins on memory and learning.

Title: Chd7 regulates GABAergic network development in zebrafish

Authors: P. JAMADAGNI[1], E. SAMARUT[2], *K. PATTEN[1]
[1]Inst. Armand-Frappier, INRS, Laval, QC, Canada; [2]Neurosciences, CRCHUM, Montreal, QC, Canada

Abstract: Mutations in the ATP-dependent chromatin remodeller chromodomain, helicase, DNA binding (CHD) 7 are the primary cause of CHARGE syndrome and have been associated with autism spectrum disorders (ASD). However, the mechanisms by which mutations in CHD7 affect brain development and function are poorly understood. To address this question, we have developed a zebrafish *chd7* CRISPR/Cas9 knockout model owing to the suitability of this vertebrate model for the study of early neurodevelopment. *chd7* knockout (*chd7-/-*) zebrafish larvae exhibit a small head phenotype, defects in craniofacial cartilage development, heart defects and had no swim bladder. We also found that *chd7-/-* fish display aberrant axonal network development. Interestingly, the mutant fish displayed hyperactivity particularly during dark light cycle. It has been proposed that an aberrant inhibitory signaling in the brain is a mechanism underlying ASD; we thus next sought to perform a detailed analysis of the brain in our model. We observed a marked decrease in proliferation as well as significant decrease in GABAergic cells in *chd7* mutants. The decreased number of GABAergic cells in certain regions of the brain is due to a failure in the migration of these cells. Treatment with the GABA-A receptor antagonist pentylenetetrazol (PTZ) showed that *chd7* mutants exhibit an increased sensitivity to PTZ-induced seizure, providing further evidence for GABAergic deficits in *chd7* mutants. Using an unbiased whole transcriptomic approach, we identified many genes involved in cell proliferation, migration and cell adhesion that are dysregulated in *chd7* mutant. Together,

our findings indicate loss of chd7 results in a deficit of inhibitory neurons and suggest an essential role of chd7 in the brain neuronal network development.

Title: Long distance plasticity of callosal connections: From men to mice

Authors: *D. SZCZUPAK[1,2], C. C. YEN[1], C. LIU[1], S.-H. CHOI[1], F. MEIRELES[3], C. VICTORINO[3], A. C. SILVA[1], R. LENT[3,2], F. F. TOVAR-MOLL[3,2]

Abstract: Brain plasticity is usually associated with microstructural changes, but it can also reflect a large macroscopic rewiring of the brain called long-distance plasticity (LDP). LDP was first described in humans with dysgenesis of the corpus callosum (dCC), a brain malformation in which some or all callosal fibers fail to find their natural tracts and end up forming completely new paths. So far, little is known about the detailed anatomical and temporal pattern of the development of those connections and, to date, no animal model could reproduce the full complexity of brain connectivity in this pathology. In the present study, we used ultra-high field diffusion-weighted MRI to map the underlying formation of white-matter fiber tracts in a long-known murine model of dCC, the Balb/c mouse. We observed that the Balb/c mouse has a large variability in size of the CC compared to wild type C57BL/6 mice (Figure 1A). Using the high-resolution DTI images, we also noticed that, compared to a normal C57BL/6 mouse, in which the inter-hemispheric fiber cross midline over a broad swath of the CC (Figure 1B), Balb/c mice have their interhemispheric connections cross midline in a very restricted point of the CC (Figure 1C). Balb/c mice have a whole brain reorganization (FIgure 2). These spontaneous abnormalities of the CC in Balb/c validate this strain as a suitable animal model to investigate the genetic origins of malformations of the CC, which may lead to a better understanding of how LDP occurs in humans.

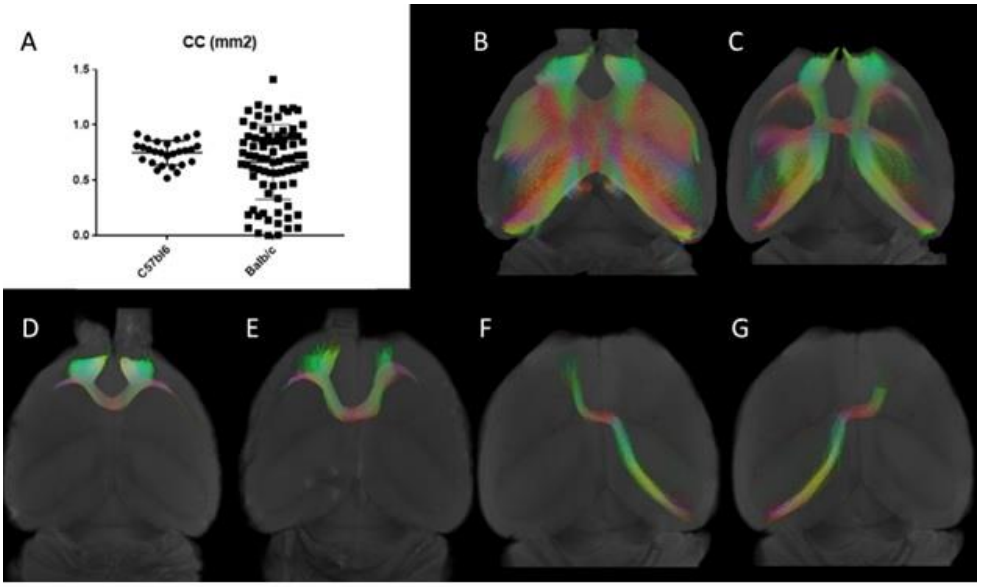

Figure 1. A. Graph showing the greater variability of the size of the CC in Balb/c as compared with controls, in axial view. B-G. Examples of the abnormal connectivity in Balb/c include the the global callosal network, where we can observe the whole interhemispheric network in (B) compared to a severely altered animal callosal network (C), connections of the prefrontal cortex, where in wild type mice occur through the genus of the CC (Figure 1D) but in Balb/c go through a CC remnant that is located more posteriorly than the genus of the CC (Figure 1E). Balb/c mice also show sigmoid bundles connecting contralateral posterior cortex to prefrontal cortex (Figure 1F, 1G). These sigmoids bundles do not exist in wild type mice, but were first discovered in human patients of dCC.

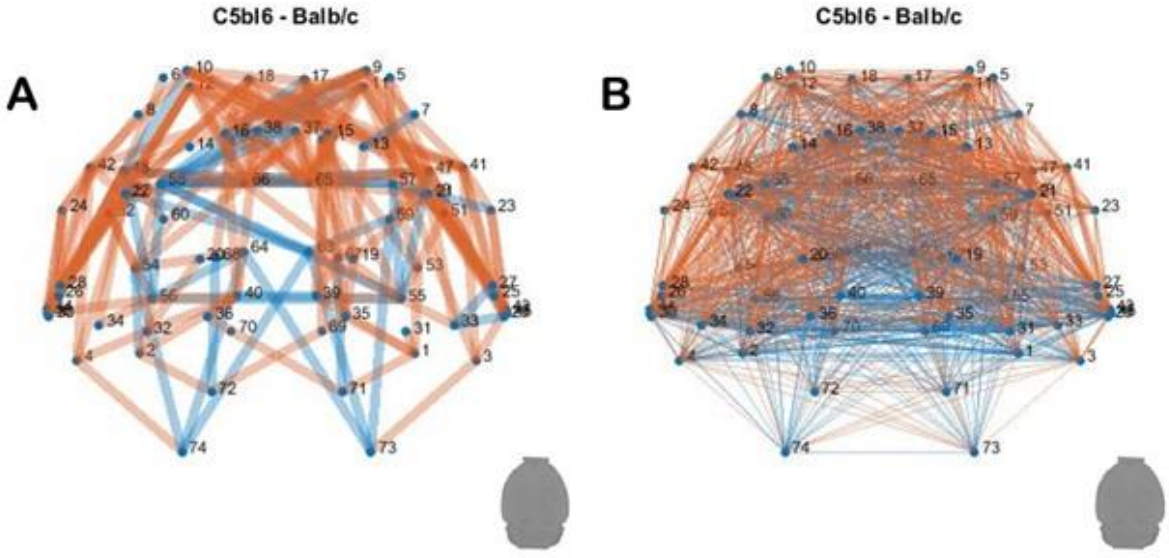

Figure 2. Binary connectome (A) and weighted connectome (B). Red indicates stronger connectivity in Balb/c compared to C57bl6 and blue represents stronger connectivity in C57bl6 compared to Balb/c. The narrowing of intrahemispheric connections in Balb/c mice leads to a completely different structural connectivity of cortical areas compared to that of C57BL/6 mice.

Title: A3 regulates self-renewal maintenance of neural progenitors

Authors: *M. OU, Z.-G. LUO
Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai city, China

Abstract: Gyrencephaly is a unique structure found in limited species including human beings. Since the expansion of neocortex providing the structure basis for much more neurons to form elaborate cortical network, it is of importance to investigate the underlying mechanism of cortex folding conformation. According to previous exploration, researchers have found that outer subventricular zone(OSVZ) is specially appears in species with complex neocortex. Further observations strengthen that outer radial glial cells may be a major source of neocortex expansion. Here, we suggest that A3 is involved in stemness maintenance of progenitor pool by adjusting mitotic process. At the level of mRNA expression, A3 is highly expressed in OSVZ human cortex detected by RNA sequencing. Consistently, in situ hybridization probe of A3 was enriched in VZ/SVZ during mouse early development. Applying in-utero electroporation, in vivo overexpression A3 yielded the potent increase of the number of proliferative progenitors. Meanwhile, A3 deficiency after RNAi causes neurogenesis defect both in vitro and in vivo assays. Furthermore, in several loss-of function experiments via CRISPR/Cas9-mediated genome editing, A3 knockdown in mouse perturb progenitors pool with mitotic delay and chromatin structure disrupted. A3 deletion mice showed deficient cortical thickness comparing with their wildtype littermate. Immunostaining displayed that projection neurons sitting in deeper layers of the cortex with Ctip2 (layer V) was diminished. Base on the potential function of A3 and related observation, our work propose that A3 plays a role in maintaining the neural progenitors and reveal the impact of mitosis delay on self-renew and development potency in corticogenesis.

Title: Constitutively active MEK1 signaling drives selective death of cortical parvalbumin-expressing GABAergic interneurons in mouse embryonic brain development

Authors: *M. HOLTER, G. R. BJORKLUND, S. SHAH, K. NISHIMURA, J. NEWBERN
Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: Cortical GABAergic interneurons are a crucial population of inhibitory cells that comprise approximately 20% of the total cortical neuron population and can be identified by numerous distinct genetic profiles, morphological characteristics, firing properties, and patterns of connectivity. Cortical GABAergic interneuron deficits have been linked to several human neurological disorders including autism spectrum disorder, schizophrenia, epilepsy, and more recently, the RASopathies. The RASopathy family of neurodevelopmental disorders arise from perturbations of RAS/MAPK signaling and often result in a variety of neurological abnormalities. However, it is unclear how altered RAS/MAPK signaling affects the trajectory of cortical GABAergic interneuron development. To address this question, we generated mice expressing the GABAergic neuron-specific VGAT:Cre recombinase to selectively target a Cre-dependent caMEK1 (*Mek1*$^{S217/222Q}$) mutation to all GABAergic cells. Adult VGAT:Cre caMEK1 mutant mice displayed a noticeable reduction in total cortical GABAergic interneuron number in comparison to controls. Inspection of GABAergic interneuron subtypes revealed a selective reduction in parvalbumin-expressing GABAergic interneurons with no changes in somatostatin-expressing GABAergic interneuron number. We detected similar reductions in the proportion of parvalbumin interneurons in a separate MGE-derived mutant mouse line using Nkx2.1:Cre. Upon further investigation, we found that some nascent caMEK1-expressing GABAergic interneurons located in the subpallial mantle zone exhibit increased activated-caspase-3 labeling and apoptotic features. This suggests that early cell death is a key mechanism driving reduced cortical parvalbumin interneuron number in adult mutants. Previous work has shown that RASopathy mutations alter the expression and secretion of extracellular matrix components from astrocytes. Preliminary evidence shows that mutated GABAergic interneurons may also contribute to differences in perineuronal net formation as assessed by immunohistochemistry and GABAergic-specific RIPseq. Overall, these data implicate RAS/MAPK signaling in early parvalbumin interneuron cell death and the subsequent formation of cortical circuitry.

Title: Repeated exposure to brief periods of enhanced visual experience rehabilitates the injured brain in xenopus tadpoles

Authors: *H. T. CLINE[1], A. C. GAMBRILL[1], R. L. FAULKNER[2], C. R. MCKEOWN[1]
[2]Neurosci., [1]The Scripps Res. Inst., La Jolla, CA

Abstract: Traumatic brain injuries introduce functional and structural circuit deficits that must be repaired for an organism to regain function. In *Xenopus laevis* tadpoles, as in other systems, injury induces neurogenesis and the newly-generated neurons then integrate into the existing circuit, however, the mechanisms governing this integration are poorly understood. We developed an injury model in which tadpoles are given a penetrating stab wound which damages the optic tectal circuit and impairs visuomotor behavior. Development of visuomotor circuit function in *Xenopus* is driven by sensory activity. We tested whether providing enhanced visual experience affects circuit recovery from injury. We found that providing animals with brief periods of enhanced visual stimulation starting 24 hours after injury increased synaptic inputs and circuit integration of newly generated neurons, and sped behavioral recovery. To investigate mechanisms of activity-mediated recovery from injury, we interfered with NMDA receptor function. Ifenprodil, which blocks GluN2B subunit containing NMDA receptors impaired dendritic arbor elaboration. GluN2B knockdown blocked functional integration of neurons generated in response to injury and prevented behavioral recovery. We conclude sensory activity mediated by GluN2B-containing NMDARs mediates structural and functional recovery of the tectal circuit following injury in *Xenopus* tadpoles.

Title: Pak1ip1 gene mutation results in neural crest-dependent developmental defects

Authors: *A. DE CRESCENZO, A. A. PANOUTSOPOULOS, A. LEE, K. S. ZARBALIS
Pathology and Lab. Med., Univ. of California Davis, Davis, CA

Abstract: Neural crest cells (NCCs) appear early in development during neurulation and are required for proper histogenesis of a variety of tissues and organs that importantly, include the peripheral nervous system and structures of the craniofacial skeleton. NCCs have also recently been the center of attention in stem cell-based research due to their regenerative multipotent abilities. Important developmental aspects of NCCs generation, migration, and differentiation and their subsceptibilty to gene mutation remain unresolved debilitating deficits that arise from abnormalities of these processes, Here, we report on a mutant mouse with a missense mutation in the Pak1ip1 gene, which encodes a protein necessary for 60S ribosomal subunit formation. The homozygous mutant of this line showed severe developmental defects, including orofacial cleft affecting palate and maxillae, cranial nerve maldevelopment, generalized hypoplasia, and embryonic lethality. Analyzing the rate of proliferation/cell death in the wild-type vs mutant, we found that the apparent craniofacial phenotypes were generated by a loss of NCC. The TUNEL assay, assessing cell death, confirmed that the rate of cell death in mutants is higher than that of the wild-type, while a pHH3 immunofluorescent analysis, targeting currently dividing cells, showed a deep decrease in proliferative activity in the mutant when compared to the normal condition. Based on these findings, we propose an explanation for the craniofacial defects seen in the mutants involving the loss of NCCs during early development. According to our hypothesis, the low numbers of NCCs would prevent them from reaching the farthest region from their origin, which are incidentally the frontonasal prominences. As Pak1ip1 is pivotal for proper ribosome activity, its functional loss would most likely translate in nuclear stress and subsequent Tp53 up-regulation. Therefore, we analyzed the expression levels of Tp53 and registered, in the mutant, an increased Tp53 activity and G1 cell cycle arrest in neuroepithelial cells, which give rise to the neural crest. Our findings illustrate that the developmental abnormalities observed in the Pak1ip1 mutants are predominantly based on the specific loss of NCCs during development and point towards pharmacological or genetic Tp53 interference as a potential rescue strategy for Pak1ip1 loss-of-function.

Title: Nutrient restriction causes reversible G2 arrest in xenopus neuronal progenitors

Authors: *C. R. MCKEOWN, H. T. CLINE
The Scripps Res. Inst., La Jolla, CA

Abstract: Nutrient status affects the developing brain, yet the effect of nutrient restriction and food availability on a cellular level *in vivo* is poorly understood. In the absence of external nutrients, *Xenopus laevis* tadpoles enter a period of developmental stasis during which neural progenitor cell proliferation is drastically reduced, with proliferation synchronously resuming when food becomes available. Here we investigate the mechanisms by which neural progenitors halt cell division in response to nutrient restriction and then re-enter the cell cycle upon feeding. We demonstrate that nutrient restriction causes tectal progenitors to stop progression through the cell cycle after S phase, and that the reintroduction of nutrients triggers progenitors to synchronously re-enter the cell cycle at M-phase, suggesting cells in stasis are paused at G2. Consistent with a model for G2 arrest, we find that levels of phosphorylated cdc2 are decreased upon stasis entry and return upon the resumption of feeding. We demonstrate that progenitors along the tectal midline have increased DNA content in response to nutrient restriction, further supporting a G2 arrest model. We also show that initiation of the nutrient-restriction-induced G2 pausing is rapamycin-insensitive, but cell cycle re-entry requires mTOR signaling. This capacity of neural progenitors to pause cell cycle progression in G2 provides a mechanism to control proliferation in response to nutrient availability and yet allows cells to be poised to divide quickly when nutrients become available. This may be a general cellular mechanism that allows for developmental flexibility during times of limited resources.

Title: Developmental changes in Gpnmb expression in the prenatal rat brain

Authors: *S. YOKOYAMA[1,2], H. ZHU[2]
[1]Kanazawa Univ., Kanazawa, Japan; [2]Res. Ctr. for Child Mental Develop., Kanazawa, Japan

Abstract: The glycoprotein non-metastatic melanoma B (Gpnmb), a type-I transmembrane protein, is produced by various types of normal cells including melanocytes, osteoclasts, osteoblasts, and dendritic cells in peripheral blood, as well as by various tumor cells. An increasing number of studies have described that Gpnmb is abundantly expressed in invasive glioblastomas, suggesting its involvement in tumor progression and metastasis. Previously we reported that Gpnmb is produced by macrophages and microglia in the normal central nervous system of postnatal and adult rats (Huang, J.-J. *et al.*, Brain and Behavior 2, 85-96, 2012; Yokoyama, S. Soc. Neurosci. Abstr., 674.14, 2016) and by cells in the choroid plexus epithelium, ventricular-subventricular zone and neocortex in the embryonic rat brain (Yokoyama, S. and Zhu, H. Soc. Neurosci. Abstr., 197.14, 2017). The purpose of this study was to define more in detail these Gpnmb-immunoreactive (IR) cells in the embryonic brain. At E10, Gpnmb-IR was only faintly detected in the ventricular wall. At E13, Gpnmb-IR cells were present in the lateral ventricle wall, extending radial fibers from ventricular zone to pial surface. These Gpnmb-IR cells were positive for nestin and vimentin, markers for radial glial cells. At E16 and E19, regional difference in Gpnmb-IR became prominent. Gpnmb-IR was predominantly distributed in the choroid plexus of the lateral and third ventricle; the soma of the Gpnmb-IR cells migrated to the subventricular zone. These Gpnmb-IR cells were frequently co-stained with specific markers including Sox2 for neural stem cells, doublecortin for neuroblasts, and bromodeoxyuridine for cell proliferation, as well as radial glia markers. These data suggest that Gpnmb is involved in the neural development in the embryonic brain.

Title: Consequences of heterozygous loss-of-function mutations to PAX6 in the adult mammalian brain

Authors: *M. K. GRANT[1], A. M. BOBILEV[3], A. M. RASYS[1], A. E. BRANCH[4], J. B. BYERS[1], H. SCHRIEVER[1], K. HEKMATYAR[2], J. D. LAUDERDALE[1]
[1]Cell. Biol., [2]Bio-Imaging Res. Ctr., Univ. of Georgia, Athens, GA; [3]Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [4]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Aniridia is a congenital and progressive disorder affecting approximately 1 in 83,000 live births. Although the disorder is most well known for its ocular phenotypes, the condition has a several other abnormalities, which are only recently emerging as prominent features of the disorder. These include neural, sensory, cognitive, and auditory processing deficits. Development of aniridia in humans is predominately caused by heterozygous loss-of-function mutations in the *PAX6* gene, a highly conserved transcription factor critical for normal eye and brain development. PAX6 has been implicated in aspects of central nervous system development such as patterning, regionalization, and the formation of neural circuits; however, PAX6's role in the adult brain have yet to be described. Our lab has utilized 3T MRI to show structural changes in the brains of aniridia patients as compared to their *PAX6*-normal comparisons. Consistent with other reports, we found reductions to major fiber tracts such as the anterior commissure, posterior commissure, and optic chiasm in addition to lack of or reduction to the pineal gland. The cellular basis for these changes are not well understood, so we have turned to the rodent model of aniridia, *Small eye*, where we can utilize a variety of tools to assess *Pax6* expression and the neural consequences of mutations in the brain. The current study employed MRI using a 7T Agilent system to acquire structural brain images using 3D T2 weighted fast spin echo sequences, volumetric analysis, histological examination, *Pax6* transgenic mouse lines, and tissue clearing of the adult brain to examine the consequences of loss of one functional copy of the *Pax6* gene. Results indicate that while our rodent model recapitulates certain structural changes seen in our human population such as the optic chiasm, it does not capture all of the structural changes seen in our aniridia patients. Our results suggest that within our human population there are potentially modifier effects contributing to the structural brain changes we

see. We are currently using the whole tissue clearing method, iDISCO, to help us better understand the role PAX6 plays in the adult brain and the consequences of heterozygous loss-of-function of this gene. Collectively, these data allow us to visualize the overlap between adult *Pax6* expression and structural brain variants, and provide new hypotheses regarding the effects of early versus adult *PAX6* haploinsufficiency in the mammalian brain. Implementation of this approach also provides a novel platform for investigating the link between gene expression and neural structure and connectivity, with broad applications for neurogenetic research.

Title: Cortical and cerebellar neurodegeneration in the absence of the nuclear protein Akirin2

Authors: *S. L. PEEK[1], J. A. WEINER[2]
[2]Iowa Neurosci. Inst., [1]Univ. of Iowa, Iowa City, IA

Abstract: The role of chromatin remodeling machinery in neurodevelopment is becoming increasingly more apparent. Akirin2 (Aki2) is a highly conserved nuclear protein believed to act as an intermediary between transcription factors (e.g., NFκB, Twist) and BAF (SWI/SNF) chromatin remodelers with roles in immunity and myogenesis. Although Aki2 is expressed prominently in neuronal progenitors, postmitotic neurons, and astrocytes, its function in the brain was, until recently, entirely unexplored. Using conditional *Aki2* knockout mice, our laboratory has shown that restricted loss of Aki2 in early cortical progenitors results in disrupted proliferation, aberrant neuronal differentiation, and massive apoptosis (Bosch et al., *Neural Development,* 2016). The role of Aki2 in *postmitotic* neurons in the postnatal brain, and the molecular mechanisms through which it regulates neuronal development and maturation, remain unknown. To test the hypothesis that Aki2 regulates patterns of gene expression critical for the maturation, maintenance, and survival of postmitotic neurons, we utilized *CaMKII-Cre* and *Pcp2-Cre* mouse lines to delete the *Aki2* gene from excitatory neurons of the forebrain or postmitotic Purkinje cells of the cerebellum, respectively. In *CamKII-Cre;Aki2*$^{fl/fl}$ mice, Aki2 expression is lost from excitatory cortical neurons by ~P18. By P50, the cortex is significantly thinner in knockout mice, with fewer neurons and reduced dendrite arborization. Expression of

GFAP is significantly increased, likely indicative of reactive gliosis. By P150, *CamKII-Cre;Aki2*$^{fl/fl}$ mice are significantly smaller than control littermates and cortical layers are severely thinned, with evidence of neurodegeneration. In *Pcp2-Cre;Aki2*$^{fl/fl}$ mice, Aki2 expression is lost from Purkinje cells at ~P6. Purkinje cell axon degeneration is already apparent 4 days after *Aki2* loss. At P35, there are fewer Purkinje cell somata, the molecular layer, containing Purkinje cell dendrites, is thinner, and Bergmann Glia also upregulate GFAP. *Pcp2-Cre;Aki2*$^{fl/fl}$ mice develop a tremor by P30 that progresses with age. Together, these data indicate crucial roles for Aki2 in the maturation and survival of postmitotic neurons. Given Aki2's role in regulating specific patterns of gene expression, current efforts are focused on generating transcriptomic data from knockout cortical and cerebellar neurons in order to identify downstream molecular mechanisms.

Title: Nervous system plasticity and regeneration in Hydra

Authors: *A. S. PRIMACK, S. SIEBERT, C. JULIANO
Dept. of Mol. and Cell. Biol., Univ. of California Davis, Davis, CA

Abstract: In the small freshwater cnidarian *Hydra,* all differentiated cells in the homeostatic adult animal are replaced every 12-20 days, including the entire nervous system. *Hydra* is also able to regenerate its nervous system following catastrophic injury. Our ultimate goal is to understand the general principles of *Hydra* neural plasticity in both homeostatic and regenerative conditions. As a first step towards this goal, we are using single cell RNA-sequencing (scRNA-seq) to build a complete molecular map of the *Hydra* nervous system. We have thus far identified eight neuron subtypes with unique molecular signatures and are mapping the location of these subtypes in the *Hydra* nervous system using in situ hybridization. Based on our preliminary scRNA-seq data and published literature, we hypothesize that continual renewal of the *Hydra* nervous system under homeostatic conditions is accomplished by a combination of two mechanisms: 1) specification of new neurons from stem cells (neurogenesis) and 2) transdifferentiation between neuron subtypes. In our future work, we aim to use our scRNA-seq data to identify and test transcription factors unique to neurogenesis and transdifferentiation, thus gaining insight into the regulatory control of nervous system plasticity. Additionally, we plan to build transgenic reporter lines to quantify the number of neurogenesis and transdifferentiation

events that occur during both homeostatic maintenance and regeneration of the nervous system. Through these exploratory studies, we hope to elucidate the molecular mechanisms that underlie neuronal plasticity and regeneration.

Title: Early migratory neurons of the olfactory placode, the oral ectoderm, and the cephalic epithelium adjacent to the forebrain

Authors: *I. BYSTRON
Univ. of Oxford, Oxford, United Kingdom

Abstract: A variety of studies have already highlighted cellular and molecular differences between human brain development and that of other mammals. At present, it is universally accepted that the early cephalic mesenchyme contain migratory neurons produced from progenitor cells in the neurogenic placodes and the neural crest, in all mammalian species. We demonstrate that the human cephalic epithelium adjacent to the forebrain contain hitherto unrecognized stem cell niches generating precocious migratory neurons, which are distinct from the pioneer neurons of the olfactory placode, and the neurons of the neural crest origin. Human embryos from Carnegie stages (CS) 10-17 (29-41 days post-conception) were obtained from the Human Developmental Biology Resource UK. We used a number of cell-specific and proliferative markers to reveal the phenotypic characteristics and migratory pathways of the first neurons in the cephalic ectoderm and mesenchyme. We developed a new approach to reconstruct cells in sections of the human ectoderm, diencephalon, cortical wall, and retina by rapid, high-resolution volume rendering of multichannel 3D confocal data sets from a Zeiss LSM 710 confocal microscope. The majority of precocious TU-20-positive ectodermal neurons appear to migrate tangentially within the ectoderm, and some delaminate from the epithelium to coalesce within the mecenhyme surrounding the rostral telencephalon. Intriguingly these neuronal populations form the first connections between the several regions of the embryonic telencephalon and the early cephalic ectoderm. Some neurons migrate into periocular mesenchyme and extend non-axonal processes through the prospective pigment epithelium into the neural retina. Others invade the presumptive cortical wall perhaps providing additional

signalling information to the local stem cell niche. The onset of local neurogenesis in ventral diencephalon presides the generation of neurons within the ectoderm at the roof of the future oral cavity. The fibers of the neurons located in the oral ectoderm form a dense network along the basement membrane adjacent to the ventral hypothalamus by CS13. Pioneer olfactory neurons constitute a distinct migratory population at CS 13-14. Their processes penetrate the rostro-ventral cerebral wall by CS17.
Thus the human cephalic epithelium adjacent to the forebrain contain hitherto unrecognized stem cell niches generating precocious neurons with distinct migratory routes.

Title: FMRP regulates adult neural stem cell maintenance

Authors: *X. ZHAO[1], Y. LI[2], M. E. STOCKTON[2], Y. ZHAO[2], J. L. MILLER[2], I. BHUIYAN[2]

Abstract: Fragile X syndrome (FXS) is the most prevalent inherited intellectual disability, resulting from a loss of fragile X mental retardation protein (FMRP). FXS patients suffer lifelong cognitive disabilities, but the function of FMRP in the adult brain and the mechanism underlying age-related cognitive decline in FXS remain unclear. We have previously shown that FMRP deficiency leads to aberrant activation of neural stem cells residing in the hippocampus of young adult mice leading to impaired cognitive deficits. Here we investigated whether over-activation of neural stem cells lead to stem cell depletion in older mice. We found that that in mature adult (6 month old) FMRP- deficient mice, there is a significant reduction in the numbers of adult

neuronal stem cells leading to reduced new neuron production and cognitive deficits. Our work reveals an important role for FMRP in adult neural stem cell maintenance and present a potential novel therapeutic strategy for treating mature adult FXS patients.

Title: Autophagy mediates astrogenesis of adult hippocampal neural stem cells

Authors: *S.-H. JEONG, S. HA, K. YI, J. J. CHU, S.-W. YU
Brain and Cognitive Sci., DGIST, Daegu, Korea, Republic of

Abstract: Neural stem cells (NSCs) have the ability to self-renew and differentiate into neurons, oligodendrocytes and astrocytes. Highly dynamic nature of NSC differentiation requires the intimate involvement of catabolic processes, such as autophagy. Autophagy is a major intracellular degradation pathway for cellular homeostasis and remodeling. Autophagy is important for mammalian development and its role in neurogenesis has recently drawn much attention. However, little is known how autophagy is associated with differentiation of NSCs into other neural lineages. Here, we report that autophagy plays a critical role for adult astrogenesis. Autophagy flux increased at the early time points, but then returned to the normal level during differentiation of adult hippocampal neural stem (HCN) cells into astrocytes. Genetic suppression of autophagy by stable knockdown of Atg7 or CRISPR-cas9-mediated knockout (KO) of p62 impaired astrogenesis, while reintroduction of p62 recovered astrogenesis in p62 KO HCN cells. Taken together, our findings demonstrate that autophagy plays a key role in astrogenesis of adult NSCs.

Title: Functional *in vivo* screen of TSC1&2 missense mutants associated with ASD in cortical GABAergic interneurons

Authors: D. WUNDRACH, S. M. BILINOVICH, A. M. STAFFORD, D. B. CAMPBELL, J. W. PROKOP, *D. VOGT
Dept. of Pediatrics and Human Develop., Michigan State Univ., Grand Rapids, MI

Abstract: The genes underlying symptoms of Tuberous sclerosis (TS), TSC1 and TSC2, have been assessed for mutations over several years. Notably, many of these mutations are missense and of unknown impact. We wanted to understand the functional impact of these mutations in the human TSC1 and 2 genes and their effect on their encoded proteins, Hamartin and Tuberin, respectively. Hamartin and Tuberin form an obligatory complex that indirectly inhibits the activity of the mammalian target of rapamycin complex 1 (mTORC1). Moreover, mTORC1 activity has been implicated as a biological hub for many autism spectrum disorder (ASD) risk genes, and in turn, a TS diagnosis has a high comorbid rate of ASD. Herein, we will test the impact that missense mutations discovered in TSC1 and 2, with a co-diagnosis of ASD, have on protein function. We are currently assessing these mutations through cellular and biochemical assays. In addition, we are performing these experiments in cortical GABAergic interneurons, a cell type altered by deletion of Tsc1, and a likely cell type involved in TS pathogenesis. We have also discovered novel phenotypes regulated by Tsc1 in mouse cortical GABAergic interneurons and will explore the role of these mutations in the respective phenotypes. In addition to the cellular and biochemical assessments, we will ascertain how human TSC1 and 2 mutations impact the cellular morphology and molecular identity of this important cell group. Overall, these data have the potential to uncover novel signaling mechanisms that lead to symptoms in TS and broaden our understanding of how human missense mutations impact the function of Hamartin and Tuberin.

Title: Efficient generation of dopaminergic neurons by transdifferentiation of cortical GABAergic neurons

Authors: *A. RAINA, S. U. MAHAJANI, M. BAEHR, S. KUEGLER
Neurol., Universitätsmedizin Goettingen, Goettingen, Germany

Abstract: Objective: The generation of functional dopaminergic neurons from fibroblasts and induced pluripotent stem cells (iPSCs) is tedious and time-consuming, therefore the objective was to efficiently generate dopaminergic neurons by transdifferentiation of readily available primary post-mitotic cortical neurons using transcription factors ASCL1, NURR1, LMX1A, and PITX3. **Methods:** Adeno-Associated Viral vectors were used to deliver each transcription factor alone and in different combinations in primary cortical neurons. 150,000 cells were seeded in each well of 24 well plates, transduced at day in vitro 0, and examined by immunocytochemistry for tyrosine hydroxylase (TH), a mature dopaminergic neuronal marker, 7 days after transduction. **Results:** We demonstrated that dopaminergic neurons can be efficiently generated in 7 days *in vitro* (div) by transdifferentiation of post-mitotic neurons. Overexpression of ASCL1, NURR1, and LMX1A together yielded 5-10% (12-18% in 14 div) of TH positive neurons, whereas ASCL1 alone, LMX1A alone and both of them together did not yield any TH positive neurons. NURR1 alone yielded 2% of TH positive neurons. A combination of LMX1A and NURR1, and ASCL1 and NURR1 yielded 2-5% of TH positive neurons. While only a sub-set of cortical neurons were transdifferentiated, it was found that 53-63% of GABAergic neurons were TH positive when NURR1 alone was overexpressed. LMX1A, NURR1, and PITX3 were functional as each of them when expressed in human iPSCs were able to pattern and differentiate human iPSCs into TH positive neurons, acting as a control system. In summary, results suggested that NURR1 was found to be a critical transcription factor in combination with ASCL1 and LMX1A for transdifferentiation of post-mitotic GABAergic neurons into dopaminergic neurons. **Conclusion:** Efficient generation of dopaminergic neurons from post-mitotic GABAergic neurons is the first ever evidence of transdifferentiation of terminally differentiated neuronal cells.

Title: The role of ECE2 in the human brain developmental disorder periventricular heterotopia

Authors: *I. Y. BUCHSBAUM[1,2], G. GIORGIO[3], C. KYROUSI[1], A. O'NEILL[4,5], S. R. ROBERTSON[5], S. CAPPELLO[1,2]

Munich, Munich, Germany; [5]Dept. of Women's and Children's Hlth., Dunedin Sch. of Medicine, Univ. of Otago, Dunedin, New Zealand

Abstract: Malformations of the human neocortex, such as periventricular heterotopia (PH), result from disturbances in the tightly regulated processes of brain development. In PH, new-born neurons fail to migrate to their destined place, leading to malpositioned grey matter along the lateral ventricles. Only mutations in a few genes (FLNA, ARFGEF2, FAT4, DCHS1) are known to cause this neuronal migration disorder in humans. To identify new molecular pathways involved in brain development and to find novel genes involved in PH, trio-based Whole Exome Sequencing was performed. Here, we concentrate on the identified candidate gene endothelin converting enzyme-2 (ECE2).
Mouse models carrying mutations in genes identified in patients with cortical malformation only partially recapitulate expected cortical phenotypes. Thus, in addition to manipulating the expression of the candidate gene in the developing mouse brain, alternative model systems are needed that are more similar to the developing human brain. Induced pluripotent stem cells derived from human somatic cells (hiPSCs) were used to generate neural precursor cells and neurons (2D, [Boyer *et al.*, 2012]), as well as cerebral organoids (COs, 3D, [Lancaster *et al.*, 2013]) as model systems for the developing human brain.
In our *in vitro* human model systems, we identified ECE2 to be expressed in vesicles of both neural progenitor cells and, at a higher level, in neurons. Global pharmacological inhibition of ECE2 activity in 2D caused a change in the dynamics of young migrating neurons, whereas its acute knockdown (KD) or overexpression had only mild effects. This hints at the involvement of mostly non-cell-autonomous mechanisms. Upon inhibition of ECE2 in COs, the production of neurons was reduced and radial glia (RG) polarity was disturbed. Acute KD of ECE2 by electroporation into ventricles of COs led to an increased amount of heterotopic neurons in the vicinity of electroporated radial glia cells, partially recapitulating the patient morphological phenotype. Thus, ECE2 expression may be necessary for correct morphology of radial glia, which are used as scaffold for neuronal migration to the cortical plate.

Accordingly, acute KD of Ece2 in the developing mouse brain, lead to partial delamination of progenitor cells, giving rise to ectopic neuronal cluster formation.
Altogether, new candidate genes for neurodevelopmental disorders can be identified by whole exome sequencing and studied by combining *in vitro* human models and *in vivo* animal models. COs can be used to recapitulate patient phenotypes and to decipher pathogenic mechanisms based on both disturbed RG scaffold and malfunctional neuronal migration.

Council, Rome, Italy; [4]San Raffaele Pisana, IRCCS, Rome, Italy

Abstract: In previous studies we reported that HSV-1 infection of cultured neurons induced the proteolytic processing of Amyloid Precursor Protein (APP) and intracellular accumulation of amyloid-β protein (Aβ) thus impairing synaptic transmission (Piacentini&Li Puma et al., 2015). Here we investigated the effects of HSV-1 on proliferation and differentiation of hippocampal neural stem cells (NSCs) isolated from newborn mice and the role played by Aβ in these effects. We found that HSV-1 infection (0.5 MOI) induced Aβ accumulation in cultured NSCs and reduced their proliferation (-30% *vs*. mock-infected NSCs, 24 h post-infection, assessed by Ki67 expression and BrdU incorporation; $P<0.05$). Infected NSCs also exhibited decreased neuronal differentiation, evaluated by MAP2 immunoreactivity. Indeed, HSV-1 infection reduced the percentage of $MAP2^+$ NSCs by 35%, 42% and 38% ($P<0.05$ *vs*. mock-infected cultures) after 3, 6 and 9 days of differentiation, respectively. Accordingly, the percentage of NSCs expressing the glial marker GFAP increased ($P<0.05$ *vs*. mock-infected cultures). The HSV-1-induced inhibition of NSC proliferation and differentiation depended on Aβ accumulation as

demonstrated by the reversion of these effects after treatment of infected NSCs with 4G8 antibody or β- and γ- secretase inhibitors. We then extended our studies to an *in vivo* model of recurrent virus infections. HSV-1 was inoculated in 1-month old C57/bl6 mice by snout abrasion in order to induce latency and virus was subsequently reactivated twice by thermal stress at 1-month intervals. One week before sacrifice mice were injected with BrdU and hippocampal neurogenesis was studied by immunohistochemistry. The number of $BrdU^+$ cells and newly generated neurons (i.e., cells positive for both BrdU and the neuronal marker doublecortin, DCX) was significantly reduced in the dentate gyrus (DG) of HSV-1-infected mice (-28% and -48%, respectively *vs*. mock; $P<0.05$). Instead, hippocampal neurogenesis was not altered in the DG of HSV-1-infected APP KO mice thus confirming the involvement of Aβ in HSV-1-driven effects on NSCs. Western blot (WB) experiments investigating DCX and NeuroD1 protein expression confirmed immunohistochemical data. The reduction of proliferation and differentiation of virus-infected NSCs observed both *in vitro* and *in vivo* did not depend on cell death, as assessed by Vybrant apoptosis assay and WB analysis of BAX/Bcl2 expression. Collectively, our results demonstrate that HSV-1 infection reduces hippocampal NSC proliferation and their neuronal differentiation via intracellular accumulation of Aβ.

Abstract: In the adult murine piriform cortex, non-proliferative neuronal precursors express the protein doublecortin (DCX) and eventually become mature neurons. The physiology of these cells and their relevance for brain functions are unknown. Here we investigated the neuronal precursors' structural and functional maturation questioning whether they eventually become equivalent to other principal neurons of this brain region. Patch clamp experiments and morphometric analysis of axon initial segment were carried out in acute brain slices and histological sections respectively. Accordingly, the fate of precursors was traced in transgenic mice (DCX/dsRED and DCX-CreRT::CAG-fl/eGFP) where these cells can be fluorescently labeled, studied throughout maturation and compared to other age-matched principal neurons. Young precursors (tangled cells) and immature neurons (young complex cells) were analyzed in 2 - 4 months old mice, and more mature (old) complex cells were analyzed in 4 - 8 months old mice. Tangled cells were small, virtually received no synaptic input and produced scarce action potential. Young complex cells received sparse synaptic input, produced low action potential frequencies, had small capacitance, small inward and outward currents and slow action potential kinetics. Young complex cells were in this respect similar to early postnatal (P03 - 04) immature principal neurons. Old complex cells displayed increased amount of synaptic input, larger capacitance, larger inward and outward current, and sharper action potential kinetics, but retained low action potential firing frequencies and developed a remarkably high rheobase, implying limited excitability. Furthermore, the axon initial segment of old complex cells was shorter than that of other aged-matched principal neurons. Strikingly, while principal neurons typically received a mixed glutamatergic and GABAergic synaptic input, gabazine completely blocked postsynaptic currents in complex cells of any age spontaneous suggesting exclusive GABAergic input. On one hand, the odd functional features of complex cells challenge their relevance for the adult brain; on the other, their unique features suggest that these cells are new coding elements in the piriform cortex rather than the simple replacement or addition of homologous coding units to the preexisting network components.

Title: Anatomical and molecular characterization of the developing entorhinal cortex neuronal circuit in the pig

Authors: *Y. LIU[1], T. B. BERGMANN[1], J. M. P. VIDAL[1], Y. MORI[2,3], M. PIHL[1], P. D. THOMSEN[1], P. HYTTEL[1], K. MØLLGÅRD[4], M. P. WITTER[5], V. J. HALL[1]
[1]Dept. of Vet. and Animal Sci., [2]Ctr. for Translational Neuromedicine, [3]Panum NMR Core Facility, [4]Dept. of Cell. and Mol. Med., Univ. of Copenhagen, Copenhagen, Denmark; [5]Kavli Inst. for Systems Neurosci., Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: The entorhinal cortex (EC) acts as a gateway for information traveling in and out of the hippocampal formation and is important for spatial memory. The stellate cell (SC) resides in the medial EC, projects to the dentate gyrus and contributes to both the grid and border cell phenotypes. However, very little is known about the molecular identity of SCs. SCs express reelin (RELN+) and calbindin negative (CALB1-) and this differentiates them from the other main principle neurons. The aim of our project is to develop novel differentiation protocols to produce SCs from induced pluripotent stem cells (iPSCs). We therefore decided to probe the developing EC to identify key growth factors and cytokines that are critical for the formation of SCs. We selected the pig as a model, since it may better reflect human EC development compared to the rodent, due to its gyrencephalic anatomy. Embryonic brain tissue was obtained from a local slaughterhouse. To identify the period of neurogenesis and EC development, we performed Nissl staining and postmortem structural MRI on brains collected at embryonic day (E) 40, 48, 60, 70, 80, 100 and postnatal day (P) 75 (gestation length 114 days, n=3). We identified cells which have entorhinal cortex cytoarchitecture properties at the Layer II border as early as E49 and a more mature EC cytoarchitecture was observed at E60 in the ventral telencephalon, within the piriform lobe. Furthermore, using histological parameters, we could delineate the lateral (LEC) from the medial EC (MEC). Furthermore, immunolabelling revealed that the posterior EC, containing the MEC, presented neurogenesis already by E40. Radial glia cells were found in the ventricular zone (VZ) and expressed GFAP/BLBP, SOX2 and PAX6. Further, a marker of intermediate progenitors, TBR2, was detected in the sub-VZ. Interestingly, we found GFAP+/BLBP+ cells, even in the ependymal layer at P75 (23.31%). We identified a population of RELN+/CALB1-/MAP2+ neurons at the superficial border of Layer II appearing at E60, which we presume to be the SCs. The percentage of these cells in Layer II increased from 1.87% of the population in the cortical plate at E60 to 51.77% within Layer II by E100. We compared RELN expression in the pig to that in 21 week old human fetal EC, and found no RELN+ neurons in the Layer II in the human. This study has led to the characterization of the developing EC in a new species and documented when SCs arise in a large mammal. We are currently analysing single-cell sequencing data from the embryonic brains, allowing us to identify growth factors and cytokines important for SC development. This may eventually lead to the creation of novel SC differentiation protocols from human iPSCs.

Title: Inhibition of an autocrine activity-dependent insulin signal is required for sensory neuron differentiation in *C. elegans*

Authors: *L. BAYER HOROWITZ, J. BRANDT, N. RINGSTAD
NYU Sch. of Medicine, Skirball Inst., New York, NY

Abstract: The nervous system comprises diverse and highly specialized neuron-types, each expressing a unique set of genes that defines its functional properties. What molecular mechanisms generate diverse neuron types remains unknown. Study of the *C. elegans* chemosensory BAG neurons showed that a p38 Mitogen Activated Protein kinase (MAPK), PMK-3, is required for their proper differentiation. How p38 MAPKs function in neurodifferentiation is poorly understood. Through analysis of mutations that restore gene expression to *pmk-3* mutant BAG cells, we found that genes that promote neural activity and secretion antagonize *pmk-3* dependent gene expression in developing BAG neurons. Silencing BAG neural activity also sufficed to restore gene expression to *pmk-3* mutant BAG cells, suggesting that an autocrine activity-dependent signal antagonizes PMK-3-dependent neurodifferentiation. To determine the identity of the secreted signal, we used RNA-Seq to transcriptionally profile wild-type and *pmk-3* mutant BAG neurons. We found that *pmk-3* mutant BAG neurons overexpressed multiple insulin like peptides (ILPs) as compared to wild-type neurons, indicating that *pmk-3* inhibits expression of ILPs. To test whether ILPs are the signal that antagonizes PMK-3 dependent neurodifferentiation, we overexpressed the dominant negative ILP *daf-28(sa191)* in *pmk-3* mutant BAG cells to disrupt insulin production and release from BAG. This manipulation was sufficient to restore gene expression and function to *pmk-3* mutant BAG neurons. Furthermore, BAG cell-specific knock-down of the insulin receptor homolog, DAF-2, also restored gene expression and function to *pmk-3* mutant BAG cells. Together our data delineate a mechanism through which p38 MAPKs promote proper sensory neuron differentiation by inhibiting an autocrine and activity-dependent insulin signal that represses expression of a BAG neuron fate. These findings reveal an unexpected role for insulin signaling in nervous system development and suggest that insulin-like factors are at the nexus of

intrinsic genetic programs and extrinsic signaling mechanisms that regulate neuronal differentiation.

Abstract: Human fetal-derived neural stem/progenitor cells (hfNSCs) are under clinical evaluation for several neurodegenerative diseases. These cells display a favorable safety profile but require immunosuppression upon allogeneic transplantation in patients. In this scenario, obtaining *bona-fide* neural stem/progenitor cell (NSC) populations from human induced pluripotent stem cells (hiPSCs) is relevant for the development of autologous approaches to treat neurological disorders. We have recently generated hiPSC-derived NSCs (hiPS-NSCs) sharing phenotypic and functional identity with hfNSCs, providing proof-of-principle of their potential application in *ex vivo* gene therapy protocols for metachromatic leukodystrophy, a demyelinating genetic disease. The transcriptional and epigenetic mechanisms underlying hiPSC commitment towards the neural lineage need to be investigated to optimize the production and to define the safety profile of hiPS-NSCs in the perspective of their potential clinical application. In this study, genome-wide transcriptomic analysis revealed a strong downregulation of transcription factors regulating pluripotency, cell cycle and cancer-related pathways and the concomitant appearance of a distinct “neural signature” in hiPS-NSCs (without donor- or clone-related bias) highlighting the role of known and unknown master regulators of the transition from pluripotent to neural-restricted stem cells. Computational integration of RNA-seq and ChIP-seq data showed a dramatic change in the usage of cell-specific enhancers and super-enhancers during hiPSC neural differentiation suggesting their major role in the generation and maintenance of hiPS-NSC population. Differences in the transcriptomic and epigenetic profiles of hiPS-NSCs and hfNSCs

can be ascribed to culture conditions, regionalization and differentiation potential, with no major signs of activation/misregulation of potential cancer-related pathways directly attributable to a pluripotent "memory" or abnormal differentiation. We envisage that combining genetic and epigenetic analyses will clarify the dynamic changes occurring during hiPSC neural fate, helping to define a consistent "NSC signature" that might aid strategies for increasing safety and efficiency of hiPS-NSC populations to be used for cell therapy approaches.

Title: Hippocampal neurons from human pluripotent stem cells enables modeling of connectivity *in vitro*

Authors: *A. SARKAR[1], A. MEI[1], S. STERN[2], A. C. M. PAQUOLA[2], M. SOKHIREV[2], H. KIM[2], F. H. GAGE[1]

Abstract: Despite widespread interest in using human induced pluripotent stem cells (hiPSCs) in neurological disease modeling, a suitable model system to study human neuronal connectivity is lacking. Here, we report a comprehensive and efficient differentiation paradigm for hiPSCs that generate multiple CA3 pyramidal neuron subtypes as detected by single-cell RNA sequencing (RNA-seq). This differentiation paradigm exhibits characteristics of neuronal network maturation, and rabies virus tracing revealed synaptic connections between stem cell-derived dentate gyrus (DG) and CA3 neurons in vitro recapitulating the neuronal connectivity within the hippocampus. Because hippocampal dysfunction has been implicated in schizophrenia, we applied DG and CA3 differentiation paradigms to schizophrenia-patient-derived hiPSCs. We detected reduced activity in DG-CA3 co-culture and deficits in spontaneous and evoked activity in CA3 neurons from schizophrenia-patient-derived hiPSCs. Our approach offers critical insights into the network activity aspects of schizophrenia and may serve as a promising tool for modeling diseases with hippocampal vulnerability.

Title: Co-morbid HIV-Tat and morphine attenuate human neural stem cell neurogenesis and alter proteins regulating neural functions

Authors: *S. MALIK, P. SETH
Natl. Brain Res. Ctr., Gurgaon, India

Abstract: Prevalence of neuro-developmental disorders in perinatally HIV-infected children or in infants born to opioid abusing mothers suggest perturbations in neural stem/progenitor cell (NPC) functions further leading to neurobehavioral abnormalities. Since co-morbid HIV and opioids have been shown to affect the proliferative potential of NPCs, we investigated if multipotency of these cells is compromised. Human fetal NPCs were exposed to co-morbid HIV-protein, Tat and morphine and differentiation into neuronal lineage was assessed. Comprehensive gene analysis revealed reduced expression of genes involved in maintenance of NPC pool and initiation of differentiation, and simultaneous increase in certain basic helix-loop-helix (bHLH) transcriptional repressors such as *Hey* and *Hes.* Further programming of NPCs into neuronal lineage in presence of co-morbid HIV-Tat and morphine exposure revealed compromised neurogenesis which may serve as a confounding factor for HIV Associated Neurocognitive Disorders (HANDs). Following neurogenesis for up to two weeks in culture with simultaneous HIV-1 Tat and morphine exposure revealed down-regulation of several genes involved in cell adhesion, establishment and maintenance of neuronal connections and synapse assembly. Ours is the first study which has looked into neuronal differentiation of human NPCs with co-morbid HIV-1 Tat and morphine exposure and provides a new facet to HIV-drug abuse co-morbidity that may have far reaching clinical consequences both in paediatric as well as adult neuroAIDS.

Abstract: Gene regulatory regions of the human genome active in the prenatal human cerebral cortex are thought to drive human brain evolution, and contain loci that confer risk for neuropsychiatric disorders. These stages are impossible to model in a longitudinal, dynamic fashion using postmortem brain tissue. Here, by comparing human forebrain organoids derived from induced pluripotent stem cells (iPSCs) and isogenic fetal cerebral cortex, we demonstrate that, on the transcriptome and epigenome level, organoids model embryonic and early fetal cerebral cortical development before 16 week post conception. By combined analyses of histone marks, transcriptome and chromatin conformation in organoids and fetal cortex, we reveal the longitudinal dynamics of transcripts and enhancer elements at stages that bridge neural stem cell proliferation with neurogenesis. We found that the transition from neural stem cells to cortical progenitors is characterized by the largest number of differentially expressed genes (71%; 3,436 out of 4,835) and differentially active enhancers (76%; 15,485 out of 20,356), the majority of which were unique to this transition. A large fraction (34%) of the enhancer acted as gene repressors. Based on expression/activity profile across differentiation days of organoids we constructed networks of transcript/enhancer modules. These modules revealed only six and four global patterns of expression and activity changes, respectively (i.e., supermodules). Furthermore, we observed convergence of expression and enhancer modules, suggesting co-regulation by common upstream mechanisms. Specific transcriptome and enhancer modules were enriched with autism/developmental disorders associated genes or enhancers that gained activity during human brain evolution, while enhancers active at different stages of neurodevelopment were differentially enriched for personal variants in subjects with autism and developmental disorders. Lastly the identified enhancers were enriched around GWAS loci of

psychiatric disorders. Combined, the evidencesuggests the likely very early onset of these diseases and point to genes and regulatory elements related to the disease onset.

Title: A dynamic view of the proteomic landscape during differentiation of human ReNcell-VM neural progenitor cells

Authors: *Y. SONG[1,2], M. J. BERBERICH[2], K. SUBRAMANIAN[1], S. RODRIGUEZ[2], R. EVERLEY[2], T. J. MITCHISON[1], P. K. SORGER[2]
[1]Systems Biol., [2]Lab. of Systems Pharmacology, Program in Therapeut. Sci., Harvard Med. Sch., Boston, MA

Abstract: Neural differentiation requires finely-tuned temporal and spatial alterations in gene expression, protein modification, and signalling. To study the molecular and phenotypic changes during differentiation of neural progenitors, we used a highly reproducible and robust human neuroprogenitor model: the immortalized ReNcell VM cell. To advance our understanding of the complex regulation critical for brain development, we applied state-of-the-art multiplexed mass spectrometry and high-content-live-imaging, correlating quantitative changes in ~8,900 proteins and ~3,500 phosphoproteins (comprising ~11,000 phosphorylation sites) with phenotypical changes at 10 stages of neural differentiation in ReNcell VM system over 15 days. Total proteomes and immunofluorescence confirmed that ReNcell VM gave rise to neurons, astrocytes, and oligodendrocytes. Proteomics and phosphoproteomics results suggested consistent changes in pathways underlying cytoskeletal rearrangement, cell phase transition, neuronal migration, axon guidance, glial differentiation, neurotrophic signalling, extracellular matrix regulation, etc. Furthermore, the poly-selective CDK and GSK3 inhibitor kenpaullone and the HMG-CoA reductase inhibitor mevastatin have previously been reported to promote neural differentiation; proteomic and imaging data were therefore also collected from cells treated with these drugs. These studies provide a systematic set of data on progenitor cell differentiation and

drug perturbation to better understand the underlying regulatory networks and future applications of neural stem cells in health and disease.

Title: Role of piRNA and interacting exosome components in neuronal differentiation from human embryonal carcinoma cells

Authors: *Q. HU[1], C. S. SUBHRAMANYAM[2]
[1]Anat., Natl. Univ. of Singapore, Singapore, Singapore; [2]Anat., Natl. Univ. Singapore, Singapore, Singapore

Abstract: piRNAs have been reported to exist in neurons and to play some interesting somatic functions, including neurite outgrowth and maintenance of memory. However, whether piRNAs are induced to express and play any prominent role during neuronal differentiation remain unknown. Hence, we first profiled the piRNA expression in NT2 cells, a human embryonal carcinoma line, treated with *all-trans* retinoic acid (ATRA) for six days and fifteen days. It was noted that ATRA induced a dramatic change in the expression profile of piRNAs as compared to control treatment. Among the piRNAs that show a consistently increasing expression (Fold change > 2.0) over the course of ATRA treatment, we manually validated one sequence, piR-6, by Northern blot. To answer the question whether this piRNA is proactively involved in regulating neuronal differentiation, we overexpressed piR-6 in ATRA-treated NT2 cells and observed that some neuronal markers such as MAP2 and TUBB3 were further elevated as compared to regular ATRA-treated cells. Reciprocally, when this piRNA sequence was quenched by inhibitory oligonucleotides, the ATRA-induced expression of neuronal markers was significantly suppressed. To elucidate how the piRNA could modulate neuronal differentiation, we performed RNA pulldown in NT2 cells using the piR-6 mimics and analyzed the precipitates by mass spectrometry. Remarkably, piR-6 was found to precipitate exoribonucleases DIS3 and DIS3L2, both containing a single-stranded oligonucleotide binding domain, the cold shock domain (CSD). RNA immunoprecipitation confirmed that the two enzymes associate with this piRNA sequence. While DIS3 is mainly localized in the nucleus and DIS3L2 mostly

cytoplasmic, RNA FISH revealed the presence of piR-6 in both the cytoplasm and nucleus of ATRA-treated NT2 cells. Interestingly, when DIS3 or DIS3L2 was knocked down, the expression of neuronal markers was significantly reduced in ATRA-treated NT2 cells, which could not be restored even with piR-6 overexpression, suggesting that the piR-6/DIS3/DIS3L2 interaction could be essential for the normal neuronal differentiation. Given that DIS3 and DIS3L2 are directly involved in exosome-related degradation of RNAs, it is conceivable that some piRNA sequence could guide these exoribonucleases to degrade stemness transcripts and early neurogenic transcripts, hence facilitating the neuronal differentiation process. This study has suggested a novel somatic function of piRNAs, potentially related to the exosome-mediated RNA degradation, in the context of neurogenesis.

Title: GLAST expression in different developmental stages of marine echinoderms

Authors: A. B. BENÍTEZ-MATA[1], R. A. ZÚÑIGA-ASTORGA[1], F. CORREA-SANDOVAL[1], A. ORTEGA[2], *T. N. OLIVARES-BAÑUELOS[1]

Abstract: Radial Glial cells (RGC) have preserved characteristics in the *Deuterostomy* and *Protostomy* taxa, and their presence has been confirmed in adults of both monophyletic groups. Within the *Deuterostomy* taxon is the phylum *Echinodermata*, molecularly related to the chordates. Echinoderms are invertebrate organisms with a relatively simple Central Nervous System (CNS) in which RGC are the only and largest type of glial cells. Adult echinoderms are able to regenerate their CNS, which makes them suitable models in biomedical research for the neurodegeneration of fully developed mammals, including humans. Nevertheless, in echinoderms, the existence of RGC in their early development stages (represented by 4-, 6- and 8-arms echinopluteus larvae, competent larvae, and postlarvae), has not been explored. In the adult sea cucumber *Holothuria glaberrima*, a model echinoderm, it has been established that RGC generate new and functional neuron cells, and constitute the leader cells in CNS post-injury

regeneration. Research in this field will lead to important biomedical advances that improve the processes of neuronal repair in patients with neurodegenerative diseases such as Parkinson, Alzheimer or Huntington. In this context, the present research project aims to identify and characterize glial cells in the early development stages of echinoderms, to establish the time-frame it which these cells become functional, as assayed by the expression of the glial glutamate/aspartate transporter GLAST. Samples of either echinopluteus larvae or postlarvae of the echinoderm *Dendraster excentricus*, a sand dollar, were collected and GLAST was detected via Western blot. We were able to detect an increase in GLAST immunoreactivity at the beginning and at the end of echinopluteus development. Functional [^{3}H]D-aspartate uptake assays will be used to fully demonstrate the presence of glial glutamate transporters in larvae. Our results strengthen the notion of the involvement of radial glial cells in echinoderms neurogenesis.

Title: Cholinergic signaling between axon and oligodendrocyte: Implications for myelin abnormalities in Gulf War illness

Authors: *J. BELGRAD[1], D. J. DUTTA[1,2], K. A. SULLIVAN[3], J. P. O'CALLAGHAN[4], R. D. FIELDS[1]
[1]Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Develop., NIH, Bethesda, MD; [2]Henry M. Jackson Fndn. for the Advancement of Military Med., Bethesda, MD; [3]Dept. of Envrn. Hlth., Boston Univ. Sch. of Publ. Hlth., Boston, MA; [4]Natl. Inst. for Occup. Safety and Hlth., Centers for Dis. Control and Prevention, Morgantown, WV

Abstract: Cholinergic signaling has been recently implicated in myelination and as a promising target for demyelinating disorders. Despite established roles as a major neurotransmitter and source of choline metabolite, the contribution of acetylcholine (ACh) to oligodendrocyte development and myelin plasticity remains to be elucidated. Here, we show that oligodendrocytes express the receptors and enzymes necessary to engage in cholinergic signaling and respond to ACh with robust and heterogenous intracellular calcium kinetics. To investigate

the purpose of cholinergic signaling in oligodendrocytes, we studied the anticholinergic pathology associated with Gulf War Illness (GWI), the heterogeneous condition that afflicts 25% of US Veterans deployed in 1990-1991 Gulf War. Based on our previous studies, we hypothesized that the myelin abnormalities reported in GWI veterans, were due to atypical cholinergic signaling in oligodendrocytes. This hypothesis was tested using an animal model of GWI, mimicking the exposure to anticholinesterase agents (modeled by Sarin gas analog Diisopropyl fluorophosphate, DFP) and extreme stress (exogenous corticosterone, Cort). Western blot data reveals increased in myelin basic protein levels, a key protein in myelin production, in the combined Cort+DFP condition in whole brain homogenate at 24 hours and persisting through 21 days post exposure (One-way ANOVA, N=3, p=0.0141). At the molecular level, live cell calcium imaging data shows that pretreatment with DFP significantly increases the number of wild type oligodendrocytes that respond to ACh in vitro (two-tailed two-sample t-test, N= 5, p=0.005). The DFP-mediated increase in oligodendrocyte responsiveness is not due to acetylcholine produced by oligodendrocytes or astrocytes (N=3, T-test, p=0.55) suggesting GWI is a pathology of neuron-glia rather than a glia-glia cholinergic signaling. Taken together, this work demonstrates GW agents disrupt oligodendrocyte development in vivo and at the molecular level. These findings both reveal the importance of cholinergic signaling for proper myelin development and indicate that the anticholinergic and corticosterone mediated signaling by GW agents, and more generally by commercial-use pesticides, may be largely responsible for myelin changes in veterans with GWI and broader myelin-related pathologies.

Title: Sox17 transgenesis reveals sonic hedgehog- and Gli2-mediated oligodendrocyte differentiation in adult white matter

Authors: *L.-J. CHEW[1], X. MING[1], J. L. DUPREE[2], B. MCELLIN[1], V. GALLO[1]
[1]Ctr. Neurosci Res., Children's Res. Inst., Washington, DC; [2]Virginia Commonwealth Univ., Richmond, VA

Abstract: Sox17 is a Sox F transcription factor whose overexpression in CNPSox17 transgenic mice promotes postnatal oligodendrocyte development and prevents oligodendrocyte loss after

focal lysolecithin demyelination. Sox17 is expressed in remyelinating adult white matter lesions, but its function in oligodendrocyte generation is not understood. To investigate Sox17 function, we analyzed signaling mechanisms in intact and demyelinating white matter in CNPSox17 mice. Electron microscopy analysis confirms that Sox17 attenuates lysolecithin-induced demyelination, and increased BrdU+Olig2+ cells indicates de novo oligodendroglial production. Unlike in wild-type(WT) mice, activated beta-catenin (ABC) was not induced in CNPSox17 lesions, and fewer Iba1+ microglia indicates attenuated reactivity to tissue damage. Since elevated GLI2 and Sonic Hedgehog (SHH)-expressing cells were observed in CNPSox17 white matter, we determined their roles in oligodendrocyte regeneration. Targeted ablation of *Gli2* using PDGFRCreERT2 abolished Sox17-enhanced white matter thickness, suggesting Gli2 involvement in cellular homeostasis. Gli2 ablation showed that Gli2 represses CC1 cell formation in WT lesions but promotes CC1 accumulation in CNPSox17. This was accompanied by increased cells expressing beta-catenin in CNPSox17. Gli2 ablation in WT lesions instead decreased beta-catenin, indicating that Sox17 alters Gli2 function from a positive to negative regulator of beta-catenin, which in turn promotes lineage progression. Similar changes in CC1 were found following PDGFRCre-targeted Smo ablation, suggesting SHH-activated differentiation. Indeed, CNPSox17 lesions showed an increased percentage of Olig2 cells that colocalized with SHH, either from its expression or sequestration. Smo ablation also increased the number of proliferative GFAP+ cells in intact white matter, which may indicate a gliotic response. Finally, the stereotaxic application of the SMO agonist SAG in WT lesions prevents ABC increase and promotes OPC differentiation. Through increasing cell production and limiting glial reactivity, the application of Sox17 signaling targets, such as Smoothened activation with SAG, may be a viable therapeutic option for adult demyelinating disease.

Title: The *Drosophila* ADAM protein MMD participates in the early formation of both epithelial and glial boundaries

Authors: *B. A. CHASE[1], C. SENIOR-REMSA[1], A. CASTRO[1], W. ZHOU[2], C. KERBER[1], G. E. GILSON[3], K. HIGGINS[1], E. KLUG[1]

Abstract: Background: Interactions between the vertebrate proteins ADAM22, ADAM23, ADAM 11 and LGI are required in the developing peripheral nervous system for axonal sorting and myelination as well as in hippocampal neurons for trans-synaptic interactions and establishing synaptic strength. In *Drosophila*, *mmd (mind-meld*) encodes one secreted and multiple membrane-bound ADAM protein isoforms that are structurally similar to these ADAM proteins. Its transcripts are deposited maternally and become localized in the early embryo just beneath the plasma membrane. Later they become abundant in the developing CNS, indicating that *mmd* has two temporally and spatially distinct roles during development. To better understand these roles, we co-localized MMD proteins (1) in early embryos relative to cytoskeletal proteins important for the establishment of cell polarity and (2) in late embryos relative to extracellular matrix (ECM), neuronal and glial proteins important for nervous system development. **Results**: In the syncytial and cellularizing embryo, MMD is localized just beneath the apical surface in patterns indicating that it participates in the establishment of apical-basal epithelial cell polarity. During gastrulation, MMD is found along the outer epithelial surface of the embryo and remains there even as cells invaginate into the embryo. The intensity of the MMD signal in this region increases long before the cuticle is synthesized. Thus, MMD appears to be an early component of the ECM at the embryo's surface. While *mmd* mRNA expression is abundant in the developing CNS, MMD protein is not abundant within the CNS. Rather, MMD is found in the developing neural lamella that will envelop the CNS and peripheral nerves. **Conclusion:** These results suggest that MMD functions in the formation of both epithelial and glial boundaries. To test this, RNAi and the UAS-GAL4 and MARCM systems are being used to evaluate the effect of maternal and zygotic knock-down of *mmd* expression in specific tissues and cell types. Clear morphological phenotypes or effects on viability have not yet been identified. Experiments are in progress to test whether MMD interacts with other proteins involved in glial development and in establishing epithelial boundaries in the developing embryo.

Title: Single cell RNA sequencing of the humanized glial chimeric mouse brain identifies the transcriptional concomitants to human white matter maturation and myelination

Authors: *J. N. MARIANI[1], S. J. SCHANZ[1], K. M. CLARK[1], S. A. GOLDMAN[1,2,3]
[1]Ctr. for Translational Neuromedicine and the Dept. of Neurol., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Ctr. for Translational Neuromedicine, Univ. of Copenhagen Fac. of Hlth., Copenhagen, Denmark; [3]Neurosci. Ctr., Rigshospitalet, Copenhagen, Denmark

Abstract: The loss of myelin is observed in numerous devastating diseases of the CNS ranging from the hereditary leukodystrophies in children to multiple sclerosis and vascular white matter disease in adults. As such, acquisition of therapeutic targets stimulating myelin generation is of profound importance. However, neither rodent models nor in vitro studies of human cells accurately reflect the molecular regulation of human glial progenitor cell (hGPC) mobilization and myelination in vivo. To this end, in this study we used a humanized glial chimeric mouse model, allowed to develop a humanized white matter and then subjected to single cell RNA-Seq (scRNA-Seq), to begin to define the changes in oligodendroglial gene expression associated with human myelination in vivo. We established chimeric mice by neonatal transplantation of PDGFRA+ hGPCs, generated from human embryonic stem cells (WA09) and then purified by FACS, into neonatal immunodeficient and myelin-deficient shiverer mice. At 19 weeks of age, mice were sacrificed (n=3), their corpus callosa dissociated, and O4+ human and mouse oligodendroglial cells were isolated via FACS for scRNA-Seq. Expression profiling revealed the large majority of mouse cells to be oligodendrocytes (OLs). In contrast, following dimensionality reduction, human cells clustered into subpopulations consisting of PDGFRA+ GPCs, BCAS1+ immature OLs, MOBP+ mature OLs, and astrocytic progenitors upregulating GFAP and CD44. These GPCs were overall quite similar to FACS isolated human fetal and pre-transplant WA09 hGPCs with in vivo GPCs exhibiting higher degrees of lineage fidelity than their in vitro counterparts. Reconstruction of single-cell trajectories arranged cells logically in pseudotime from early GPCs to mature OLs, predicted an early branch point where GPCs opted towards astrocytic ends, and allowed for identification of genes changing as a function of time and fate. We next sought to identify transcription factors (TFs) active in subpopulations, through a combination of gene co-expression, motif enrichment, and extrapolation over cell-trajectories. This technique appropriately identified several lineage-specific TFs including SOX10 and NKX2-2 in OLs and SOX9 and HES1 in astrocytes. Through integration of these analyses, we generated a transcriptional network governing both early and late stages of myelination and astrocytic differentiation including novel TFs TFEB and ZIC1 respectively. By analyzing over 12,000 cells, we have identified pathways whose targeting may permit the therapeutic modulation of both the expansion and terminal maturation of human parenchymal glial progenitor cells.

Title: Unbiased stereological estimates of total number of astrocytes in the developing human cochlear nucleus

Authors: *S. SAINI[1], T. G. JACOB[2], A. THAKAR[3], K. K. ROY[4], T. S. S. ROY[1]
[1]Anat., All India Inst. of Med. Sci., New Delhi, India; [2]Anat., [3]Otorhinolaryngology, [4]Obstetrics and Gynaecology, All India Inst. of Med. Sci., New Delhi, India

Abstract: Introduction: Cochlear nucleus is the first central relay station in the auditory pathway that is responsible for transmitting and processing auditory information. Studies which have reported the morphological development of the cochlear nucleus in human lacks the description of glial cells. Glial cells are one of the major cell populations of the central nervous system (CNS). Astroglia, in the developing brain, help in guiding the migration of developing neurons and their processes. They also help in forming and pruning connections between neurons. Hence, these cells and their identification have key significance in any study on developing nervous tissue.A protein that is expressed early in these cells is Glial Fibrillary Acidic Protein (GFAP). Here, we have quantified astrocytes in the developing human cochlear nucleus by using unbiased stereology. **Materialsand Methods**: Twenty human brains were obtained from the departments of Obstetrics and Gynaecology and Forensic Medicine, with prior approval of the Institute Ethics Committee and informed consent from legal representatives. Sixteen were fetuses of 18-32 weeks of gestation WG; three were from the brainstems of neonates(two, three, five postnatal days- PND) and one was obtained from an infant of two-months of age. The brainstems were dissected, fixed in 4% buffered paraformaldehyde (0.1M phosphate buffer, pH 7.4), cryopreserved in 30% sucrose and sectioned on a cryomicrotome to obtain 40 µm thick serial sections. Using systemic random sampling, the sections were immunostainedfor the expression of GFAP (ab10062, 1:1000) using standard protocol. The total number of astrocytes were estimated by using the Optical Fractionator. Comparisons between the groups samples- 18-20, 21-25, 26-30 weeks of gestation and one group of postnatal samples were made using Kruskall-Wallis test. **Results:** The astroglial cells identified by GFAP contained round or elongated nucleus, outlined by a thin rim of chromatin with long processes and fine branching. The median value with interquartile range at 18-20; 21-25; 26-30 weeks of gestation and after birth were 32,087(27,399,39,033); 40,437(37,930, 45,348); 78,654(67,114, 94,614); 165,124(102,409, 182,867),respectively. A significant increase was observed in the number of astroglia in the postnatal samples versus the fetuses of weeks 18-20 ($p = 0.007$) and gestational age of 21-25 weeks ($p = 0.04$). This increase may explain the increasing size and

functioning of the cochlear nucleus with gestational age and that the gliogenesis continues postnatally too.

Title: FGF8 signaling plays an integral role during cuprizone-dependent astrocyte activation

Authors: *C. E. STEWART, W. C. CHUNG
Biol. Sci., Kent State Univ., Kent, OH

Abstract: Fibroblast growth factor (FGF) 8 signaling deficits delayed the maturation of anterior brain midline glial fibrillary acidic protein (GFAP) astrocytes. In contrast to perinatal development, the adult anterior brain midline GFAP astrocyte population did not exhibit marked deficits. Nonetheless, we cannot rule out the possibility that reduced FGF8 signaling may have disrupted adult astrocyte function. Especially in light of *in vitro* studies reporting that FGF8 increased cortical astrocyte branching complexity to facilitate wound healing. Here, we asked whether deficits in FGF8 signaling impair adult astrocyte activation. For this purpose, adult wildtype (WT) and *Fgf8* hypomorphic $^{(+/neo)}$ mice were fed with a 0.2% cuprizone (CPZ) diet for 2, 3, or 6 weeks or control chow. CPZ treatment increased GFAP expression in the medial corpus callosum (i.e., genu) in a non-genotype dependent fashion. In contrast, CPZ treatment increased GFAP expression in the lateral corpus callosum (i.e., cingulum) of $Fgf8^{+/neo}$ mice less compared to WT mice. Furthermore, we showed that after 2 weeks of CPZ treatment secondary branching was higher in WT mice than $Fgf8^{+/neo}$ mice, whereas tertiary branching was less in WT mice than $Fgf8^{+/neo}$ mice. To better understand this astrocyte activational mechanism, we used qPCR to examine CPZ effects on *Gfap*, *Stat3*, and *Fgf receptor (Fgfr) 1* mRNA expression. Prolonged CPZ exposure induced a more robust upregulation in *Stat3* and *Fgfr1* within $Fgf8^{+/neo}$ mice compared to WT mice. We then asked whether FGF8 signaling deficits impaired the CPZ-induced inflammatory response in the corpus callosum, and showed that callosal *Tnfα* mRNA production is FGF8-dependent. Together, our results showed that a developmental disruption in FGF8 signaling had long-term effects on the responsiveness of anterior brain midline astrocytes under demyelinating conditions.

Title: Signaling pathways that regulate oligodendroglia migration and differentiation

Authors: *D. J. OSTERHOUT, B. BADILLO, H. BHATTI, I. GENEVA
Dept Cell & Developmental Biol, SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Oligodendroglial progenitor cells (OPCs) are produced in the ventral neuroepithelium at later stages in the ontogenesis of the cortex. They migrate into the brain parenchyma, where they will contact axons and differentiate. As they undergo terminal differentiation, OPCs undergo prominent morphological changes, turning from a simple bipolar cell to a cell with multiple complex processes extending from the cell body. Once in contact with an axon, the oligodendrocyte process expands and begins to form the myelin membrane, which will wrap and ensheathe the axon.

Fyn tyrosine kinase is an important signaling pathway that can regulate both the migration and differentiation of oligodendroglial progenitor cells. Fyn activation occurs in progenitor cells before any changes in cellular morphology are observed. PDGF treatment will stimulate migration of OPCs and the activation of Fyn. Once active, Fyn also regulates the morphological differentiation of these cells, initiating process outgrowth and myelin sheet formation *in vitro.* In Fyn deficient mice, myelin formation is markedly reduced, demonstrating the importance of this kinase in myelination.

Fyn can interact with many downstream effectors, including molecular signaling pathways that interact with the cytoskeleton, regulating cell morphology and movement. One important interaction involves the adaptor protein Dab1. We have demonstrated that Fyn-Dab1 interactions are important for OPC migration, as animals deficient in either Fyn or Dab1 show reduced OPC migration from the subventricular zone *in vivo.* Further *in vitro* studies reveal more components of this pathway. Inhibition of Fyn-Dab1 interactions will reduce OPC migration and process outgrowth. Downstream targets of Fyn and Dab1 include Cdk 5, which may be important for migration, but not process outgrowth. Fyn interactions with additional cytoskeletal proteins influence the dynamic morphological changes during OPC differentiation.

Title: Rapid generation of mature cortical and spinal astrocytes from human iPSCs

Authors: *B. DUNGAR[1], Z.-W. DU[2]
[1]Brainxell, Madison, WI; [2]BrainXell Inc., Madison, WI

Abstract: Growing evidence implicates glia, particularly astrocytes, in neurological and psychiatric diseases. Astrocytes perform a variety of essential functions including glutamate regulation, axonal guidance, trophic support, inflammatory response, wound healing, formation of the blood-brain barrier, and neuronal synapse formation. Human cortical astrocytes are larger, structurally more complex and diverse, and respond differently to extracellular glutamate compared to their rodent counterparts. Given the unique biology of human astrocytes, it is critical that improved human-specific cell-based systems be established to enable the study of human astrocytes in health and disease. Because of the limited availability of primary human astrocytes, human iPSCs are currently used as a source of astrocytes. However, existing methods for astrocyte generation are slow (up to 6 months) or require additional selection to reduce heterogeneity. To rapidly generate mature astrocytes for disease modeling, we have developed a novel protocol that uses inducible expression of astrocyte differentiation master transcription factors NFIA and SOX9 and an optimized astrocyte differentiation medium. Human cortical or spinal astrocytes can be generated from normal or disease iPSCs in only one month. They express the key astrocyte markers GFAP and S100β at >90% and exhibit mature process-bearing morphologies. These astrocytes can promote neuron synapse formation and functional activity in MEA and calcium imaging applications and elicit a strong and rapid pro-inflammatory response. This protocol represents an important tool for modeling neurological diseases using a human iPSC-based astrocyte-neuron coculture platform, allowing the role of diseased astrocytes in neuronal degeneration to be probed.

Title: Decreased adenosine alters microglial morphology and activation during embryonic cortical development

Authors: *J. '. KEITER[1], V. MARTINEZ-CERDENO[3], S. C. NOCTOR[2]
[1]UC Davis, Vacaville, CA; [2]Psych & Behavioral Sci., UC Davis, Sacramento, CA; [3]Pathology, UC Davis/Shriner's Hosp., Sacramento, CA

Abstract: Background: ATP, a strong pro-inflammatory signal, is released under normal conditions and is converted into adenosine, a potent anti-inflammatory signal, through a series of ectoenzymes, which balances the inflammatory effect of ATP. Adenosine is removed through re-uptake or the enzymatic action of adenosine deaminase (ADA), which reduces the anti-inflammatory signal. Regulating the level of ADA therefore, modulates the suppressive effects of adenosine on inflammation. We treated animals with ADA, through either direct injection into the cerebral ventricles of embryonic pups or IP injection into pregnant dams, to determine the effect of reducing the level of adenosine on microglial cells in the cerebral cortex.
Method: ADA or saline was injected into the cerebral ventricles of rat embryos at day E18 for the direct inject group, or injected IP into pregnant dams (E18) for the dam-injected group. Microglial cell morphology was assessed 24 hours later in the ventricular zone (VZ) and in the subventricular zone (SVZ). Microglial cell morphology was quantified across groups using a defined objective morphological index value (MI), that took into account cell soma size and process length, with a low MI value representing microglial cells with an amoeboid shape, and higher MI values representing microglial cells with complex morphology and increased ramification. CD68 expression by microglia was also quantified.
Results: ADA injected into the cerebral ventricle increased the MI value of microglia in both the VZ and SVZ, with the greatest increase in MI value occurring within the VZ. We also noted increased CD68 expression within the VZ after ADA injection. ADA dam injections increased MI values for microglial cells in the SVZ but produced no change in CD68 expression.
Conclusion: Decreasing the adenosine signal with direct application of ADA into the cerebral ventricles of E18 rat embryos increased the morphological complexity of cortical microglial cells over controls, and increased CD68 expression within the VZ. These data suggest that decreasing adenosine’s suppressive effect does not produce the same effect as ATP. We also found that

microglia in the VZ and SVZ responded differentially to ADA treatment, indicating a difference in the signaling milieu within these proliferative zones and potentially pointing to functional differences in VZ versus SVZ microglial cells. Maternal injection of ADA increased the morphological complexity of microglial cells within the SVZ over the VZ, demonstrating that maternal immune perturbations can influence embryonic microglia in a region specific manner, potentially through intermediaries.

Title: Microglia and their associations with neural stem cells vary spatiotemporally in fetal human and nonhuman primate neocortical neurogenesis

Authors: *N. BARGER[1], S. C. NOCTOR[2]
[1]Univ. of California, Davis - MIND Inst., Sacramento, CA; [2]Psych & Behavioral Sci., UC Davis, Sacramento, CA

Abstract: In large-brained primate species, the cellular generation of the neocortex is a complex, protracted process that occurs primarily in utero. Microglia, brain immune cells, are increasingly recognized as critical participants in this process. We have shown that microglia interact with neural stem cells and regulate their numbers, while others suggest they contribute to wiring the fetal neocortex. Yet, little is known about microglial distributions across the primate brain during the neocortical neurogenic period, especially in the context of neural stem cells. To fill this gap, we present a comprehensive analysis of microglia and neural progenitor interactions in the developing fetal macaque neocortex at four age points through early and late neocortical neurogenesis and a preliminary comparison with human neocortex at multiple points in the second trimester. We used multiple immunofluorescence to label 10 or more coronal sections through the full rostrocaudal extent of the macaque neocortex with the general nuclear marker DAPI and antibodies against iba1, a microglial marker, and EOMES (Tbr2), a marker of cortical progenitor cells committed to a neuronal fate. We also incorporate these labels and the stem cell marker, Pax6, in a series of macaque and human cases. This design has a twofold advantage. First, it enables us to use an explicit molecular label, EOMES, to identify the ventricular, inner

subventricular, and outer subventricular zones to accurately assess microglial distribution in discrete germinal niches. Second, it provides a window into microglial interactions with different stem cell types. To assess cellular distributions, scalable images of entire coronal sections were constructed from images taken at 20x magnification on a Keyence BZ-X700 microscope. Cell-cell interactions were visualized with an Olympus FV1000 confocal microscope. We show that microglial distribution in the germinal zones changes dramatically over gestation, increasing in complexity as the primate cortex begins to differentiate. Additionally, we illustrate that stem cell-microglial interactions increase in number and complexity through human and macaque neocortical development. Given the reported role for microglia in shaping the developing cortex, this data can provide important information about the processes contributing to neocortical expansion and elaboration in human and nonhuman primates. Additionally, it may prove critical to understanding how immune disruption at specific developmental time-points contributes to lifetime susceptibility to neurodevelopmental disorders, as has been reported in the literature on maternal immune activation.

Title: The retinoic acid-synthesizing enzyme retinaldehyde dehydrogenase 2 is required for normal oligodendrogenesis and myelination in the developing postnatal brain

Authors: *V. MORRISON, J. K. HUANG
Biol., Georgetown Univ., Washington, DC

Abstract: The vitamin A-derived signaling molecule retinoic acid (RA) has been shown to affect oligodendrocyte lineage cell (OLC) progression *in vitro*. It remains unknown, however, if endogenously synthesized RA in the central nervous system (CNS) has a role in OLC progression, and therefore myelination, *in vivo*. This study uses a cell-specific knockout of the key RA-synthesizing enzyme retinaldehyde dehydrogenase 2 (Raldh2) to test the hypothesis that RA is necessary for correct OLC progression and myelination in the early postnatal period. Cell-specific excision of loxP-flanked Raldh2 was achieved using Cre recombinase under the control of the neural/glial antigen 2 (Ng2) promoter, Ng2 being largely co-expressed with Raldh2 in CNS cells. Conditional Raldh2 knockout (cKO) mice were compared to control littermates at four time points during developmental myelination (postnatal days 2, 7, 14, and 21). Using immunofluorescence microscopy, we examined differences in OLC number, maturational state, proliferation, and death, as well as the degree of myelination in the corpus callosum. We found

that cKO mice had a persistent deficit in OLCs compared to controls. Of those OLCs, more of them were oligodendrocyte precursors cells (OPCs) in cKO mice when compared to controls, while, conversely, the proportion of mature oligodendrocytes (OLs) was decreased in cKO mice. Also, in cKO mice, more OPCs were dividing, but also, more cells were undergoing cell death. Finally, cKO mice had less myelin in the corpus callosum. Together, these findings support the hypothesis that RALDH2 and the RA it creates are necessary for normal OLC progression and myelination. These findings shed light on the role of RA in the postnatal brain, and in particular, its role in regulating myelination.

Title: Identification of the Nab2 nuclear localization signal

Authors: J. M. LAVALLEE, T. GRANT, N. BERRY, S. KLETSOV, K. M. ABT, *K. W. ADAMS
Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: NGFI-A binding protein 2 (Nab2) is a transcriptional coregulator that modulates gene expression through protein-protein interactions with early growth response proteins 1-3 (Egr1-3), which play roles in a wide variety of cell behaviors. Egr1 and 2 contribute to the transcriptional program underlying neuronal differentiation of PC12 cells in response to nerve growth factor, while Nab2 plays a role in a negative feedback loop to repress their transactivation. Essential roles for Nab2 and Egr2 in development and maintenance of peripheral nerve myelination are also well established, whereas roles for Egr1 and 3 are better documented in the central nervous system, where they contribute to learning and memory through regulation of genes that mediate synaptic plasticity and long-term potentiation. Nab2 acts largely as a transcriptional repressor, at least in part by recruiting the nucleosome remodeling and deacetylase (NuRD) complex upon binding Egr1-3. However, much remains unknown about the molecular mechanisms that regulate Nab2. This study expands our knowledge of Nab2 by identifying its nuclear localization signal (NLS). More specifically, we generated an expression construct encoding a Nab2-GFP fusion protein, which localized to the nucleus following transfection. Analysis of the Nab2 sequence identified two putative NLS sequences, one spanning amino acids 263-277 that match the bipartite NLS consensus sequence ($RKX_{10}KRR$) and a second site spanning 343-346 (KKXK).

K/R-to A mutation of the site spanning 343-346 resulted in predominantly cytoplasmic localization, indicating it represents the functional Nab2 NLS. Evaluation of Nab2-GFP truncation mutant providing corroborating data; Nab2-GFP truncations that retained amino acids 343-346 all retained the nuclear localization pattern, while truncations lacking 343-346 did not. Lastly, fusion of Nab2 amino acids 340-350 to the cytoplasmic protein eIF2Bε resulted in nuclear localization. Altogether, this study used multiple approaches to determine that amino acids 343-346 (KKLK) of Nab2 function as its NLS.<!--EndFragment-->

Title: Hemocyte regulates the development of neuromuscular junctions in *Drosophila*

Authors: *D. DUAN[1], J. CHU[2], C. WU[2], Z. TING[2], S. LU[2], Y. LIU[2], S. DUAN[2]
[1]Zhejiang Univ., Zhejiang, China; [2]Zhejiang Univ. Med. Sch., Zhejiang, China

Abstract: The development of nervous system requires precise control to establish functional neuronal connectivity. Although several related processes in central nerve systems (CNS), such as synapse formation and subsequent pruning, have been well documented, the underlying regulatory mechanism in periphery nerve system (PNS) remains elusive. Here, we report that *Drosophila* macrophages, also called hemocytes, orderly migrate followed the route of ventral nerve cord (VNC) development. Localized with the marker of neuromuscular junctions (NMJs), HRP, hemocytes were observed engulfing NMJ structures spontaneously. Ablation of hemocyte decreases the number of large synaptic boutons, while increases immature ghost boutons and active zones in large boutons. Meanwhile, depletion of hemocyte also decreases amplitude of excitatory functional potentials (EJPs) while increases the frequency of miniature EJPs (mEJPs) without affect its amplitude, accompanied by an ascent in the paired-pulse ratio. Furthermore, loss of hemocytes induces locomotion behavior defects in third instar larva. Taken together, our results suggest that hemocytes regulate the morphologic and functional development of

Drosophila NMJs by controlling the ratio of large synaptic boutons and associated electrophysiological activities.

Title: A critical role of Autism-related chromatin remodeler CHD8 for oligodendrocyte development and remyelination

Authors: *C. ZHAO, C. DONG, R. LU
Brian Tumor Center, Cancer & Blood Dis. Inst., Cincinnati Children'S Hosp. Med. Ctr., Cincinnati, OH

Abstract: Disruptive mutations in chromatin remodeler CHD8 cause autism spectrum disorders, a heterogeneous disease with significant phenotypic complexity, exhibiting widespread white matter abnormalities; however, the underlying molecular and cellular mechanisms remain elusive. We show that cell-type specific deletion of Chd8 in oligodendrocyte progenitors, but not in neurons, results in myelination defects, revealing a cell-intrinsic dependence on CHD8 for oligodendrocyte lineage development, myelination and post-injury re-myelination. CHD8 activates expression of BRG1-associated SWI/SNF complexes that in turn activate CHD7, thus initiating a successive chromatin remodeling cascade that orchestrates oligodendrocyte lineage progression. Genome-wide occupancy and accessibility analyses reveal that CHD8 establishes an accessible chromatin landscape, and recruits KMT2 histone methyltransferase complexes distinctively around proximal promoters to promote oligodendrocyte differentiation. Inhibition of histone demethylase activity partially rescues myelination defects of CHD8-deficient mutants. Our data indicate that CHD8 exhibits a dual function through inducing a cascade of chromatin reprogramming and recruiting H3K4 histone methyltransferases to establish oligodendrocyte identity, suggesting potential strategies of therapeutic intervention for CHD8-associated white matter defects.

Title: A noble finding of miRNAs in neurogenic differentiation of human adipose tissue derived mesenchymal stem cells

Authors: *S. JANG, J.-S. PARK, S.-H. PARK, H.-S. JEONG
Chonnam Natl. Univ. Med. Sch., Gwangju, Korea, Republic of

Abstract: MicroRNAs (miRNAs) are small noncoding RNAs that emerge as regulators of stem cell lineage such as proliferation, development, differentiation, and apoptosis. We hypothesized that miRNA was involved in the neurogenic differentiation of mesenchymal stem cells. Here, the role of miRNAs in the neurogenic differentiation of human mesenchymal stem cells (MSCs) is investigated. By performing a miRNA-mRNA paired microarray screening, we identified miR-4650-5p and miR-3146 among the most upregulated miRNAs during neurogenic differentiation. After selection of the miRNAs, we investigated the ability of neurogenic differentiation of miRNAs in human adipose tissue-derived MSCs (hADSCs). We found that miR-4650-5p or miR-3146 was increased the most of neuronal gene expressions by a quantitative PCR. Using bioinformatics and functional assay, we confirmed that miR-4650-5p and miR-3146 potentially targeted on JNK and GSK3β to regulate Wnt signaling pathway. Overall comparative analysis revealed that Wnt signaling was enhanced more potently and played a more important role in neurogenic differentiation of hADSCs. These findings suggest that the miR-4650-5p and miR-3146 expression contributes the neurogenic differentiation of MSCs by increasing the neuronal genes and Wnt signaling pathway. The miRNAs regulation and downstream pathway network suggested the important role of miRNAs and Wnt signaling in the neurogenic differentiation of MSCs.

Title: The influence of Wnt5a activator and antagonist in neurogenic differentiation of mesenchymal stem cell *in vitro*

Authors: *H.-S. JEONG[1], S.-H. PARK[1], J.-S. PARK[1], H.-H. CHO[2], B.-C. KIM[3], S. JANG[1]
[1]Chonnam Natl. Univ., Jeollanam-Do, Korea, Republic of; [2]Otolaryngology Head and Neck Surgery, [3]Neurol., Chonnam Natl. Univ. Med. Sch., Gwangju, Korea, Republic of

Abstract: Mesenchymal stem cells (MSCs) have an ability to differentiate into multiple lineages, therefore, the possibility of neurogenic differentiation is important as a target for the clinical field. Wnt signaling, which is one of the remarkable regulators, plays a role in the development of the central nervous system and regulates the controlling neuronal differentiation. We hypothesized that regulating of Wnt signaling both activation and inhibition participated in the neurogenic differentiation of human adipose tissue-derived MSCs (hADSCs). In the present study, we developed the neurogenic differentiation of cells using an Anandamide, a Wnt5a activator, and Box5, a Frizzled-5-dependent Wnt5a antagonist, and studied the mechanisms for further differentiation *in vitro*. We treated Anandamide or Box5 and found that the Anandamide-treated cells have features such as neuron-like cells; exhibited distinct bipolar or multipolar morphologies with branched processes. Following PCR and quantitative PCR experiments, neuronal gene expressions were increased with Anandamide treatment; it was the same result; the protein levels of NFL and Tuj1 were highly expressed by immunofluorescence staining. We studied mechanisms of differentiation and found that Wnt signaling and downstream MAP kinase, especially GSK-3β pathway, were involved in neurogenic differentiation following Wnt5a activator. Especially, Wnt4 and Wnt11, which are a group of non-canonical Wnts, protein levels were highly increased after treatment of Anandamide; the Wnt5a activator could regulate the non-canonical Wnts signaling broadly. In addition, Anandamide activated through regulating Dvl2 and Dvl3 and resulted in expression of Axin level following highly increasing phosphorylated-JNK. Taken together, Wnt5a activator regulated the most of non-canonical Wnt signaling and the downstream pathway, especially controlling GSK-3β and JNK levels in the neurogenic differentiation of MSCs.

Title: Differentiation of suprachiasmatic nucleus (SCN) neurons from mouse and human fibroblasts

Authors: *M. HIRAYAMA, H. D. LE, L. S. MURE, S. PANDA
Salk Inst. For Biol. Studies, LA Jolla, CA

Abstract: The suprachiasmatic nucleus (SCN) in hypothalamus composed of heterogeneous population of 20,000 neurons acts as a master oscillator to orchestrate the approximately 24 hour cycle of behavior and physiology, which is essential for an organism to optimally adapt to environmental changes accompanying the 24 hours day/night cycle. The SCN is composed of neuropeptide expressing cells including VIP and AVP. The neuropeptides released from the SCN neurons play important roles in synchronizing circadian oscillations among SCN neurons and for communication with extra-SCN neurons. During embryonic hypothalamus ontogenesis, SCN differentiates from neuro-epithelium caudal to the optic recess. Distinct spatial and temporal patterns of expression of a small set of transcription factors (TFs) are presumed to mediate SCN development. In this study, we generated the induced SCN neurons (iSCN) from mouse and human fibroblasts by a direct conversion method with a small subset of TFs, which promotes neuronal conversion of fibroblasts into neurons with SCN neuronal phenotypes. We have identified TFs that are enriched in SCN tissue, many of which have been implicated in the differentiation and function of two principal subpopulations of SCN neurons - VIP and AVP neuropeptide expressing GABAergic neurons. We used a modified protocol of the induction method of neurons (iN) with pro-neuronal TFs of Ascl1 (Mash1) and Ngn2 (AN) with small molecule-based inhibition of glycogen synthase kinase 3β and SMAD signaling. The iN protocol in combination with a cocktail of SCN enriched TFs successfully differentiated SCN neurons (iSCN) from mouse embryonic fibroblasts (MEF). The iSCN showed efficient neuronal conversion from MEF in the neuronal conversion and maturation culture environment into

bipolar / multipolar GABAergic neurons, co-expressing VIP, which is the post-mitotic SCN enriched neuropeptides critical for the rhythmic circadian oscillation. The expression of VIP, AVP or Rorα was verified in the iSCN. The calcium transient in the iSCN showed spontaneous activities characteristic of mouse SCN neurons. Using the similar protocol we could also differentiate human fibroblasts to iSCN neurons containing GABAergic neurons with VIP or AVP expression. Our results suggest a possibility to generate principal subpopulations of SCN neurons from patients with suspected circadian rhythm disruption.

Title: Neocortical projection neurons instruct inhibitory interneuron circuit development in a lineage dependent manner

Authors: *J. C. WESTER[1], D. CALVIGIONI[5], S. HUNT[2], X. YUAN[3], C. J. MCBAIN[4]
[2]NICHD, [1]NIH, Bethesda, MD; [3]NIH, NICHD, MD; [4]Lab. Cell/Molec Neurosci, NIH, Bethesda, MD; [5]Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: In the cerebral cortex, excitatory pyramidal cells (PCs) can be segregated based on the target of their long-range axonal projection: intratelencephalic (IT) PCs target cortex/striatum while pyramidal tract (PT) PCs target the midbrain, brainstem, and spinal cord. Their output is regulated by inhibitory interneurons (INs), which can be segregated into two non-overlapping subgroups based on their embryonic lineage from either the caudal or medial ganglionic eminences (CGE and MGE). Interestingly, PCs and INs are biased in their laminar distributions: superficial layers contain exclusively IT PCs and the majority of CGE INs, while all PT PCs and the majority of MGE INs reside in deep layers. Here, we show that IT PCs influence the radial migration, molecular expression profile, and circuit integration of CGE INs during postnatal development. We used a Cre-Lox strategy in mice to conditionally knockout (KO) the transcription factor Satb2 from PCs during embryogenesis to induce them to adopt a PT-type identity. These mice were further crossed to the 5HT3A-GFP line to selectively label CGE INs. Loss of IT PCs disrupted CGE IN radial migration, such that a higher percentage of these cells settled in deep layers relative to controls. In contrast, the laminar positioning of MGE INs (PV and SOM+) was not affected. In cortex, CGE INs can be broadly parsed into VIP and Reelin

expressing subtypes. In KO mice, VIP INs were mislaminated, while the Reelin cohort was not and remained confined primarily to layer 1. VIP and Reelin expression remained non-overlapping. We probed for a third marker, CCK, which labels a small subset of superficial CGE INs. Surprisingly, the density of CCK+ CGE INs was dramatically increased in KO mice and they were found ectopically in deeper layers. We next performed dual whole-cell patch clamp recordings between PCs and CGE INs in superficial layers of KO and control mice to test for synaptic connections. We found that the probability of finding a connection from a PC to CGE IN (but not IN to PC) was significantly reduced in KO mice, suggesting IT PCs selectively target these INs. To confirm this, we injected retrograde tracers into the contralateral visual cortex or ipsilateral superior colliculus of control mice to target IT or PT PCs, respectively. In deep layers, where these types are intermingled, IT PCs made excitatory connections on to CGE INs whereas no connections from PT PCs to CGE INs were found. This connectivity bias was confirmed using combinations of transgenic mouse lines and viral vectors to drive channelrhodopsin-mediated input selectively from populations of PCs of either type. Our data show a selective influence of IT PCs on CGE IN circuit development.

Abstract: Direct reprogramming of local glial cells into neurons is a promising approach for brain repair. A key question is which glial cells to target. Astrocytes are promising candidates as they retain expression of patterning transcription factors from their ancestors in development, the radial glial cells. Thus, astrocytes may be best specified to generate neuronal subtypes appropriate for the respective brain region. However, proliferating astrocytes perform beneficial functions after brain injury. We therefore decided to target non-proliferating astrocytes using AAVs that have a slow onset of expression peaking when astrocyte proliferation is over. The neurogenic factors were cloned in flexed orientation, so they are reverted only in GFAP-Cre expressing astrocytes.
Using this system we compared direct neuronal reprogramming in different positions in the Grey Matter (GM) and White Matter (WM) of the cerebral cortex after injury. We discovered a novel combination of either proneural factors (Neurog2 or Ascl1) with a transcription factor repressing oxidative stress that allows highly efficient neuronal reprogramming in GM astrocytes. Surprisingly, this very same combination did not reprogram WM astrocytes. We further show that the reprogrammed neurons in the cortex GM acquire different identities at different layer positions, demonstrating for the first time the profound influence that the region- and layer-specific identity of astrocytes has on the neuronal subtype generated in direct reprogramming in vivo.

Abstract: Forced expression of defined transcription factors leads to the direct conversion of various cell types into induced neurons (iNs). Specifically, successful reprogramming of resident brain astrocytes *in vitro* as well as *in vivo* represents a great advantage for the generation of neurons and derived circuits. However, whether astrocytes from distinct brain regions might show a reprogramming specificity towards a unique iN type remains largely unknown. Here, we use direct reprogramming of thalamic astrocytes by *Neurog2* to generate specific excitatory sensory-modality thalamocortical neurons. Moreover, we show that the origin, but not the environment of the astrocytes determines the fate of the iNs after direct reprogramming. Indeed, clonal analysis in the thalamus shows that astrocytes from the distinct thalamic nuclei are clonally related determining the specificity of the iNs generated from those astrocytes. We also found that the potential of the same transcription factor to reprogram nuclei-specific thalamic astrocytes into precise subsets of thalamocortical neurons depends on particular epigenetic modifications. In sum, our study provides novel insights into the mechanisms that control the specification of thalamic neurons and importantly those that are required for direct programming of sensory neurons. Generation of specific sensory brain circuits might be an approach for future rehabilitation strategies.

Title: Molecular mechanisms of direct astrocyte-to-neuron conversion revealed by transcriptome analysis

Authors: *N. MA, B. PULS, J. YIN, G. CHEN
Biol., Pennsylvania State Univ., University Park, PA

Abstract: Our lab has previously demonstrated direct astrocyte-to-neuron conversion through either overexpression of a single neural transcription factor NeuroD1 (Guo et al., 2014, Cell Stem Cell) or a cocktail of small molecules (Zhang et al., 2015, Cell Stem Cell). Such direct

reprogramming technology represents a potential remedy for neuronal loss in neurodegenerative diseases and brain injuries. Despite the high conversion efficiency and fast procedure, the molecular events and downstream effectors during the astrocyte-to-neuron conversion are not well understood. To tackle these questions, we used time series analysis of RNA-seq data to characterize the transcriptome dynamics before, during, and after conversion, in order to understand the critical factors mediating such cell transition process. Administration of small molecules (core drugs: CHIR99021, DAPT, SB431542, LDN193189) significantly modified signaling pathways such as hedgehog, Wnt / β-catenin, SMAD and JAK / STAT. These signals rapidly elicited the neurogenic transcription factor network, including the members of bHLH family, and activated both excitatory and inhibitory neuronal genes. Meanwhile, converted cells exhibited a metabolic transition from glycolysis to oxidative phosphorylation, and reduced proliferation rate. Within two weeks, the gene ontology terms associated with neuronal functions became highly expressed. Moreover, we investigated the similarity and difference between chemical reprogramming mediated by core drugs and transcription factor NeuroD1 mediated cell conversion. Although both schemes turned on neurogenic programs, NeuroD1 overexpression showed more specific targeting and expedited conversion process, while core drugs had much broader effects. Together, these findings provide insights into the molecular mechanism of astrocyte-to-neuron reprogramming and may help develop efficient therapy for clinical applications. Abstract: Understanding the genetic basis for the unique power of the human brain is a fundamental goal of neuroscience and has direct implications for eradicating neural pathologies.

An approach to understand the function of genes in brain development is to genetically manipulate progenitors using single cell manual microinjection of mRNA or dye in brain models and observe the effects on neural proliferation, migration, and differentiation. A limitation of manual microinjection is that it is time consuming, results in low yield, and requires expertise which has limited its adoption as a tool for investigating cell fate. We developed a computer vision guided robot, termed the 'Autoinjector', to overcome limitations of manual microinjection (Figure 1A, 1B). We used the Autoinjector to inject neural progenitors with mRNA, and/or dye and investigated the efficiency of the process using organotypic slices of the E14.5 mouse telencephalon. We demonstrated that the Autoinjector increases yield of injection relative to manual use (10-46 fold increase, Figure 1F), allows for targeting of large (800 μm) regions of tissue (Figure 1C), does not affect viability over 0, 24, and 48 hours in culture (Figure 1D), and enables mRNA translation of injected RFP after 24 hours in culture (Figure 1E). The autoinjector platform can thus open the door to new types of experiments investigating effects of mRNA concentration, composition on cell fate and tracking these effects on cell reprogramming and lineage using fluorescent dyes.

Title: A bio-inspired artificial transcription factor for effective cellular reprogramming

Authors: *K. LEE[1], D. CHUENG[2], W. YOUNG[1], X. QIU[1], D. SUN[1]
[2]Chem. and Chem. Biol., [1]Rutgers Univ., Piscataway, NJ

Abstract: This presentation will focus on the interface between nanoscience and cellular reprogramming. Even though it is well-established that stem cell fate and cellular reprogramming are regulated by interactions that occur between microenvironmental cues and intrinsic cellular programs, our understanding of the function of the microenvironment and gene expression during the aforementioned process is hampered by the limitations of conventional methods and the lack of extensive knowledge of multiple regulatory signals. For example, the devastation associated with spinal cord injury (SCI) causes severe and permanent neurological loss. Given the intrinsically limited regenerative potential of the central nervous system (CNS) and the complex inhibitory SCI environment, there is an urgent need for effective strategies towards robust axon regeneration and neurite outgrowth of neurons to re-establish the damaged neural circuitry. In this collaborative project, we have integrated several fields of research, Nanotechnology, Biomaterials, Chemical Biology, Neuroscience, and Stem Cell Biology, to develop a novel nanomaterial-based platform that induces axon regeneration and neurite outgrowth that are safe for *in vivo* transplantation and potential clinical applications. To address the fundamental impediment of regeneration associated with SCI, we propose to develop a non-viral delivery method of axon regeneration promoting transcription factor to the injured neurons. ***NanoScript***, ***nano****particle-based artificial tran****script****ion factor protein capable of efficiently and selectively regulating genes in a non-viral manner*, is a novel synthetic transcription factor platform suited for regulating transcriptional activity and targeted gene expression (e.g., PTEN, which has been identified as a targeted protein that modulates the PTEN/mTOR pathways regulating axon growth and regeneration). In this presentation, a summary of the most updated results from these efforts and future directions will be discussed.

Abstract: The availability of viable *in vitro* models of the human retina is crucial to investigate potential therapeutic approaches and perform toxicological studies. An essential step for developing such models is the ability to generate laminated, physiologically functional and light-responsive retinal organoids from renewable and patient specific sources. We investigated different human embryonic stem cell (hESC) and human induced pluripotent stem cell (iPSC) lines and found that there is significant variability in their efficiency to generate retinal organoids. Despite such variability, by month 5 of differentiation, the organoids were able to generate light responses, albeit immature, comparable to the earliest light responses recorded from the neonatal mouse retina, around the time of eye opening. By that time, all lines exhibited laminated retinal organoids with well-formed outer nuclear like layers containing photoreceptors with inner segments, connecting cilium and outer like segments. The differentiation process was highly dependent on seeding cell density and nutrient availability. We adopted the differentiation protocol to a multiwell plate format which enhances generation of retinal organoids with retinal pigmented epithelium and improves ganglion cell development and the response to physiological stimuli. We tested the response of iPSC-derived retinal organoids to Moxifloxacin and showed that similarly to *in vivo* adult mouse retina, the primary affected cell types were photoreceptors. Together our data indicate that light responsive retinal organoids derived from carefully selected and differentiation efficient human stem cell lines can be generated at the scale needed for pharmacology and drug screening purposes.

Title: Exploring the interaction between stage II retinal waves and the glutamate release from retinal ganglion cells during development

Authors: *S.-P. HSU[1], C.-Y. YANG[1], H.-Y. CHEN[1], C.-T. WANG[1,2,3,4]
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl.

Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: During a critical period of visual circuit refinement, stage II retinal waves are initiated by the release from starburst amacrine cells (SACs), propagating to retinal ganglion cells (RGCs). We previously found that overexpressing a calcium sensor triggering exocytosis, synaptotagmin I (Syt I), in RGCs enhances wave frequency and this effect can be abolished by iGluR antagonists, suggesting that RGCs may release glutamate to modulate stage II retinal waves. However, how the glutamate release from RGCs affects stage II retinal waves remains unknown. Here, we explore the interaction between stage II retinal waves and the glutamate release from RGCs. First, to determine the presence of glutamate in developing retinas, we performed immunofluorescence staining and found that glutamate was present in RGCs and inner plexiform layer in developing retinas. Second, to detect whether glutamate release is the volume release, we applied the cell-based glutamate optical sensor in developing retinas. In retinas overexpressing Syt I in RGCs, we found that the glutamate volume release was increased in the presence of CGS 21680, a selective agonist of adenosine A2AR shown to increase wave frequency via SACs. By contrast, the glutamate volume release cannot be increased by CGS 21680 in retinas overexpressing the Syt I dominant-negative mutant in RGCs, suggesting that increasing wave frequency further enhances the glutamate volume release from RGCs. Third, to determine the causal relation between wave frequency and glutamate transmission, we bath-applied CGS, iGluR antagonists, or both. We found that the CGS-mediated increase in wave frequency was abolished by iGluR antagonists, suggesting that glutamate transmission acts at the downstream of CGS-regulation of wave frequency. Further, to determine if glutamate acts in an autocrine/retrograde manner, we transfected the glutamate optical sensor in RGCs/SACs and found that glutamate was detectable by RGCs/SACs, suggesting that glutamate acts in an autocrine or retrograde manner. Moreover, intraocular injection of iGluR antagonists diminished the eye-specific segregation of dorsal lateral geniculate nucleus. Together, our data suggest that the glutamate release from RGCs is important for regulating stage II retinal waves.

Title: Effects of the early eye removal on the visual DVR (molecular and neural) organization in chicks

Authors: R. REYES, C. NORAMBUENA, C. WEISS, G. MARIN, *J.-C. LETELIER, J. MPODOZIS
Univ. of Chile, Santiago, Chile

Abstract: One of the main components of the avian pallium is a dorsal intraventricular protrusion termed dorsal ventricular ridge (DVR), which is constituted by two apposed cellular masses: the internal nidopallium (N) and the more external mesopallium (M). The internal most aspect of the N contains discrete areas receiving auditory, visual and trigeminal ascending projections. Of particular interest to us is the visual DVR, which can be regarded as a complex composed of three highly interconnected layers: an internal nidopallial layer, the entopallium (E), in receipt of visually driven afferents from the thalamic nucleus rotundus (Rt); an overlaying nidopallial layer, the intermediate nidopallium (NI), which serves an associative role connecting to other pallial areas; and a more external mesopallial layer, the ventral mesopallium (MV) which participate in the local interlaminar circuitry. Interconnections between these layers follow a “columnar/recurrent” arrangement that features a striking resemblance with that of the interlaminar circuitry of the mammalian sensory cortex. Previously, we have found that the establishment of the highly organized Rt- E projection, as well as that of the E-MV reciprocal connectivity, occurs very early in chick development and before the retinal fibers had reached their central targets. In the present study we investigated the possible influence of the establishment of retino-central synapsis in the development and maintenance of this intrapallial circuitry. To that end we performed monocular and binocular enucleations in chick embryos early in development in order to analyze the neural arrangement as well as the molecular profile of the visual DVR at different developmental stages, from E6 to E18. We found, as classic works did, that these manipulations altered the cytoarchitecture of retinorecipient structures such as the ventral lateral Geniculate Nucleus (GLv) and the Tectum opticum (TeO), which is the source of visually driven afferents to the Rt. Even more, these enucleations also altered the structure of second order visual centers, such as the isthmic nuclei. However, neither mono nor binocular enucleations modified the pattern of connectivity and molecular pattern expression of the visual DVR at any stage of the developmental series analyzed. These results indicate that, unlike mammals, in birds the establishment and maintenance of a highly organized pallial visual circuitry is independent of the retinal afferent influences.

Title: Cross-hierarchical corticothalamic plasticity following sensory deprivation in the mouse visual system

Authors: *C. GIASAFAKI, E. GRANT, S. HAYASHI, A. HOERDER-SUABEDISSEN, Z. MOLNAR
Dept. of Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: The thalamus is considered the relay center for sensory information to the cortex and has an essential role in the regulation of fundamental brain processes, including sleep, alertness, consciousness and cognition, via various distinct nuclei. However, the mechanisms governing corticothalamic connectivity and plasticity are still largely unknown. In this study, we examine neuronal rewiring of cortical Layer 5 (L5) projections and the plasticity of these axons to structurally rearrange following visual deprivation. This compensatory mechanism is observed in the absence of visual input as a result of congenital blindness. After visually depriving L5-labelled (Rbp4-Cre::tdTomato) transgenic mice at birth by performing monocular enucleation (MoE), we study the effects on the ingrowth of corticofugal projections into visual thalamic nuclei, the first-order dorsal lateral geniculate nucleus (dLGN) and the higher-order lateral posterior nucleus (LP). L5 fibres do not normally innervate dLGN, but only higher order thalamic nuclei; however, they rewire to innervate dLGN after MoE (Grant et al., 2016 *Cereb Cortex* 26(3):1336-48). In order to investigate the origin of aberrant L5 projections in the sensory deprived dLGN (only receiving ipsilateral retinal input after enucleation), we performed injections of Cre-dependent, GFP-expressing adeno-associated virus 2 (AAV2) in the primary visual (V1) and somatosensory (S1) cortices of adult Rbp4-Cre mice (n=5 for V1, n=2 for S1) that had been monocularly enucleated at birth. Our findings indicate innervation of GFP positive axons in dLGN and LP only from V1 with formation of aberrant side branches and vesicular glutamate transporter 1 (VGluT1) positive boutons in the deprived dLGN. No alterations in the S1 projections to thalamus were observed following MoE. Additionally, we examine the molecular changes induced by MoE in the thalamus at postnatal days 6 and 8 as previous microarray and real-time quantitative PCR data from our lab demonstrated changes in gene expression in dLGN upon MoE (Grant E., 2017, unpublished data). We performed *in situ* hybridization for validating gene expression of cell signaling and extracellular matrix molecules, and confirmed differential expression in control and deprived dLGN (n=4), suggesting a potential functional role of these genes in L5 aberrant ingrowth. These findings provide opportunities for further investigation of the cellular and molecular factors implicated in the

rewiring of L5 projections in dLGN after visual deprivation, which could potentially give insights into the mechanism of cross-hierarchical corticothalamic plasticity in the mouse visual system.

Title: The organisation, dynamics and development of neural assemblies in the tectum

Authors: *T. SAINSBURY[1], G. DIANA[2], M. MEYER[2]
[2]Dept. of Developmental Neurobio., [1]King's Col. London, london, United Kingdom

Abstract: Neural assemblies (or ensembles) are groups of coactive neurons whose activity may be triggered spontaneously, by sensory stimuli or behaviour. Such assemblies are therefore likely to constitute the building blocks of brain function, but little is known about their structure, organization and dynamics. Such descriptions will provide insight into circuit connectivity, constraints and preferred states and will be crucial for determining how brain function emerges from assembly firing sequences. Here we use functional imaging in larval zebrafish to describe the structure and dynamics of spontaneous activity in the optic tectum. Using 2-photon volumetric imaging we can capture the activity of between 8,000-10,000 neurons throughout both tectal hemispheres at 4.8Hz. Using Bayesian inference techniques we are able to make probabilistic estimates of assembly number, three-dimensional structure, and within- and between-assembly dynamics. We are also using these methods to determine how tectal assemblies emerge over the course of development and how their development is shaped by activity-dependent plasticity. Specifically, we are testing how developmental shifts in the subunit composition of the NMDA receptor contribute to the developmental refinement of tectal assemblies.

Title: Profiling synapse density changes across development in the visual cortex of rats using quantitative immunofluorescence

Authors: *G. S. WITHERS, M. B. LAWRENCE, H. B. FADENRECHT, J. C. HODGSON, C. S. WALLACE
Whitman Col., Walla Walla, WA

Abstract: Classic neuroanatomical studies have shown that the net number of synapses in the visual cortex of rats increases dramatically for a period after eye opening and thereafter plateaus into adulthood. More recently, live imaging studies have demonstrated that filopodia and spines are dynamic over this entire time course, but the relative rates of addition and removal shift in ways that appear to reflect developmental status, and are likely to be predictive of synapse dynamics. Combined, these studies show an initial developmental phase that involves a higher rate of addition than removal (consistent with a net increase in synapse number), and a plateau in adulthood that suggests the rates of addition and removal attain equilibrium, and increased synapse stability. Live imaging has also revealed an intermediate period in rodent cortex when removal outpaces addition. This stage of "pruning" predicts a net reduction in synapse number. In mouse visual cortex, the temporal parameters from peak to adult levels vary by cortical region and method of imaging, but in visual cortex, it is around one month. Similar data on dynamics are not available for the rat, but determining the time course of synapse density changes could help reveal if the patterns observed in mice can be generalized to rats. Here, we used quantitative immunofluorescence and stereology to analyze how synapse and neuron density changed across development in the primary visual cortex of the Long Evans hooded rat. Littermates were housed socially, under controlled, identical conditions. Brain tissue was collected at postnatal days 7, 14, 21, 24, 30, 45, 60 and 90. Synapses were detected using an automated image analysis algorithm for coincident staining of both pre- and post-synaptic markers (antibodies for Synapsin I, or VGLUT1/2 for presynaptic sites; PSD95 was used to identify postsynaptic sites). To minimize potential variability associated with the stratified organization of cortex, we restricted our analyses to layers II/III of the primary visual cortex, and distinguished between monocular and binocular regions. The highest density of synapses was between P30 and P45, and was significantly greater than at P90. These data fit well with critical periods for visual system

plasticity in the rat, but also help to identify strategic time points for analysis of mechanisms of synapse formation and pruning associated with developmental plasticity in the rat.

Title: Mutant mouse models with reduced ionic signaling pathways have cochlear outer hair cells with disrupted efferent and afferent innervation patterns

Authors: *D. D. SIMMONS[1,2], A. COX[1], J. MCCLUSKEY[1], F. CERIANI[2], A. HENDRY[2], J.-Y. JENG[2], W. MARCOTTI[2]
[1]Biol., Baylor Univ., Waco, TX; [2]Univ. of Sheffield, Sheffield, United Kingdom

Abstract: In the mammalian cochlea, outer hair cells (OHCs) amplify vibrations of the cochlear partition that directly enhance sensitivity and frequency selectivity. The onset of OHC function depends on a variety of ionic signaling mechanisms and is associated with major changes in both afferent and efferent connections to the OHCs. Prior to the onset of hearing, afferent Type II spiral ganglion fibers and terminals form extensive arbors with OHCs, and efferent cholinergic olivocochlear fibers form terminals below OHCs.
We investigated whether disruption of either non-sensory GAP junctions or Ca^{2+} membrane channels alter afferent or efferent OHC innervation in pre-hearing mice. We used connexin 30 $(Cx30)^{-/-}$ mice to investigate disruption of GAP junctions in non-sensory cells, and voltage-gated Ca^{2+} channel 1.3 $(Cav1.3)^{-/-}$ mice to investigate disruption of Ca^{2+} entry through voltage-gated channels. Compared to wild-type controls, $Cx30^{-/-}$ mice had fewer peripherin-labeled outer spiral fibers (OSFs), reduced peripherin-labeled OSFs crossing the tunnel of Corti, fewer choline acetyltransferase (ChAT)-labeled efferent fibers crossing the tunnel of Corti, and absent or irregular efferent terminals. Compared to wild-type controls, $Cav1.3^{-/-}$ mice demonstrated a similar reduction in peripherin-labeled OSFs but unlike either $Cx30^{-/-}$ or wild-type controls, OSFs in $Cav1.3^{-/-}$ mice spiraled in both apical and basal directions. Also compared to wild-type controls, $Cav1.3^{-/-}$ mice had fewer ChAT-labeled tunnel crossing fibers, highly disorganized efferent terminal patterns, and very dense ChAT labeling below inner hair cells. For both $Cx30^{-/-}$

and Cav1.3$^{-/-}$ mice, these innervation abnormalities were more severe in the apex. Furthermore, we found presynaptic ribbons (e.g., CtBP2) and postsynaptic proteins (e.g., SK2) altered in Cav1.3$^{-/-}$ mice, but only presynaptic ribbons altered in Cx30$^{-/-}$ mice. We conclude that disruption of ionic signaling mechanisms via the absence of connexins in non-sensory cells or the lack of Ca^{2+} voltage-gated membrane channels severely alters afferent and efferent innervation patterns. Thus, both of these signaling paths are critical for the maturation of normal cochlear OHC innervation.

Title: Rapid terminal reorganization within local target territories during formation of the giant nerve terminal, the calyx of Held

Authors: *D. R. JACKSON[1], J. M. HEDDLESTON[2], M. MOOREHEAD[1], T.-L. CHEW[2], S. PIDHORSKYI[1], P. S. HOLCOMB[1], S. SIVARAMAKRISHNAN[1], S. M. YOUNG, JR[3], S. RAY[1], T. DEERINCK[4], M. H. ELLISMAN[4], G. A. SPIROU[1]

Abstract: The large CNS nerve terminal, the calyx of Held (CH), provides strong and temporally precise excitation to targeted principal cells of the medial nucleus of the trapezoid body (MNTB). CHs exhibit hallmark developmental features of strengthening and pruning necessary to yield monoinnervation of MNTB neurons. Using serial block-face scanning electron microscopy (SBEM) collected from neonatal littermate mice (24-48 hr sampling), we previously found that between postnatal (P) days 2 and 4, most of 10-20 small pioneering inputs on each cell are pruned while 1-3 terminals grow at rates of 200 μm^2 per day. By P6, 75% of principal cells are monoinnervated. During this period, collateral processes of variable length extend from

the edges of the CH and are known sites of Ca entry. Although we found no evidence of direct interaction between CHs along the principal cell soma, collaterals largely occupy shared territories. However, little is known about their function in this system. Our lab is interested in the competition that mediates this competitive process. Here, we sought to examine the temporal dynamics of synaptic organization in the MNTB as it relates to the ultrastructure revealed with SBEM. We employed lattice light-sheet (LLS) microscopy which offers rapid and high-resolution image acquisition with minimal bleaching. Acute coronal brainstem slices (300-600 μm thickness) were collected in neonatal mice ranging from P0-14. Following 4D image acquisition, data was imported into syGlass, a custom software package designed in-house, for immersive virtual reality (VR) aided-analysis. Processes were manually tracked in syGlass to reveal growth dynamics of CHs and their associated processes, both filopodia- and growth cone-tipped terminal arbors. We found these collaterals form a dynamic field around each CH. Peak motility coincided with CH growth and peak dynamics rival or exceeded rates of axonal extension described elsewhere in the CNS. Growth cones, perhaps the most dynamic feature of this system, extended fastest during the ages of CH expansion, yet slowed as monoinnervation was established (P2: 21±18 μm/hr; P3: 43±20 μm/hr; P4: 58±24 μm/hr; P5: 58±21 μm/hr). Moreover, live imaging and ultrastructural analysis presented here established CH arbors repeatedly form transient associations with other CHs, neurons and glia within the neuropil. Thus, physical interaction may serve an instructive role in circuit formation within the MNTB. In summary, these data are effective in monitoring the navigation patterns of assembling neural circuits in an intact system and reveal the dynamic nature of growth and retraction of developing neurite reorganization.

Title: Contributions of peri-neuronal nets to parvalbumin-positive interneuron excitability in developing mouse auditory cortex (A1)

Authors: S. MAPLES[1], J. KOKASH[2], K. RAZAK[1], T. A. FIACCO[3], *P. W. HICKMOTT[1]
[1]Psychology & Interdepartmental Neurosci. Pgm., [2]Interdepartmental Neurosci. Pgm., [3]Dept. of

Cellular, Mol. and Systems Biol. & Interdpartmental Neurosci. Pgm., Univ. California, Riverside, Riverside, CA

Abstract: Cellular and circuit properties of primary auditory cortex (A1) change during postnatal development. In particular, by approximately P21 in mice and rats, the response properties and the balance of excitation and inhibition in A1 are similar to those found in adults. This maturation of the A1 circuit also approximately coincides with the closure of the critical period for changes in tonotopy in A1. Thus, the period from P14-P21 in mice is a time of considerable change in the properties of A1.

One important population of inhibitory interneurons in neocortex are parvalbumin-positive (PV) cells. PV cells are known to participate in the proper development and regulation of the balance of excitation and inhibition in a variety of cortical areas. An interesting feature of these PV cells is that most of them are surrounded by an extracellular matrix structure referred to as a peri-neuronal net (PNN). PNNs are known to regulate the excitability of neurons that they surround, and the number of PV cells that are surrounded by PNNs increases from P14 to P21 in mouse A1. Therefore, we hypothesize that at least some of the changes in A1 circuit properties from P14-P21 are regulated by the emergence of PNNs, due to their influence on PV neuron excitability.

We have performed whole-cell recordings *in vitro* from slices of A1 in mice that express the fluorophore tdTomato specifically in PV cells. This preparation allows us to specifically target only PV neurons. We have analyzed data from P14-P21 mice because it is during this developmental period that the PNNs are developing in A1. In order to assess their intrinsic excitability, we have determined their responses to hyperpolarizing and depolarizing steps of current (500 msec duration). We have also examined synaptic excitability onto these cells by analyzing spontaneous synaptic events. After these recordings the presence or absence of PNNs around the PV cells was determined using staining for wisteria floribunda lectin (WFA), which labels PNNs, and confocal microscopy. We will present data comparing the excitability of PV neurons that are surrounded by PNNs and those that are not. We hypothesize that PV neurons without PNNs will exhibit reduced excitability (either intrinsic or synaptic) as compared to those that express PNNs.

Title: Clustered protocadherins regulated high reciprocal connectivity between clonal cortical neurons are selectively modified by short sensory deprivation in mouse barrel cortex

Authors: *E. TARUSAWA[1], M. SANBO[2], M. HIRABAYASHI[2], T. YAGI[1], Y. YOSHIMURA[3]

Abstract: The specificity of neural connections in the sensory cortex is fundamental for the proper processing of sensory information. We previously have shown that high reciprocal connectivity is established between clonal cortical neurons and it's regulated by clustered protocadherins in mouse barrel cortex. In this study, we analyzed the effect of sensory experience on the establishment of the cell-lineage-dependent reciprocal connectivity. To visualize clonal neurons, we generated chimeric mice by injecting a small number of induced pluripotent stem cells (iPS cells) marked with GFP into blastocysts. We conducted dual whole-cell recordings from GFP-positive neuron pairs (presumed clonal pairs) or GFP-positive and negative neuron pairs (non-clonal pairs) within a layer 4 barrel in cortical slices prepared from the chimeric mice. Sensory deprivation was produced by whisker trimming from postnatal day 13 (P13) to a day before recording.
In normal development, there was no significant difference in the connection probability (the number of detected connections/the number of tested connections) between clonal and non-clonal pairs at P9-11. The probability increased significantly from P9-11 to P15-16 and then decreased only in clonal pairs, resulting in the same connection probability in clonal and non-clonal pairs at P18-20. Sensory deprivation completely prevented the temporal increase in the connection probability only in clonal pairs. Therefore, cell-lineage-specific neural connections seem selectively modified by sensory experience.
We next analyzed the reciprocity, the proportion of reciprocally connected pairs among connected pairs. The reciprocity was not significantly different between clonal and non-clonal neuron pairs at P9-11. Then the reciprocity continued to increase significantly in clonal pairs until P18-20, whereas it showed only an insignificant increase in non-clonal pairs during that period. Sensory deprivation prevented almost completely the increase in the reciprocity in clonal pairs, while it did not affect the reciprocity in non-clonal pairs. These results suggest that the sensory inputs are required for the proper function of clustered protocadherins leading to establishment of cell-lineage-dependent reciprocal connections.

Abstract: Proper neuronal circuit function relies on precise dendritic projection, which is established through activity-dependent refinement during early postnatal development. Here we revealed the dynamic mechanisms associated with dendritic refinement in the mammalian brain by conducting long-term in vivo imaging of the neonatal mouse barrel cortex. In the mature mouse barrel cortex, spiny stellate (SS) neurons and thalamocortical (TC) axon termini form “barrels” that are morphologically and functionally distinct modules corresponding to individual whiskers on the face. In each barrel, SS neurons are located around the barrel edge and extend the basal dendrites (BDs) selectively toward the barrel center to make synapses with TC axons. We visualized SS neurons in vivo by using in utero electroporation-based Supernova labeling (Mizuno et al., 2014; Luo et al., 2016) and TC axons by using the TCA-GFP Tg mouse (Mizuno et al., 2014). By “retrospective” analyses, we identified “prospective” barrel-edge SS neurons in early neonates, which had an apical dendrite and primitive BDs. These neurons retracted the apical dendrite gradually and established strong BD orientation bias through continuous “dendritic tree” turnover. A greater chance of longevity was given to BD trees emerged in the barrel-center side, where TC axons cluster. Additionally, we conducted long-term in vivo imaging and in vivo calcium imaging of infraorbital nerve cut mice to investigate the impact of the neural activity on the dendritic refinement. Our in vivo imaging system contributes to understanding of developmental mechanisms of cortical maturation in neonates.

Title: Effects of exogenously administered cannabinoids on axonal projections of L4 neurons in the mouse barrel cortex

Authors: *C. ITAMI[1], J.-Y. HUANG[2], H.-C. LU[3], F. KIMURA[4]
[1]Saitama Med. Univ., Saitama, Japan; [3]Dept. of Psychological & Brain Sci., [2]Indiana Univ. Bloomington Dept. of Psychological and Brain Sci., Bloomington, IN; [4]Grad. Sch. Med., Osaka Univ., Suita, Japan

Abstract: Recent studies revealed that cannabinoid CB_1 receptors (CB_1Rs) play important roles in the development of neural circuit formation and plasticity. In the rodent barrel cortex, CB_1Rs at the thalamocortical terminals causes a developmental switch from long-term potentiation (LTP) to long-term depression (LTD) both in a spike timing dependent manner (tLTP, tLTD) during the second postnatal week. In addition, endogenous cannabinoid ligands help regulate the thalamocortical termination within layer 4 (L4) barrel areas since disorganized thalamocortical termination was observed in CB_1R-KOs (Itami, 2016). Subsequently, CB_1Rs appear at L4 terminals from the beginning of the third postnatal week (P13-15), as we showed previously, which again causes a switch from tLTP to standard STDP with LTP and LTD components. We also showed that L4 axon morphology is attenuated in mutant mice lacking an endogenous ligand, 2-arachidonoylglycerol (2-AG) synthesizing enzyme, diacylglycerol lipase α (DGLα). In the present study, we asked whether administration of cannabinoid agonists causes any effects on L4 axon morphology. We injected either Δ^9-tetrahydrocannabinol (THC, 2mg/Kg body weight, i.p.), or WIN, a CB1R agonist (5mg/Kg, i.p.) from postnatal day 12 (P12) to P22. At P18-22, thalamocortical slice were made and whole-cell patch recordings were performed from L4 spiny stellate neurons using neurobiotin in the recording pipettes. Slices were fixed with PFA, then observed under confocal microscopy, and axon morphology was analyzed with Image-J and Neurolucida. There were significant reduction in total axon length of L4 spiny stellate neurons in CB1R agonist-treated animals. In control, total axon length was 9037±716 μm (n=12), but it was 8237±444 μm in THC ($p<0.05$, n=13), and 6272±531 μm in WIN ($p<0.01$, n=5). Similarly, axon length in L2/3, home column in L2/3 were also significantly reduced in THC and WIN treated

animals. These results, together with DGLα-KO study, indicate that cannabinoid signalling plays an important role in regulating L4 axon morphology during development.

Title: Single-cell molecular connectomics of somatosensory cortex circuit assembly

Authors: *E. KLINGLER[1], J. PRADOS[1], J. KEBSCHULL[2], A. ZADOR[3], A. DAYER[1], D. JABAUDON[1]
[1]Basic Neurosci., Univ. of Geneva, Geneve, Switzerland; [2]Biol., Stanford university, Stanford, CA; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Intracortically projecting neurons are a heterogeneous population, which send their axon across cortical areas, both within and across hemispheres. Understanding the precise connectivity and diversity of these neurons is important, because intracortical projections allow coordination of neuronal activity across cortical areas and behaviourally critical sensorimotor transformation. Although population-based intracortical wiring diagrams have been identified, the single-cell connectivity of these neurons and their corresponding developmental transcriptional programs remain unknown. Here, we address this question by combining a barcoding strategy to identify single-cell connectomics (Kebschull et al., Neuron, 2016), with single-cell RNA sequencing to identify the developmental gene expression programs of hodologically-defined single neurons. By combining these two scalable single-cell resolution approaches, we showed developmental dynamics of primary somatosensory intracortical projections and found transcriptional programs defining specific connectivity patterns.

Title: Multiple morphological factors underlie experience-dependent crossmodal plasticity in the sensory cortices

Authors: M. WANG, Z. YU, *X. YU
Inst. of Neurosci., Shanghai City, China

Abstract: During the early postnatal period, neural activity, both in the form of spontaneous electrical activity and sensory stimulation, is critical to the formation of functional neural circuits. A large body of work using unimodal sensory deprivation manipulations has shown that depriving the appropriate inputs during early development reduced responsiveness in the corresponding cortical region. Previous work in our laboratory showed that whisker deprivation (WD) during early development not only reduced the excitatory synaptic transmission of the correspondent cortical region, but also crossmodally reduced synaptic transmission in other sensory cortices (Zheng et al., Nat. Neurosci., 2014, doi:10.1038/nn.3634). Here, we investigate the morphological basis of this crossmodal plasticity. We found that WD from P0 to P14 reduced presynaptic bouton density, and possibly also spine density, of L2/3 pyramidal neurons in the primary somatosensory cortex (S1), as well as crossmodally in the primary auditory cortex (Au1). Combining *in utero* electroporation with an optimized optical clearing agent for high-resolution fluorescence imaging (SeeDB2), we identified various changes in dendrite and axon arborization the S1 and Au1 of WD mice. Increasing sensory experience by rearing mice in an enriched environment significantly rescued the effects of sensory deprivation, providing evidence for directional regulation of structural plasticity by sensory experience. Together, these results demonstrate that multiple morphological factors contribute to experience-dependent structural plasticity during early neural circuit development.

Title: Integrative behavioral, molecular and electrophysiological analyses of female Mecp2$^{tm1.1\ Bird}$ Rett syndrome model

Authors: *J. A. SANCHEZ, J. PALMA, K. KRETSCHMANNOVA, J. BELTRAN, M. KWAN, L. THIEDE, T. HANANIA, A. GHAVAMI
Psychogenics, Inc, Paramus, NJ

Abstract: Rett Syndrome is a neurodevelopmental disorder caused by mutations in the *Mecp2* gene encoding for the methyl-CpG-binding protein 2 (MeCP2). While most studies have analyzed male *Mecp2* mice, analysis of female mice is clinically relevant to the female population of Rett syndrome patients. A combination of behavioral, molecular, and electrophysiological techniques has been employed here in the female Mecp2$^{tm1.1Bird}$ model (CreLox-deletion of exon3-4 deletion). Behavioral studies in female Mecp2$^{tm1.1Bird}$ mice show that the heterozygous mice have motor imbalance, gait deficits, breathing abnormalities, and impaired cognitive function. Extracellular field recordings in hippocampal slices from 6-month old female Mecp2$^{tm1.1Bird}$ mice displayed a reduction in long-term potentiation (LTP) at the Schaffer collateral-CA1 synapse. Given that MeCP2 protein regulates gene expression, quantitative polymerase chain reaction (qPCR) analysis was employed here using hippocampal tissue from 4 and 10-month old female Mecp2$^{tm1.1Bird}$. qPCR analysis revealed a reduction in three known genes regulated by MeCP2: *Bdnf*, *Sapap3*, and *Kir4.1*. A reduction in mRNA coding for synaptic markers *Psd95* and *synaptophysin* was also detected along with upregulated mRNA levels for glutamate receptors (*Glur1*, *Glur2*, *Nr2a*, and *Nr2b*). Altogether, this integrative analysis suggests that female *Mecp2* mice displayed significant behavioral and synaptic plasticity deficits, along with robust alterations in gene expression that can be utilized as disease readouts for preclinical testing.

Title: Neuronal redox-imbalance in Rett syndrome affects mitochondria as well as cytosol, and is accompanied by intensified mitochondrial O_2 consumption and ROS release

Authors: *M. MUELLER, K. CAN, C. MENZFELD, P. REHLING, S. KUEGLER, J. DUDEK
Zentrum Physiologie & Pathophysiologie, Universitätsmedizin Göttingen, Göttingen, Germany

Abstract: Rett syndrome (RTT), an X chromosome-linked neurodevelopmental disorder affecting almost exclusively females, is associated with various mitochondrial alterations. Mitochondria are swollen, show altered respiratory rates, and their inner membrane is leaking protons. To advance the understanding of these disturbances and to clarify their link to redox impairment and oxidative stress in RTT, we assessed mitochondrial respiration in defined brain regions and cardiac tissue of male wildtype (WT) and MeCP2-deficient (*Mecp2*$^{-/y}$) mice. Also, we quantified for the first time neuronal redox-balance with subcellular resolution in cytosol and mitochondrial matrix. Quantitative roGFP1 redox imaging revealed more oxidized conditions in the cytosol of *Mecp2*$^{-/y}$ hippocampal neurons than in WT neurons. Furthermore, cytosol and mitochondria of *Mecp2*$^{-/y}$ neurons showed clearly exaggerated redox-responses to hypoxia and cell-endogenous reactive oxygen species (ROS) formation. Biochemical analyzes exclude a disease-related increase in mitochondrial mass in *Mecp2*$^{-/y}$ hippocampus and cortex. Protein levels of complex I core constituents were slightly lower in *Mecp2*$^{-/y}$ hippocampus and cortex than in WT; those of complex V were lower in *Mecp2*$^{-/y}$ cortex. Respiratory supercomplex-formation did not differ among genotypes. Yet, due to reverse electron flow into complex I, mitochondria of *Mecp2*$^{-/y}$ cortex and hippocampus consumed more O_2 than WT. Furthermore, mitochondria from *Mecp2*$^{-/y}$ hippocampus released more ROS. In conclusion, we further advanced the molecular understanding of mitochondrial dysfunction in RTT. Intensified mitochondrial O_2 consumption, increased mitochondrial ROS generation and disturbed redox balance in mitochondria and cytosol represent a causal chain, which provokes dysregulated proteins, oxidative tissue damage, and finally neuronal network dysfunction in RTT.

Abstract: Rett syndrome is a rare neurological disorder associated with a mutation in the X-linked gene MECP2. This disorder mostly affects females, who typically have normal early development followed by a regression of skills. The Mecp2 transgenic rat model of Rett syndrome exhibits similar symptoms shown in patients such as seizures, anxiety, breathing abnormalities, motor and auditory deficits. Individuals with Rett syndrome and Mecp2 heterozygous rats both exhibit atypical neural and behavioral processing of auditory stimuli, which likely impacts effective speech processing. The development of therapies that can enhance plasticity in auditory networks and improve speech processing has the potential to impact the lives of individuals with Rett syndrome.
Here, we tested two potential strategies, Insulin-like growth factor 1 (IGF-1) or vagus nerve stimulation (VNS) paired with auditory stimuli, to restore auditory processing in MeCP2 transgenic rats. IGF-1 has been successfully utilized in both human clinical trials and in rodent models, with improvements in apnea, anxiety, and restoration of plasticity deficits. Similarly, evidence suggests that precisely-timed VNS-sound pairing can drive robust neuroplasticity and enhance the benefits of rehabilitation.
Following 2 weeks of IGF-1 or saline therapy during development, heterozygous Mecp2 and WT rats were trained to discriminate speech sounds in quiet and in various levels of background noise to assess speech discrimination abilities. IGF-1 therapy did not improve speech discrimination performance in Mecp2 rats. In a separate experiment, auditory cortex responses were examined in heterozygous Mecp2 rats following 20 days of VNS-tone pairing or sham therapy. Preliminary results suggest that VNS may improve abnormal auditory cortex responses

in Mecp2 rats. These studies could lead to the development of novel adjunctive therapies that could enhance auditory functioning, and ultimately improve the quality of life of individuals with Rett syndrome.

Title: Programmable transcription of MECP2 and CDKL5 suggests limited binding of dCas9 to the inactive X chromosome

Authors: *J. A. HALMAI[1], P. DENG[3], J. L. CARTER[5], D. CAMERON[1], N. COGGINS[4], D. SEGAL[4], J. NOLTA[1], K. FINK[2]

Abstract: Neurological diseases are a heterogeneous group of disorders caused by alterations in nervous system function and many of these disorders can be attributed to genetic factors such as chromosomal aberrations or gene mutations. The neurodevelopmental disorders Rett Syndrome (RTT) and CDKL5 deficiency disorder (CDD) are caused by de novo mutations in MECP2 and CDKL5 on the X-chromosome, respectively. Females with RTT or CDD undergo X-chromosome inactivation (XCI) forming a mosaic of cells expressing mutant and wild type alleles. Our research is focused on methods to specifically reactivate the healthy CDKL5 and MECP2 allele on the silenced X-chromosome in human neuronal-like cell lines. Despite the availability of small molecule drugs that can globally reactivate XCI-silenced genes, locus specific approaches remain elusive. Our group has been the first to identify proximal cis regulatory elements in the CDKL5 and MECP2 core promoter regions using CRISPR/dCas9 fused to effector domains for programmable transcription in several neuronal-like cells, including the male U87 as well as in the female SH-SY5Y and LUHMES cell lines. The observed increase in gene expression and protein levels could be due to superactivation of the

active allele, activation of the silenced allele, or a combination of the two. We sought to investigate if the preferred superactivation of CDKL5 and MECP2 expression is due to limited binding of dCas9 to the inactive X chromosome. Overlay of >80,000 SNPs in SH-SY5Y cells with ATAC-seq data sets further allowed us to investigate the accessibility of the inactive versus active X-chromosome with our dCas9 approach. Synergistic approaches using targeted DNA demethylation of CDKL5 and MECP2 paired with LwCas13a RNA targeting of the XCI key player long-non coding RNA XIST suggest increased accessibility by ATAC-seq and induction of locus-specific escape from XCI. This approach holds great potential for individuals suffering from RTT and CDD.

Title: Characterization of mammalian target of rapamycin (mTOR) pathway alterations in Rett syndrome mice model

Authors: *S. RANGASAMY, B. GERALD, L. LLACI, M. STRINGER, G. MILLS, E. FRANKEL, R. GUPTA, V. NARAYANAN

Abstract: Rett syndrome (RTT), an X-linked dominant neurological disorder, is caused by *MECP2* gene mutations. Although multiple neurological abnormalities characterize RTT, reduced brain and neuronal soma size are the most consistent neuropathological findings observed in human brain and Mecp2 mutant mouse models. Studies in several organisms have shown that mTOR signaling pathway regulates cell size. Emerging evidence indicates the general dysfunction of the Akt/mTOR pathway connected to neuronal soma size in RTT models. The mTOR pathway operates through two different complexes: i) mTORC1, linked to RAPTOR, that response to signals, including growth factors and nutrients, and ii) mTORC2, connected to RICTOR, responds primarily to growth factors. The relative contribution of mTORC1 and mTORC2 signaling modifications in the pathogenesis of RTT remains still elusive. In this study, we explored the role of mTORC1 and mTORC2 signaling pathway alteration in the *Mecp2 A140V* and *Mecp2*$^{-/-}$ mouse models. Using qPCR, western blot and immunofluorescence assays, we quantified the relative levels of mTOR pathway molecules from brain and tissue sections of

male and female mice of age-matched *Mecp2* mutant and wild type. We found that mTORC2 pathway is considerably downregulated in *Mecp2 A140V* mice. Furthermore, comprehensive protein analysis revealed alterations overlapping both the mTORC1 and mTORC2 signaling pathway in the *Mecp2* mouse models. We further tested if mTOR activation rescues biochemical deficits in the Mecp2 mutant animals by crossing female carriers *(Mecp2$^{-/+}$)* with *Tsc2 (Tsc2$^{-/+}$)* mutant males. Genetic rescue reverses some of the biochemical abnormalities in mTOR signaling, including Akt activity. Akt-T308 phosphorylated form is essential for the Akt activation and the downstream function. In our study, we found that the phosphorylation of Akt-T308 was significantly downregulated, and this was rescued in *Mecp2 A140V-Tsc2$^{+/-}$* model (TSC2-A140V). We also found a significant reduction in the phosphorylation of S6K1 in A140V mice, which was rescued in the TSC2-A140V brain. We provide here direct biochemical evidence supporting the role of downregulated mTOR signaling pathway, which can be salvaged in Rett syndrome model. Our current studies defining the role of mTOR activation in the reversal of RTT phenotype may serve as a central strategy for the development of novel therapeutics to treat Rett syndrome.

Title: Glial-targeted glutamate antagonism for the treatment of Rett Syndrome phenotype in Mecp2-deficient mice

Authors: *E. S. SMITH[1], A. SHARMA[2], M. NEDELCOVYCH[3], C. O'FERRALL[1], R. RAIS[3], M. V. JOHNSTON[4], B. S. SLUSHER[3], R. M. KANNAN[2], M. BLUE[4], S. KANNAN[1]

Abstract: Glutamate dysregulation plays a prominent role in the neuropathology in Rett Syndrome (RTT) and in mouse models of RTT. Patients show increased presence of glutamate and glutamate metabolites in CSF. Work in *Mecp2*-null mouse models has shown that this increase in glutamate may be specific to microglia and can contribute to excitotoxicity and cellular injury. This combined with other coinciding neuropathology (i.e. oxidative stress, altered

NMDA receptor expression) could potentially contribute to cell stress and toxicity as well as neurobehavioral consequences associated with RTT. Blockade of glutamate synthesis via inhibition of the enzyme glutaminase is a potential therapeutic avenue for targeting diseases where glutamate levels are excessive. However, known glutaminase inhibitors are poor drug candidates for RTT due to limited brain penetration. Furthermore, global/universal inhibition of glutamate production throughout all cells in the nervous system would not be desirable in a developing brain, as neurons require glutamate for proper functionality. Our data demonstrate elevated levels of glutamine in both hippocampus and striatum of *Mecp2*-deficient mice suggesting that targeting glutamine may be a more effective route. Glutamine antagonists such as 6-diazo-5-oxo-L-norleucine (DON) have a structure similar to L-glutamine and broadly inhibit glutamine-utilizing pathways including glutaminase, but their clinical application has been limited due to toxic side effects. Thus we chose to investigate the utility of PAMAM dendrimers to deliver a glutamine antagonist to the brain to decrease glutamate production. PAMAM dendrimers are selectively taken up in 'activated' microglia and astrocytes making them an ideal candidate for targeted inhibition of glutamate formation in these cells. We conjugated a prodrug of DON to the dendrimer and evaluated the efficacy in a *Mecp2*-null mouse model of RTT. Preliminary findings indicate that weekly dendrimer-delivered DON prodrug administration beginning at postnatal day 21 improves the neurobehavioral phenotype including paw clench and gait abnormalities in *Mecp2*-null mice. Further work is being done to characterize the impact of systemic injection of the dendrimer-drug conjugates on microglia health and phenotype as well as glutamate production. Our preliminary results indicate that dendrimer-mediated inhibition of glutamate production may be a viable treatment approach for reducing glutamate-related neuropathology in RTT.

Title: Effects of the antitussive cloperastine on a rett syndrome mouse model

Authors: *C. M. JOHNSON, N. CUI, H. XING, Z. LI, C. JIANG
Biol., Georgia State Univ., Atlanta, GA

Abstract: Rett Syndrome (RS) is a neurodevelopmental disorder caused mostly by mutations in the *MECP2* gene. RS patients show characteristic breathing abnormalities that respond to GABA receptor agonists, and are likely to be a result of increased brainstem neuronal excitability. GIRK channels play a role in regulation of membrane potentials, and thus may be a potential therapeutic target for RS symptom release. GIRK channels have previously been shown to act on brainstem neurons. Indeed, the GIRK channel inhibitor Cloperastine is currently available as an over-the-counter antitussive in several Asian and European countries. In this study, we tested whether Cloperastine had effects on breathing abnormalities in *Mecp2*-deficient mice as well as potential mechanisms. We found that Cloperastine reduced apnea counts in *Mecp2*-null mice. Significant reduction in apnea counts started 0.5 hours after Cloperastine administration (30mg/kg, ip), and lasted ~4 hours. Similar inhibition of breathing frequency variability was also seen. In the heterologous HEK expression system, Cloperastine potently inhibited GIRK1-GIRK2 channels with an IC50 ~2 μM. In whole-cell current clamp, 10 μM Cloperastine had both inhibitory and excitatory effects on norepinephrinergic neurons in the locus coeruleus and GABAergic neurons in the dorsal tegmental nucleus. Because these opposite effects could be produced by pre- and postsynaptic mechanisms, we studied GABAergic inhibitory postsynaptic currents (IPSCs) in locus coeruleus neurons in voltage clamp. The predominant effect of Cloperastine was an increase in GABAergic IPSC frequency as well as IPSC amplitude to a lesser degree, which was inhibited in the presence of the $GABA_B$ receptor inhibitor Phaclofen. These results suggest that Cloperastine seems to have beneficial effects on breathing abnormalities in the RS model, which has fast onset lasts 4 h, and involves inhibition of GIRK channel-dependent presynaptic $GABA_B$ receptors.

Title: Reduction of aberrant NF-kB signaling and vitamin D supplementation ameliorate Rett syndrome cortical phenotypes in Mecp2-null mice

Authors: *M. D. RIBEIRO[1], S. M. MOORE[1], N. KISHI[2,3], J. D. MACKLIS[3], J. L. MACDONALD[1,3]

Abstract: Rett syndrome (RTT) is a severe, progressive X-linked neurodevelopmental disorder caused by mutations in the transcriptional regulator *MECP2*. We previously identified an aberrant up-regulation of the NF-κB pathway in the cortex of *Mecp2*-null mice and demonstrated that genetically attenuating NF-κB signaling rescues some of the well characterized neuronal phenotypes in RTT, such as the reduced dendritic complexity of layer II/III neocortical callosal projection neurons (CPN). These results raised the intriguing question of whether NF-κB pathway inhibitors could provide a therapeutic avenue in RTT, at least in part. Among the many known inhibitors of the NF-κB pathway are vitamin D and its analogues, and, strikingly, vitamin D deficiency is prevalent in RTT patients. We find that *Mecp2*-null mice similarly have significantly reduced total serum levels of 25(OH)D compared to wildtype littermates. Further, treating cortical neurons *in vitro* with calcitriol, the activated form of vitamin D, increases the reduced neurite outgrowth observed after *Mecp2* knockdown. Thus, to investigate whether vitamin D supplementation reduces the aberrant NF-κB activity in *Mecp2*-null cortex *in vivo*, and might have therapeutic benefit, we treated both male *Mecp2* hemizygous null and female *Mecp2* heterozygous mice and wild-type littermates with vitamin D supplemented chow, beginning at an early symptomatic stage. We found that this simple, cost-effective dietary supplement ameliorates neocortical dendritic morphology and soma size phenotypes in a dose-dependent manner, although it only modestly improves the reduced lifespan of *Mecp2*-null mice. In addition, vitamin D supplementation rescues immature spine morphology in *Mecp2*-null mice. These results provide new insight into the fundamental neurobiology of RTT and could provide critical information about vitamin D dietary supplementation as a potential cost-effective partial therapeutic intervention for RTT.

Title: Identification of post-translational regulators of MeCP2 protein levels as treatment targets

Authors: *M. ZAGHLULA[1], J.-Y. KIM[1], C. E. ALCOTT[1], H.-H. JEONG[1], Z. LIU[1], W. KIM[1], S. J. ELLEDGE[2], H. Y. ZOGHBI[3,1]

Abstract: Advances in clinical sequencing continue to highlight the involvement of dosage-sensitive genes in the pathogenesis of neurological disorders. Proper brain function depends on the maintenance of the levels of these proteins within a narrow range. Methyl-CpG-binding protein 2, *MECP2*, is one such gene: loss-of-function mutations in *MECP2* cause Rett syndrome (RTT) while duplications spanning *MECP2* cause *MECP2* duplication syndrome (MDS). Normalization of protein levels has been shown to ameliorate disease phenotypes in mouse models of both disorders. Therefore, our goal is to identify post-translational modifiers of MeCP2 that can be targeted therapeutically to normalize MeCP2 levels. To this end, we performed arrayed siRNA and pooled CRISPR screens in a reporter cell line that allows us to monitor changes in MeCP2 levels. From these screens we obtained hundreds of hits, which we are currently validating by evaluating their effects on endogenous MeCP2 in HEK293T cells. In parallel, we have also selected two promising candidates, *RIOK1* and *USP1*, to perform mechanistic and genetic interaction studies. We have previously shown that shRNA-mediated knockdown of *RIOK1* reduces MeCP2 levels in cells; to test the *in vivo* effects of RIOK1 reduction, we generated a null allele in the mouse using CRISPR-Cas9 editing. We found that *Riok1*$^{+/-}$ mice have a 15% decrease in MeCP2 protein levels in whole brain lysate. However, RIOK1 does not exhibit kinase activity towards MeCP2 *in vitro* and the two proteins also do not interact directly, leading us to believe that MeCP2 regulation is occurring via an intermediate interactor. Given that reducing MeCP2 by a mere 15% is unlikely to significantly improve behavioral abnormalities, we selected another candidate that we validated in HEK293T cells, *USP1*. To assess the effect of *Usp1* knockdown on MeCP2 levels *in vivo*, we delivered AAV-shRNA viruses targeting *Usp1* by intraventricular injection into P0 mouse pups. At 8 weeks of age, we harvested the posterior cortex of these mice and found a 30% decrease in MeCP2 levels *in vivo.* We are now focused on elucidating the molecular mechanisms by which USP1 and RIOK1 regulate MeCP2 levels, and evaluating whether combinatorial targeting of these genes may have additive effects. Overall, this screening approach is proving to be a powerful tool to identify post-translational regulators of MeCP2 and potentially druggable targets for *MECP2* duplication syndrome.

Title: Pontine modulation of laryngeal adductor reflex is suppressed in a Mecp2 mutant mouse model of Rett syndrome

Authors: *G. SONG[1], C.-S. POON[2]
[1]Inst. for Med. Engin. and Sci., MIT, Cambridge, MA; [2]Inst. for Med. Engin. and Sci., Mass Inst. Tech., Cambridge, MA

Abstract: Respiratory disturbances with repetitive apnea (breathholding) during wakefulness is a hallmark of patients with Rett syndrome, a neurologic disease in females often caused by mutation of the *MECP2* gene. The repetitive breathholding phenotype is recapitulated in *Mecp2* mutant mice. Under anesthesia these mutant mice exhibit hypersensitivity of efferent modulation of laryngeal adductor activity when premotor neurons in the pontine Kölliker-Fuse nucleus (KFN) are stimulated by glutamate. In previous study[1] we have shown that laryngeal adductor activity is driven by a specific population of premotor neurons in KFN that are characterized by their critical dependence on NMDA receptor and a decrementing activity pattern during the postinspiratory (post-I) phase of the respiratory rhythm. These previous findings led to our hypothesis that the repetitive breathholding phenotype in *Mecp2* mutant mice might represent a peculiar form of wake state-dependent recurrent laryngospasm caused by abnormalities of post-I driver neurons in the KFN. In healthy humans and animals, laryngospasm may also result from the classic laryngeal adductor reflex (LAR) evoked by activation of irritant receptors in the laryngeal mucosa or electrical stimulation of the superior laryngeal nerve (SLN). In the present study, we found that low-intensity short-train electrical stimulation of the SLN (0.1-0.2 s at 50 Hz during the expiratory phase) in WT female mice evoked both ipsilateral short-latency (~8 ms) and bilateral long-latency (~60 ms) excitations of recurrent laryngeal nerve discharge that are characteristic of the biphasic LAR response, along with simultaneous inhibition of phrenic discharge that is consistent with a concurrent activation of post-I activity. Interestingly, microinjection of the NMDA receptor antagonist AP5 at bilateral KFN significantly attenuated the long-latency component of the LAR response without affecting the short-latency component. In contrast, in *Mecp2* heterozygous (female) mutant mice at a similar age (110 ± 7 days old), the same SLN stimulus evoked a similar short-latency component of the LAR response but the long-latency component became much weaker or abolished. These data suggested that modulation of the LAR by post-I driver neurons in KFN was suppressed in *Mecp2* mutant mice. Finally, pre-

treatment of the *Mecp2* mutant mice with the Rett syndrome drug candidate rhIGF-1 (1 mg/kg, i.p., daily for 3 weeks) did not restore the long-latency component of the LAR or mitigate the breathing abnormalities in these mice.

Title: Local CRISPR knockout of Mecp2 at Kölliker-Fuse nuclei produces Rett-like respiratory abnormalities in adult rats without anxiety symptoms

Authors: G. SONG, A. CAO, *C.-S. POON
Inst. for Med. Engin. and Sci., Mass Inst. Tech., Cambridge, MA

Abstract: Breathing dysfunction with repetitive apnea (involuntary breathholding) and other respiratory abnormalities during wakefulness is a hallmark of patients with Rett syndrome, a neurologic disease in females often caused by mutation of the *MECP2* gene. Previous studies have indicated that malfunction of neurons in the dorsolateral pontine Kölliker-Fuse nucleus (KFN) may underlie similar respiratory abnormalities observed in animal models of Rett syndrome. However, because of the whole-body *Mecp2* mutation in these animal models, influences from other brain regions cannot be ruled out. In particular, *Mecp2* mutant mice and patients with Rett syndrome often exhibit heightened anxiety which may contribute to the breathing abnormalities. To eliminate this possibility, we have employed a brain site-specific CRISPR gene editing technique[1] to selectively knockout the *Mecp2* gene in the adult rat KFN. 4-8 weeks after injection of a mixture of two AAV vectors respectively encoding SpCas9 (AAV9-pMecp2-SpCas9-spA, Addgene plasmid #60957) and Mecp2 sgRNA (AAV9-U6-rMecp2-gRNA-hSYN1-eGFP) at bilateral KFN where electrical stimulation caused apnea, the KFN-Mecp2 knockout rats (of either sex) exhibited breathing disturbances similar to those observed in *Mecp2* mutant mice, including significant increases in the incidences of apnea, sighs and respiratory variability as compared with normal rats. By comparison, injection of a mixture of AAV9-SpCas9 and AAV9-LacZ (AAV9-U6-LacZ-sgRNA-hSYN1-eGFP) at bilateral KFN (LacZ control) did not cause similar breathing disturbances as in the KFN-Mecp2 knockout rats. As with *Mecp2* mutant mice, the breathing disturbances in the KFN-Mecp2 knockout rats were

mitigated by i.p. injection of a 5-HT1A receptor agonist (8-OH-DPAT) or a GABA reuptake inhibitor (NO-711). In contrast to *Mecp2* mutant mice, however, both the KFN-Mecp2 knockout rats and KFN-LacZ control rats did not exhibit increased anxiety (as determined by the open-field test) compared with normal rats. Post-mortem immunohistology showed that the number of neurons expressing Mecp2 was significantly reduced in the dorsolateral pons of KFN-Mecp2 knockout rats but no significant changes were observed in the KFN-LacZ control rats. These results demonstrated that the breathing disturbances observed in *Mecp2* mutant mice could result from abnormalities of neurons in the KFN alone that are responsive to drug therapies. Behavioral disturbances such as increased anxiety are not necessary for the induction of such respiratory abnormalities.

Title: Characterization of the adenosinergic system and the BDNF-mediated signalling in heterozygous females of a Rett syndrome model

Authors: *J. L. ROSA[1,2], C. MIRANDA-LOURENÇO[1,2], A. M. SEBASTIÃO[1,2], M. J. DIÓGENES[1,2]
[1]Inst. de Medicina Mol. João Lobo Antunes, Faculdade De Medicina Da Univ. De Lisboa, Lisboa, Portugal; [2]Inst. de Farmacologia e Neurociências, Faculdade de Medicina e Inst. de Medicina Molecular, Univ. de Lisboa, Lisboa, Portugal

Abstract: Rett syndrome is a neurodevelopmental disorder characterized by an apparently normal development during the first 6-18 months followed by a regression period. It is known that at least 90% of the cases of Rett syndrome are caused by mutations in the *MECP2* gene which is located in the X-chromossome. The MeCP2 protein is able to regulate genetic expression through its role as an activator and repressor of transcription. BDNF is an important neurotrophic factor that has its expression controlled by MeCP2. BDNF activates TrkB-FL

receptor to promote neuronal differentiation and survival and also synaptic plasticity. It has been shown that the BDNF-mediated signalling in RTT animal models is impaired. On the other hand it has been seen that the increase of the BDNF expression leads to an augmentation of the lifespan and an improvement in motor skills. In spite of these promising results the inability of BDNF to cross the blood-brain barrier makes it difficult to use it as a therapeutic strategy. Alternatively the activation of adenosine A_{2A} Receptors ($A_{2A}R$) potentiates the BDNF synaptic actions. The characterization of the adenosinergic system in *KO* mice (male hemizygous mice knock-out for *MECP2* gene) was previously accomplished, in our lab, and results revealed an increase in the protein expression level of A_1R and a decrease in the protein expression level of $A_{2A}R$ in the cortex and diminished endogenous adenosine levels in the hippocampus. Lower levels of TrkB-FL were also observed in the hippocampus and in the cortex of male *KO* mice. Considering that the severity of this disorder is very variable and that females are the most affected it is mandatory to evaluate if the alterations found in *KO* mice can also be found in heterozygous females as they have a less severe phenotype. Thus the aims of this work were to characterize the adenosinergic system and the BDNF-mediated signalling in heterozygous females of the Rett syndrome model. The results obtained through Western Blot revealed diminished BDNF and MeCP2 levels in the cortex and diminished $A_{2A}R$ levels in the hippocampus of 26 weeks old heterozygous symptomatic females (n=5-6). Overall the results observed are similar to those obtained in *KO* mice. This points to an impairment in the adenosinergic system of heterozygous females which, in turn, can somehow clarify the BDNF-mediated signalling dysfunction. The fact that in a less severe phenotype, such as the one presented by heterozygous females, adenosinergic system is also significantly affected demonstrates that potentially the adenosinergic system can be used as a therapeutic target for Rett syndrome.

Abstract: Rett Syndrome (RTT) is a neurodevelopmental disorder primarily caused by mutations in the methyl-CpG binding protein 2 (*MECP2*) gene. MeCP2 is known to modulate the expression of brain-derived neurotrophic factor (BDNF), a neurotrophin with essential functions in cell differentiation, synaptic plasticity and survival. BDNF signalling is impaired in RTT. However, the therapeutic use of BDNF is a challenge due to its inability to cross the blood-brain barrier. Adenosine (ADO) is a neuromodulator that acts mainly through A_1 and A_{2A} receptors (A_1R, $A_{2A}R$). The activation of $A_{2A}R$ potentiates BDNF synaptic actions, important to overcome cognitive deficits presented by RTT patients. On the other hand, A_1R activation has antiepileptic effect important to ameliorate epilepsy in RTT patients. Thus, activation of both ADO receptors could be a potential therapeutic strategy. To overcome the lack of knowledge about ADO system in RTT we developed a new line of research on this topic by using: **i)** a well-established animal model of RTT: male hemizygous mice knock-out for Mecp2 gene (KO) and **ii)** *post-mortem* human brain samples from a RTT patient. The results obtained, by binding assays, revealed that the protein expression level of A_1R, is significantly increased in the cortex of *Mecp2 KO* mice (n=5-6, $p<0.05$), while protein expression level of $A_{2A}R$, evaluated by western blot, is decreased when compared with *WT* (n=5-6, $p<0.05$). The levels of ADK, the most relevant enzyme for the regulation of ADO levels, are significantly decreased in the hippocampus from KO mice at pre-symptomatic stage when compared to wild type (WT) mice (n=4-5, $p<0.05$). Hippocampal electrophysiological recordings of field excitatory post-synaptic potentials (fEPSPs), revealed that the inhibitor of ADK, ITU, and the selective agonist of A_1R, DPCPX, induce a significantly higher disinhibition of synaptic transmission in hippocampal slices from *WT* mice, suggesting lower ADO levels in *KO* mice (n=4-10, $p<0.05$). In addition, changes in TrkB-FL protein levels were found in cortex and hippocampus of KO mice at symptomatic stage when compared to the age matched WT (n=13-14, $p<0.05$). In one *post-mortem* human cortical brain sample, an increase in A_1R mRNA expression levels and a decrease in $A_{2A}R$ mRNA expression levels were detected. Overall, the results show a dysfunction in the adenosinergic system, which could explain, at least in part, BDNF dysfunction and epilepsy in RTT. This data could, therefore open a new avenue in the treatment of RTT considering ADO receptors as new therapeutic targets.

Title: Pre-clinical study on CDKL5 deficiency disorder: Class I metabotropic glutamate receptors as a promising therapeutic target

Authors: *M. GIUSTETTO[1,2], A. GURGONE[1], R. PIZZO[1], A. RASPANTI[1], A. ALFIERI[3], N. MORELLO[1], F. PILOTTO[1], F. GARDONI[4], P. DEFILIPPI[3], E. TURCO[3], T. PIZZORUSSO[5,6]

Abstract: CDKL5 deficiency disorder is a rare disease without a cure, caused by mutations in the cyclin-dependent kinase-like 5 gene, that is characterised by severe cognitive, sensorimotor and autonomic dysfunctions. CDKL5 is a serine/threonine kinase that can localize at excitatory synapses and it participates in the regulation of dendritic spines as well as synaptic transmission and plasticity. However, how CDKL5 intervenes in the mechanisms underlying the molecular organization of synaptic contacts and what are the consequences of its loss remains obscure. We believe that answering to these questions will help uncovering druggable targets for this disease. We identified Shank1, a synaptic scaffolding-protein required for both maturation and stabilization of dendritic spines, as a novel interactor of CDKL5 using both in-vitro and in-vivo assays. Our data indicated that Shank1 may form a bridge between CDKL5 and Homer1bc, a protein scaffold that regulates the synaptic expression of Class I metabotropic glutamate receptors (mGluR). Accordingly, we found a reduction of the synaptic expression of both Homer1bc and mGluR5, but surprisingly not Shank1, in primary sensory cortices of CDKL5 KO mice. This altered molecular organization of excitatory synapses was associated with a decreased expression of Arc, a protein downstream of mGluR5-mediated activity, and atypical NMDA receptors currents. Because mGluR5 is crucial for synaptic contacts maturation occurring during the critical period of cortical plasticity, we then followed the expression and activity of this receptor in the developing visual cortex of CDKL5 KO mice. Our data showed a sharp decrease of both the synaptic localization of mGluR5 and Arc expression in this cortical area, indicating

that CDKL5 loss could hamper the functional refinement of visual cortical connections at crucial developmental phases by altering the correct expression/localization of postsynaptic receptors. Finally, we explored the therapeutic potentials of targeting mGluR5 activity for CDKL5 deficiency disorder by administering to mutant mice CDPPB, a positive allosteric modulator of this class of receptors. Interestingly, our results showed that, one hour after an acute injection with CDPPB (i.p.; 3mg/Kg), the deficits shown by CDKL5 KO mice in both sensory (adhesive removal) and cognitive (Y-maze) tests were rescued. In conclusion, our study discloses novel molecular interactors of CDKL5 that are crucial for dendritic spines formation, maintenance and plasticity. Moreover, we unveiled a promising druggable pathway that we are extensively exploring for its therapeutic efficacy and translational potentials.

Abstract: CDKL5 deficiency disorder (CDD) is a neurodevelopmental disorder still without a cure. The devastating symptoms comprise seizures, impairment of motor skills, lack of language and a substantial delay in many aspects of development. In order to develop and test preclinical treatments and to understand the biological processes underlying the disease, our lab has previously established the analysis of cortical responses to visual stimuli as a precision tool to probe cortical circuits function. This experimental strategy has proven to be successful in discriminating mutant from wild type mice with remarkably high accuracy, and to predict

amelioration of other anatomical and behavioral deficits after experimental treatments. We are currently expanding this research along three lines: first, since CDKL5 null mice show a decreased signalling of the metabotropic glutamate receptor mGLuR5, we are testing the effect of a single dose of an mGluR5 agonist drug (CDPPB) on visual responses. Preliminary data showed a remarkable recovery of normal visual processing in treated animals. Second, we are investigating if neuroplasticity, another fundamental feature deeply studied in the visual system, is impaired when CDKL5 is missing. We analyzed Ocular Dominance Plasticity (ODP) after 3 days of Monocular Deprivation (MD) beginning at P27-P28, a protocol that mainly results in the depression of cortical inputs coming from the deprived eye. We found no differences of ODP between wt and mutants. Finally, due to the importance of behavioral phenotyping, we are investigating behaviors that are tightly coupled with visual function but still reflects integrated functions. We have started this analysis by developing a custom fully automated setup for Appetitive Conditioning (AC). In this setup, mice are trained to press a button in response to a visual stimulus to get a reward in a Skinner-like manner. Mice performance is translated into various behavioral parameters including real-time tracking, number of trials initiated and latency to response. AC showed that CDKL5 null mice display an hyperactive behavior: they complete more trials for each session and the stimulus to button-press latency is shorter. Strikingly, we found that the general performance of mice is tightly correlated with the amplitude of visual responses measured by intrinsic signal optical imaging, thus establishing AC as an effective test to probe integrated behaviors directly coupled to the visual biomarker in CDKL5 null mice.

Abstract: De novo mutations in the X-linked gene *CDKL5* are associated with a rare neurodevelopmental disorder characterized by early neonatal/infantile onset of epilepsy, developmental delays and cortical visual impairment. CDKL5 is expressed from late gestation into early postnatal life and likely contributes to the assembly of neuronal circuits and their experience-dependent refinement during critical neurodevelopmental periods. How CDKL5 affects such complex processes is still largely unknown.
Through an RNA Seq screen, we have identified CDKL5 as a potential signaling molecule that may be involved in activity-dependent callosal synapse refinement. Callosal connections are the major connection across the cerebral hemispheres and mediate the integration of information and acquisition of a functionally lateralized brain. The disruption of their development has been linked to neurodevelopmental disorders. To assess the impact of CDKL5 deficiency on callosal connectivity, we performed *in vitro* recordings from cortical sections of CDKL5 KO and WT mice at postnatal day P5 and P15. We found that while no differences were present at P5, there were significantly more callosal synaptic inputs at P15 in the KO mice compared to WT, suggesting these connections may fail to refine in the absence of CDKL5.
In order to evaluate whether such abnormal functional connectivity would persist in adulthood and impact network activity across brain regions, we performed resting-state fMRI and ex-vivo DTI in CDKL5 mutant and control adult mice (n=10-11 each). BOLD time series were extracted using the Allen Reference Atlas ontology and their connectivity couplings were measured using Pearson's correlation coefficients across 65 regions of interest. We discovered that mice lacking CDKL5 exhibited robust over-connectivity between retrosplenial, anterior cingulate and somatomotor cortices, and across inter-hemispheric posterior associative, entorhinal hemispheres and between the retrosplenial cortex and the anterior portion of anterior commissure/motor cortex when analyzed by voxel-wise (network analysis) or roi-roi analysis (connectome analysis). These default networks are involved in motor and visual areas. Consistent with these findings, when we recorded VEP from visual cortex, we found a significant decrease of both amplitude of response to low spatial frequency, as well as spatial resolution. Our results indicate that CDKL5 is necessary for the proper refinement of callosal projections, and point at the use of DTI, rs-fMRI and VEP as syndrome-specific translational biomarkers, which may be employed to predict progression of the disorder and response to treatment.

Abstract: Cultured Neuronal cells derived from Olfactory Neuroepithelium (CNON) display transcriptomic patterns similar to neural progenitors, a type of cell that plays a key role in neurodevelopment. Not only can these cells be obtained from large numbers of individuals via nasal biopsy, they are renewable via growth in culture. As part of PsychENCODE, we have developed comprehensive 3-dimensional epigenomic profiles of CNON using biopsies from 63 individuals. To identify regulatory elements, nucleosome positioning, and transcription factor binding sites in CNON, we used chromatin immunoprecipitation (ChIP-seq) and nucleosome occupancy and DNA methylome (NOMe-seq) assays. We also performed in situ Hi-C looping assays to detect chromatin interactions, including large active and inactive topological associating domains (TADs), high-resolution enhancer-promoter loops, and repressive loops. We identified hundreds of thousands of regulatory elements in CNON and mapped transcription factor binding platforms within these elements. We identified 6,800 TADs, which include inactive TADs enriched with genes involved in sensory reception of smell, and hundreds of thousands of intra-chromosomal loops, with the majority being anchored by regions of repressed or heterochromatic chromatin. Using NOMe-seq, we characterized nucleosome positioning at promoters, enhancers, and insulators, as well as a novel category of nucleosome-depleted regions (NDRs) that do not have marks of active chromatin. Comparison of CNON active enhancers (the epigenetic state most closely linked to cellular identity) to active enhancers in a hundred different cell types revealed that CNON cluster with neuroblastoma cells and that thousands of CNON enhancers are active in the brain. Also, CNON active enhancers are enriched with motifs associated with cells of neuronal origin. Schizophrenia is a neurodevelopmental psychiatric disorder with 81% heritability and has been associated with deficits in olfactory perception. Therefore, we used CNON as a model to identify and characterize regulatory elements linked to schizophrenia. We identified 147 TADs harboring ~1,000 variants in regulatory elements active in CNON, including one TAD at chr17p11 with hundreds of schizophrenia risk-associated variants. Finally, we predicted enhancer:target gene interactions linked to increased risk for schizophrenia. Our results suggest that CNON is a useful model for epigenetic studies of mechanisms underlying neurodevelopmental components of psychiatric disorders.

Title: Ketamine-induced mitochondrial toxicity in zebrafish embryos

Authors: *J. KANUNGO[1], Q. GU[2], B. ROBINSON[3], S. F. ALI[4], M. G. PAULE[5], M. DUMAS[5]
[1]Neurotoxicology, Natl. Ctr. For Toxicological Research/Food and Drug Admin., Jefferson, AR; [2]FDA Natl. Ctr. for Toxicological Res., Jefferson, AR; [3]Neurotoxicology, Natl. Ctr. For Toxicological Res., Jefferson, AR; [4]Neurochemistry Lab, Div. of Neurotoxicology, Natl. Ctr. Toxicological Res/Fda, Jefferson, AR; [5]Div. of Neurotoxicology, FDA's Natl. Ctr. For Toxicological Res., Jefferson, AR

Abstract: Ketamine, a phencyclidine derivative, is an antagonist of the calcium-permeable N-methyl-d-aspartate (NMDA)-type glutamate receptors. A pediatric anesthetic implicated in developmental neurotoxicity, ketamine has been shown to deplete ATP in mammalian cells. Based on our previous studies showing acetyl L-carnitine (ALCAR) prevented ketamine-induced cardiotoxicity and neurotoxicity in zebrafish embryos, the effect of which was blunted by oligomycin A, an inhibitor of ATP synthase, we further investigated the effects of ketamine and ALCAR on ATP levels, mitochondria and ATP synthase in zebrafish embryos. Embryos at 28 h post fertilization (hpf) were treated with 2 mM ketamine (equivalent to an internal concentration of 8.4 μM) for 20 h. Analyses of the 48 hpf embryos post-exposure demonstrated that ketamine reduced ATP levels in the embryos but not in the presence of ALCAR. Ketamine also reduced total mitochondrial protein levels and mitochondrial potential, which were prevented with ALCAR co-treatment. To determine the cause of ketamine-induced ATP deficiency, we explored the status of ATP synthase. The results showed that a subunit of ATP synthase, atp5alpha1, was transcriptionally down-regulated by ketamine, but not in the presence of ALCAR, although ketamine caused a significant upregulation in another ATP synthase subunit, atp5beta, and total ATP synthase protein levels. In addition, ketamine-treated embryos developed an abnormal heart structure. In these embryos, with an enlarged heart, the atrioventricular (AV) valve separating the auricle and ventricle did not develop. ALCAR co-treatment, however, prevented ketamine-induced defects in the heart structure. This study suggests that ketamine's adverse effects could be mediated by ATP deficiency due to mitochondrial dysfunction.

Title: Exploring mechanisms behind zdhhc9 mutations that cause x-linked intellectual disability

Authors: K. S. SERRANEAU[1], *L. N. KIROUAC[2], K. REDDY[2], R. DESCHENES[2]
[2]Mol. Med., [1]Univ. of South Florida, Tampa, FL

Abstract: zDHHC9 is a protein acyltransferase (PAT) that enzymatically adds palmitate to cysteine residues on specific protein substrates. This modification results in increased protein hydrophobicity and membrane association and is reversible by the action of depalmitoylating thioesterases. This dynamic process plays a key role in the spatiotemporal distribution of proteins within the neuron. zDHHC9 is abundant in the brain and while there are over 300 potential substrates, only H- and N-Ras are known substrates of the enzyme. Recently, three loss of function mutations in the zDHHC9 gene have been identified in individuals with X-Linked Intellectual Disability (XLID). Our lab has previously determined that two missense point mutations, P150S and R148W, result in a enzymatically deficient zDHHC9. Here, we characterize the zDHHC9 R298* nonsense mutation that results in the expression of a C-terminal truncated protein, in the context of the mature hippocampal neuron. Using primary rat hippocampal neurons, we perform techniques such as subcellular fractionation, immunofluorescence and live cell imaging to understand the underlying pathophysiology that this specific mutation imparts. From our observations, we find that the nonsense R298* zDHHC9 mutation associated with XLID results in restricted trafficking of the mutant protein. While WT-zDHHC9 is trafficked through the axons and dendrites, the c-terminal truncated R298* mutant is restricted to the Golgi within the cell body. This finding suggests that the subcellular mislocalization of R298* zDHHC9 mutant potentially limits its access to specific protein substrates involved in maintaining synaptic function. Additionally, we examine how loss of function mutations in zDHHC9 might affect downstream signaling. Palmitoylation of zDHHC9 substrates, H- and N-Ras, dictates activity by changing the localization of the protein to the plasma membrane where it can interact with its effectors. In the brain, Ras signaling is an important event involved in synaptic plasticity and dendritic morphogenesis. Utilizing control or zDHHC9 knock out human chronic myelogenous leukemia cell lines, we examine Ras-dependent signaling cascades using Western blot analysis. Additionally, we examine the activity

of Ras in these cell lines utilizing a Ras activation pull-down assay. These experiments are novel and largely unexplored. We believe our data will be insightful to understanding the pathophysiology in the brains of XLID patients.

Title: Exosome-derived mitochondrial components as a potential diagnostic/therapeutic markers for neurodevelopmental and neurodegenerative disorders

Authors: *B. HA, J. HEO, Y.-J. JANG, T.-S. PARK, J.-Y. CHOI, J. JOO, S.-J. JEONG
Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: Exosomes are cell-derived nanoscale size vesicles, playing roles with a paracrine messenger affecting nearby recipient cells as well as presenting a systemic messenger in the all eukaryotic fluids, including blood, urine, and cultured medium of cell cultures. Exosomes include tissue-specific and disease-related molecules such as lipids, proteins and RNAs. In central nervous system, recent evidences show that exosomes are remarkably stable in body fluids proving their utility as disease biomarkers. Exosomes can transfer pathogens such as prion protein (PrP), responsible for Creutzfeldt-Jakob disease; α-synuclein, involved in the pathogenesis of Parkinson's disease; amyloid β (Aβ) and phosphorylated tau deposited in the brain of Alzheimer's disease (AD). In contrast, exosomes may have a protective function by relieving the cells from toxic accumulation of these pathogens or transferring beneficial molecules. Intact mitochondria can be transferred between cells in disease conditions such as cancer, stroke, and lung injury, but the details on the mechanism of transfer remains elusive. Recently, extracellular vesicles (EVs) from mesenchymal stem cells (MSCs), were reported to contain some mitochondrial components, including proteins and mtDNA. These studies suggest that mitochondrial components are secreted from the cells in the form of EVs. However, it is still unknown whether mitochondrial proteins are secreted as exosomes. In this study, we investigated the expressions of mitochondrial components in exosomes isolated from brains, plasma, and primary neuron/astrocyte of neurodevelopmental and neurodegenerative disorders mouse model. Our findings show that mitochondrial components were decreased in disease mouse models,

compared with wild type mouse models. In conclusion, these results suggest that mitochondria and exosome biogenesis pathway are interconnected and exosomes-derived mitochondrial components have a possibility as potential diagnostic/therapeutic targets.

Title: PQBP1 promotes protein translation through suppressing EEF2 phosphorylation

Authors: *S. Y. QIAN, Z. Z. CHAO
Inst. of Life Sci. Southeast Univ., Jiangsu, China

Abstract: Polyglutamine binding protein-1 (PQBP1) is a splicing factor whose mutations have been associated with Renpenning syndrome, a type of X-linked intellectual disability. Recent studies find that cytoplasmic PQBP1 may be involved in protein translation but the underlying mechanism is unclear. Here, we identify PQBP1 as a ribosome binding protein that directly binds with ribosomal proteins on the 80S ribosome. Furthermore, we reveal that PQBP1 interacts with non-phosphorylated eukaryotic elongation factor 2 (eEF2) and suppresses its phosphorylation through blocking the phosphorylation site of eEF2. These findings identify PQBP1 as a novel translational regulator and indicate that PQBP1 promotes protein translation through suppressing eEF2 phosphorylation.

Abstract: Deltamethrin (DM), a commonly used pyrethroid insecticide, exerts its effect on insects by delaying onset of inactivation in voltage gated sodium (Nav) channels fundamental for neuronal excitability. Epidemiological data showed a correlation between pyrethroid metabolites in urine and increased risk of ADHD diagnosis in children. In rats, exposure to DM results in behavioral phenotypes that mimic aspects of ADHD and are associated with the dopaminergic (DA) reward pathway in the nucleus accumbens (NAc). Dysregulation of DA medium spiny neurons (MSNs) in the NAc is thought to play a critical role in neuropsychiatric disorders like ADHD, anxiety, and depression. The Nav 1.6 channel, critical in synaptic transmission, is abundant in the MSNs. Here, we investigate the mechanism of MSNs dysfunction due to both acute and developmental DM exposure. For the acute model, rodent brain slices containing the NAc were incubated in 10uM DM. Using whole-cell patch clamp electrophysiology, we assessed changes to intrinsic excitability of MSNs. An increase in the instantaneous firing frequency and the total number of action potentials and a decrease in the peak amplitude was observed at multiple injected current steps (n=7-8, data was normal with equal variance, two-sample t-test, $p<0.05$). For the early-life exposure model, pregnant female B6 mice were exposed to 3.0 mg/kg of DM throughout pregnancy and lactation. Then, male mice litter-mates from post-natal day ~30 were used for subsequent experiments. We employed whole-cell patch-clamp electrophysiology in coronal brain slices to monitor changes in NAc MSNs firing due to developmental DM exposure. A decrease in the total number of action potentials and instantaneous firing frequency was observed (n=7-12, data was normal with equal variance, two-sample t-test, $p<0.05$). These studies will advance our knowledge of the toxic activity of DM in the developing brain and help assess risk exposure in the human population and potential increased vulnerability to neurodevelopmental disorders.

Title: Environmental contribution to transcriptome and methylome dynamics of excitatory neurons in the maternal immune activation model of autism spectrum disorder

Authors: *C.-Y. LAI[1], J. LI[3], J. D. LUCERO[1], R. G. CASTANON[2], J. R. NERY[2], A. PINTO-DUARTE[1], T. J. SEJNOWSKI[1], S. B. POWELL[4], J. R. ECKER[2], E. A. MUKAMEL[3], M. BEHRENS[1]

Abstract: Maternal immune activation (MIA) in rodents during early embryonic development causes profound neurodevelopmental alterations in the offspring. This leads to neurotransmitter system and behavioral abnormalities that resemble those of human autism spectrum disorder (ASD). How activation of the maternal immune response interacts with underlying genetic factors during early development to influence ASD phenotypes is still largely unknown. Recent evidence suggests that dysregulation of epigenetic pathways, and ensuing altered gene expression, could cause the neurodevelopmental alterations observed in the offspring. Our previous analysis showed intricate dynamics of methylation and transcriptional changes during embryonic and early postnatal development, suggesting this period is highly vulnerable to disruption by environmental insults. To address this hypothesis, we performed MIA by injecting polyinosinic:polycytidylic acid (PolyI:C) in pregnant mice at embryonic day 12.5. We measured the transcriptome in mouse frontal cortex of MIA and control offspring by mRNA sequencing (RNA-Seq) at embryonic day 14.5 (E14) (n=4/group), postnatal day 0 (P0) (n=4/group), and in adults at 10 weeks of age (n=6/group). PolyI:C exerted profound effects on gene expression in offspring at P0. However, these transcriptome data at the whole tissue level may reflect a complex pattern of gene expression regulation across multiple cell types. To further investigate neurodevelopmental alterations in a cell-type specific manner, we used INTACT to label nuclei in excitatory neurons using the ClSun-Nex-Cre mice. We generated transcriptomes (nuclear RNA-Seq, n=9-11 mice from 3 litters/group/time point) and single base resolution methylomes in frontal cortex excitatory neurons (n=6 mice from 3 litters/group/time point) at P0 and P13. Consistently, PolyI:C exerted a strong effect on excitatory neurons in MIA offspring at P0. Specifically, 38 synapse-related genes were down-regulated in MIA, including ion transporters (*Nkcc1)*, ion channel subunits (*mGlur5/mGlur7, Cacna1b*), and cell adhesion molecules (*Nrxn3)*.

Importantly, at P0 the ratio of mRNA expression of Nkcc1 to Kcc2 was 70% higher in MIA offspring in comparison with the control group. A higher Nkcc1/Kcc2 ratio in immature neurons suggests that MIA may delay the excitatory-to-inhibitory GABA switch in MIA offspring. These differences were not observed at P13. This study identified transcriptome as well as methylome dynamics at key developmental time points that can further our understanding of the underlying contribution of environmental factors to autism spectrum disorder.

Title: Human brain lysosomal cathepsin gene expression profiles during normal development from prenatal to infant, childhood, adolescent, and young adult

Authors: *V. Y. HOOK[1,3,4], A. HSU[2], S. P. PODVIN[2]
[2]Skaggs Sch. of Pharm. and Pharmaceut. Sci., [1]Univ. of Calif., San Diego, La Jolla, CA; [3]Dept. of Neurosciences, [4]Dept. of Pharmacol., Sch. of Medicine, UCSD, La Jolla, CA

Abstract: Cathepsin protease genes are necessary for protein homeostasis in normal brain development and function, and numerous brain disorders of development. Cathepsins are present in lysosomes that participate in protein degradation and cellular proteostasis, and are composed of fifteen cathepsins consisting of cysteine, aspartyl, and serine protease subtypes. The diversity of cathepsin proteolytic activities raises the question of what are the human brain expression profiles of the cathepsin genes during development from early prenatal to infant, childhood, adolescence, and young adult stages. This question was addressed by evaluating the gene expression profiles of the cathepsin genes in sixteen human brain regions during normal developmental periods by quantitative RNA-sequencing data obtained from the Allen Brain Atlas resource. The novel finding was the remarkable consistency in relative proportions of cathepsin gene expression levels among brain regions during the developmental stages of prenatal, infancy, childhood, adolescence, to young adult. Expression of the cathepsin genes in brain regions among the ages showed (a) high expression of cathepsins B, F, and D, (b) moderate expression of cathepsins A, L, and Z, (c) low expression of cathepsins C, H, K, O, S, and V, and

(d) very low expression of cathepsins E, G, and W. It is of interest that widely different cathepsin expression profiles among brain regions and ages were not observed. These findings demonstrate that the lysosomal cathepsin genes display similar rank orders of expression during human brain development. The consistent pattern of these expression profiles suggests that human brain developmental functions utilize well-defined, balanced profiles of cathepsin gene expression. Knowledge of the normal expression profiles of lysosomal cathepsin proteases during human brain development provides an important basis for future investigation of lysosomal cathepsin protease dysregulation occurring in traumatic brain injury, lysosomal storage disease, schizophrenia, and many related brain disorders.

Title: Regulation of filamin and Fmn2 on proliferation and differentiation of neural progenitor cells

Authors: *G. LIAN, V. EKUTA, V. SHEEN
Dept. of Neurology, Beth Israel Deaconess Med. Center, Harvard Med. S, Boston, MA

Abstract: Neural progenitor proliferation and cell fate decision from self-renewal to differentiation are crucial factors in determining brain size and morphology. The cytoskeletal dependent regulation of these processes is not entirely known. The actin-binding filamin A (FlnA) and Fmn2 were shown to regulate proliferation of progenitors by transducing upstream Wnt signals through b-catenin to downstream changes in cell cycle proteins such as Cdk1. Here, we report that activated RhoA-GTPase disengages Fmn2 N- to C-terminal binding to promote Fmn2 activation and redistribution into lysosomal vesicles. Fmn2 colocalizes with β-catenin in lysosomes and promotes its degradation. Further, Fmn2 binds the E3 ligase Smurf2, enhances Smurf2-dependent ubiquitination and degradation of Dishevelled-2 (Dvl2), thereby initiates β-catenin degradation and impairs cell proliferation. Moreover, functional loss of FlnA not only affects the rate of proliferation by altering cell cycle length but also causes a defect in early differentiation through changes in cell fate specification. FlnA interacts with Rho GTPase RhoA, and FlnA loss impairs RhoA activation. Disruption of either of these cytoskeletal associated proteins delays neurogenesis and promotes neural progenitors to remain in proliferative states. Inhibition of FlnA or RhoA impairs Aurkb degradation and alters its localization during mitosis.

Our findings suggest that shared cytoskeletal processes can direct neural progenitor proliferation by regulating the expression and localization of proteins that are implicated in the cell cycle progression and cell fate specification.

Title: Mechanisms of glutamate release during neural tube formation

Authors: R. GOYAL, *L. N. BORODINSKY
Univ. of California Davis, Sacramento, CA

Abstract: Failure of neural tube closure leads to one of the most common human birth defects, known as neural tube defects (NTDs), which can have serious neurological consequences or be lethal. The use of antiepileptic drugs (AEDs), during pregnancy increases the incidence of NTDs. Our previous studies have shown that glutamate signaling through NMDA receptors is important for the formation of the neural tube and that the AED valproic acid perturbs this signaling which induces an increase in neural plate cell proliferation and impairs neural plate cell migration, resulting in NTDs. The mechanism of glutamate release by neural plate cells is unclear since synapses are not assembled yet at these early stages of development. In this study we investigate the molecular mechanisms by which glutamate is released and signals in the folding neural plate of *Xenopus laevis* embryos. To determine whether vesicular release of glutamate occurs in the neural plate we first assessed the expression of the vesicular glutamate transporter 1 (VGluT1) during neurulation and found that VGluT1 transcripts are present at these developmental stages. Through whole-mount immunostaining we found that VGluT1 protein localizes to medial regions of the neural plate. Knocking down VGluT1 expression by injecting a specific VGluT1 translation-blocking morpholino in 2-cell stage embryos leads to NTDs, indicating that VGluT1 expression in neural plate cells is necessary for neural tube formation. In order to determine the source of glutamate and the dynamics and mechanisms of its release during neural plate folding we expressed the genetically-encoded, glutamate-sensor, iGluSnFR. *In vivo* imaging of neurulating embryos reveals that the fluorescent signal from iGluSnFr is selectively brighter in the neural plate compared to the non-neural ectoderm, thereby suggesting that glutamate is

released from neural plate cells. In turn, released glutamate may recruit calcium dynamics in neural plate cells. We found that unilateral knockdown of VGluT1 decreases the number of spontaneous calcium transients in the affected half neural plate and impairs its folding. Moreover, exogenous addition of ionomycin enhances the fluorescence intensity of iGluSnFr in neural plate cells, which suggest that glutamate is released by calcium-dependent vesicular exocytosis. Altogether these findings suggest that vesicular glutamate release occurs in the neural plate, elicits calcium dynamics, and is necessary for the formation of the neural tube. Elucidating the mechanisms of neurotransmitter signaling during neurulation may contribute to identify antiepileptic drugs that are safe during pregnancy.

Genetics, MSU Col. of Human Med., Grand Rapids, MI; [5]Hawaii Community Genet., Honolulu, HI; [6]Oklahoma Med. Res. Fndn., Oklahoma City, OK; [7]Oklahoma Univ. Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: βIV spectrin functions together with ankytinG to cluster Na+ and KCNQ2/3 K+ channels at axon initial segments (AIS) and nodes of Ranvier. These channels are necessary for the initiation and propagation of action potentials in the nervous system. Pathogenic variants of αII spectrin (SPTAN1) cause severe infantile epilepsy including seizures, hypomyelination and brain atrophy; pathogenic variants of βI (SPTB) and βIII (SPTBN2) spectrin lead to hereditary spherocytosis and spinocerebellar ataxia type 5, respectively. Although a variety of *quivering* mice bearing mutations in βIV spectrin (*Sptbn4*) have been reported and studied, our understanding of human pathogenic variants in βIV spectrin (SPTBN4) is limited to one single

case report of an individual with congenital myopathy, neuropathy and deafness. However, the pathogenic mechanism still remains elusive. Here, we report five family cases of bi-allelic pathogenic variants (three homozygous and two compound heterozygous) in SPTBN4 that cause profound intellectual disability, congenital hypotonia, and motor axonal neuropathy. We show that 5/7 are loss-of-function variants that disrupt AIS localization or phosphoinositide binding. Nerve biopsies from a proband with a loss-of-function variant also showed reduced nodal Na+ channels and no nodal KCNQ2 K+ channels. We also demonstrate that although ankyrinR/βI spectrin can partially compensate for the clustering of Na+ channels upon the loss of ankyrinG/βIV spectrin, ankyrinR/βI spectrin cannot recue the clustering of KCNQ2/3 K+ channels. In summary, our studies reveal the molecular pathologies of variants in SPTBN4 and define a new class of spectrinopathies.

Abstract: Fetal alcohol spectrum disorders (FASD) collectively classify neurodevelopmental and psychiatric problems attributed to maternal ingestion of alcohol. Previous genetic studies of FASD have primarily focused on variants associated with risk, but have not investigated genomic alterations that may result from ethanol exposure to the developing brain. Genomic mosaicism, or cell-to-cell DNA variability, has been established as a feature of the normal cerebral cortex, with significant genomic variations occurring during development. We worked to determine if ethanol exposure during neurogenesis in the developing brain could alter the rate of genomic variation in neurons. We developed a novel, single-cell whole genome analysis approach to assess these somatic genomic changes in the developing cortex. Integration of multiple approaches allowed us to determine the effects of *in utero* ethanol exposure in both

dividing and interphase cells. Analysis of embryonic mouse brain cells after *in utero* ethanol exposure during neurogenesis showed altered genomic variations when compared to control mice. Results from this study reveal lasting genomic alterations resulting from ethanol exposure during development and suggest that the aberrant genomic changes observed contribute to the range of neurological defects present in FASD.

Title: A novel pseudogene-encoded long noncoding RNA mediates fetal alcohol effects

Authors: *N. A. SALEM[1,2], A. TSENG[1], A. H. MAHNKE[1], C. GARCIA[1], H. KOLAHI-JAHROMI[1], R. C. MIRANDA[1,2]
[1]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Prenatal alcohol exposure is a leading non-genetic cause of neurodevelopmental disability. Neural stem cells (NSCs) that give rise to most neurons of the adult brain during the first and second trimester are particularly vulnerable. We previously found that ethanol exposure did not result in NSC death, but rather, the loss of NSCs due to premature maturation. This effect was mediated in part by the loss of specific miRNAs in NSCs. Here, we investigate whether ethanol also specifically prevents NSC renewal. We assessed the regulation of the homeobox transcription factor, Oct4/POU5F1, which is important for maintaining stem cell renewal and pluripotency. The Oct4 family includes several long non-protein coding RNAs (lncRNA) transcribed from pseudogene loci. We identified Octpg9 as one pseudogene-derived lncRNA transcript that was expressed in NSCs at significantly higher levels than the parent Oct4 mRNA transcript. Ethanol exposure results in elevated levels of Oct4pg9, whereas Oct4 protein levels are reduced. We studied the effect of ethanol exposure on the expression of Oct4 and Oct4pg9. Ethanol decreased Oct4 protein levels, but increased Oct4pg9 lncRNA. We assessed the effects of elevated Oct4pg9 on stem cell fate markers in NSCs, compared to the effects of ethanol. Oct4pg9 overexpression increased DCX, NeuN and GFAP mRNA transcripts, an effect that was mimicked by ethanol exposure. In contrast, siRNA-mediated Oct4pg9 knockdown resulted in downregulation of DCX and MAP2 mRNA. These data suggest that ethanol-mediated elevation

of Oct4pg9 shifts NSCs towards a neuronal/oligodendrocytic fate. Moreover, we found that CRISPR mediated knockdown of Oct4pg9 disrupts the correlated expression of stemness and differentiation markers. We show that siRNA mediated Oct4 knockdown, mimicking the effect of ethanol, resulted in an increased rate of DNA synthesis rate, an effect which can be reversed by knocking down Oct4pg9.Our results suggest that a novel OCT4-related lncRNA regulates NSC renewal and mediates some of the teratogenic effects of ethanol. Manipulating this lncRNA may be an interventional approach to reverse some of ethanol effects on neural stem cells.

Title: Regulation of the basic helix-loop-loop transcription factor TCF4 activity in neuronal cells

Authors: *A. SIRP, K. ROOTS, K. LEITE, K. LUBERG, M. SEPP, T. TIMMUSK
Dept. of Chem. and Biotech., Tallinn Univ. of Technol., Tallinn, Estonia

Abstract: Transcription factor 4 (TCF4) belongs to a family of basic helix-loop-helix transcription factors also known as E-proteins. TCF4 has been associated with several mental disorders such as schizophrenia, intellectual disability, bipolar disorder and a very rare disease known as Pitt-Hopkins syndrome (PTHS). Furthermore, expansion of trinucleotide repeats in an intron of TCF4 have been shown to be responsible for the development of Fuchs' endothelial corneal dystrophy. We have previously demonstrated that human TCF4 gene is transcribed using numerous 5' exons potentially yielding in TCF4 protein isoforms with different N-termini that vary in their subcellular distribution and ability to regulate transcription. Additionally, we have found that PTHS-associated mutations impair the functions of TCF4 by diverse mechanisms ranging from hypomorphic to dominant-negative effects. Our recently published data show that neuronal activity and protein kinase A lead to phosphorylation of TCF4 and activation of its transcriptional activity indicating that synaptic activation of nerve cells, that is the basis of brain

function, regulates TCF4 function. We have further investigated regulation of TCF4 function in neurons by studying how various sequence variations, mutations and interaction partners modulate the activity of TCF4. Most recent results obtained in these studies will be presented.

Title: Analyzing pathogenic missense variants in GNB5

Authors: *C. KITTOCK, J. ZHANG, P. ADIKARAM, M. PANDEY, W. F. SIMONDS
NIH, Bethesda, MD

Abstract: The refinement of high-throughput sequencing technologies has led to an increase in the application of Whole Genome Sequencing and Whole Exome Sequencing (WES) to the diagnosis of human diseases. Recently, through WES analysis, Loss of Function (LoF) and missense variants in the GNB5 gene have been identified as causative in patients with a novel syndrome called intellectual developmental disability with cardiac arrhythmia (IDDCA), characterized by cognitive disability, cardiac abnormalities, and other neurological phenotypes. The GNB5 gene encodes Gβ5, a structurally and functionally divergent isoform of the Gβ family of Gα/Gβ/Gγ heterotrimeric G proteins, and is primarily expressed in neural, neuroendocrine, and endocrine tissues. Gβ5 binds with regulator of G protein signaling (RGS) proteins from the R7-RGS sub-family to hasten the inherent GTPase activity of the Gαi/o subunit causing a faster turn over in G protein signaling. Uncovering the mechanism by which missense variants impair Gβ5 function can help elucidate the role of Gβ5 in this syndrome. We hypothesized that these missense variants could alter Gβ5 structure, causing a disruption of function in one of two ways: by decreasing Gβ5 stability or by impacting the interaction between Gβ5 and its binding partners. We conducted various experiments to investigate Gβ5 carrying the missense variants found in patients. First, we employed the Iterative Threading ASSEmbly Refinement (iTASSER) server to model the potential structural impacts of these missense variants on the Gβ5 molecule. We found perturbations in the predicted structures of these variants when compared to the wild-type structure. Next, we performed *in vitro* experiments to assess the stability Gβ5. While initial data do not suggest that Gβ5 is destabilized with these missense variants, it cannot yet be ruled out as a mechanism for Gβ5 dysfunction. Lastly, experiments probing the interactions between

RGS7/Gβ5 and their binding partner R7BP were performed. Data from these experiments do not suggest that these variants have significant impacts on these interactions. More studies will be necessary to understand the mechanisms of LoF of these missense variants in IDDCA.

Title: Placental allopregnanolone loss alters fetal GABAergic signaling

Authors: *J. J. O'REILLY[1,2], D. BAKALAR[2], J. ABBAH[2], C. M. VACHER[2], J. SALZBANK[2], H. LACAILLE[2], V. GALLO[2,3], A. A. PENN[1,2,4]
[1]Inst. for Biomed. Sci., George Washington Univ., Washington, DC; [2]Ctr. for Neurosci., [3]Children's Res. Inst., [4]Fetal Med. Inst., Children's Natl. Hlth. Syst., Washington, DC

Abstract: A major consequence of preterm birth is the loss of the placenta and the support it provides. The placenta supplies the developing fetus with critical hormones, including the neurosteroid allopregnanolone (ALLO). ALLO is a progesterone metabolite, synthesized by 3α-hydroxysteroid dehydrogenase (3αHSD; in mouse encoded by the *Akr1c14* gene). ALLO is a potent positive allosteric modulator of $GABA_A$ receptors ($GABA_A$-Rs) which also regulates $GABA_A$-R subunit expression. In the immature cortex, GABA acts an excitatory signal, due to the expression of the ion transporters NKCC1 and KCC2, which create a high-chloride environment inside the cell. This excitatory GABAergic signaling is critical for neuronal development and maturation. Importantly, high levels of placental ALLO coincide with a predominance of GABAergic (vs glutaminergic) synapses in the cortex. To directly test the hypothesis that placental ALLO loss disrupts the development of the GABAergic system, we utilize our $Akr1c14^{Cyp19a}$KO mouse model (KO), in which placental ALLO production is reduced. These mice have cortical changes and behavioral deficits that mirror those seen in human preterm survivors. Here, gene expression, protein quantification, and in-situ hybridization were used to assess molecular changes in the cortical GABAergic system during development in the absence of placental *Akr1c14*. KO mice had long-lasting, sex-specific alterations in $GABA_A$-R subunit expression and developmentally disrupted NKCC1 and KCC2 expression. These molecular changes correlate with electrophysiological changes: at P30, KO pyramidal cells had

IPSCs with faster decay rates, without changes in IPSC frequency, consistent with the changes in $GABA_A$-R subunits and ion transporters. Experiments are now focused on determining the mechanistic links between ALLO loss, GABAergic alterations and the loss of upper layer cortical neurons that we previously described. This is a novel and key link between placental function and long-term neurological outcomes, emphasizing the importance of the growing field of neuroplacentology.

Abstract: Intellectual disability (ID), which affects 1-2% of the general population, is a devastating neurodevelopmental disorder with the most lifetime costs of all diagnoses in the U.S. However, males are more susceptible to ID than females and are often found to have severe outcomes. Mutations in X-chromosomal genes are thought to account for this male-biased phenomenon. KLHL15 was recently identified as a novel XLID gene. It encodes Kelch-like protein 15 (KLHL15), a substrate adaptor of a Cullin-3 (CUL3)-based E3 ubiquitin ligase complex that targets proteins, including the brain-enriched B′β regulatory subunit of protein phosphatase 2A (PP2A), for degradation by the ubiquitin/proteasome system (UPS). Several KLHL15 mutations have been found in the poorly characterized BACK domain, which is a "hotspot" for many deleterious variants of the other KLHL family members resulting in either Mendelian diseases or human cancers. We identified both loss-of-function (ΔFY241, ::ACOT9)

and gain-of-function (R249H) alleles, and we hypothesize that small deletions and point mutations in KLHL15's BACK domain lead to structural rearrangement that change the alignment between bound substrates and the ubiquitin-transfer (E2/E1) complex to either slow or accelerate substrate ubiquitination and degradation, causing dysregulated protein turnover of $CUL3^{KLHL15}$-targeted substrate(s) and eventually pathogenesis of ID.

Title: Determining pathogenesis of a rare pediatric intellectual disability and progressive microcephaly syndrome

Authors: *K. JOHNSON[1], L. SCHAFER[3], A. SCHAFFER[2], G. YEO[3]
[2]Genet. and Genome Sci., [1]Case Western Reserve Univ., Cleveland, OH; [3]Dept. of Cell. and Mol. Medicine, Stem Cell Program and Inst. for Genomic Med., Univ. of California San Diego, San Diego, CA

Abstract: Human mutations in nuclear proteins that regulate mRNA export have been shown to be causative for multiple rare pediatric intellectual disability and progressive microcephaly syndromes. These proteins are conserved among higher organisms and are known to facilitate nuclear to cytoplasmic mRNA export in addition to regulating the cellular processes of transcription elongation and genome stability; however, the function of each protein in the complex remains unknown. We aim to resolve the temporal and spatial expression of these proteins and determine their requirement during neurogenesis. In addition, we will investigate the mechanism of disease for the known pathogenic human variants using in-vitro and in-vivo approaches.In order to determine protein expression during neurogenesis, we have developed a mouse model harboring a proximal V5 tag. We will characterize expression of V5 in conjunction with brain specific cell-type markers to identify potentially vulnerable cell types to loss of this complex during brain development. To test the requirement for these proteins during neurogenesis, we will characterize a knockout mouse model we recently developed. Based on the patient phenotype of progressive microcephaly suggestive of postnatal neurodegeneration, we will characterize brain morphology and assess changes in proliferation, R-loop formation (DNA

damage), and apoptosis during embryogenesis. To create a cellular model for the disease to study the molecular mechanism of this syndrome, we have also generated primary mouse neuronal progenitor cells (NPC) lines from multiple V5/- and V5/+ embryos at e12.5. Of note, the null embryos are embryonic lethal prior to e12.5, thus NPC lines from knockout mice can not be developed. First, we will validate our in-vitro system is representative of the in vivo phenotype by assessing for cell proliferation, R-loop formation, and apoptosis. Following validation, we will assess levels of mRNA export by collecting whole cell lysate RNA, as well as nuclear and cytoplasmic fractions of RNA for sequencing. If mRNA export is defective in mutant cells, we predict we will see retention of cytoplasmic RNAs within the nucleus compared to controls. Since this protein complex is also known to play a role in transcriptional elongation and RNA splicing, we may observe changes in mRNA expression levels and splicing as another possible mechanism of disease. Overall, we aim to characterize the role of this complex in brain development, as well as characterize the pathogenic mechanisms leading to pediatric brain disease.

Title: Placental allopreganolone loss alters postnatal cerebellar development and long-term function

Authors: *J. SALZBANK[1,2], C.-M. VACHER[2], H. LACAILLE[2], D. BAKALAR[2], J. O'REILLY[1,2], A. A. PENN[3,2,1]
[1]Inst. for Biomed. Sci., George Washington Univ., Washington, DC; [2]Ctr. for Neurosci. Res., [3]Fetal Med. Institute, Neonatology, Children's Natl. Med. Ctr., Washington, DC

Abstract: Preterm birth is a substantial risk factor for autism and related disorders. A major consequence of premature birth is early loss of the key endocrine organ of pregnancy, the placenta. Placental endocrine dysfunction or loss may place many thousands of fetuses at risk of

life-long neurodevelopmental impairments each year. We have been investigating the contribution of a neuroactive steroid, Allopregnanolone (ALLO), primarily synthesized by the placenta during late gestation, to neurodevelopmental impairments. ALLO exerts neurotrophic and neuroprotective effects in neurons and glial cells through allosteric activation of the GABA-A receptor suggesting that its loss could substantially alter the normal developmental GABAergic milieu. To assess the impact of placental ALLO deficiency, we generated a transgenic mouse line (AKR1c14^{CYP19a}KO) in which the gene encoding the enzyme responsible for ALLO production is specifically deleted by Cre-Lox recombination in the placenta. We examined cerebellar development because its rapid 3rd trimester growth makes it particularly vulnerable in preterm birth. Here we report three key cerebellar findings in our model. First, there are significant, sex-specific anatomical and molecular alterations in maturing cerebellar white matter. Second, social-cognitive cerebellar function is impaired but motor function is largely intact. Third, genes dysregulated in the KO compared to littermate controls overlap significantly with autism-linked genes from the SFARI database, particularly in myelin-related genes. White matter injury, a primary cause of deficits in preterm birth survivors, is also commonly seen in autism, particularly in the human cerebellum and cerebellar circuits. However, cerebellar white matter development is primarily a postnatal phenomenon, so placental endocrine alteration leading to this change is a particularly striking result. We are now investigating the mechanism by which placental ALLO loss leads to cerebellar white matter differences in an autism-like behavioral phenotype. The concept that compromised placental function may program lifelong mental disorders is a promising angle from which to approach their etiology and to identify new therapeutic targets that could decrease risk even before birth.

Title: Ranbp1 mutations disrupt development of cranial neural crest

Authors: *E. M. PARONETT, C. A. BRYAN, B. A. KARPINSKI, A. S. LAMANTIA, T. M. MAYNARD
George Washington Univ., Washington, DC

Abstract: 22q11.2 Deletion Syndrome (22q11 DS) is a neurodevelopmental disorder that impacts 1 in 4,000 live births. Craniofacial anomalies associated with multiple neural crest-derived tissues, including structural defects of the palate and cranial bones, as well as defects in sensory/motor coordination that impair speech and swallowing, are apparent in most individuals carrying 22q11.2 deletions. We have found that *Ranbp1,* a 22q11.2 DS candidate gene, is a key regulator of multiple aspects of craniofacial development. Mice with homozygous null mutations of *Ranbp1* have a severe, strongly penetrant cleft palate phenotype, with a complete failure of palatal closure, and a concomitant failure to form key neural-crest derived palatal bone structures including the palatal processes of the maxilla and premaxilla. Conditional neural crest-specific knockout of *Ranbp1* yields a highly-penetrant but less-severe phenotype: *Wnt1*-Cre::*Ranbp1* null embryos have closed but highly dysmorphic palatal structure. Other crest-derived cranial bones show dysmorphology; in particular the structure of the vomer is altered such that its anterior aspect is enlarged at the expense of the posterior aspect. *Ranbp1* mutation also disrupts the formation of the trigeminal ganglion, mirroring (but significantly more severe than) anomalies we have observed in the *LgDel* mouse model of 22q11 DS. Heterozygous *Ranbp1* mutants display more subtle and variable forms of each of these phenotypes. Thus, *Ranbp1* appears to compromise palate formation, as well as disrupt the development of other craniofacial structures, possibly by disrupting the function of key craniofacial signals that pattern the cranial neural crest.

Title: MMP9/RAGE pathway overactivation underlies the inhibitory/excitatory imbalance induced by the feedforward loop of oxidative stress and neuroinflammation: A translation study in schizophrenia patients

Authors: *D. DWIR[1], B. GIANGRECO[1], L. XIN[2], L. TENENBAUM[3], J.-H. CABUNGCAL[1], P. STEULLET[1], A. GOUPIL[1], M. CLEUSIX[1,4], R. JENNI[1,4], P. BAUMANN[1,4], P. KLAUSER[1,4], P. CONUS[4], R. TIROUVANZIAM[5], M. CUENOD[1], K. Q. DO[1]

Abstract: Besides oxidative stress (OxS), evidence indicates the implication of immune dysregulation in schizophrenia. As OxS is known to induce inflammation, we explored the mechanisms involved in their interaction using both a well-characterized cohort of early psychosis (EP) SZ patients that carry GAG trinucleotide-repeat polymorphisms in glutamate-cysteine ligase (GCL, the key synthesizing enzyme of the major antioxidant GSH) and a transgenic model of redox dysregulation, the Gclm knockout (*Gclm*-KO) mouse, which has a 70% reduction in brain GSH due to the lack of the GCL modulatory subunit (Gclm). OxS (8-oxoDG), microglia activation (Iba1, CD11b and CD68), parvalbumin interneurons (PVI) and perineuronal net (PNN), Receptor for Advanced Glycation End-product (RAGE) shedding, matrix-metalloproteinase 9 (MMP9), and NFkB activation (using an Adeno-Associated Virus) were investigated in the anterior cingulate cortex of *Gclm*-KO mice at both peripuberty (P40) and adulthood (P90), after an additional stress (dopamine uptake inhibitor GBR, P10-P20). At both P40 and P90, increased OxS and microglia activation were found in *Gclm*-KO, which peaked at P40, revealing a period of vulnerability during youth. In *Gclm*-KO at P40, RAGE shedding was increased in neurons and induced by MMP9, sensitive to OxS, as *In vivo* inhibition of MMP9 with a siRNA completely prevented RAGE shedding. Moreover, NFkB activation was increased in neurons of *Gclm*-KO, as well as pro-inflammatory cytokines. Then, in order to test the hypothesis that the following pathway: oxidative stress→MMP9 activation→RAGE shedding→NFKb activation→cytokines induction→microglia activation→reactive oxygen species production→OxS, could be causal to the long lasting PVI/PNN deficit observed in the 2 hits *Gclm*-KO model (±GBR, Cabungcal et al., 2013), the latter was treated with MMP9 inhibitor during puberty (P20-30). MMP9 inhibitor treatment, after the additional OxS, reversed PVI/PNN deficit, and reduced OxS as well as microglia activation in adulthood (P90). In EP patients with a genetic vulnerability to OxS, an increase in soluble RAGE was associated with low prefrontal GABA levels, potentially predicting a central inhibitory/excitatory imbalance, in line with our preclinical model in which OxS-induced MMP9 activation and increased RAGE shedding lead to PVI deficits. The circular pathway described above constitutes a positive feedforward process by which inflammation and OxS amplify each other, which is particularly damaging to PVI/PNN and might explain the persistence of the observed cellular damage. Therefore, MMP9 inhibitor holds promise for preventive treatment approaches.

Title: Somatic mutation in SLC35A2 leads to focal epilepsy

Authors: *A. PODURI[1], M. R. WINAWER[2], P. B. CRINO[3], E. L. HEINZEN[2]
[1]Epilepsy & Clin. Neurophysiol., Boston Children's Hosp., Boston, MA; [2]Columbia Univ., New York, NY; [3]Univ. of Maryland, Baltimore, MD

Abstract: Malformations of cortical development, including focal cortical dysplasia, have long been hypothesized to result from somatic, post-zygotic mutation. Recently, post-zygotic, or mosaic, variants in genes encoding mTOR-AKT-PI3K pathway proteins have been identified as a common cause of focal malformations through the study of brain tissue resected in the course of epilepsy surgery. We sought to identify novel causes of focal epileptic lesions through the study of brain tissue from patients with focal epilepsy with and without neuroimaging evidence of focal cortical dysplasia. We identified 18 patients without explanatory imaging findings (non-lesional) and 38 patients with focal malformations on imaging, all of whom were undergoing clinical evaluation and focal resection. We performed high-depth sequencing (gene panel and exome) on DNA from the resected brain tissue, as well as blood for comparison. We identified 5 distinct novel pathogenic variants in the same gene, *SLC35A2*, 3 from among the 18 who were non-lesional on imaging (2 of whom had neuropathological evidence of focal cortical dysplasia) and 2 from among the 18 with focal malformations on imaging, both of whom had radiological evidence of FCD. The variant allele frequency (VAF) ranged from 2-53%, with lower VAF for the non-lesional cases and higher VAF for the lesional cases. *SLC35A2* has been traditionally associated with epilepsy in the context of glycosylation defects. Our identification of post-zygotic variants in this gene—in cases ranging from non-lesional focal epilepsy to cases with neuroimaging or neuropathological evidence of abnormal cortical development—highlights the important role of somatic mutation in focal epilepsy. Further, we have identified a new role for glycosylation defects in epilepsy and in the pathogenesis of focal epileptic lesions.

Title: Cortical malformations in pediatric epilepsy

Authors: *L. SUBRAMANIAN, M. ANDREWS, A. BHADURI, M. PAREDES, A. R. KRIEGSTEIN
Eli and Edythe Broad Ctr. of Regeneration Med. and Stem Cell Res., UCSF, San Francisco, CA

Abstract: Medically intractable epilepsies are one of the most common neurological disorders that affect children. Focal Cortical Dysplasia (FCD) is a developmental malformation that is a major cause of surgically treated, medication-resistant pediatric epilepsy. FCD originates in the cerebral cortex of the embryo as a result of defects in proliferation, neuronal maturation, and/or neuronal migration. These developmental errors lead to focal regions of disorganization in the cerebral cortex of patients, characterized by disrupted lamination, misplaced neurons, dysplastic neurons and focal seizures. The molecular and cellular causes of these developmental errors are poorly understood. Recent studies suggest that somatic mutations in the genes regulating the mammalian Target of Rapamycin (mTOR) signaling pathway may be responsible for the condition. However, there is no clear understanding of the role played by the mTOR pathway in the development of the human cerebral cortex. It is also unclear if particular cell types are particularly vulnerable to these mutations during development and how the disrupted cellular identities contribute to the disease phenotype in patients with FCD. In order to gain a better insight into this condition, we examined the cellular composition of donated brain tissue from patients with focal cortical dysplasia. Our results suggest that the dysplasia may be the result of errors in the maturation of a specific group of progenitor cells. In order to understand how these errors in a progenitor cell type translate into the disease condition, it is necessary to build a detailed cellular profile of the disease focused on molecular and lineage relationships between cells. We are generating such a profile using advanced genomic technologies on donated human patient tissue samples to compare gene expression patterns between several thousand individual dysplastic and healthy neurons from multiple patients. In order to understand how FCD alters vulnerable cell types during development, we have also developed and validated slice culture models of human brain development. By pharmacologically manipulating mTOR signaling in this model, we can recapitulate key cellular characteristic of dysplastic cells in vitro. Together, these approaches will help unravel the developmental causes of FCD. In addition, they will

provide novel insights into the molecular and cellular events that shape the development of the human cerebral cortex, thus opening the door towards a broader understanding of other neurodevelopmental conditions.

Title: Defining links between an intellectual disability-associated RNA-binding protein and planar cell polarity in neurodevelopment

Authors: *E. B. CORGIAT, III[1], J. ROUNDS[1], P. CHEN[1], W. LEE[1], P. SHENG[1], A. CORBETT[2], K. MOBERG[1]
[1]Dept. of Cell. Biol., [2]Dept. of Biol., Emory Univ., Atlanta, GA

Abstract: The human *ZC3H14* gene encodes a ubiquitously expressed zinc-finger polyadenosine RNA-binding protein. Mutations in *ZC3H14* that impair function of it encoded protein have been linked to an inherited form of non-syndromic intellectual disability (NS-ID). We developed a *Drosophila melanogaster* model of ZC3H14 NS-ID by deletion of *dNab2*, the fly ortholog of *ZC3H14*. These *dNab2*-deficient animals display defects in survival, locomotion, and memory which correlate at a cellular level with neurodevelopmental defects. Importantly, pan-neuronal expression of human ZC3H14 in *Drosophila* neurons can rescue the overt locomotor and survival phenotypes of *dNab2*-deficient flies, suggesting that dNab2 and ZC3H14 serve conserved roles in neurons. To probe this role, we used a dominant-modifier approach to identify alleles of genes that interact with *dNab2*. This approach has uncovered genetic interactions between *dNab2* and multiple components of the planar cell polarity (PCP) pathway, such as *Disheveled, Frizzled, and Van Gogh*. Additionally, we have characterized classic PCP-like defects in wing hair orientation and cochlea inner hair cell orientation in dNab2 null flies and ZC3H14 knockout mice, respectively. Furthermore, loss of function alleles of PCP components can rescue a portion of dNab2 null neuro-morphology defects observed in the mushroom bodies, twin neuropil structures analogous to the mammalian hippocampus. What underlies the rescue of this neurodevelopmental defect is of particular interest. Here we conduct a comparative proteomic analysis of control and dNab2 null brains at a critical timepoint in *Drosophila*

neurodevelopment. 4302 proteins were represented with significant changes in 144: 56 are increased and 88 are decreased in abundance by a factor of 1.6-fold or greater. Interestingly, a number of these are candidate PCP effectors or factors with PCP-like phenotypes by RNAi screens including: Treh, Akap200, and CG31738. Additionally, many actin and cytoskeletal-related proteins were identified including: Arc1, Lasp, Map205, and Polo. These data suggest that multiple pathways relevant to neurodevelopment are regulated by dNab2 but that PCP may be critical.

Title: The chromatin regulatory factor ASH1L regulates neuronal development by modulating the neurotrophin-signaling pathway

Authors: *S. B. LIZARRAGA[1], S. H. CHEON[2], E. CHUKWURAH[2], A. BAGNELL[2]
[1]Columbia, SC; [2]Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstract: Autism spectrum disorders (ASD) are associated with defects in neuronal connectivity and are highly heritable. Genome wide association studies in large ASD family cohorts identified high risk variants associated with autism in genes that regulate histone modifications and remodel chromatin. These findings highlight the relevance of chromatin regulatory mechanisms in the pathology of ASD. Changes in Histone H3 methylation have been identified in a subset of neuronal genes in postmortem cerebral cortex of autism patients. ASH1L is a Histone H3-Methyltransferase that was previously identified in whole exome sequencing studies, as a gene strongly enriched for variants likely to increase ASD risk. ASH1L dimethylates Histone H3 on Lysine 36 (H3K36me2), this histone mark has been implicated in transcriptional activation. Therefore, ASH1L could modulate expression of genes that are essential for neuronal development. However, how mutations in ASH1L lead to deficits in neuronal connectivity associated with autism pathogenesis is largely unknown. We are using genome editing and shRNA knockdown approaches in stem cell derived human neurons to interrogate the function of

ASH1L. In particular we are defining how changes in chromatin structure and function elicited by loss of ASH1L could disrupt the structural development of early neuronal connectivity. Our preliminary data suggests that knockdown of ASH1L in human neurons impacts neurite outgrowth and that it might do so by modulating the expression of neurotrophic receptors. This is the first time that neurotrophic receptors gene expression have been shown to be regulated by the chromatin regulatory factor ASH1L, suggesting the relevance of ASH1L to human neuronal development.

Central Hosp., Helsinki, Finland; [9]Finnish Inst. of Occup. Hlth., Helsinki, Finland; [10]The Criminal Sanctions Agency, Helsinki, Finland

Abstract: Psychopathy is a disorder characterized by a loosely correlated set of interpersonal, affective, and behavioral features, including pronounced emotional deficits such as diminished sense of guilt and empathy. Psychopathy involves also an increased risk for antisocial behavior and poor impulse control. Although psychopaths represent less than 1% of the general population and 15-25% of prison populations, they perpetrate even 30-50% of all violent crimes. Thus, psychopathy is one of the strongest predictors of aggression and severe violence. This study aims to identify the neurobiological characteristics associated with psychopathic violence as markers, and targets for intervention and prevention of violent behavior by generating induced pluripotent stem cell (iPSC) lines from psychopathic violent substance abusers and healthy controls and substance abusers without psychiatric manifestations. The iPSC lines were differentiated to TUJ1+ and VGLUT1+ glutamatergic neurons via dual SMAD inhibition. The neuronal RNA

was sequenced with Illumina Hiseq sequencing system to compare the global gene expression profiles of the psychopaths and the two control groups. A total of 168 genes were up- or down-regulated (|FC| >3, p <0.05) in psychopathic violent substance abusers when compared to control groups. One particular gene showed strong and statistically significant upregulation among psychopathic prisoners (upregulated FC=4.4 p=0.044). Even though this gene has not been previously reported to be related to psychiatric disorders, its expression correlates positively with PCL-R scores of psychopathic violent substance abusers ($R^2 = 0.951$). Future proteomic studies will uncover interacting proteins for the gene and elucidate its contribution to psychopathic violence.

Title: Dysregulation of developmental and synaptic networks in a cellular model of intellectual disability

Authors: *B. J. WILKINSON[1,1], F. S. ALKURAYA[2], J. ICHIDA[1], M. P. COBA[1]
[1]USC, Los Angeles, CA; [2]Developmental Genet. Unit, King Faisal Specialist Hosp. and Res. Ctr., Riyadh, Saudi Arabia

Abstract: Advances in human genetics have identified a variety of candidate genes implicated in a number of developmental disorders such as intellectual disability (ID) and schizophrenia (SCZ). However, it is not known if mutations associated with candidate genes can be used to define alterations within developmental signaling networks. Here, we use the Traf2 and Nck Interacting Kinase (TNIK) as a model to explore changes in signaling pathways as a truncating mutation in the kinase domain (p.Arg180*) of TNIK has recently been shown to be causal for ID. TNIK plays essential roles in regulating synaptic function and interacts with multiple key postsynaptic density (PSD) proteins involved in complex brain disorders, including SHANK3 and SYNGAP1. We determined protein interaction networks of TNIK and potential substrates of the kinase domain in early neural development and adult PSD via mass spectrometry, which highlighted the involvement of TNIK in centrosomal dynamics and synaptic function. This

network was further expanded by immunoisolation of the centrosomal TNIK-interacting proteins AKAP9 and PDE4DIP. To investigate the function of TNIK within early stages of neural development, we generated multiple models using induced pluripotent stem cells (iPSCs). These include a TNIK kinase dead cell line and an iPSC line derived from a patient harboring the p.Arg180* mutation which was further corrected using CRISPR/Cas9 genome engineering. Functional analyses shows how TNIK regulates specific components within human neural progenitor cell (hNPC) developmental signaling networks such as beta-catenin and how they are dysregulated in mutant TNIK hNPCs. Furthermore, using mutant TNIK iPSC-derived glutamatergic neurons, we show the role of TNIK function in the regulation of synaptic activity through development and compare developmental and adult synaptic signaling networks in ID and SCZ.

Title: Human neural progenitor cells harbor DSB clusters in genes linked to Autism

Authors: *M. WANG[1], P.-C. WEI[2], S. MARSHALL[1], I. S. GALLINA[1], C. K. LIM[1], F. W. ALT[2], F. H. GAGE[1]

Abstract: Human neurons contain high level of somatic genomic variations that might derive from DNA double-strand break (DSB) intermediates. To study replication stress-induced DSB hotspots, we applied high throughput genome-wide translocation sequencing, identifying 36 replication-associated genomic fragile regions overlapping genes in neural progenitor cells (NPCs) derived from human pluripotent stem cells. Our analysis also reveals cell type-dependent gene fragility associated with transcription. Here we show that NPCs derived from autism

patients exhibit increased DNA damage and elevated DSBs in long genes associated with autism. Our results demonstrate that replication-associated genome instability may cause neurological dysfunction by disrupting long neural genes linked to neurodevelopmental diseases.

Title: Excitatory/Inhibitory imbalance in hiPSC derived cortical neurons from patients with autism associated with MEF2C haploinsufficiency

Authors: *S. GHATAK[1], D. TRUDLER[1], J. PARKER[2], N. DOLATABADI[1], S. MCKERCHER[1], R. AMBASUDHAN[2], M. TALANTOVA[1], S. A. LIPTON[3]

Abstract: We and others have previously shown that transcription factor MEF2C is critical for neuronal differentiation, synapse formation and neuronal survival. Human MEF2C haploinsufficiency results in a syndrome with clinical features resembling autism spectrum disorder (ASD), intellectual disability, and epilepsy. However, molecular mechanisms underlying MEF2C haploinsufficiency syndrome (MHS) in patients remain poorly understood. Here we report that human induced pluripotent stem cell (hiPSC)-derived cerebrocortical neurons from MHS cultured on mouse astrocytes for 5-6 weeks exhibit excitatory to inhibitory (E/I) synaptic imbalance. By patch-clamp recording and fluo-4AM calcium imaging, we show greater spontaneous bursts of action potentials and increased frequency of calcium transients in MHS patient neurons when compared to controls including isogenic-correction. MHS patient neurons exhibit greater glutamate current density in response to 100 µM glutamate and smaller GABA current density in response to 100 µM GABA than control neurons. Sodium and potassium current density, cell size and resting membrane potential remain unchanged. MHS

patient neurons also display increased frequency and amplitude of miniature excitatory postsynaptic currents (mEPSCs), but decreased frequency of miniature inhibitory postsynaptic currents (mIPSCs). These results provide mechanistic insight into the abnormal neuronal electrical activity that leads to the observed functional deficits in patients with MHS. These aberrant electrical properties of MHS hiPSC-derived neurons will be useful for screening of putative novel therapeutic compounds in a patient-specific genetic context.

Title: The Unc93b1 mutation 3d attenuates neuropathic painthrough increasing M2 polarization of spinalmicroglia

Authors: *S. LI[1], N. HIROSHI[2], D. SHUMIN[1]
[1]Inst. of Neurosci., Zhejiang Univ. Sch. of Med., Hangzhou, China; [2]Kyushu Univ. Fac. of Dent. Sci., Department of Aging Science and Pharmacology, Japan

Abstract: Evolving evidence suggest that Tool-like receptors (TLRs) are associated with the maintenance of neuropathic pain. However, little is known about the precise mechanisms underlying the TLRs. UNC93B1 associated with TLR3, TLR7 and TLR9, mediating their translocation from the endoplasmic reticulum to the endolysosome, hence allowing proper activation of glia cells. We found that the triple deficient‘3d’mice, which lack functional UNC93B1, significantly attenuated the maintenance of tactile allodynia, activated microglial cellnumber. It was also noted that,either gene mutation of UNC93B1 or by neutralizing antibody, can significantly suppress the harmful cytokines (IFN-γ,IL-1β,TNF-α) expression and assist the beneficial cytokine (IL-10) expression. When applying the human recombinant HMGB1 into the MG6 microglial cell line, NF-κB and STAT1 activation was detected and significantly blocked by pretreating UNC93B1 neutralizing antibody. These observations suggest the crucial roles of TLR3, TLR7 and TLR9 in the development of neuropathic pain.

Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan; [6]Leiden Universuty Med. Ctr., Leiden, Netherlands; [7]Dept Neurosci/Neurol, Johns Hopkins Sch. Med., Baltimore, MD

Abstract: We found that human heroin addicts have, on average, a 54% increase in the number of detectable hypocretin neurons (N=5) relative to human controls (N=7, p=0.0009, t=8.89, df=10). Hypocretin cell size is reduced by 22% in the addicts (p= 0.01, t=2.78 df=10). In mice (C57BL/6) doses of 10 mg/kg or higher for 14 days produced a significantly elevated number of detected hypocretin neurons compared to saline. The increase in hypocretin cell number at 50 mg/kg was 38%. Doses above 50 mg/kg produced no further increase (10mg - p=0.009, t=-4.77 df=4; 25mg - p=0.019,t=-3.81, df=4; 50mg - p=0.002, t=-7.07, df=4; 75mg - p=0.01, t=-5.14, df=4; 100mg - p=0.01, t=-4.52 df=4). With daily dosing for a 60 day period changes in cell number were smaller than that after 14 days of administration. mRNA amounts of preprohypocretin, Narp and preprodynorphin were significantly elevated with morphine injection (Preprohypocretin p=0.03, t=2.99 df=5; Narp p=0.02, t=3.36, df=5; Prodynorphin p=0.01, t=3.65 df=5). The number of melanin concentrating hormone cells, a cell type intermixed with hypocretin cells in the hypothalamus, was not changed by morphine administration. BrdU labelling to identify new neurons showed no increase in the number of BrdU labelled cells in the hypothalamic hypocretin cell field after 14 days of morphine treatment in mice. Human narcoleptics with cataplexy given morphine over a long period were found to have a higher number of hypocretin cells than the available narcoleptic control case. Morphine administration

restored the population of detected hypocretin cells to the normal level in partially hypocretin depleted mice (orexin-tTA;TetO DTA mice), and eliminated or greatly decreased cataplexy in narcoleptic mice, suggesting that opiate agonists may have a role in the treatment of narcolepsy. Induction of specific long-term changes in peptide production may be useful in treating diseases characterized by neuronal loss. Our findings also indicate that some portion of the loss of specific cell types that have been reported in neurological diseases may be due to reduced production of the identifying label used for counting the neurons, rather than to neuronal death.

Title: Protease systems in dense core secretory vesicles for neuropeptide biosynthesis and degradation analyzed via global proteomics, peptidomics, and multiplex substrate profiling-mass spectrometry (MSP-MS)

Authors: *C. B. LIETZ[1], Z. JIANG[2], T. TONEFF[1], C. MOSIER[1], S. PODVIN[1], A. J. O'DONOGHUE[1], V. HOOK[1,3]
[1]Skaggs Sch. of Pharm. and Pharmaceut. Sci., [2]Dept. of Chem., [3]Dept. of Neurosci., Univ. of California San Diego, La Jolla, CA

Abstract: Dense core secretory vesicles (DCSVs) of neurons, glia, and neuroendocrine cells secrete peptide signal molecules to regulate physiological systems and facilitate cell-cell communication. These peptides perform crucial functions in biological processes that range from neurotransmission to hunger, analgesia, circadian rhythm, and cognition. Neuropeptide precursors, or proneuropeptides, are packaged in DCSVs along with a diverse array of proteases responsible for processing them into bioactive neuropeptides. This begins inside the DCSVs at pH ~5.5 and is followed by secretion into the extracellular environment of neutral pH 7.4. The acidic pH within DCSVs is thought to be an important factor for protease function. To gain understanding of the DCSV proteolytic systems, we utilized high-resolution liquid chromatography (LC)-mass spectrometry (MS) proteomics, peptidomics, and multiplex substrate

profiling (MSP)-MS of purified DCSVs from adrenal chromaffin cells (bovine) to determine 1) the identities of DCSV proteases and their endogenous inhibitors, 2) the primary cleavage properties of DCSV proteases at intravesicular and extracellular pH, and 3) which classes of DCSV proteases are responsible for the biosynthesis and degradation of neuropeptides such as Neuropeptide Y, Galanin, and Met-Enkephalin. Proteomics data identified approximately 65 proteases comprised of the cysteine, aspartyl, serine, and metallo protease sub-classes. The identification of this diverse group demonstrates the extensive spectrum of DCSV proteases. To characterize the specificity of proteolysis within the DCSVs at their internal pH of 5.5, MSP-MS was used to measure the relative abundances of cleavages of a comprehensive synthetic peptide library. Further, peptidomic analyses of endogenous peptides generated by DCSV proteases is being conducted to illustrate the protease sub-classes involved in neuropeptide production and degradation. Results will advance understanding of the vital DCSV proteolytic controls of neuropeptide precursor processing to generate active neuropeptides for intercellular communication.

Title: Desynchronized lower alpha rhythms were associated with functional ischemia in the prefrontal cortex in heroin patients after protracted abstinence: A concurrent EEG-fNIRS study

Authors: *H. IEONG[1,2], Z. YUAN[2]
[1]Univ. of Macau/Icms, Taipa, Macao; [2]Fac. of Hlth. Sci., Univ. of Macau, Taipa, Macao

Abstract: Opiate addiction involves cycles of lapse and relapse. Despite diverse treatment options nowadays, the relapse rate is still extremely high, and there is no biomarker to predict relapse. Prefrontal cortex (PFC) has been a target for drug addiction, in large part, because of its well-known executive functioning and its strong connection with limbic reward regions. However, the mechanism underlying the systems-level neuroadaptations during abstinence has

not been fully characterized across drug classes. It has been suggested that resting-state functional connectivity (rsFC) can serve as a systems-level biomarker to predict various neuropsychiatric trajectories. Is it possible to establish an intermediate level that explores a large population of cells and vessels within PFC network to better understand the adaptation in opiate addiction after prolonged cessation from the drug? The objectives of our study were to determine which neural oscillatory activity contributed to the chronic effect of opiate exposure on abstinence and whether the electrical activity could be coupled with neurovascular information in the PFC. The oscillatory activity was recorded through electroencephalography (EEG); whereas the hemodynamic activity was recorded through function near-infrared spectroscopy (fNIRS). Resting-state desynchronization in lower alpha rhythm, decreased functional connectivity and degree strength in PFC network among heroin-dependent patients. Through modern machine learning computation, asymmetric interhemispheric excitability evidenced by hemodynamic patterns in PFC was observed, suggesting as a potential biomarker for heroin protracted abstinence. Our findings have potentially important implications for future brain state-dependent electrotherapy applying wearable optical neuroimaging in clinical psychiatry to predict relapse.

Title: Co-administration of mixed μ/ƙ-agonist attenuate the opioid dependence

Authors: *R. RAGHAV[1,2], R. JAIN[2], T. ROY[3], A. DHAWAN[2], P. KUMAR[3]
[2]Natl. Drug Dependence Treatment Centre, Psychiatry, [3]Anat., [1]All India Inst. of Med. Sci., New Delhi, India

Abstract: Background: The most actions of exogenous opioids, such as morphine, are mediated through μ-opioid receptors. By contrast, the activation of the κ-receptor antagonizes various μ-receptor mediated actions in the brain, including analgesia, tolerance, reward and memory processes. Therefore, the aim of present study was to provide more information about the possible action of acute and chronic co-administration of κ-agonist, nalbuphine on opioid dependence also it is not properly known whether the effect of acute and chronic doses of nalbuphine are similar in attenuating the opioid dependence.
Method: Male adult Wistar albino rats (n=160) were made physically dependent by

administrating increasing dose of morphine and withdrawals were precipitated with naloxone. Nalbuphine was co-administered acutely and chronically in variable doses (0.1, 0.3, 1.0, 3.0 mg/kg, i.p.) with morphine. Somatic signs of withdrawals were scored by using Gellert-Holtzman (GH) rating scale. Thereafter, brain was carefully dissected out for tyrosine hydroxylase, μ and κ expressions.
Results: Withdrawals from chronic morphine administration produces profound increase in GH-score whereas, TH levels were significantly decreased. Chronic co-administration of nalbuphine significantly suppressed the GH Score and μ-opioid receptor levels whereas, increase the TH and κ -opioid receptors levels. No change was observed with acute co-administration.
Conclusion: These findings suggest that withdrawal-induced reduction in TH levels could be responsible for somatic and as well as subjective symptoms of opiate withdrawal and anti-morphine action of the κ-receptor systems may lead to new drug design and therapeutic strategies for opioid addiction (Supported by ICMR, Govt. of India and nalbuphine gifted by RUSAN Pharma Ltd.).

Title: Characterizing reproductive function in POMC-deficient mice

Authors: *Z. THOMPSON[1], G. L. JONES[2], H. YU[1], M. J. LOW[1]
[1]Mol. and Integrative Physiol., [2]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: The pro-opiomelanocortin (*Pomc*) gene encodes POMC, which is differentially processed to produce adrenocorticotrophin, beta-endorphin, and three melanocyte-stimulating hormones, among other peptides. POMC neurons are principally located in the arcuate nucleus (Arc) of the hypothalamus, where they are essential in the control of food intake, energy expenditure and body weight. Several different homozygous null mutations in the *POMC* gene have been shown to cause early-onset obesity and adrenal cortical insufficiency in a small number of humans. *Pomc* expression in Arc neurons is regulated by two distal enhancers. Mutations in these enhancers selectively reduce the amount of *Pomc* mRNA and POMC peptides in Arc neurons, but not pituitary cells. Furthermore, estrogen receptor alpha can bind to one of these enhancers *in vitro*, and about 25% of Arc POMC neurons express this receptor. Mice with combined deletions of both enhancers (FNΔ1Δ2) have less than one percent of Arc *Pomc* mRNA compared to wildtype mice. Like other mouse models of obesity, FNΔ1Δ2 mice are infertile, but it is unclear whether their reproductive disruption is due primarily to POMC-deficiency in the brain or is secondary to obesity. We are comparing aspects of reproductive function in wildtype and FNΔ1Δ2 female mice, including day of vaginal opening, day of first estrus, estrous cyclicity and fertility. In addition, we are using a related, conditional mutant mouse model (FNΔ2) in which *Pomc* gene expression can be restored by the action of a tamoxifen-inducible Cre-ERT2 transgene after the mice have developed obesity. Because humans with mutations in the *POMC* gene also experience disruptions in timing of puberty, or a cessation of pubertal development, understanding more about how hypothalamic POMC-deficiency impacts reproduction in mice may help to develop therapies for humans impacted by similar mutations.

Title: Human brain gene expression profiles of the cathepsin V and cathepsin L cysteine proteases, with the PC1/3 and PC2 serine proteases, involved in neuropeptide production

Authors: *S. PODVIN[1], A. WOJNICZ[1], V. HOOK[1,2,3]
[1]Skaggs Sch. of Pharm. and Pharmaceut. Sci., UCSD, La Jolla, CA; [2]Dept. of Neurosciences, [3]Dept. of Pharmacol., Sch. of Medicine, UCSD, La Jolla, CA

Abstract: Proteases are required to generate active peptide neurotransmitters, known as neuropeptides, from pro-neuropeptides. Model animal systems have recently illustrated roles for

the cathepsin V (CTSV) and cathepsin L (CTSL) cysteine proteases, combined with the serine proteases PC1/3 (PCSK1) and PC2 (PCSK2), and exopeptidases in the production of neuropeptides. There is notable interest in the human-specific cathepsin V gene that is not present in rodent and other animal models used in prior studies of neuropeptide production. A gap in the field is of the human brain gene expression patterns of these neuropeptide-producing protease systems. Therefore, the goal of this study was to characterize the expression profiles of these pro-neuropeptide processing proteases in human brain. Quantitative gene expression microarray data for 169 human brain regions was obtained from the Allen Institute Human Brain Atlas resource, analyzed as $\log_2$ of gene expression intensity normalized to the mean of human genes (21,245 genes) expressed in human brain. These proteases had $\log_2$ values of 2-12, indicating expression levels above the average of all genes in the human brain, with varying expression levels among the 169 brain regions. CTSV and CTSL displayed moderate to high expression values of 1.9-8.6 and 7.1-10.6, respectively. Interestingly, CTSV and CTSL showed high expression in white matter composed of myelinated axons, consistent with the knowledge that neuropeptide production occurs within axons that transport neuropeptide secretory vesicles to nerve terminals. PCSK1 had a broad range of moderate to very high expression with $\log_2$ of 2-12. PCSK2 had somewhat lower expression levels than PCSK1. The exopeptidase genes RNPEP, CTSH, and CPE each showed fairly even levels of expression throughout the brain, with CPE displaying high expression. The prevalence of these processing proteases throughout human brain regions, including areas rich in neuropeptides such as hypothalamus, is consistent with their roles for neuropeptide production. Further, proenkephalin and NPY precursors, substrates of CTSV and CTSL shown in prior model animal studies, were co-expressed with CTSV and CTSL. These data demonstrate that the human brain expresses the neuropeptide-producing cysteine and serine proteases, with exopeptidases, throughout a multitude of brain regions.

Title: Cell-type-specific expression of neuropeptide precursor and receptor genes in mouse neocortical neurons

Authors: *S. J. SMITH, F. C. COLLMAN, L. ELABBADY, O. GLIKO, L. T. GRAYBUCK, M. KARLSSON, M. NAUGLE, J. SCHARDT, R. SERAFIN, S. SESHAMANI, B. TASIC, Z. YAO, H. ZENG
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Function of the brain's synaptic networks depends profoundly upon adjustment of synaptic weights by spike activity and neuromodulatory chemical signaling. Among the numerous chemical signals known to modulate synaptic transmission, neuropeptides have long attracted attention due to discoveries of their potent effects in critical brain processes such as pain perception, mood and motivational state. Neuropeptides are produced as cleavage products of precursor proteins and stored in dense-cored secretory vesicles, which are released by regulated exocytotic secretion. In mouse, approximately 90 genes have been identified as encoding neuropeptide precursor proteins. In addition, similar numbers of protein species, predominantly G-Protein-Coupled Receptors (GPCRs), have been identified as neuropeptide receptors. The functional architecture of neuropeptide signaling systems has nonetheless remained enigmatic. The high ligand affinities of most neuropeptide receptors suggest the possibilities of humoral and volume transmission signaling, while the presence of neuropeptide secretory vesicles in many presynaptic boutons suggests more focal synaptic actions.
This poster presents new insights into neocortical neuropeptide signaling from deep single-cell RNA-seq transcriptomic analysis and clustering of approximately 20,000 neurons in VISp and ALM regions of mouse cortex (Tasic B, et al., *bioRxiv*. doi.org/10.1101/229542). This clustering identified 53 inhibitory neuron types and 58 excitatory neurons types in these two regions. Eighteen neuropeptide precursor genes with high and strongly cell-type-dependent expression patterns (Npy, Vip, Sst, Cck, Tac2, Penk, Crh, Tac1, Pdyn, Cort, Igf1, Nxph1, Pthlh, Pnoc, Cbln2, Cbln4, Adcyap1, Nucb2) were identified based on the RNA-Seq data. Strongly cell-type-specific expression of 20 GPCRs genes cognate to these 18 peptide precursors (Npy1r, Npy2r, Npy5r, Oprm1, Oprd1, OprK1, Oprl1, Ogfr, Sstr1, Sstr2, Sstr3, Sstr4, Vipr1, Vipr2, Cckb2, Tacr1, Tacr3, Hcrt1, Hcrt2) were similarly identified. The neuropeptide precursor mRNAs were found predominantly in the inhibitory neuron clusters, while the cognate receptor mRNAs genes were more commonly found in excitatory neuron clusters, suggesting a prevailing polarity of neuropeptidergic signaling from inhibitory to excitatory neurons. We are using array tomography to test for the presence of specific neuropeptide secretory vesicles in specific cell types as predicted by the transcriptomic analysis.
We thank Allen Institute for Brain Science founders, Paul G. Allen and Jody Allen, for their vision, encouragement and support.

Abstract: Orphanin FQ (aka nociception; OFQ/N) binds to its cognate opioid-receptor-like 1 (ORL1) in many different areas within the hypothalamus, including those that partake in the regulation of energy balance. It has been shown that ORL1 receptors are expressed in proopiomelanocortin (POMC) neurons within the arcuate nucleus (ARC), as well as in excitatory terminals impinging upon them, and that OFQ/N inhibits POMC neurons both pre- and post-synaptically[Conde, 2016]. Pre-synaptically, OFQ/N inhibits glutamatergic input onto POMC neurons, while post-synaptically, OFQ/N activates G-protein coupled inwardly-rectifying K^+ channels (GIRK) channels. Steroidogenic factor (SF) 1-expressing neurons in the dorsomedial ventromedial nucleus (VMN) of the hypothalamus, which are known to be glutamatergic, have been shown to synapse directly with ARC POMC neurons. Gonadal hormones regulate the hypothalamic energy balance circuitry in part by modulating $G_{i/o}$-coupled receptors and their linkage to GIRK channels. Thus, we tested hypothesis that OFQ/N inhibits neurotransmission via pleiotropic actions at VMN SF-1/ ARC POMC synapses. Electrophysiological recordings were done in slices from both intact male and female NR5A1-Cre mice and eGFP-POMC mice. In optogenetic recordings from POMC neurons in NR5A1-Cre mice, OFQ/N (1μM) significantly decreased the light-evoked excitatory postsynaptic current (leEPSC) more so males than in diestrus or proestrus females, and this inhibition was further accentuated in males fed a high- fat diet (HFD) for approximately 4-8 weeks. In recordings from POMC neurons in eGFP-POMC mice, OFQ/N induced a robust outward current and increase in conductance in voltage clamp, and a hyperpolarization and decrease in firing in current clamp. This effect was again greater in males than in diestrus, proestrus and estrus females. These pre- and postsynaptic actions were abolished upon application of the ORL-1 receptor antagonist BAN ORL-24 (10μM).These findings show that the OFQ/N-induced decrease in glutamate release and activation of GIRK channels at VMN SF-1/ ARC POMC synapses is greater in males than in females, and that diet-induced obesity caused by long term HFD exposure further potentiated OFQ/N-induced

inhibition of excitatory transmission at SF-1/POMC synapses. Overall, these findings demonstrate that OFQ/N regulates neurotransmission at SF-1/ POMC synapses in a sex- and diet-dependent manner.

Title: Colocalization of mor1 and gad67 in mouse nucleus accumbens

Authors: *C. HINKLE, T. N. FERRARO, E. I. DEDKOV, R. J. BUONO
Cooper Med. Sch. of Rowan Univ., Camden, NJ

Abstract: Current understanding of the rewarding and addictive effects of opioids involves mu-opioid receptor (MOR) binding within the nucleus accumbens (NAcc), a region of the basal forebrain. GABA neurons in the NAcc are thought to function to potentiate the rewarding response to opioids, and in fact, drugs that generally stimulate GABAergic activity are also addictive, a phenomenon mediated in part by endogenous opioid systems. It is still unclear how some individuals become susceptible to opioid addiction and thus, further understanding of the interaction between the MOR and other neurotransmitter systems in the reward pathway is needed. We report here evidence supporting the direct interaction between GABA and MOR within the mouse NAcc. Male and female FVB/NJ mice (12-16 months of age) were euthanized via carbon dioxide inhalation and brains processed for histology and immunohistochemistry (IHC). Coronal sections (10-12 um in thickness) were taken through the NAcc at the level of the anterior commissure. A mouse monoclonal antibody against GAD67, an enzyme catalyzing GABA production, was used in conjunction with an anti-mouse rhodamine red-X-labeled secondary antibody to identify GABA neurons. Alternating sections were stained for MOR using a rabbit polyclonal MOR1 antibody linked to the fluorophore FITC. The location of expression of GAD67 and MOR1 was identified using a DAPI nuclear stain. As expected, fluorescence microscopy results show that GAD67 staining is localized predominately in the cytoplasm. Unexpectedly, the MOR1-FITC stain tended to localize in the cytoplasm and cell membrane, but more prominently within the nucleus and nuclear membrane. In separate experiments, we used double-immunostaining to study the co-expression of MOR1 and GAD67 within the same NAcc neurons. A similar localization pattern for these proteins was detected. There are few published reports of GAD67 and MOR1 co-expression within neurons of the NAcc. Previous studies of

MOR expression show the receptor to be localized to the plasma membrane and, to a smaller degree, intracellularly. Here we found the MOR1 staining to be predominantly in the nucleus and nuclear membrane. Further studies are required to validate the nuclear expression of MOR in GABAergic NAcc neurons. We conclude that individual mouse NAcc neurons may express both MOR1 and GAD67, potentially providing a functional link between opioid and GABAergic systems in the reward pathway.

Title: Evaluation of novel dual-activity opioid-NPFF ligands for receptor affinity, antinociception and tolerance liabilities

Authors: *J. P. MCLAUGHLIN[1], K. L. MCPHERSON[2], M. MOTTINELLI[2], W. SHENG[3], S. O. EANS[3], V. B. JOURNIGAN[4,5], C. MESANGEAU[5], C. R. MCCURDY[2,5]

Abstract: Tolerance limits the analgesic clinical value of mu-opioid receptor (MOR) agonists. Neuropeptide FF (NPFF) mediates hyperalgesia and opioid-induced tolerance through the activation of NPFF-1 and -2 receptors. We hypothesized that ligands with dual MOR agonist/NPFF receptor antagonist activity would produce antinociception with reduced tolerance. Accordingly, a series of ligands were designed with putative dual opioid and NPFF pharmacophoric elements. Nineteen of these novel ligands were synthesized and screened with competition radioligand binding assays *in vitro*, demonstrating a range of affinity for mu-, kappa-, and delta-opioid receptors (nM) as well as NPFF-1 and -2 receptors (μM). Subsequent *in vivo* screening of all compounds (30 nmol, i.c.v.) in mice with 55^{o}C and 48^{o}C warm-water tail-withdrawal assays identified three compounds with better analgesia and anti-hyperalgesia performance, VBJ-192, VBJ-215 and KGM01082. Following up with a more detailed assessment, all three compounds dose-dependently produced equipotent antinociception lasting

at least 50 min, with ED50 (and 95%CI) values of 6.9(4.7-9.5), 16(3.5-38.8) and 22.2(11.3-36.6) nmol, i.c.v., respectively that was antagonized by pretreatment with mu- or kappa-opioid receptors antagonists. All three compounds also dose-dependently attenuated NPFF-induced hyperalgesia. Unlike morphine, when tested in the acute antinociceptive tolerance test, repeated dosing of VBJ-215 showed no tolerance, while VBJ-192 and KGM01082 showed moderate tolerance commensurate with their magnitude of NPFF antagonism. In further examination of the three compounds, mice administrated with VBJ-192 or VBJ-215 showed neither respiratory depression nor elevated ambulation in the Comprehensive Lab Animal Monitoring System (CLAMS), and both VBJ-215 and a low dose of VBJ-192 did not impair coordinated locomotor activity on the rotorod (30 and 100 nmol, i.c.v.). Together, these results confirm the mediating effect of NPFF on opioid tolerance, and suggest the potential of dual-action opioid-NPFF ligands as analgesics with fewer liabilities of use.

Title: Different roles of PD-L1 and PD-L2 in regulating nociceptive synaptic transmission in spinal cord dorsal horn neurons

Authors: *C.-Y. JIANG, M. MATSUDA, Z. WANG, R.-R. JI
Dept. of Anesthesiol., Duke Med., Durham, NC

Abstract: Programmed cell death ligand-1 (PD-L1) is typically produced by cancer cells and has been shown to suppress immunity through PD-1 receptor expressed on T cells. Emerging immune therapies such as anti-PD1 and anti-PD-L1 monoclonal antibodies have shown success in treating cancers such as melanoma, as well as lymphoma, lung cancer, ovarian cancer, and head and neck cancers. We recently demonstrated that PD-1 is also expressed by primary sensory neurons in dorsal root ganglion (DRG). PD-L1 inhibits acute and chronic pain by suppressing nociceptive neuron activity via PD-1 (Chen et al., Nat Neurosci, 2017). PD-L2 is another ligand of PD-1, but its role in nociception is unclear. We compared PD-L1 and PD-L2

expression using RNAscope. We found broad expression of PD-L1 in many DRG neurons but very limited expression of PD-L2 in mouse DRGs. We also tested the effects of PD-L1 and PD-L2 in spinal cord synaptic transmission using patch clamp recordings in isolated spinal cord slices. While PD-L1 significantly reduced sEPSC in lamina IIo neurons, PD-L2 had very mild effects on sEPSCs. Currently, we also comparing the antinoceptive effects of PD-L1 and PD-L2. Our findings suggest that PD-L1 has normal physiological function and may serve as an endogenous neuromodulator or neurotransmitter as well as an endogenous pain inhibitor.Thus, PD-L1 is not only an immune checkpoint inhibitor but may also act as a "neuro checkpoint inhibitor".

Title: Examining the chronic effects of indirect and direct cannabinoid receptor agonists on dopamine transmission in the nucleus accumbens of mice

Authors: K. M. HONEYWELL, T. FREELS, A. CHAFFIN, M. MCWAIN, H. NOLEN, H. J. SABLE, *D. B. LESTER

Abstract: A major problem with current anxiolytic medications is abuse liability; thus, new pharmaceutical targets are being explored. The cannabinoid (CB) system is one potential target. Previous behavioral studies have shown that indirect agonists of the CB system may be more beneficial as anxiolytics than direct CB receptor agonists. Determining the effect of such CB agonists on dopamine release in the nucleus accumbens (NAc), a brain area well known for regulating the rewarding effects of drugs, is critical to assess potential abuse liabilities. The current study compared the effects of chronic administration (one injection per day for 7 days) of the indirect CB agonist arachidonoyl serotonin (AA-5-HT 2.5 mg/kg, i.p.), the direct CB receptor agonist arachidonyl-2-chloroethylamide (ACEA 1 mg/kg, i.p.), and vehicle (control solution with saline and 10% DMSO) on locomotor activity using open field tests and stimulation-evoked NAc dopamine release using in vivo fixed potential amperometry in anesthetized mice. AA-5-HT indirectly agonizes the CB system via inhibition of fatty acid amide hydrolase (FAAH) while also inhibiting transient vanilloid type 1 channels ($TRPV_1$), providing this drug with 2 anxiolytic mechanisms. Open field tests revealed that the 7^{th} injection of ACEA but not AA-5-HT decreased locomotor activity relative to pre-drug baseline (ACEA = 14.41% ± 6.51, AA-5-HT = 54.92% ± 11.85, and vehicle = 55.74% ± 13.2). Amperometric recordings revealed that mice

chronically treated with ACEA but not AA-5-HT had significantly decreased stimulation-evoked dopamine release (ACEA = 0.18 uM ± 0.03, AA-5-HT = 0.23 uM ± 0.03, and vehicle = 0.29 uM ± 0.03). Furthermore, mice chronically treated with ACEA but not AA-5-HT had an increased dopaminergic response to cocaine (10 mg/kg, i.p.) (ACEA = 289% ± 27, AA-5-HT = 197% ± 22, and vehicle = 223% ± 17). Overall, in regards to potential anxiolytic use, these findings suggest that indirect mechanisms of agonizing the CB system may be a better alternative than direct mechanisms if concerned with disrupting dopamine function and inducing abuse liability.

Title: 2-Aminoindan and its ring-substituted derivatives interact with plasma membrane monoamine transporters and α_2-adrenergic receptors

Authors: *A. L. HALBERSTADT[1], S. D. BRANDT[2], W. DONNA[3], M. H. BAUMANN[3]

Abstract: Over the last decade many new controlled psychostimulant substance analogues have appeared on the recreational drug market and many of these substances are derivatives of amphetamine or cathinone. Another class of designer drugs are derived from the 2-aminoindan structural template. Several members of this class, including the parent compound 2-aminoindan (2-AI), have been available in Europe as designer drugs. Here we tested 2-AI and its ring-substituted derivatives 5-methoxy-2-aminoindan (5-MeO-AI), 5-methoxy-5-methyl-2-aminoindan (MMAI), and 5,6-methylenedioxy-2-aminoindan (MDAI) for their abilities to interact with plasma membrane monoamine transporters for dopamine (DAT), norepinephrine (NET) and serotonin (SERT). We also compared the binding affinities of the 2-aminoindans at 29 receptor and transporter binding sites. We found that 2-AI was a selective substrate for NET (EC_{50} = 86 nM) and DAT (EC_{50} = 439 nM). Ring substitution increased potency at SERT while reducing potency at DAT and NET. MDAI was moderately selective for SERT (EC_{50} = 114 nM) and NET (EC_{50} = 117 nM), with 10-fold weaker effects on DAT (EC_{50} = 1,334 nM). 5-MeO-AI exhibited some selectivity for SERT (EC_{50} = 134 nM), having 6-fold lower potency at NET

(EC_{50} = 861 nM) and 20-fold lower potency at DAT (EC_{50} = 2,646 nM). Conversely, MMAI was highly selective for SERT (EC_{50} = 31 nM), with 100-fold lower potency at NET (EC_{50} = 3,101 nM) and DAT (EC_{50} > 10,000 nM). In addition to their effects on monoamine release, the 2-aminoindans had relatively high affinity for α_2-adrenoceptor subtypes. 2-AI had particularly high affinity for α_{2C} receptors (K_i = 41 nM) and slightly lower affinity for the α_{2A} (K_i = 134 nM) and α_{2B} (K_i = 211 nM) subtypes. α_2-Adrenoceptor affinity was reduced by ring substitution but 5-MeO-AI, MMAI, and MDAI still bound with submicromolar or micromolar affinity. 5-MeO-AI and MMAI also had moderate affinity for the 5-HT_{2B} receptor (K_i values of 4,793 nM and 902 nM, respectively). Based on these results, 2-AI is predicted to have (+)-amphetamine-like effects and abuse potential whereas the ring-substituted derivatives may produce 3,4-methylenedioxymethamphetamine (MDMA)-like effects but with less abuse liability

Title: Encoding of phasic nucleus accumbens dopamine release by ventral tegmental area neurons revealed through simultaneous single-unit recording and fast-scan cyclic voltammetry

Authors: *D. F. HILL[1], Z. OLSEN[1], M. L. HEIEN[2], S. L. COWEN[3,4]
[1]Physiological Sci., [2]Dept. of Chem. and Biochem., [3]Dept. of Psychology, [4]Evelyn F. McKnight Brain Inst., Univ. of Arizona, Tucson, AZ

Abstract: Dopaminergic signaling is known for its role in reward valuation, reinforcement learning, and memory. Dysregulation of dopamine signaling is also implicated in neuropathological conditions such as depression, schizophrenia, movement disorders, and addiction. Dopamine is released from ventral tegmental area (VTA) neurons and acts on dopamine receptors in the nucleus accumbens (NAc) to modulate cortical input. Dopaminergic terminals in the NAc are thought to release dopamine in response to large population-level burst activity in the VTA. However, the exact relationship between VTA cell activity and NAc dopamine release has not been established due to technological limitations that have prevented

simultaneous measurement of both dopamine release and single-unit activity. To address this, we collected simultaneous measurements of cell firing in the VTA and dopamine release in the NAc using a novel measurement tool developed in our laboratory that integrates extracellular electrophysiological recording with fast-scan cyclic voltammetry. To induce phasic dopamine release, anesthetized Sprague Dawley rats (n = 10, 3 - 4 months old, 1 - 1.5 % isoflurane) were injected with dopamine transporter inhibitor GBR-12909 (17.5 mg/kg, i.p.) and D2 receptor antagonist eticlopride (0.75 mg/kg, i.p.). Although we predicted that a large portion of recorded dopamine neurons would fire before the onset of transient dopamine release events, we found instead that only ~ 8 % of VTA dopamine neurons exhibited reliable peri-event responses before a dopamine transient release event. Additionally, transient dopamine release events were associated with small (< 1 Hz) increases in dopamine neuron activity. Neurons that did exhibit reliable responses to transient dopamine release events responded long before the onset of transient dopamine release (980 ± 403 ms SEM; n = 5 neurons). We also observed that the firing rate of putative GABAergic neurons in the neighboring 'tail' of the VTA (tVTA), a region thought to be the 'master brake' of the VTA, decreased as cell firing of both dopaminergic and non-dopaminergic neurons in the VTA increased. Taken together these data suggest that NAc dopamine release is encoded by sparse signals from VTA dopamine neurons that are under tight control by inhibitory neurons of the tVTA.

Title: Electrochemical characterization of chemogenetically modulated dopamine transmission in the olfactory tubercle

Authors: *R. BHIMANI[1], C. E. BASS[2], J. PARK[1]
[1]Univ. at Buffalo, Buffalo, NY; [2]Univ. at Buffalo SUNY, Buffalo, NY

Abstract: The selective targeting of specific neuronal subtypes using chemogenetic techniques, such as Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), has facilitated the understanding of the functional roles of complex brain circuits. While DREADDs are a powerful tool for transient and repeated manipulation of neurons, how activation of excitatory or inhibitory DREADDs affects neurotransmitter dynamics (release and clearance) is poorly understood. In this study, we used a combinatorial viral targeting system to restrict

DREADD expression to dopamine (DA) neurons in the ventral tegmental area (VTA)/substantia nigra (SN) of wild-type rats. We then employed in vivo fast-scan cyclic voltammetry (FSCV) to determine how systemic administration of Clozapine-N-oxide (CNO), a biologically inert ligand for DREADDs, modulates DA transmission in the olfactory tubercle (OT), an important limbic structure located in the ventral-most part of the ventral striatum that is implicated in mediating the rewarding effects of drugs. Through immunohistochemical and electrochemical evidence, we demonstrated selective viral targeting of DA neurons and determined that CNO dose-dependently (0.3 - 6.0 mg/kg, i.p) activates DREADDs, leading to excitation and/or inhibition of DA release evoked by electrical stimulation of the VTA/SN in urethane-anesthetized rats. These results will facilitate the understanding of DA neurons in essential brain functions, as well as establish guidelines for the use of DREADDs in behavioral studies.

Title: Robust expression of 5HT2A and 5HT2B in glia cells: A comparative immunohistochemical study of non-principal cells

Authors: *A. CONTRERAS[1], R. M. HINES[2], D. J. HINES[2]
[1]Psychology, Univ. of Nevada, Las Vegas, Las Vegas, NV; [2]Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Serotonin action on principal excitatory cells is implicated in mood regulation and thought to be mechanistic for part of the dysfunction in many psychiatric disorders. While pharmacological treatments targeting serotonin signaling can be highly effective their exact mechanism is not clearly understood. Released serotonin may bind to any of seven 5HT receptor subtypes, with the 5HT2 family having a critical role in mood disorder pathology. Recent findings in cultured cells and expression systems have demonstrated serotonin receptor expression and function in non-principal cells, yet a comprehensive and comparative localization of these receptors in intact tissue has yet to be completed. In the present study, we examined 5HT2A and 5HT2B receptor expression in parvalbumin-positive inhibitory interneurons, GFAP-positive astrocytes, and Iba1-positive microglia in the mouse cortex and hippocampal CA1 region. Using immunohistochemistry and confocal microscopy, we characterize differential 5HT2A and 5HT2B receptor expression that varies both by cell type and brain region. We detected robust expression levels of 5HT2A in microglia cells, which are not conventionally thought to participate in serotonin signaling. These findings elucidate the potential contributions

of specific 5HT2 receptor subtypes to normal brain function via non-principal cells and may have implications for the mechanisms of action of drugs that target these receptors.

Title: *Caenorhabditis elegans* as a molecular model organism for drug addiction

Authors: *M. HAY, M. SMITH, R. EL BEJJANI
Davidson Col., Davidson, NC

Abstract: Drugs of abuse cause addiction through neuronal modulations, though the molecular mechanisms of addiction are poorly understood and targeted treatment options are scarce. The immense social and financial costs of drug addiction necessitate further investigation. The rewarding effects of these drugs act through many of the same monoamine proteins in humans as in invertebrates. Since the human nervous system is quite complex, this research utilizes a simple, reliable model for investigation of the molecular mechanisms of action underlying cocaine and MDMA using the invertebrate nematode *Caenorhabditis elegans*. Previous research confirms high molecular conservation of the dopamine and serotonin reward systems between humans and *C. elegans*. We set out to investigate the effects of cocaine and MDMA on *C. elegans* egg laying as a marker for activation of the serotonergic system. Cocaine inhibits the dopamine, serotonin and norepinephrine transporters in mammals, whereas MDMA interferes in vesicle packaging of neurotransmitters and is a known serotonergic agonist. Our results show a dose-dependent increase in egg-laying in response to cocaine (mean eggs laid/animal/hour = 6.56 at 70 mM and 2.82 at 35 mM, $p < 0.0001$ for both concentrations as compared to an osmotic and a negative control) and a smaller increase in response to MDMA (mean eggs laid/animal/hour = 1.1 at 35 mM, $p = 0.0048$ compared to osmotic control and $p = 0.0019$ compared to negative control). Significantly, we observed a curled posture of worms subjected to MDMA (88.00% curled). Reduction of function mutations in the ortholog of the vesicular proton ATPase required for neurotransmitter transport into vesicles show an identical posture in the same assay (*unc-32;him-5* control strain, 79.49% curled, Fisher's exact test MDMA treated wild type *vs* untreated *unc-32* mutants $p = 0.3802$). To further investigate this finding, we will test for resistance to

MDMA when *unc-32* is overexpressed. Finally, we are also adapting a Conditioned Place Preference experiment to be applied on relevant mutant strains. We aim to use this system and our posture and egg laying assays to measure addictive behavior to MDMA and cocaine and elucidate the molecular mechanisms involved.

Abstract: The medial prefrontal cortex (mPFC) plays a key role in cognitive and emotional behaviors affected in many neuropsychiatric disorders. Dopamine is a major modulator of layer 5 (L5) pyramidal neurons, which are a main output from mPFC. L5 neurons can be divided into subpopulations based on their expression of various dopamine receptors. Previous studies from our laboratory showed that subcortically projecting L5 pyramidal neurons exhibit a specific modulation of intrinsic excitability after dopamine type 2 receptor (D2R) activation. However, the effects of dopaminergic modulation on specific circuits and behavior remain unclear. To test whether dopamine modulates behavior through defined circuits, we have used a combination of genetic models, behavioral assays, optogenetic manipulations, pharmacology, patch-clamp recordings and *in vivo* calcium imaging. We have found that D2R activation can enhance responses of mPFC neurons to inputs from the mediodorsal thalamus (MD) but not other sources. This mechanism is cell-type specific and depends on specific voltage gated ion channels. D2R deletion in the mPFC disrupts normal social behavior. Furthermore, optogenetic inhibition of projections from the MD thalamus to mPFC can decrease social interactions. Together, these observations suggest a role for this mechanism in social behaviors. Interestingly, we found that the D2R-mediated potentiation of MD-mPFC synapses can be abolished under

pathological conditions: cocaine administration, DISC1 dominant negative and chronic social defeat stress. In these cases, the D2R-mediated potentiation can be rescued by preventing D2R internalization and degradation, suggesting that under some conditions, the downregulation of surface D2Rs may lead to the loss of this modulation, potentially driving behavioral effects.

Title: A novel serotonergic microcircuit in the *Drosophila* visual system

Authors: *M. M. SAMPSON[1], K. MYERS GSCHWENG[2], M. FRYE[3], D. KRANTZ[2]
[1]Mol. Toxicology, [2]Psychiatry, [3]Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Serotonergic projections densely innervate the visual system of the fruit fly *Drosophila melanogaster*, yet the role of serotonin signaling in the optic lobe remains unknown. Here, we characterize cells expressing serotonin receptors and identify a microcircuit modulated by serotonin. *Drosophila* have five serotonin receptors that are homologous to mammalian 5-HT1A, 5-HT1B, 5-HT2A, 5-HT2B and 5-HT7. We found that 5-HT1A, 5-HT1B and 5-HT7 are expressed in serotonin-immunoreactive projections, presumably functioning as autoreceptors. We also identified several neurons that house serotonin heteroreceptors, including lamina monopolar cell 2 (‘L2’), expressing excitatory 5-HT2B and 5-HT7 receptors, and ‘T1’, expressing inhibitory 5-HT1A and 5-HT1B receptors. Serotonin neurons were not found to synapse onto L2 or T1 neurons, indicating signaling via volume transmission. However, L2 and T1 neurons both synapse onto serotonergic projections, in contrast to several other serotonin receptor-expressing cells we examined. Intriguingly, there are reciprocal synaptic connections between L2 and T1 neurons themselves. Thus, activation of serotonin receptors independently modulates each visual neuron, while the L2/T1 synaptic connection acts as a potential integration site. L2 and T1 both form reciprocal synapses with lamina monopolar cell one (‘L1’), together encompassing the light-OFF and -ON visual pathways. This is the first description of serotonin signaling to visual processing neurons that function as inputs to fly visuomotor behaviors. The

Drosophila visual system's well-characterized circuitry provides an ideal model system to inform our understanding of long range serotonergic signaling and reveal basic principles of modulatory network function.

Title: CTR1 in normal striatum, substantia nigra, and cortex

Authors: *K. E. SCHOONOVER[1], C. NGUYEN[2], C. FARMER[3], R. C. ROBERTS[4]
[1]Psychology and Behavioral Neurosci., [2]Psychiatry, Univ. of Alabama At Birmingham, Birmingham, AL; [3]Univ. of Alabama at Birmingham, Birmingham, AL; [4]Psychiatry and Behavioral Neurobio., Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: Copper is crucial for several cellular functions including proper monoamine metabolism, mitochondrial activity, and myelination. Abnormal copper levels are implicated in several brain disorders such as Menke's disease, Wilson's disease, and probably schizophrenia (SZ). In fact, copper-decreasing experimental manipulations (such as a diet containing the copper chelator cuprizone) produce demyelination, increased dopamine, decreased expression of oligodendrocytic (OLI) proteins and SZ-like behavioral impairments. The copper transporter CTR1 transports copper across the blood brain barrier, but has rarely been studied in human postmortem brain. In this study we used immunohistochemistry to localize CTR1 in the striatum, substantia nigra (SN), and prefrontal cortex of twelve normal controls, with four cases examined for each brain area (5F&7M; overall mean PMI and age were 11.83hr and 46yrs). Rabbit anti-CTR1 (dilution 1:2000, Novus Biologicals NB100-402) was used. Preadsorbtion with CTR1 blocking peptide neutralized all staining, confirming antibody specificity. Cellular staining was infrequent throughout most of the striatum, while endothelial cells, labeled punctate structures, and beady fibers were observed. There was dramatic staining of fibers and ependymal cells at the ventricular border of the caudate. Very few, if any, stained astrocytes (AST) and OLI were observed in the striatum; however, AST were occasionally labeled in the external and internal capsule. Diffusely labeled puncta were observed in the white, but not grey, matter of the striatum. The SN contained a large number of stained endothelial cells within dopaminergic and

nondopaminergic regions; prominently labeled endothelial cells were also common in white matter. Most dopaminergic neurons appeared to be labeled. Very few, if any, labeled AST and OLI were observed. However, densely labeled neuropil was observed throughout the SN. Labeled beady fibers were also present. Labeling was present in neuropil, neurons and glia of the cortex. Labeled neurons, including pyramidal neurons, were scattered throughout grey matter. Blood vessels lined with stained endothelial cells were prominent in both grey and white matter. Subcortical white matter was heavily stained with fibers, punctate structures, glial cells and endothelial cells. CTR1 labeling differed between regions. The rich staining of CTR1 in the SN, cortex and hippocampus (previous work) parallels the known concentrations of copper in the brain. This study yields novel information about cell-specific CTR1 copper transport in postmortem human cortex, SN and striatum, which could elucidate disease state etiology.

Title: Dual actions of Psalmotoxin at ASIC1a and ASIC2a heteromeric channels (ASIC1a/2a)

Authors: R. H. HAGAN, J. SCHOELLERMAN, *Y. LIU
Neurosci., Janssen Res. and Develop. La Jolla, San Diego, CA

Abstract: Acid-Sensing Ion Channels (ASICs) are gated by extracellular protons and play important roles in physiological and pathological states, such as pain and stroke. ASIC1a and ASIC2a, two of the most highly expressed subunits in the brain, form functional homo- and hetero-meric (ASIC1a/2a) channels. The function of ASIC1a has been widely studied using psalmotoxin (PcTx1), a venom-derived peptide, as an ASIC1a-selective antagonist. Here, using whole-cell patch clamp, we show that PcTx1 has dual actions at rodent ASIC1a/2a. It can either inhibit or potentiate the heteromeric channel, depending on the conditioning and stimulating pHs. Potent inhibition occurs only at conditioning pHs that begin to desensitize the channel (IC_{50} = 2.9 nM at pH7.0, a threshold pH for desensitization of ASIC1a/2a). By contrast, potent potentiation of the channel can occur at the physiological pH in both CHO cells (EC_{50} = 56.1 nM) and cortical neurons (threshold concentration < 10 nM). PcTx1 potentiates ASIC1a/2a by increasing the apparent affinity of channel activation for protons. As such, potentiation is the strongest at moderate pHs, diminishing with increasing proton concentrations. Our findings identify PcTx1 as a valuable tool for studying ASIC1a/2a function and expand the diverse and complex pharmacology of PcTx1.

Title: New insights into the pathology of glycine receptor autoantibodies in stiff person syndrome

Authors: V. ROEMER[1], N. VON WARDENBURG[1], N. SCHAEFER[1], E. TÜZÜN[2], C. L. SOMMER[3], *C. VILLMANN[1]
[1]Univ. Wuerzburg, Wuerzburg, Germany; [2]Inst. of Exptl. Med., Istanbul Univ., Istanbul, Turkey; [3]Dept. of Neurol., Univ. of Wuerzburg, Wuerzburg, Germany

Abstract: The rare neurological disease stiff person syndrome (SPS) is triggered by autoantibodies against various neuronal structures including intracellular proteins like the GABA-synthesizing enzyme glutamate decarboxylase (GAD) and the vesicle-associated protein amphiphysin or membrane-bound proteins like NMDA receptors and glycine receptors (GlyR). Typical symptoms of SPS-patients are stiffness and painful spasms in axial and proximal limb muscles sometimes accompanied by anxiety and sudden falls. So far, immunotherapy is the most effective treatment but relapses often occur. We focus on SPS-patients carrying GlyR autoantibodies. The first identification of GlyR autoantibodies in a patient was in 2008. This patient showed symptoms similar to the hereditary neurological disorder hyperekplexia, rigidity, brainstem signs and CSF lymphocytosis. Enhanced GlyR internalization induced as a consequence of autoantibody-binding was suggested as the underlying pathomechanism. Furthermore, internalized GlyRs colocalized with the late endosomal marker LAMP2. We use live staining experiments of transfected HEK293 cells to identify GlyR autoantibody-positive sera from SPS-patients. Live stainings of cultured motoneurons resulted in a similar staining pattern. Competition analyses were used for evaluation of the GlyR autoantibody epitope. Therefore, monoclonal anti-GlyR alpha1-antibody mAb2b and sera positive for GlyR autoantibodies were co-incubated in different dilution ratios, thus revealing a shared epitope of both antibodies. Chimeric construct of human and zebrafish GlyR alpha1 could further restrict

the epitope to the N-terminus. Autoantibody-binding to GlyRs had no effect on the ligand affinity of glycine. HEK293 cells transfected with GlyRs as well as spinal cord motoneurons labeled by GlyR-autoantibodies were investigated for further functional GlyR analysis. Using electrophysiological recordings, GlyR efficacy and potency were determined following autoantibody binding in a time window that excluded GlyR internalization as the primary mechanism. Hence, our data widen the knowledge of the pathomechanism of GlyR autoantibodies in SPS.

Abstract: Glycine receptors (GlyRs) are anion-permeable ligand-gated ion channels of the Cys-loop superfamily. In the mammalian CNS, the enhancement of the chloride conductance through the activation of GlyRs results in a transient hyperpolarization of the membrane potential, which is critical to control the neuronal excitability. The relevance of glycinergic inhibition is underlined by the presence of malfunctional GlyRs in many pathophysiological states, including chronic pain. Previous studies have shown that the dysfunction of GlyRs containing the alpha 3 subunit is a pivotal mechanism of pain hypersensitivity. This pathway involves the activation of prostaglandin receptors and the subsequent PKA-dependent phosphorylation of alpha 3 GlyRs

within the intracellular domain (ICD), which decrease the GlyR-associated currents and in turn enhance the neuronal excitability. Despite the importance of this pain sensitization pathway associated with the dysfunctional alpha 3 GlyRs, our current understanding of the molecular events involved is very limited. Here we report that PKA-mediated phosphorylation of alpha 3 GlyR decreases the ion channel conductance. We show in addition that the substitution of the PKA-targeted serine with a negatively charged residue within the ICD of alpha 3 GlyRs and of chimeric GLIC-GlyR receptors was necessary and sufficient to generate receptors with impaired conductance. Furthermore, we show that a recently characterized GlyR modulators showing in vivo analgesic activity normalized the impaired conductance of phospho-mimetic alpha 3 GlyRs. Our findings thus propose a molecular framework for a pain sensitization mechanism involving neuronal dis-inhibition and suggest that the allosteric modulation of alpha 3 GlyR alleviates chronic pain at least in part through the restoration of phosphorylated ion channels with impaired chloride conductance.

Title: Modulating ivermectin sensitivity at glutamate-gated chloride channels (GluCls) of haemonchus contortus (Hco) and biophysical properties of inhibitory postsynaptic currents mediated by alpha and alphabeta HcoGluCl receptors

Authors: *M. ATIF[1], J. SMITH[2], A. KERAMIDAS[3], J. LYNCH[3]
[1]Univ. of Queensland - St. Lucia Campus, brisbane, Australia; [2]Inst. of Mol. Biosci., [3]Queensland Brain Inst., Univ. of Queensland, Brisbane, Australia

Abstract: Background: Glutamate-gated chloride channel receptors (GluClRs) are expressed by invertebrates where they mediate neuronal and muscle inhibition. GluClRs are important therapeutic targets for controlling parasitic pest species in agriculture, veterinary practice and human health. The most widely used drug to control pest species is ivermectin (IVM). This drug acts by binding to and potentiating the activity of GluClRs with high potency. However, the continuous and long-term use of IVM has led to the emergence of resistance in many pest

species.
Aim: Our aim was to explore possible mechanisms of IVM resistance in pest species by measuring the glutamate and IVM sensitivity of different homomeric and heteromeric isoforms of GluClRs. We used different methods for this purpose a) two-electrode voltage clamp electrophysiology (TEVC) and oocyte expression b) heterosynapses to measure the inhibitory postsynaptic currents (IPSCs) of GluClRs subunits from the ruminant animal parasite, *Haemonchus contortus* (HcoGluClR).
Results: Glutamate dose-response experiments demonstrated that homomeric HcoGluClRs comprising α subunits and heteromeric HcoGluClRs made of α and β subunits of have similar EC_{50}s, being between 20-30 μM. In contrast, homomeric HcoGluClRs containing β subunits exhibit an increased EC_{50} of 300 μM. The most IVM-sensitive receptors were the α HcoGluClRs with an EC_{50} value of 20 nM. An intermediate IVM sensitivity was exhibited by heteromeric αβ HCoGluClRs with EC_{50} of 130-200 nM. Homomeric receptors of HCoGluClRs comprising β subunits were insensitive to IVM (EC_{50} > 10 μM).
We also studied IPSCs mediated by the two isoforms in a cortical neuron-HEK 293 co-culture assay. The IPSC decay time constant was faster for the heteromeric receptors (αβ:15 ms) than for α homomeric receptors (α:40 ms). IVM application prolonged the decay times for both the isoforms wherein increasing the decay time of the α homomer by 2.5 fold to 100 ms and that of αβ heteromer to 70 ms.
Conclusion: Our data from TEVC and IPSCs suggests that a significant determinant of IVM sensitivity at GluClRs is the subunit composition. This implies that an organism can increase resistance to IVM without losing glutamate sensitivity by upregulating the expression of an IVM-insensitive subunit to produce heteromeric receptors.

Title: Modulation of inhibitory receptors by gelsemine, a gelsemium plant alkaloid

Authors: *C. O. LARA[1], A. M. MARILEO[1], V. P. SAN MARTÍN[1], B. MUÑOZ[2], C. F. BURGOS[1], A. SAZO[1], L. G. AGUAYO[1], J. L. GUZMÁN[1], J. FUENTEALBA[1], G. MORAGA-CID[1], G. E. YÉVENES[1]

[1]Dept. of Physiol., Univ. of Concepcion, Concepcion, Chile; [2]Dept. of Physiol., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: $GABA_A$ and glycine receptors ($GABA_A$Rs and GlyRs) are anion-selective ligand-gated ion channels that mediate the inhibitory neurotransmission in the central nervous system. Activation of $GABA_A$Rs and GlyRs controls relevant biological processes, including pain processing, sleep and anxiety. Recent reports coincidentally have shown that natural alkaloids from the *Gelsemium* genus plants, such as gelsemine and koumine, displayed analgesic and anxiolytic activity in behavioral models. Interestingly, these effects were dependent on the activity of inhibitory receptors. However, it is currently unknown whether *Gelsemium* alkaloids can directly modulate the function of GlyRs and $GABA_A$Rs. Here, we examined the functional effects of gelsemine, one of the principal alkaloids produced by the *Gelsemium* genus of plants, on recombinant and native $GABA_A$Rs and GlyRs by using electrophysiological techniques. Using whole-cell recordings of inhibitory receptors expressed in HEK293 cells, we determined that gelsemine exerted conformation-specific and subunit-selective effects on GlyRs. On the other hand, recombinant benzodiazepine-sensitive $GABA_A$Rs were inhibited by gelsemine. The gelsemine modulation of GlyRs was associated with differential changes in the apparent affinity for glycine and in the open probability of the ion channel. Additional electrophysiological studies with chimeric and mutated GlyRs indicated that specific residues within the extracellular domain of GlyRs were essential for the gelsemine effects. Molecular modeling and docking calculations suggest that gelsemine binds to the orthostheric site of GlyR. Similar studies performed on $GABA_A$Rs also suggest that gelsemine binds to the GABA binding site at the interphase between α and β subunits. Further studies performed on cultured neurons showed that gelsemine significantly diminished the frequency of glycinergic, GABAergic and glutamatergic miniature post-synaptic events without altering the average amplitude. Our results show that gelsemine can directly modulate the activity of recombinant and neuronal GlyRs and $GABA_A$Rs. At the molecular level, our data also suggest that gelsemine binds to the orthostheric site of GlyRs and $GABA_A$Rs. In addition, our results showed that gelsemine negatively modulate both inhibitory and excitatory neurotransmission. Future studies may contribute to shed light on the mechanisms underlying the beneficial effects of the *Gelsemium* alkaloids in the control of pathological pain and anxiety through the modulation of inhibitory receptors.

Title: The GLRB mouse mutant spastic - A model system to study agoraphobic behavior

Authors: *N. SCHAEFER, C. VILLMANN
Inst. For Clin. Neurobio., Wuerzburg, Germany

Abstract: The adult glycine receptor is a pentamer of three α and two β subunits that enables fast inhibitory neurotransmission in the central nervous system. The β subunit is encoded by the *GLRB* gene. Mutations in the *GLRB* gene have been assigned as the third most common cause of the neuromotor disorder startle disease. Patients with this rare neurological disorder suffer from exaggerated startle responses following unexpected noise or tactile stimuli. Moreover, a genome-wide association study provided evidence for a link between *GLRB* gene polymorphisms of agoraphobic (AG) patients with an anxiety phenotype based on an Agoraphobic Cognitions Questionnaire (ACQ) in healthy German volunteers. To further investigate the issue of a panic phenotype, we used the mouse model *spastic*. Homozygous *spastic* mice show a neuromotor phenotype due to a splice defect within the *Glrb* gene. The splice defect generates aberrant splice products that lack exon 6 or a combination of exons 5 and 6. As a consequence, reduced amounts of full-length GlyR β protein have been observed. Since homozygous animals die at the age of three weeks after birth, the homozygous animals do not represent a good model to study panic behavior. Heterozygous *Glrb* mutants lack about 50% of full-length GlyRβ in brain regions including cortex, cerebellum, thalamus, striatum, hippocampus, brain stem and spinal cord. Heterozygous animals have no motor phenotype, which is in line with the human volunteers carrying *GLRB* gene polymorphism that most probably do not result in large changes of glycine receptor β expression. Thus, heterozygous *spastic* mice were analyzed at the age of 8-10 weeks for an anxiety phenotype. Heterozygous animals show an avoidance of a novel open space, a behavior in line with the agoraphobic fear in human volunteers with *GLRB* polymorphisms. In addition, the distance the animals walked as well as the entries into the open field did not change between heterozygous animals and controls. Furthermore, mice were analyzed in the elevated plus maze, the dark/light field, for the startle reaction, and in the Morris water maze. The last was used as a control for lack of a motor phenotype and a control for learning and memory in heterozygous *spastic* animals. In summary, our findings show that the *Glrb* gene does not only contribute to the neurological disorder hyperekplexia, but also represent a model system useful to investigate agoraphobic behavior associated with differences in the expression level of the glycine receptor β subunit.

Title: The role of phenylalanine residues in the extracellular domain of the glycine receptor

Authors: *S. C. LUMMIS, B. TANG
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The extracellular domains (ECDs) of Cys-loop receptors characteristically contain many aromatic amino acids, but only those in the binding pocket have been extensively studied. Here we show that many Phe residues in the ECD which are not located in the binding pocket are also involved in the function of the glycine receptor, a typical Cys-loop receptor. The Phe residues were explored by creating a range of mutant receptors, characterising them using two electrode voltage clamp in *Xenopus oocytes*, and interpreting changes in receptor parameters using currently available structural information on the open and closed states of the receptor. The data reveal that substitution of most of the Phes in the ECD with Ala alters the function of the receptor; of the 14 Phe residues 2 Ala substitutions ablate function, 3 cause >100 fold changes in EC_{50}, 3 cause changes in EC_{50} 10-100 fold, and 2 change EC_{50} 2-10 fold. Only 4 of these mutants resulted in EC_{50}s similar to WT. Substitution with other amino acids, combined with examination of nearby residues that could potentially interact with these Phes, suggests interactions that could be important for the correct functioning of glycine receptors, and possibly also for other members of the Cys-loop receptor family. Overall the data suggest many regions of the ECD are important for receptor function, and they also indicate potential novel regions that could be targeted in the design of novel therapeutic agents.

Title: Gastrokinetic agent, mosapride inhibits 5-hydroxytryptamine 3 receptor currents in NCB-20 cells

Authors: *K.-W. SUNG[1], S. JEUN[2], Y. PARK[3]
[1]Pharmacol., The Catholic Univ. of Korea, Med. Col., Seoul, Korea, Republic of; [2]Catholic Univ., Seoul, Korea, Republic of; [3]Anat., The Catholic Univ. of Korea, Seoul, Korea, Republic of

Abstract: Mosapride accelerates gastric emptying through acting on a 5-hydroxytryptamine (5-HT) 4 receptor and is used for the treatment of gastritis, gastroesophageal reflux diseases, and irritable bowel syndrome. But its mechanism is still unclear, therefore we tested the effect of mosapride on 5-HT_3 receptor currents, because the 5-HT_3 receptors are known to be expressed in the gastrointestinal system and have an important role for the regulation of bowel movement. Using whole cell voltage clamp method, we compared the currents of 5-HT_3 receptor when 5-HT was applied alone and co-applied with mosapride in cultured NCB-20 cells known to express the 5-HT_3 receptors. The 5-HT_3 receptor current amplitudes were inhibited by mosapride in a concentration dependent manner. Mosapride blocked the peak currents in a competitive manner, because the EC50 was shifted to the right without the change of maximal effect evoked by the 5-HT application. The 5-HT_3 receptor current rise slopes were decreased by the mosapride. It accelerated the desensitization of 5-HT_3 receptor, but did not affect the receptor deactivation. There were no voltage-, and use-dependency in its blocking effects. Mosapride also did not change the recovery process from the receptor desensitization. These results suggest that mosapride inhibits the 5-HT_3 receptor through a competitive blocking mechanism. From this study, we could expand our understanding the pharmacological and therapeutic mechanisms of mosapride to improve gastrointestinal motility and to treat several gastrointestinal disorders.

Title: Effects of acid-sensing ion channels on modulation of locomotor activity by amphetamine

Authors: Q. JIANG[1], N. GOVALLA[1], *X. CHU[2]
[1]Biomed. Sci., [2]Basic Med. Sci., Univ. of Missouri Kansas City, Kansas City, MO

Abstract: Drug addiction is a persistent mental illness and there is no effective therapy for patients. The precise mechanisms underlying addictive responses have not been completely deciphered. New evidence has been shown that ion channels in the brain reward circuits are believed to play a vital role in drug addiction. Acid-sensing ion channels (ASICs) are highly expressed in brain with ASIC1a and ASIC2 channels being the predominant subtypes. These channels are enriched at synaptic sites and are central for the regulation of normal synaptic transmission. Moreover, increasing evidence is linking ASICs to the pathogenesis of various neurological and neuropsychiatric disorders. We and others have shown that ASICs are involved in cocaine addiction. Here, we hypothesized that amphetamine, a psychostimuland similar to cocaine, may also impact the function of ASICs. Adult wild-type (WT) C57BL/6J, ASIC1 and ASIC2 knock-out (KO) mice were placed in individual test chambers to allow accommodation to novel environment for 60 minutes. They then received a single intraperitoneal (i.p) injection of amphetamine at 3.0 mg/kg, and their locomotor activities were recorded for 150 minutes. The experiment was repeated daily for a total of 5 days. After a 2-week withdrawal period, the mice were brought back to the behavioral chamber followed by a final challenge i.p injection of amphetamine at 1.5 mg/kg. Locomotor activity to this challenge dose was measured for 150 min. Acute amphetamine injection induced a typical dose-dependent increase in locomotor activities in WT, ASIC1 and ASIC2 KO mice (both male and female mice). However, the increase in locomotor activities were attenuated in ASIC1 and ASIC2 KO mice as compared to WT mice. Both WT, ASIC1 and ASIC2 KO mice showed sensitization to amphetamine. However, ASIC1 KO mice showed more, while ASIC2 KO mice showed less behavioral sensitization to amphetamine. Our data provides new understanding of the complex genetic and molecular mechanisms of ASICs in response to amphetamine exposure.

Title: Development of $GABA_A$receptor positive modulators with low abuse potential

Authors: *M. CLAUDIO[1], R. HUANG[2], G. H. DILLON[1], K. A. EMMITTE[3], N. MISHRA[3]

Abstract: $GABA_A$ receptors have long been considered as targets for treatment of acute pain and neuropathic pain conditions. Our previous studies have shown that carisoprodol (CSP), a widely

prescribed muscle relaxant to treat low back pain, differentially potentiates $GABA_A$ receptor subtypes with strongest potentiation on α1- containing $GABA_A$ receptors. Furthermore, it has been reported that α1-containing $GABA_A$ receptors are associated with abuse-related effects while α2/α3-containing receptors are linked with anti-nociceptive and muscle relaxant effects. The purpose of the present study is to investigate the structure and function relationship of CSP in an effort to seek a compound with lower α1 efficacy and putative α2/α3 selectivity and thus maximize CSP's clinical utility with lower abuse liability. Focusing on particular positions of our parent compound, CSP, a series of novel compounds were synthesized with various side-chain modifications. The subtype selectivity profile was examined on HEK cells expressing various recombinant $GABA_A$ subtypes with whole-cell patch clamp. Animal behavioral assays were performed to assess the effects of drugs on motor function, nociception and abuse potential. We show that modifications made to CSP's structure were able to shift its original subunit selectivity profile. Some of the synthesized CSP analogs have shown relatively high efficacy on α2-containing receptors. Our preliminary results provide a future direction for the development of subtype-selective GABAergic drugs for the treatment of chronic pain and other neuropathic pain conditions.

Title: Function and pharmacology of the $GABA_A$θsubunit

Authors: *J. NUWER, M. W. FLECK
Albany Med. Col., Albany, NY

Abstract: $GABA_A$ receptors are chloride channels that are the primary mediators of inhibitory neuronal transmission. These channels are pentamers composed from 19 possible subunits (α_{1-6}, β_{1-3}, γ_{1-3}, δ, ε, θ, π, and ρ_{1-3}). The canonical $GABA_A$ receptor contains 2 α subunits, 2 β subunits, and 1 other subunit - typically γ. However, non-canonical subunit combinations can also create functional receptors with unique pharmacology. Non-canonical θ-containing combinations have been shown to create plasma membrane-expressed receptors that are not activated by GABA or known $GABA_A$ ligands. θ is expressed primarily in aminergic midbrain and brainstem nuclei, the hypothalamus, and the hippocampus. This is a discrete expression pattern, unlike that of the

subunits that make up the canonical receptor. Therefore, we believe the θ subunit could prove to be a novel, druggable target for aminergic dysfunction without widespread side effects. To date, there are only two publications exploring the role of θ in $GABA_A$ pharmacology, however they report contradictory findings. Our lab has observed that θ does not assemble into pentamers when expressed in recombinant HEK293 or COS7 cells. Whole-cell voltage-clamp comparisons of $\alpha_3\beta_3$, $\alpha_3\theta$, and α_3-only transfections reveal that $\alpha_3\theta$ is not different than α_3-only with regard to current amplitude (both ~90 pA), EC_{50} (both ~30 uM), and histamine potentiation (both ~300% potentiation). Non-permeabilized staining of $^{HA}\theta$ in combinations that were previously shown by another lab to be present at the plasma membrane was nonexistent in our hands; however, $^{HA}\theta$ expression was confirmed intracellularly and the protein was not degraded, as shown by permeabilized staining and Western blotting. The absence of assembly could be due to a lack of an accessory protein, the presence of a protein that inhibits assembly, or cell type and species differences. To circumvent the problem with recombinant systems, we have identified cell lines that natively express the θ subunit. If θ is assembled into the $GABA_A$ receptors in these cell lines, the results of this study are expected to reveal any interacting proteins as well as expand our knowledge about the pharmacological contributions of θ to $GABA_A$ function.

Title: GABA accumulation during theta-rhythms is responsible for second order oscillations

Authors: *A. V. SEMYANOV[1,2,3], A. PUSHKAREV[2], E. IVLEV[2], I. NOVOZHILOV[2], A. MIRONOV[2,4]
[1]Inst. of Bioorganic Chem., Moskva, Russian Federation; [2]Univ. of Nizhny Novgorod, Nizhny Novgorod, Russian Federation; [3]All-Russian Res. Inst. of Medicinal and Aromatic Plants, Moscow, Russian Federation; [4]Fundamental Res. Inst., Privolzhsky Res. Med. Univ., Nizhny Novgorod, Russian Federation

Abstract: Hippocampal theta-rhythm appears in oscillation epochs (episodes of synchronized activity followed by silent intervals) that contribute to encoding of spatial and behavioral information. Here we suggest a mechanism responsible for appearance of these second-order oscillations. We recorded hippocampal theta-rhythms with a wireless system in freely moving mice. Rhythmic modulation of the theta power was studied using wavelet analysis. 1 μM

picrotoxin was injected through a chronically implanted cannula to selectively block tonic $GABA_A$ conductance. The injection significantly increased the length of the theta-rhythm epochs and decreased the inter-epoch intervals. Larger concentrations of picrotoxin (10 μM and 100 μM), which also block synaptic $GABA_A$ mediated signalling, shortened the theta-rhythm epochs and prolonged the inter-epoch intervals. This finding is consistent with previous reports that synaptic GABAergic signalling is required for synchronization of neuronal networks. Then we facilitated activity-dependent tonic $GABA_A$ conductance increase by blocking GABA uptake. Both a GAT-3 inhibitor SNAP-5114 (100 μM) and a GAT-1 inhibitor NNC-711 (10 μM) significantly shortened the epochs and increased the inter-epoch intervals. 100 nM allopregnanolone, highly potent positive allosteric modulator of extrasynaptic $GABA_A$ receptors, shortened the epochs and increased the inter-epoch intervals likewise. In summary, we suggest that accumulation of extracellular GABA during synchronized neuronal activity inhibits neurons and stops their firing, hence rhythmic activity. When the neuronal activity is reduced, the ambient GABA concentration also decreases. Such fluctuations in the ambient GABA are responsible for the rhythmic modulation of the theta oscillations. GABA uptake or enhancement of tonic $GABA_A$ current with allopregnanolone modulate the epochs of the theta rhythms. Our findings also shed light upon possible mechanisms by which endogenously produced allopregnanolone exerts its physiological effects.

Title: The GABA-A receptor antagonists TETS and RDX bind in the pore of the GABA-A channel

Authors: *B. PRESSLY[1,2], I. PESSAH[3], H. WULFF[2]
[1]UC DAVIS, Davis, CA; [2]Pharmacol., [3]Unit Dept. of Mol. Biosciences, Sch. of Vet. Med., Univ. of California Davis, Davis, CA

Abstract: The rodenticide tetramethylenedisulfotetramine (TETS) is a potent convulsant (lethal dose in humans 7-10 mg) that is listed as a possible threat agent by the United States Department of Homeland Security. TETS has previously been studied *in vivo* for toxicity and *in vitro* in

binding assays, with the latter demonstrating it to be a non-competitive antagonist on $GABA_A$ receptors. However, since it was unknown whether TETS exhibits subtype selectivity for a particular $GABA_A$ receptor combination, we used whole-cell patch-clamp to determine the potency of TETS on the major synaptic and extrasynaptic $GABA_A$ receptors associated with convulsant activity. We found that TETS exhibited the highest potency towards blocking α2β3γ2 (IC_{50} 480 nM, 95% CI: 320-640 nM) and α6β3γ2 (IC_{50} 400 nM, 95% CI: 290-510 nM). We next decided to map the TETS binding site on the α2β3γ2 receptor by using a combination of electrophysiology, site-directed mutagenesis and molecular modeling with the Rosetta membrane method to help identify critical residues. In parallel, we are also investigating the structurally related compound RDX (royal demolition explosive; 1,3,5-trinitroperhydro-1,3,5-triazine), a high energy explosive, which is widely used for military and civilian purposes and regulated as an environmental contaminant. RDX induces seizures in humans following accidental exposure during manufacture or in soldiers following inadvertent or intentional ingestion as a perceived illicit drug. We first constructed a homology model of the α2β3γ2 receptor using the published structures of the β3 homopentamer and the β3α5-TMD chimera as templates. Both TETS and RDX were docked in the homology model using Rosetta ligand docking with the membrane function. Rosetta identified three possible interaction sites for both compounds in the pore region of the channel: Site one at the 2' position previously hypothesized as a site of TETS action; site two at T6', which is the traditional non-competitive antagonist site for picrotoxin, TBPS and EBOB; and site three located much higher up in the pore with favorable interactions at the R19' position. We are currently experimentally testing these predictions but hypothesize that both the TETS and the RDX binding sites overlap with, but are not identical to, the picrotoxin binding site.

Title: Adapting the proteostasis network to restore function of epilepsy-associated GABAA receptors

Authors: *T. MU, X. DI
Case Western Reserve Univ., Cleveland, OH

Abstract: Proteostasis deficiency in ion channels leads to a variety of ion channel diseases called channelopathies, which are often caused by excessive endoplasmic reticulum-associated degradation (ERAD) and inefficient membrane trafficking of mutant ion channels. We focus on

proteostasis maintenance of gamma-aminobutyric acid type A (GABAA) receptors, the primary inhibitory ion channels in the mammalian central nervous system. Numerous epilepsy-associated missense mutations in the receptor subunits predispose them to rapid ERAD, reduce their cell surface expression, and cause loss of their function. We aimed to use small molecules to adapt the proteostasis network in the ER to restore the surface trafficking and function of such mutant receptors. Our screening assay from a structurally diverse FDA-approved drug library identified lead compounds that enhanced the surface expression of a number of trafficking-deficient mutant receptors. Furthermore, patch clamping electrophysiology showed that these lead compounds restored their function on the plasma membrane. Mechanistic studies revealed that they reduced the degradation by attenuating the ERAD pathway. In addition, they enhanced the folding of the mutant subunits by enhancing their interactions with major GABAA receptors-interacting chaperones. Both ERAD inhibition and folding enhancement contributed to the improved ER-to-Golgi trafficking efficiency of the mutant receptors. These compounds hold the promise to be further developed to ameliorate idiopathic epilepsy resulting from excessive GABAA receptor degradation.

Title: Impaired GABAergic signaling at the axon initial segment alters bursting activity and sleep architecture

Authors: *A. J. BOREN, D. J. HINES, R. M. HINES
Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Interneurons act on principal neurons to pattern excitatory output allowing for neuronal synchronization and maintenance of homeostatic rhythms. Changes in excitatory patterning due to disruptions in inhibitory signaling are thought to be mechanistic in neuropsychiatric and neurodevelopmental disorders including developmental epilepsy, autism spectrum disorder, and schizophrenia. In support of a critical role of inhibitory regulation, neuropsychiatric and neurodevelopmental disorders share common symptomology including spontaneous recurrent seizure, abnormal sleep architecture, and altered circadian rhythmicity. Providing phasic inhibition necessary for patterning excitatory output, γ-aminobutyric acid type A receptors ($GABA_ARs$) are heteropentameric chloride channels constructed from a diverse set of subunits resulting in 26 known human isoforms with several subtypes having unique signaling characteristics. $GABA_ARs$ containing the α2 subunit are trafficked to the axon initial segment

(AIS) postsynaptic to chandler cells, a synaptic site central to neuronal synchronization. Despite the high abundance of α2 at the AIS, little is known about its contribution to common symptomology seen in neuropsychiatric and neurodevelopmental disorders. Behavioral and electroencephalographic techniques were used to examine cortical bursting activity, sleep-state architecture, and circadian rhythmicity in transgenic mice with a knock-in mutation that reduces α2 trafficking onto the AIS (Gabra2-1). Our results indicate reduced α2 signaling at the AIS plays a pivotal role in the breakdown of rhythmic homeostatic functions and abnormal cortical activity common to neuropsychiatric and neurodevelopmental disorders. Increased understanding of the contribution of α2 signaling on the AIS to common symptomology seen in these disorders will allow for the development of novel, targeted, therapeutics
as well as further our understanding of the mechanisms underlying excitatory patterning.

Title: Effects of neurosteroids and phosphorylation on $GABA_A$receptor currents and piriform cortex circuit in epilepsy

Authors: *J. JEONG, M. O. POULTER
Robarts Res. Inst., London, ON, Canada

Abstract: Neurosteroids such as tetrahydrodeoxycorticosterone (THDOC) are well known modulators of gamma-aminobutyric acid (GABA) receptor activities, and thus, they have great influence on circuit activities. THDOC is a potent positive allosteric modulator of $GABA_A$ receptor, and it has been shown to be involved in epilepsy. THDOC potentiates $GABA_A$ receptor by prolonging the decay of inhibitory postsynaptic currents (IPSCs). The modification of IPSC kinetics by neurosteroid can also be influenced by phosphorylation by kinases. However, the interaction of neurosteroids and kinases have not yet been thoroughly investigated and the available information is conflicting.
Previous studies have shown widely varying effects of neurosteroids on GABAergic currents. We hypothesized that the variability is due to varying phosphorylation states of $GABA_A$ receptors. In this study, we have investigated the activity of neurosteroids THDOC on GABAergic miniature IPSCs (mIPSCs) and tonic currents after activation of various kinases, and

their activities in brain circuit. Tonic currents and IPSCs were measured from Sprague-Dawley rat pyramidal neurons (>14 days) in primary culture. Decay of IPSCs were in two phases, fast decay lasting ~10 ms (τ_1) followed by slow decay lasting ~50 ms (τ_2).
THDOC by itself caused shortening of τ_1 and prolongation of τ_2. It also greatly increased the negative charge transfer. Activation of protein kinase C (PKC) using the phorbol ester PMA, or activation of tyrosine receptor kinase B (TrkB) by 7,8-dihydroxyflavone (DHF), did not significantly alter the effects of THDOC. Treatment with THDOC after activation of protein kinase A (PKA) by forskolin resulted in two distinct populations of response. One population showed increased mIPSC amplitude. The other showed prolonged τ_2 compared to the first population. For tonic currents, THDOC caused a large inward shift in holding current, and thus increase in tonic inhibition. All three kinases suppressed the change in tonic current by THDOC. These data show that kinases differentially modulate the effects of neurosteroids on phasic and tonic GABA currents.
Next, we utilized voltage sensitive dye imaging (VSDI) technique to visualize circuit activity of the piriform cortex (PCtx) in brain slice, and how these kinases and THDOC function to modulate circuit activity. The PCtx is one of the most seizure-susceptible region of the brain. Application of THDOC decreased the circuit activity by 40%. However, our preliminary data show that when THDOC is applied in the presence of PMA, THDOC failed to suppress circuit activity. Our preliminary finding suggests that PKC activation blocks the effect of THDOC in the PCtx.

Title: Nonlinear α5-$GABA_A$Rs effectively regulate NMDAR recruitment in CA1 pyramidal neuron dendrites

Authors: *J. M. SCHULZ[1], F. KNOFLACH[2], M.-C. HERNANDEZ[2], J. BISCHOFBERGER[1]
[1]Dept. of Biomedicine, Univ. of Basel, Basel, Switzerland; [2]Pharma Res. and Early Development, Discovery Neurosci. Dept., F. Hoffmann-La Roche Ltd, Basel, Switzerland

Abstract: Dendrite-targeting GABAergic interneurons powerfully control dendritic electrogenesis, synaptic plasticity and learning. However, the underlying mechanisms are not well understood. In the current study, we show that dendritic $GABA_A$ receptors ($GABA_ARs$) in CA1 pyramidal neurons exhibit pronounced outward rectification. Optogenetically activated IPSCs from somatostatin (SOM)- and NOS-positive interneurons linearly increased with holding potential above -50 mV. By contrast, at more negative potentials the synaptic peak conductance was about 3-fold smaller, showing a pronounced non-linear voltage-dependence. On the other hand, fast peri-somatic IPSCs evoked in parvalbumin (PV)-ChR2 mice showed a classical, much more linear behavior. Pharmacological experiments showed that α5-subunit containing $GABA_ARs$ substantially contributed to the non-linear IPSCs generated by SOM and NOS interneurons, while somatic IPSCs evoked by PV interneurons were independent of a5-$GABA_ARs$. Next we tested the impact of synaptic α5-$GABA_ARs$ on the activation of NMDARs. Application of an α5-NAM (RO4938581) increased the amplitude of subthreshold burst PSPs to about 140% of control. This increase was strongly dependent on NMDARs, as it was fully reversible by AP5-application. By contrast, low concentration of gabazine (100 nM) increased burst EPSP to a similar extent, however, in a largely NMDAR-independent manner. Computational modeling in NEURON demonstrated that the slow time course and the nonlinear voltage-dependence of the IPSCs evoked by SOM and NOS interneurons are essential for its powerful control of voltage-dependent NMDAR recruitment. Taken together, nonlinear rectifying α5-$GABA_ARs$ with slow kinetics match functional NMDAR properties and thereby mediate powerful control of dendritic postsynaptic integration by dendrite-targeting interneurons**.**

Title: Elevated O-GlcNAcylation depresses inhibitory transmission recorded from granule cells in the rat dentate gyrus

Authors: *K. ABIRAMAN[1], L. T. STEWART[1], L. L. MCMAHON[2]
[1]Univ. of Alabama at Birmingham, Birmingham, AL; [2]Dept Cell, Developmental, and Integrative Biol., UAB, Birmingham, AL

Abstract: O-GlcNAcylation is crucial for protein function, and involves the addition and removal of an O-linked N-acetylglucosamine (O-GlcNAc) to serine or threonine residues by the enzymes O-GlcNAc transferase (OGT) and OGlcNAcase (OGA), both of which are highly expressed in the hippocampus. We have previously shown that acutely increasing O-GlcNAcylation using the substrate glucosamine or the OGA inhibitor, thiamet-G (TMG), induces long-term depression (LTD) at CA3-CA1 hippocampal synapses that requires O-GlcNAc modification of GluA2 AMPA type glutamate receptor (AMPAR) subunits. Additionally, we found that increasing O-GlcNAcylation dampens epileptiform activity at these same synapses. Because function of $GABA_A$ receptors ($GABA_A$Rs) is modulated by serine phosphorylation, we have begun to ask whether the strength of $GABA_A$R mediated synaptic inhibition is modulated by O-GlcNAcylation. We have found that pharmacologically increasing O-GlcNAc levels in acute slices decreases the amplitude and frequency of spontaneous IPSCs (sIPSCs) but only the amplitude of miniature IPSCs recorded from CA1 pyramidal cells. This indicates that much like phosphorylation, O-GlcNAcylation affects postsynaptic $GABA_A$R function. To assess if this is general mechanism by which inhibition is modulated in the brain, we used whole-cell voltage-clamp recordings from dentate granule cells (DGCs) to investigate whether increasing O-GlcNAcylation modulates the frequency and/or amplitude of spontaneous IPSCs (sIPSCs) onto DGCs. Preliminary experiments found a reduction in both sIPSC amplitude and frequency following pharmacologically increasing O-GlcNAcylation. Collectively, these data will help us parse the effects of O-GlcNAcylation on the input and output stages of hippocampal processing.

Title: Cell-specific transgenic manipulation of $GABA_A$ receptor synaptic clustering in hippocampal neurons

Authors: *S. GEORGE, A. L. DE BLAS
Dept Physiol & Neurbiol, Univ. of Connecticut Dept. of Physiol. and Neurobi, Storrs, CT

Abstract: Synaptic inhibition in the brain is essential to regulate neuronal excitability and is primarily achieved through gamma-aminobutyric acid (GABA) acting on fast-acting GABAA receptors. Collybistin (CB) is critical in the postsynaptic localization of gephyrin and GABAA

receptors at these synapses. The constitutively active isoform of collybistin, CBSH3-, has been shown to be particularly adept at recruiting gephyrin and GABAA receptors to post-synaptic clusters. This effect, which we have shown both in culture and in vivo, is coupled with an increase in synaptic strength, suggesting that CBSH3- is a good target candidate for modulating the strength of inhibitory neurotransmission. For this purpose, we have created an adeno-associated virus (AAV) with a double-floxed cassette that bicistronically expresses the constitutively active isoform of collybistin, CB2SH3-, and mCitrine (as a transduction marker), in a cre-dependent manner. Through unilateral stereotactic injection of our AAV construct into the hippocampus of two mouse lines, VGLUT1-ires2-cre or VGAT-ires-cre, we were able to investigate changes in GABAergic synaptic clusters specifically in hippocampal glutamatergic pyramidal neurons and GABAergic interneurons, respectively. Interneurons transduced with this construct display higher densities and larger sized gephyrin clusters compared to contralateral interneurons or transduced interneurons of VGAT-cre mice injected with a control eGFP-AAV construct. Preliminary data in VGLUT1-cre mice indicate a similar increase in GABAergic postsynaptic proteins in transduced glutamatergic neurons. We therefore conclude that this approach can be used for the controlled manipulation of the strength of GABAergic synapses in specific brain regions and in specific cell-types. We are exploring the possibility of using this AAV in a mouse epilepsy model to reduce seizure seizures and provide neuroprotective effects against excitotoxicity.

Title: Neuroimmune interactions of interleukin 10 (IL-10) with $GABA_AR$

Authors: *S. DECKER, A. SURYANARAYANAN, E. ALTOWAIRQI
Univ. of the Sci., Philadelphia, PA

Abstract: We have previously shown that Interleukin-10 (IL-10), an anti-inflammatory cytokine, is upregulated following a single intoxicating exposure to ethanol (EtOh) in rats (*Neuropharmacology, 2016*). In addition, we have also shown that IL-10 inhibits GABAergic transmission in the hippocampus, causing hyperexcitability via both pre- and postsynaptic mechanisms. However, the molecular mechanisms of the interaction of IL-10 with $GABA_AR$ are not known. Understanding these mechanisms are important in elucidating neuroimmune

regulation of $GABA_AR$ and other ion channels. To further explore these neuroimmune interactions, we are studying the effects of IL-10 exposure on cell-surface expression and phosphorylation of $GABA_AR$ in human neuroblastoma and glial cells. Our results suggest that IL-10 exposure increases the phosphorylation of the β_3 subunit of the $GABA_AR$. To explore a direct interaction of IL-10 with $GABA_AR$, we have also employed two-electrode voltage clamp (TEVC) studies in *xenopus laevis* oocytes expressing human $\alpha_1\beta_2$ and $\alpha_1\beta_2\gamma_2$ $GABA_AR$. The TEVC experiments are looking at the effect of dose-dependent IL-10 exposure on $GABA_AR$ mediated currents. Based on results obtained from *in vitro* cell lines and TEVC experiments, we will perform *ex vivo* studies on rat hippocampal slices to elucidate the mechanisms of interaction of IL-10 with $GABA_AR$.

Taiwan Univ., Taipei, Taiwan

Abstract: We found that the α6-subunit-containing $GABA_A$ receptors ($\alpha6GABA_ARs$) in trigeminal ganglia (TG) are functional since $\alpha6GABA_AR$ positive allosteric modulators (PAMs) attenuated the activation of the trigeminovascular (TGVS) system in a migraine model induced by intracisternal injection of capsaicin (Lee et al., SFN2018 poster). Here, we further evaluate

the potential of α6GABA$_A$R PAMs in migraine treatment in a clinical presentation align animal model, the repetitive nitroglycerin (NTG) -induced migraine model in mice since NTG can trigger migraine in human migrainer. NTG (10 mg/kg, *i.p.*) was injected into mice (6-8 weeks, male ICR) every two days for 5 sessions. The mouse grimace scale (MGS) was used to score the severity of migraine. All five parameters of MGS in NTG-treated mice were significantly greater than in saline-treated mice. In the 5th session, Compound 6 (3 and 10 mg/kg, *i.p.*), an α6GABA$_A$R-selective PAM, injected 20 min after NTG administration significantly attenuated the elevated grimace score in the NTG group to the level as in the saline-treated group. Importantly, this effect of Compound 6 was antagonized by *i.p.* injection of furosemide (20 mg/kg), an α6 GABA$_A$ R-selective antagonist.
There are three trigeminal nerve branches from TG. In addition to the dural ophthalmic branch (V1) that is involved in migraine pathogenesis, the maxillary (V2), and mandibular (V3) branches are important for transmitting orofacial pain. We therefore also assessed the effect of Compound 6 in an orofacial pain model. Type III dental pulp injury (DPI) in mice (8 weeks, male ICR), which resembles irreversible pulpitis in humans and causes severe orofacial pain, was induced by drilling their left maxillary first molars. The DPI-induced orofacial pain in mice was accessed by the reduction of their burrowing behaviors, which are indicators of well-being of mice. DPI significantly decreased the burrowing activity in mice on Day 1, 3, 7, but not Day 14. Ibuprofen (30 mg/kg, *p.o.*) and Compound 6 (3 mg/kg, *i.p.*) restored the burrowing activity on Days 1, 3 and 7 to the level as in sham-operated mice. These results support the effectiveness of an α6GABA$_A$R PAM in animal models with clinical representations of migraine and orofacial pain.

Neurosciences, Med. Univ. Vienna, Vienna, Austria

Abstract: The α6 subunit-containing GABA$_A$ receptors (α6GABA$_A$Rs) are abundant in cerebellar granule cells while their functions remained unclear due to a lack of selective ligands. Recently, we identified several pyrazoloquinolinones to be positive allosteric modulators (PAMs) selective to α6GABA$_A$Rs.[1,2] Using the prototypical Compound 6 (PZ-II-029), we have revealed that positively modulating cerebellar α6GABA$_A$Rs, via attenuating granule cell activity, can rescue disrupted prepulse inhibition (PPI), which reflects sensorimotor gating deficits manifested in several neuropsychiatric disorders.[3] Compound 6 (3 and 10 mg/kg, *i.p.*) significantly rescued methamphetamine-induced PPI disruption in mice. Importantly, this effect was prevented by intra-cerebellar (*i.cb.*) microinjection of furosemide, an α6GABA$_A$R antagonist, and mimicked by Ro15-4513 and loreclezole, (two α6GABA$_A$R PAMs), but not by diazepam (an α6GABA$_A$R-inactive benzodiazepine). In the same animal model, we further examined effects of Compound 6 and three other pyrazoloquinolinones, Compound 11 (PZ-II-028), LAU159 and LAU463, as well as their methoxy-deuterated derivatives. All compounds, applied at 10 mg/kg (*i.p.*) rescued methamphetamine-induced PPI disruption in mice with an efficacy similar to Compound 6. These results indicate that methoxy-deuterated derivatives of pyrazoloquinolinones, which are less susceptible to metabolic O-demethylation,[1] retain the *in vivo* efficacy in the PPI-disrupted animal model. This suggests that deuterated pyrazoloquinolinones with appropriate half-lives (9-13 hr)[1] are first-in-class drugable candidates for treating sensorimotor gating deficits in neuropsychiatric disorders, including but not limited to schizophrenia.

Inst. of Acupuncture Sci., China Med. Univ., Taichung, Taiwan

Abstract: Migraine remains an unmet medical need. Its pathogenesis is attributed to activation of the trigeminal vascular system (TGVS). The α6-subunit-containing $GABA_A$ receptors (α6$GABA_A$Rs) are expressed in trigeminal ganglia (TG), the hub of the TGVS. Here we revealed an unprecedented role of α6$GABA_A$Rs in TGVS activation using several pharmacological approaches in a migraine model induced by intra-cisternal (*i.c.*) instillation of capsaicin. Capsaicin (*i.c.*) induced both central and peripheral TGVS responses in rats. Centrally, it activated the trigeminal cervical complex (TCC), measured by the increased number of c-Fos-immunoreactive (c-Fos-ir) TCC neurons. Peripherally, it elevated calcitonin gene-related peptide immunoreactivity (CGRP-ir) in TG and caused CGRP release from sensory nerve fibers, which was measured by the reduced length of CGRP-ir fibers, in the dura mater. Pharmacological approaches included a recently identified α6$GABA_A$R-selective positive allosteric modulator (PAM), the pyrazoloquinolinone Compound 6[1] and its 4'-deuterated derivative (4'-OCD_3-Compound 6)[2], two α6$GABA_A$R-active PAMs (Ro15-4513 and loreclezole), an α6$GABA_A$R-inactive benzodiazepine (diazepam), an α6$GABA_A$R-selective antagonist (furosemide), and a

clinically effective antimigraine agent (topiramate). Compound 6 (3-10 mg/kg, *i.p.*) and 4'-OCD_3-Compound 6 (3-10 mg/kg, *i.p.*) significantly attenuated the TCC neuronal activation and TG CGRP-ir elevation, and dural CGRP depletion induced by *i.c.* capsaicin. All effects of Compound 6 were mimicked by Ro15-4513, loreclezole and topiramate, but not diazepam. The brain-impermeable furosemide antagonized the peripheral, but not central, effects of Compound 6 and 4'-OCD_3-Compound 6. These results suggest that the α6$GABA_AR$ in TG is a novel drug target for migraine and the potential of α6$GABA_AR$-selective PAMs as novel anti-migraine agents.

Title: Aromatic-dependent interactions control Kv1.1 voltage-gated potassium channel conformational equilibria

Authors: *S. M. HASAN[1], T. HUNTER[2], G. HUNTER[2], M. PESSIA[2,3], M. C. D'ADAMO[2]
[1]Physiol. Dept., Kuwait Univ., Safat, Kuwait; [2]Univ. of Malta, Msida, Malta; [3]Univ. of Perugia, Perugia, Italy

Abstract: We found in a young proband who displayed continuous myokymia, ataxic gait episodes, motor incoordination and spastic skeletal muscle contractions, a novel heterozygous mutation in the *KCNA1* gene that encodes the delayed-rectifier potassium channel Kv1.1. The missense mutation causing debilitating symptoms involved a highly evolutionary conserved aromatic non-polar phenylalanine at position 303. Using site-directed mutagenesis mutant and wild-type *KCNA1* constructs were heterologously expressed in *Xenopus laevis* oocytes, after which electrophysiological characterization followed. The mutation resulted in decreased Kv1.1 current amplitude, significant positive shifts of voltage-dependence, altered kinetics of activation, deactivation and slow inactivation, and reduced window currents. We constructed a model using rat Kv1.2 coordinates that shows the open channel structure may be stabilized by

hydrophobic interactions. Substitution of the aromatic phenylalanine with the smaller aliphatic valine in the model revealed altered neighboring interactions important in keeping the channel open. These findings suggest the bulky hydrophobic phenylalanine occupies a sterically confined area that allows essential hydrophobic interactions and restricts conformational movements towards channel closure. We propose the rigid phenylalanine at position 303 as an open-state conformation stabilizing residue and aromatic-dependent interactions as a mechanism for the fine-tuning of conformational equilibria in the Kv1.1 channel.

Title: Regulation of Eag1 K^+ channel biosynthesis by a RING E3 ubiquitin ligase

Authors: Y.-C. FANG[1], Y.-L. GAN[2], C.-Y. TANG[1], *C.-J. JENG[2]
[1]Dept. of Physiology, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [2]Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: The Eag1 K^+ channel is a member of the e*ther-à-go-go* (Eag) potassium (K^+) channel that belongs to the superfamily of voltage-gated K^+ channel. In mammals, the expression of Eag1 is largely restricted to the brain. Mutations in the gene encoding human Eag1 (KCNH1) K^+ channel have been associated with the congenital neurodevelopmental diseases Temple-Baraitser syndrome and Zimmermann-Laband syndrome. Some of the disease-associated Eag1 mutants may manifest enhanced protein degradation. A dynamic equilibrium between synthesis and degradation contributes to the proteostatic regulation of K^+ channels. However, little is known about the molecules mediating protein synthesis and degradation of Eag1 channels. To better understand the physiological function of Eag1 K^+ channel, we study the molecular machinery responsible for the ubiquitin-dependent regulation of Eag1 K^+ channels. By performing yeast two-hybrid screening of a rat brain cDNA library, we identified a specific RING E3 ubiquitin ligase, MKRN1 (also known as RNF61), as a potential binding partner of Eag1 proteins. We have performed the co-immunoprecipitation, GST pull-down assay, and immunofluorescence staining to confirm the interactions between Eag1 and MKRN1. The expression level of Eag1 proteins was significantly increased in HEK293T cells when using siRNA to knockdown the expression of MKRN1. Immunoblotting analyses of Eag1 *per se* revealed two protein bands that correspond to full- and core-glycosylated channel proteins. Interestingly, when co-expressed with MKRN1, Eag1 displayed a third low molecular-weight band that was also be detected when

treated with the proteasomal inhibitor MG132. Deglycosylation treatment showed that the third band had the molecular weight similar to the deglycosylated form of Eag1. Co-immunoprecipitation also indicated that MKRN1 interacted mostly with the immature Eag1 at the endoplasmic reticulum (ER). Moreover, MKRN1 overexpression enhanced Eag1 ubiquitination and prevented protein maturation. Taken together, our data suggest that MKRN1 may contribute to the ER quality control of Eag1 channels.

Title: Kv3.3 channels regulate the formation of multivesicular bodies

Authors: *Y. ZHANG[1], L. VARELA[2], K. SZIGETI-BUCK[3], T. L. HORVATH[4], L. K. KACZMAREK[1]
[1]Yale Univ. Sch. Med., New Haven, CT; [2]Comparative Med., [3]Yale Univ., New Haven, CT; [4]Comparative Med., Yale Med. Sch., New Haven, CT

Abstract: The voltage-dependent potassium channel Kv3.3 is encoded by the KCNC3 gene. Human mutations in this gene result in Spinocerebellar ataxia type 13 (SCA 13), a condition associated with cerebellar degeneration. We have found by electron-immunostaining that Kv3.3 channels are highly expressed in Purkinje cells of the cerebellum at locations where the plasma membrane comes into close apposition with underlying mitochondria. We have also found that depolarization of Kv3.3 channels directly activates Tank Binding Kinase 1 (TBK1), an enzyme that plays a key role in the formation of multivesicular bodies, autophagy and mitophagy. A disease-causing mutation, G592R Kv3.3, produces enhanced TBK1 activation both in cell lines and in the cerebellum of knock-in mice bearing this mutation. By electron microscopy, we find that the enhanced activation of TBK1 in G592R Kv3.3 knock-in mice is associated with increased numbers of intracellular multivesicular bodies, and increased levels of CD63, a molecular marker for these structures. Mitochondrial function may also be impacted by the mutation because levels of mitofusin-1 and mitofusin-2, proteins that are required for fusion and maintenance of mitochondrial structure, are altered in the mutant mice. Using cell lines expressing the mutant channel, we have shown that the G592R Kv3.3-induced multivesicular bodies contain Hax-1, a protein essential for the survival of cerebellar neurons. Inhibition of TBK1 in the cell lines prevents in increase in CD63 levels produced by the Kv3.3 mutation. Our

findings suggest that Kv3.3 channels are directly coupled to pathways that regulate the trafficking of proteins into multivesicular bodies. Moreover, disease-causing mutations of these channels may promote the formation of autophagosomes and potentially trigger mitophagy of mitochondria that are co-localized with the channels at the plasma membrane.

Br., Airman Systems Directorate, San Antonio, TX; [6]Radio frequency and bioeffects, national research council research associateship program, San Antonio, TX

Abstract: Infrared laser pulses (IRLPs) modulate the activity of excitable cells, making it a potentially valuable tool for a variety of clinical applications. We have shown that 1869 nm IRLPs can reversibly inhibit action potential (AP) firing in hippocampal neurons. One explanation for this observation is that the IRLPs influence the activity of the ion channels contributing to the APs. By applying the patch-clamp technique, we investigated the effect of IRLPs on membrane potential and channel activity in hippocampal neurons. We found that while IRLPs induce a depolarization of the plasma membrane of up to 18 mV and above the AP firing threshold, the majority of hippocampal neurons failed to fire synchronized APs. Moreover, when APs were stimulated by voltage-step protocol, we observed complete inhibition of APs by 3 and 3.5 ms IRLPs applied at the beginning of the voltage step. By reducing IRLPs duration to ≤2.5 ms some AP recovery was observed, but with shorter duration or/and smaller magnitude. The membrane depolarization induced by IRLPs was followed by a longer-lasting hyperpolarization. The hyperpolarizing current was voltage-dependent and blocked in neurons sensitive to low

concentrations of tetraethyl ammonium (TEA, 1mM), indicating the involvement of Kv3.1 channels, a thermo-sensitive potassium channel subtype. When K+ channels where blocked in TEA-sensitive neurons, 3.5 ms IRLPs induced only a 3% reduction in magnitude of the voltage-step-stimulated depolarization waveform, suggesting a relatively small effect on Nav+ channels from IRLPs. Involvement of Kv3.1 was confirmed in NG108 cells, which primarily express Kv3.1 channels, where IRLPs caused an instant potentiation of current when channels were opened by a voltage (Vh) stimulus. The amplitude of the response depended on holding voltage and was significantly decreased by 20 mM TEA.

Title: Cooperative synaptic and intrinsic plasticity onto NAc D1MSNs drive depressive-like behavior induced by aversive learning

Authors: *M. PIGNATELLI[1], H. TEJEDA[2], L. BONTEMPI[2], A. LOPEZ[3], D. BARKER[2], R. MARINO[2], S. PALMA RIBEIRO[2], J. WU[2], Z.-L. CAI[4], M. XUE[4], M. MORALES[2], A. BONCI[2]
[1]NIDA, NIH, Baltimore, MD; [2]NIDA, Baltimore, MD; [3]NIDA, baltimore, MD; [4]Baylor Col. of Med., Houston, TX

Abstract: Anhedonia and behavioral despair represent core symptoms of depression. While these features are in part mediated by maladaptive neuroadaptation within the brain reward circuitry, a comprehensive framework of how information flows through these nodes in depression is lacking. Here, we show that aversive learning induces anhedonia and behavioral despair. These phenotypes can be reversed independently by depotentiating the observed increased synaptic strength of ventral hippocampus (VH) excitatory synapses onto D1 medium spiny neurons (D1R-MSNs) in the nucleus accumbens shell (NAc), or by restoring depression-induced decreased potassium channel function in hyperexcitable D1R-MSNs. Moreover, mimicking the observed decreased potassium channel function observed after aversive learning in D1R-MSNs in naïve animals is sufficient to drive depressive behavior. Finally, utilizing a novel disconnection procedure, we demonstrate that strengthening of VH synapses and excitability changes in D1-MSNs induced by potassium channel dysfunction are serial processes that promote anhedonia and behavioral despair after aversive learning. These results provide a

novel, cellular mechanism for decreased motivation and increased behavioral despair after an aversive experience. They highlight a previously unappreciated role for D1R-MSNs in driving negative affective states, thus elucidating innovative targets for treatment of depression and other psychiatric disorders characterized by negative affective states.

Title: SUMOylation of the mouse voltage-gated potassium channel Kv4.2 at two distinct sites independently regulates surface expression and the biophysical properties of the A-type potassium current (I_A)

Authors: *M. A. WELCH[1], L. A. FORSTER[2], S. I. ATLAS[1], D. J. BARO[1]
[1]Biol., [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Small ubiquitin-like modifier (SUMO) is a ~100 amino acid peptide post-translationally added to lysine (K) residues on target proteins to alter their protein-protein interactions. SUMOylation can occur in an activity-dependent manner, and ion channel SUMOylation can regulate surface expression and biophysical properties. These data suggest that dynamic SUMOylation could mediate activity-dependent regulation of ionic currents. The voltage-gated potassium channel Kv4.2 mediates the A-type potassium current, I_A. We are examining the role of Kv4.2 channel SUMOylation. Immunoprecipitation followed by western blot experiments showed that Kv4.2 channels were SUMOylated in the rodent CNS and in a human embryonic kidney (Hek) cell line stably expressing a GFP-tagged Kv4.2 channel (Hek-Kv4.2g). Transiently cotransfecting Hek-Kv4.2g cells with plasmids encoding SUMO and the SUMO conjugating enzyme, Ubc9, produced a significant 35% increase in Kv4.2 SUMOylation ($p<0.05$ t-test) and a significant 27% reduction in I_A maximal conductance (G_{max}) as measured with whole cell patch clamp recordings (34.75±2.65 vs 25.45±2.24µS $p<0.05$ MWU). Surprisingly, the conductance decrease was accompanied by a significant 78% increase in Kv4.2 channel surface expression as determined with biotinylation experiments (0.80±0.09 vs1.42±0.28 $p<0.05$ MWU). Prediction software identified two high-probability SUMOylation sites on the Kv4.2 channel, K437 and K579, and we surmised that they had opposing functions in Hek cells. We tested this by mutating one or both sites: K437R and K579R. Preliminary data showed that mutating both sites abolished the 35% increase in Kv4.2 SUMOylation elicited by transient

overexpression of SUMO and Ubc9. When one site was mutated, the 35% increase was reduced to ~16%. These data suggest that both predicted sites can be SUMOylated. Consistent with our hypothesis, SUMOylation at each site produced a distinct effect. Transient overexpression of SUMO+Ubc9 in Hek-Kv4.2g K579R cells still produced the increase in Kv4.2 surface expression (1.0±0.19 vs 1.9±0.37 $p<0.05$ t-test) but not the decrease in I_A G_{max}. In fact, increased SUMOylation now elicited a mean increase in I_A G_{max} consistent with augmented surface expression (27.6 vs 36.2µS $p=0.17$). We are currently examining the properties of Hek-Kv4.2g K437R. Preliminary data suggest that the mutation prevented the increase in surface expression elicited by transient overexpression of SUMO+Ubc9 (1.00 vs 1.027 n=1), but we have not yet examined I_A G_{max}. In sum, Kv4.2 channel biophysical properties and surface expression can be independently regulated by SUMOylation of the channel at two distinct sites.

Title: Resistance to chronic stress by GABAergic regulation via TREK-1 channel

Authors: *J. CHOI[1,2], H. JUNG[1], A. KIM[1], S.-C. KIM[1], Y.-E. KIM[1], E. HWANG[1]
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Div. of Bio-Medical Sci. & Technol., KIST Sch. ,Korea Univ. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Exposure to chronic stress is responsible for many psychiatric diseases, such as depression, anxiety, and reduction of social ability. TREK-1 has been believed to play an important functional role in mood regulation, as already known that TREK-1 Knockout (Kcnk2 -/-) mice showed a depression-resistant phenotype. TREK-1 localized with GABAergic interneuron in mouse hippocampus. Particularly, in the temporal DG(Dentate gyrus), a sub region related to stress response and emotion. However, TREK-1's involvement in GABAergic regulation under chronic stress has not been studied. we made a depression model in TREK-1 Knockout (KO) and Wild type (WT) littermate control mice, and depression validation was performed through a forced swim test (FST), a tail suspension test (TST) and social interaction behavior After 21 days of stress, social interaction was reduced in WT stressed mice, whereas the TREK-1 KO stressed mice showed increased social interaction significantly. These findings suggests that TREK-1 may be involved in the inhibitory regulation of social behavior circuits as well as the depression resistant phenotype.

Abstract: The hippocampus is an essential brain structure for learning and memory processes. Its correct performance relies on the balance between excitatory/inhibitory synaptic transmission. G protein-activated inwardly rectifying potassium (GirK) channels regulate neuronal excitability by mediating inhibitory effects of different G protein-coupled receptors. Activation of GirK channels induces neurons to hyperpolarize, compensating neuronal excitation excess. In addition, they are constitutively active contributing to resting conductances. Recent evidence shows that GirK-dependent signal is altered in pathologies related to excitatory/inhibitory neuronal activity imbalances, such as Down syndrome, epilepsy, and Alzheimer's disease. Here, we have examined the role of GirK-dependent signalling in the mouse dorsal hippocampus at different levels of complexity (synaptic, network and behavioral) and its relevance in the maintenance of normal cognitive functions. To reach that objective, GirK-dependent signal was pharmacologically modulated by specific drugs, the GirK opener ML297, and the blocker Tertiapin-Q. *In vitro,* we studied in dorsal hippocampal slices, the effect of GirK-dependent signalling modulation on LTP induced in CA1 by Schaffer collaterals stimulation. *In vivo*, we performed acute intracerebroventricular injections of GirK specific drugs and studied: 1) at the synaptic level, I/O and PPF protocols in CA3-CA1 synapse, 2) at the circuit and network levels, oscillatory properties of CA1 region and LTP induction in CA3-CA1 synapse and 3) at the

behavioral level, learning and memory capabilities during open field and object recognition tests, both dependent on CA3-CA1 synapse. Our data shows that an imbalance of GirK-dependent signalling, whether caused by increased or decreased activity of the channel, results in abnormalities on neuronal excitability, LTP and oscillatory rhythms recorded from CA3-CA1 hippocampal synapse. These effects are accompanied by learning and memory impairments in behavioral tasks. Taken together, our results suggest that GirK channels are necessary for normal hippocampal activity at synaptic, neural network and behavioral levels and an accurate control of its activity must take place in the hippocampus to sustain cognitive faculties.

Title: Characterization of Kir channels in neurovascular pericytes in the brain

Authors: *X. ZHANG[1], X. HONG[3], X. TONG[2]
[1]Shanghai Jiao Tong Univ. Sch. of Med., Shanghai City, China; [2]Dept. of Anatomy, Histology and Embryology, Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China; [3]Shanghai jiaotong university school of medicine, Shanghai City, China

Abstract: Pericytes are one of the most important component of neurovascular units and are essential in angiogenesis, blood-brain barrier formation, and blood flow regulation. Pericytes can be identified by expressing different molecular markers, such as PDGF$_{\beta}$R, α-SMA, CD13, desmin and nerve-glia antigen 2 (NG2 / CSPG4) [1]. Interestingly, NG2-glia as the fourth type of macroglia which are broadly distributed in the white and grey matter in the central nervous system (CNS), also express the pericytic specific marker NG2. Our previous study has shown that NG2-glia exhibit very hyperpolarized resting membrane potentials (RMPs) around -90 mV which is close to the K^+ equilibrium potential (E_K) and this hyperpolarized RMP is largely due to the high expression of inwardly rectifying K^+ channels subtype Kir4.1. However, compared with NG2-glia, our recent data has found that the neurovascular pericytes have much depolarized RMPs which is around -60 mV. It's well known that Kir4.1 channels express in glial cells and

play an important role in the maintenance of RMP and extracellular K^+ uptake in the CNS. In addition, Kir channels are also reported to be expressed in smooth muscle cells (SMCs) as well as in pericytes [2,3]. However, the functions of Kir channels in pericytes are largely unknown. To explore what is the major subtype of K^+ channel contributing to a depolarized RMP in pericytes and what is the physiological relevance underlying, we will combine RNA-Seq transcriptional analysis with electrophysiological patch recordings technique obtained from NG2DsRed transgenic mice. In this poster, we will present the characteration and function of K^+ channels especially Kir channels in neurovascular pericytes. This study will reveal a potential significance of how pericytes expressing Kir channels integrate into the maintenance of the BBB homeostasis in the brain.

Title: Seizure induces Kv4.2 phosphorylation by p38 MAPK

Authors: *J.-H. HU[1], D. A. HOFFMAN[2]
[1]NICHD, Bethesda, MD; [2]NIH, Bethesda, MD

Abstract: Kv4.2 is the main A-type voltage-gated potassium channel in hippocampal CA1 pyramidal neuron dendrites. Their currents play an important role in regulating the back-propagating action potentials and limiting the propagation of local dendritic spikes. Kv4.2 control of dendritic excitability impacts neuronal plasticity and contributes to learning and memory. Thus, it is important to know how Kv4.2 is regulated. Previous findings showed that Kv4.2 can be phosphorylated at T602, T607 and S616 by ERK in vitro. However, how phosphorylation is regulated and the identity of the proline-directed kinase us unknown. Here, we report that Kv4.2 is dynamically phosphorylated at T607 in mouse brain. We first

characterized specific antibodies against phosphor-T602 and phosphor-T607 using Kv4.2 mutations expressed in HEK293T cells. Kv4.2 phosphorylation at T602 and T607 were increase when co-expressed Erk1 suggesting that Erk1 can phosphorylate the two sites. However, the increase was small, which leads us to consider other kinases that could phosphorylate these two sites. We co-transfected Kv4.2 with other proline-directed kinases such as CDK5, GSK3B and P38 in HEK293 cells and found that P38 had the largest effect. Interestingly, a point mutation of P38 which abolished P38 kinase activity largely blocked Kv4.2 phosphorylation suggesting P38 is the main kinase responsible for T602 and T607 phosphorylation in HEK293T cells. We found that P38 binds to Kv4.2, supporting this idea. Furthermore, we found that both P38 activity and T607 phosphorylation of Kv4.2 was induced by seizure that is triggered by pentylenetetrazol (PTZ) administration, while T602 phosphorylation remained unchanged in mouse brain. Interestingly, P38 inhibitor SB203580 administration blocked PTZ-induced Kv4.2 phosphorylation at T607 site in mouse hippocampi. Taken together, these data show that P38 phosphorylates Kv4.2 at T607 in mouse hippocampi after seizure induction suggesting that Kv4.2 phosphorylation may play an important role in its pathophysiology.

Title: The regulation of Kir4.1 in the development of epilepsy

Authors: *J. BONI[1], A. RANDOLPH[2], M. L. OLSEN[3]
[1]Virginia Tech, Sch. of Neurosci., Blacksburg, VA; [2]Univ. of Alabama at Birmingham, Birmingham, AL; [3]Virginia Tech, Sch. of Neurosci., Blacksburg, VA

Abstract: Kir4.1, a glial-specific inwardly rectifying potassium channel, is essential for astrocytic maintenance of K+ homeostasis. Underscoring the role of Kir4.1 in CNS functioning, genetic mutations in Kcnj10, the gene which encodes the Kir4.1 protein have been linked to seizures, ataxia and developmental disability. Furthermore, numerous studies consistently demonstrate reduced levels of Kir4.1 protein and mRNA expression in multiple injury paradigms and disease models, typically accompanied by reactive gliosis. While reduced Kir4.1 protein and mRNA expression is a common observance in CNS insult, it is unclear what molecular mechanism/s govern this process. Utilizing a pilocarpine model of status epilepticus in adult rats we demonstrate Kir4.1 protein is significantly reduced as early as 24 hours post-status. This downregulation persists though 30 days, the last time point examined. A concomitant loss of mRNA was observed at all time points examined, suggesting a transcriptional mechanism of

regulation. Using a different injury paradigm, a fifth cervical (C5) vertebral hemi-contusion model of spinal cord injury, we observed similar results. Previous work by our group revealed the DNA methylation status of the Kcnj10 gene functions to regulate developmental levels. To analyze the role of DNA methylation in injury, studies were completed in the hippocampus and in isolated astrocytes after SE. Here we demonstrate hypermethylation of 7 CpG sites in CpG Island 2 in both the SE and SCI models. In contrast, our previous work indicates during development when Kir4.1 expression increases this region demonstrates significant hypomethylation. Our results suggest that bidirectional modulation of methylation may function to modulate Kcnj10 gene transcription. DNA methylation may represent a candidate mechanism to rescue astroglial Kir4.1 expression following CNS insult providing therapeutic benefit.

Title: Missense epilepsy mutations in neuronal KCNQ/Kv7 channels occur at hotspots within highly conserved functional domains of Kv7.2 and Kv7.3

Authors: *J. ZHANG[1], C. CHEN[1], E. KIM[1], E. PROCKO[2,3], J. PATEL[1], R. CHOI[1], M. HONG[1], D. JOSHI[1], G. LEE[1], A. GZAPLICKI[1], E. C. COOPER[4], E. BOLTON[1], H. CHUNG[1,3]

Abstract: Neuronal KCNQ/K_v7 channels composed of KCNQ2/K_v7.2 and KCNQ3/K_v7.3 subunits are voltage-gated potassium channels that potently inhibit neuronal excitability. Close to 200 mutations in KCNQ2 and KCNQ3 genes are associated with neonatal epilepsy in humans including Benign Familial Neonatal Epilepsy (BFNE) and Epileptic Encephalopathy (EE) (rikee.org). In particular, EE patients show refractory seizures and severe behavioral comorbidities including developmental delay, psychomotor retardation, and autism. Currently, it remains unknown whether these mutations are randomly distributed throughout the coding region of K_v7.2 and K_v7.3. In this study, we analyzed 177 KCNQ2 and 14 KCNQ3 missense epilepsy mutations using nonrandom mutation clustering (NMC) and resampling statistical methods. Nonpathogenic missense mutations and silent mutations were used as negative

controls. These analyses revealed that KCNQ2 mutations are more likely to locate in the voltage-sensing S4 transmembrane domain, the pore loop and S6 that control ion permeability, helix B in the intracellular C-terminal tail that mediates calmodulin (CaM) binding, and helix B-C linker. When mutations are analyzed based on the severity of outcomes, EE mutations are more concentrated in the same hotspots whereas BFNE mutations do not exhibit any enrichment. Mutations in KCNQ3 are enriched in pore loop and helix A. For characterization of mutation hotspots, we selected EE mutations including L203P in S4, L268F in the pore, K524T and R525L in helix B. K524T and R525L decrease apoCaM and Ca^{2+}-CaM binding. All 4 mutations decrease channel expression at the membrane surface. The pore mutant L268F nearly abolishes the enrichment of the channel at the axon initial segment (AIS). Furthermore, we demonstrated that L203P induces right-shift voltage dependence, while K524T and R525L disrupt PIP_2 dependence with electrophysiolgy. Altogether, our results reveal the hotspots of pathogenic epileptic mutations in KCNQ2 and KCNQ3. Current efforts include systematic analyses of mutations within the hotspots to predict the functional and clinical outcome of the mutations.

Title: Neurocalcin delta translocation is not dependent on its dimerization

Authors: N. I. KONONENKO[1], A. DOVGAN[1], J. VIVIANO[2], A. DROMARETSKY[1], J. ZHANG[2], V. VENKATARAMAN[2], *P. V. BELAN[1,3]

Abstract: Similar neuronal Ca^{2+} sensor (NCS) proteins, Neurocalcin δ (NCALD) and Hippocalcin (HPCA), control many neuronal functions via their differential Ca^{2+}-dependent translocation from the cytosol to the plasma membrane. Our preliminary results indicate that in solutions Ca^{2+}-bound HPCA is mainly present as a monomer while Ca^{2+}-bound NCALD exists as a homodimer. Besides, three AA that are critical to the formation of the dimer interface of NCALD were identified in biochemical experiments. However, the functional consequences of

NCALD dimerization have never been studied in cellular systems. We suggested that disruption of NCALD dimerization would result in its translocation to the plasma membrane that is similar to one for HPCA. To test this hypothesis, we developed a set of NCALD mutants having single, double, and triple point mutations disrupting dimerization interface of NCALD, tagged them by fluorescent proteins and co-expressed paired wise NCALD and HPCA or one of the NCALD mutants in cultured rat hippocampal neurons. Fast depolarization-induced $[Ca^{2+}]_i$ transients led to the very different time courses and amplitudes of HPCA and NCALD translocation to the plasma membrane. Surprisingly, all NCALD mutants did not reveal a significant difference in Ca^{2+}-dependent translocation compared the wild type NCALD. Even a triple NCALD mutant, which revealed HPCA-like monomeric behavior in the biochemical experiments, demonstrated no signs resembling HPCA translocation in the cellular system. We conclude that in the cellular system Ca^{2+}-bound NCALD promptly translocates to the plasma membrane before it can be dimerized in the cytosol. Thus, dimerization of NCALD revealed by its crystal structure is not important for this protein translocation in native cellular systems.

Title: Localisation of Kv3 subunits within the spinal micturition reflex and the effect of novel modulation on bladder output

Authors: *P. MULLEN[1], N. PILATI[2], C. H. LARGE[3], J. DEUCHARS[1], S. DEUCHARS[1]
[1]Fac. of Biol. Sci., Univ. of Leeds, Leeds, United Kingdom; [2]Autifony Srl, Verona, Italy; [3]Autifony Therapeut. Limited, Stevenage, United Kingdom

Abstract: Kv3 channels are voltage-gated potassium ion channels that are highly expressed in the brain and important in neuronal firing and synaptic transmission (Rudy et al., 1999). However, in some brain regions, Kv3 channel expression decreases with age with functional consequences (Zettel et al., 2007). Kv3 channels are also expressed in the spinal cord (Deuchars et al., 2001) but little is known about their role in spinal circuitry and whether age-related changes are also observed here. To investigate this, we studied the expression of Kv3 subunits in spinal circuitry that underlies bladder function, and the effect of AUT1, a novel modulator selective for Kv3 channels (Alvaro et al. 2011), on bladder function. Parasympathetic

preganglionic (PGN), sympathetic preganglionic (SPN) and dorso-lateral nucleus (DLN) motoneurones were retrogradely traced with fluorogold (1%, i.p). 3 month (n=3) and 28 month (n=3) C57bl6 mice were anaesthetised intraperitoneally (i.p.) with 60mg/kg pentobarbitone, perfused transcardially and fixed with 4% paraformaldehyde. Lumbosacral spinal levels (L1, L6 and S1) were dissected, sectioned to 20 µm and processed for double labelling immunohistochemistry of Kv3 subunits, Kv3.1b and Kv3.3, with inhibitory synaptic markers, VGAT and GlyT2, and excitatory synaptic marker, VGluT2. 3 and 20 month mice were given vehicle or AUT1 (30 mg/kg, 60 mg/kg, i.p.) and their behaviour (micturition and locomotor activity) was recorded in metabolic cages over a 3 hour period. Kv3 puncta around bladder motoneurones in the lumbo-sacral spinal cord co-localised with both excitatory and inhibitory synaptic immunoreactivity. In a comparison of young and aged mice, the number of Kv3 puncta around motoneurones was significantly reduced (DLN, Kv3.3; Ind. Equ. T-test, young, 57.67 ± 16.5 vs aged, 49.26 ± 14.3, $p<0.01$, PGN, Kv3.3; Ind. Equ. T-test, young, 67.18± 14.8 vs aged, 43.8 ± 15.47, $p<0.001$, SPN, Kv3.1b; Ind. Unequ. T-test, young, 124.4 ± 27.0 vs aged, 87.7 ± 36.5, $p<0.001$. Data as mean ± SEM). AUT1 treatment produced an acute dose dependent reduction in bladder output (60mg/kg, 100%, $p<0.05$; 30mg/kg, 42.3%, $p<0.05$) and reduced activity (recorded by a sedation rating scale and video tracking software). We hypothesise that the reduced Kv3 expression observed in aged mice may have a functional significance within bladder circuitry and on the bladder reflex. Furthermore, the reduction in bladder output produced by AUT1 may have therapeutic relevance to age-related conditions such as nocturia.

Title: Excitability increases while BK channel contribution decreases in neonatal hippocampal neurons

Authors: *M. HUNSBERGER, A. MONICAL, M. MYNLIEFF
Biol. Sci., Marquette Univ., Milwaukee, WI

Abstract: There are fundamental differences between the immature and the mature brain resulting in a greatly increased risk of seizures in infancy and early childhood. We used heterogeneous cultures of rat CA1 hippocampal neurons to investigate the maturation of the action potential and excitability as well as the contribution of Ca^{2+}-activated K^+ channels to these biophysical characteristics. Whole-cell patch clamp recording in the current clamp configuration was used to study action potentials and excitability. Single action potentials (AP) were evoked by a 0.1 ms, 8 nA current and AP trains were evoked by 100 ms depolarizing pulses. The mean action potential duration, represented by spike width at half-amplitude, decreased from 3.43±0.12 ms (22 animals, 133 cells) in cells from 0-5 day old pups to 2.65±0.10 ms (23 animals, 144 cells) in cells from 6-10 day old pups ($p<0.001$). Excitability of neurons, measured by the maximum number of APs that could be evoked by a 100 ms depolarizing pulse, increased between these age ranges from 2.00±0.10 (22 animals, 157 cells) to 2.86±0.13 (23 animals, 150 cells; $p<0.001$). These data may represent a maturation of inhibitory circuitry that can better coordinate hippocampal outputs and reduce seizure risk. As BK currents have been implicated in seizure susceptibility, we analyzed APs in cells treated with the BK antagonist Iberiotoxin (IbTx). Recordings were taken before, during, and after 100 nM IbTx perfusion and the drug effect was calculated by comparing the values during drug treatment to the average of the values before and after treatment to account for rundown effects. IbTx decreased action potential duration by 0.74±0.15 ms in cells from 3-5 day old pups (5 animals, 38 cells) but only by 0.22±0.06 ms in cells from 6-8 day old pups (5 animals, 41 cells; $p<0.002$). The Ca^{2+} activated K^+ channels SK and KCNQ also significantly contributed to AP kinetics but did not exhibit significant age-related changes in their effects so the difference in BK effect is likely not due to unrelated changes in AP kinetics. Preliminary data from voltage clamp recordings suggest that the BK component of the total K^+ current halves from day 5 to day 8. Our data demonstrate that action potential durations shorten and excitability increases in a heterogenous population of hippocampal neurons in the early postnatal period. We also demonstrate that contributions of BK channels to total K^+ currents and the action potential waveform decreases during this period. These results suggest that reduced excitability of inhibitory neuron populations and increased BK currents may underlie seizure susceptibility in infants.

Title: Mechanisms of suppression by the amyloid peptide fragments 1-42 and 25-35 on Kv1.1 channel activity

Authors: *K. DEBOEUF, M. ISLAM, N. THELEN, J. FARLEY
Psychology and Neurosci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: The beta amyloid peptide (Aβ) has long been a hallmark of Alzheimer's Disease (AD) pathology. Past studies have linked its involvement in the disruption of Ca^{2+} homeostasis, synaptic communication, and long-term potentiation (LTP), but the underlying mechanism(s) is still largely unclear. Because Kv1.1 and related channels are activated during an action potential, regulate depolarization Ca^{2+} influx, and inhibition of Kv1 channels can be neurotoxic, we speculate that Aβ-suppression of Kv1 channels may be early targets in AD pathogenesis. Using murine Kv1.1 channels expressed in *Xenopus* oocytes, we have observed the effects of both Aβ(1-42) and the "core" peptide (25-35) on both macro- and micro-scopic currents. Both the bath application of Aβ(1-42) and Aβ(25-35) produced 40-50% suppression of macroscopic Kv1.1 current within 30 m. The suppression of Kv1.1 by Aβ(1-42) was partially dependent on intracellular Ca^{2+} and PP2B, being reduced by ~50% when cells were loaded with BAPTA-AM or exposed to the PP2B-inhibitor cyclosporine A (CsA). Patch-clamp results suggest that Aβ-suppression of Kv1.1 involves both PP2B-dephosphorylation and direct protein-protein interaction of Aβ with Kv1.1 channel subunits. Exposure of inside-out single Kv1.1 in ripped-off oocyte patches to application of purified, catalytically-active PP2B produced gradual reductions in *p*(open), followed by the abrupt disappearance of Kv1.1 activity. Application of Aβ to the intracellular face of Kv1.1 channels also produced dramatic reductions in *p*(open). To better study the direct interaction between Aβ and Kv1.1, we have made use of artificial membranes which have more stable preparations and easier access to both intra- and extra-cellular faces of the channel compared to oocyte patch clamping. Using "tip-dip" methods, Aβ(25-35) exposure eliminated Kv1.1 channel activity when applied to the intracellular face. Experiments are currently underway looking at the effects of Aβ on Kv1.1 channels incorporated in a Black Lipid Membrane (BLM) apparatus. Suppression of Kv1.1 and related K^+ channels presynaptically could lead to larger and longer action potentials, allowing more influx of Ca^{2+}, increased release of glutamate, and possibly the beginning of a disruption of Ca^{2+} homeostasis. Postsynaptically, the increased glutamate release, through activation of AMPA and NMDA receptors, may contribute to excitotoxicity.

Title: Novel enhancement of KCNQ M-type K+ channels and TRPC cation channels after muscarinic receptor activity in hippocampus controlling neuromodulation and excitability

Authors: *C. CARVER, M. S. SHAPIRO
UT Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: KCNQ2/3 (M-channel) current maintains homeostatic control over neuronal firing and excitability. Classically, M-channels have been characterized by sensitivity to suppression by Gq-coupled muscarinic acetylcholine receptor stimulation due to intracellular membrane-PIP2 hydrolysis. The muscarinic signaling plays important functional roles in modulation of neuronal excitability. We investigated the neuromodulatory effects of muscarinic receptor stimulation on hippocampal M-currents in-depth.
Patch-clamp electrophysiology recordings were aquired from mouse dentate gyrus granule cells (DGGCs) and CA1 pyramidal neurons in brain slice. Stimulation of M1Rs with M1-selective allosteric agonist 77LH281 resulted in surprising and significant enhancement of M-current in DGGCs, however CA1 neurons exhibited muscarinic-induced suppression of M-current. We also observed significant increase to GIRK current acting as a a PIP2 biosensor, supporting our hypothesis that in DG, net intracellular PIP2 was increased after Gq-coupled muscarinic stimulation. The PIP5 kinase inhibitor UNC3230 was included to block PIP2 synthesis, and M1R stimulation then suppressed M-current in DGGCs. KCNQ2 knockdown in DG ablated the muscarinic receptor-dependent enhancement of M-current. Furthermore, the net effect of muscarinic stimulation was an increase in action potential firing frequency, despite enhancement of M-current. We found intracellular Ca2+ signals were robustly increased in DGGCs after muscarinic stimulation, as detected with a calcium sensor dye. Increased Ca2+ was dependent on TRPC channel activation of neuronal excitability, as TRPC blockers ablated excitability and Ca2+ increase. Interestingly, activation of TrkB receptors also enhanced M-current via PLCgamma activity in DGGCs.
We describe novel muscarinic receptor-induced effects on neuronal excitability in the DG involving a heretofore undiscovered, cell-type specific role of M-channel neuromodulation. Muscarinic receptors may serve a wider and more complex role in governing hippocampal excitability through cholinergic signals. These novel findings in DG suggest an entirely different relationship between muscarinic receptors, PIP2 availability, and M-channels than found in peripheral sensory neurons or other glutamatergic CNS neurons.

Title: Deletion of KCNQ2/3 potassium channels from PV+ interneurons leads to homeostatic potentiation of excitatory transmission

Authors: *H. SOH[1], S. PARK[2], K. SPRINGER[3], K. RYAN[4], A. MAHESHWARI[2], A. TZINGOUNIS[3]
[1]Physiol. and Neurobio., Neurosci. Grad. Program, Storrs, CT; [2]Baylor Col. of Med., Houston, TX; [3]Physiol. and Neurobio., [4]Univ. of Connecticut, Storrs, CT

Abstract: Potassium channels play important roles in a range of cellular physiological processes in normal brain function. KCNQ2/3 channels, in particular, have arisen as critical regulators of neonatal brain excitability. Highlighting the importance of these channels, a growing number of loss-of-function (LOF) and gain-of-function (GOF) variants in*KCNQ2* and *KCNQ3* have been reported in patients with severe neonatal and infantile epileptic encephalopathy. The main features of KCNQ2/3-associated epileptic encephalopathy are progressive cognitive deterioration and early onset of a severe seizure disorder that does not respond to most anticonvulsant drugs. In contrast to the wealth of knowledge on KCNQ2/3 channels functioning in excitatory neurons, the roles of these channels in interneurons is still unclear. This is a major gap in our knowledge as interneurons play a critical function in shaping the activity of neuronal populations and promoting the development of excitatory synaptic circuits. KCNQ2/3 channels have been associated primarily with neurons that undergo pronounced spike frequency adaptation, a feature not traditionally associated with interneurons. However, using microscopy and more recently single cell exome sequencing, KCNQ2/3 channels have been detected in cortical interneurons such as parvalbumin (PV)- and somatostatin (SST)-positive interneurons. Here, by using *ex vivo* and *in vivo* electrophysiology show that deletion of *Kcnq2/3* channels from parvalbumin, but not somatostatin, interneurons increased their excitability, leading to elevated inhibitory transmission and homeostatic excitatory drive potentiation in CA1 pyramidal neurons. Additionally, *PV-Kcnq2* null-mice showed increased seizure susceptibility, suggesting that decreases in KCNQ2/3 activity in interneurons remodels excitatory networks, providing a previously unrecognized function of KCNQ2/3 channels in the brain.

Title: The action potential as a modulator of synaptic transmission

Authors: *L. PANZERA[1], M. CHIN[2], M. B. HOPPA[2]
[1]Biol., [2]Biol. Sci., Dartmouth Col., Hanover, NH

Abstract: Individual presynaptic terminals often behave differently to electrical stimuli in terms of vesicle fusion probability. The probability of vesicle fusion or synaptic strength of a terminal can be modulated by many factors including vesicle pool dynamics and fusion machinery, as well as the properties of voltage gated calcium channels. It is often assumed that the electrical inputs are digital in nature and that individual synapses along an axon receive uniform action potential waveforms. However, recent experiments have called this observation into question for many central neurons. Action potential broadening is one of the most classically observed phenomena during various stimulation protocols, yet it is unclear how this broadening alters vesicle fusion and release of neurotransmitter. This is primarily due to the small size of *en passant* central neuron synapses which are not easily accessed by classic electrophysiology. Here we provide the first simultaneous quantitative measurements of presynaptic action potentials, calcium influx and exocytosis in *en passant* synapses using genetically encoded fluorescent indicators in cultured hippocampal neurons. We combine these measurements with genetic and pharmacological manipulations to understand how changes in action potential waveform shape alter presynaptic transmission. Inhibition of Kv1s, one of the predominant voltage gated potassium channels found in these synapses, results in a predictable increase in action potential amplitude and full width at half maximum. Interestingly, we found only excitatory cells rely on Kv1 channels to modulate the presynaptic action potential waveform. Further, action potential broadening results in an uncoupling of the classically defined relationship between vesicle fusion probability and net calcium influx, with an enhancement of neurotransmission over what is predicted. To determine the mechanism behind this phenotype we restricted the size of presynaptic calcium microdomains using the calcium chelator EGTA and found no effect on the percent change of vesicle fusion, indicating the radius of microdomains are not responsible for

the increase in fusion with action potential broadening. Our results suggest that modulation of the action potential waveform is a powerful modulator of synaptic strength.

(EPFL), Lausanne, Switzerland; [6]Univ. of Exeter, Exeter, United Kingdom; [7]Yale Sch. of Med., New Haven, CT

Abstract: Essential Tremor (ET) is one of the most common neurological diseases, with an estimated 7 million affected individuals in the US; the pathophysiology of the disorder is poorly understood. Recently, we identified a mutation (*KCNS2* (*Kv9.2*), c.1137 T>A, p.(D379E) in an electrically silent voltage-gated K^+ channel α-subunit,*Kv9.2*, in a family with ET, that modulates the activity of Kv2 channels. We have produced transgenic *Drosophila* lines that express either the human wild type Kv9.2 (hKv9.2) or the ET causing mutant Kv9.2 (hKv9.2-D379E) subunit in all neurons. We show that thehKv9.2 subunit modulates activity of endogenous *Drosophila* K^+ channel Shab. The mutant hKv9.2-D379E subunit showed significantly higher levels of Shab inactivation and a higher frequency of spontaneous firing rate consistent with neuronal hyperexcitibility. We also observed behavioral manifestations of nervous system dysfunction including effects on night time activity and sleep. This functional data further supports the pathogenicity of the *KCNS2* (p.D379E) mutation, consistent with our prior observations including co-segregation with ET in a family, a likely pathogenic change in the channel pore domain and absence from population databases. The *Drosophila* hKv9.2 transgenic model recapitulates several features of ET and may be employed to advance our understanding of ET disease pathogenesis.

Title: Organization of Ca^{2+} and lipid signaling domains by the Kv2 family of voltage-gated potassium channels

Authors: *M. KIRMIZ, N. C. VIERRA, J. S. TRIMMER
Neurobiology, Physiol. & Behavior, Univ. of California, Davis, Davis, CA

Abstract: Voltage-gated potassium (Kv) channels play diverse roles in regulating neuronal excitability. Of these, Kv2.1 and Kv2.2 are robustly expressed as micron-sized plasma membrane (PM) clusters on the soma, proximal dendrites, and axon initial segment of most brain neurons. These Kv2 paralogs are distinct in their cellular expression patterns, extent of multisite phosphorylation, and responses to stimuli that trigger phosphorylation-dependent changes in the localization and voltage activation of Kv2.1, but not Kv2.2. The clusters of Kv2.1 and Kv2.2 are found at endoplasmic reticulum (ER)-PM junctions (EPJs), and we have recently demonstrated that organization of EPJs is a conserved and *bona fide* non-conducting function of both members of the Kv2 family (Kirmiz et al., 2018. bioRxviv 10.1101/296731). As such, Kv2 ion channels are the first family of PM proteins whose expression is sufficient to govern organization of these membrane contact sites. EPJs in diverse cell types are known to participate in Ca^{2+} signaling [*e.g.*, excitation-contraction coupling in striated muscle *via* the association of PM L-type Ca^{2+} channels and ER ryanodine receptors (intracellular Ca^{2+} release channels)] and/or regulation of lipid trafficking/metabolism (*e.g.*, regulation of phosphatidylinositol-4-phosphate levels by Sac1). Kv2-containing EPJs are also defined by the presence of vesicle associated membrane protein-associated proteins (VAPs). VAPs are known to participate in regulation of lipid metabolism in cultured mammalian cells, and Kv2 clusters often colocalize with RyRs in cultured hippocampal neurons, raising the question as to whether EPJs mediated by the Kv2 family have the capacity to function in dual capacities as distinct sites of lipid metabolism/trafficking and Ca^{2+} signaling. Here, using total internal reflection fluorescence and conventional fluorescence microscopy of cultured rat hippocampal neurons and heterologous

cells, we investigated the potential role(s) of Kv2-associated EPJs as sites of lipid metabolism/trafficking and Ca^{2+} signaling. We found that expression of Kv2 channels is sufficient to reorganize/recruit L-type Ca^{2+} channels, as well as proteins involved in lipid metabolism/trafficking including Sac1 and PITPNM1/Nir2, to EPJs organized by Kv2 channels. We also found that L-type Ca^{2+} channel-mediated Ca^{2+} responses are enhanced in cells coexpressing either conducting or nonconducting isoforms of Kv2.1. Our findings suggest that these abundant neuronal Kv2 channels can influence lipid trafficking/metabolism and Ca^{2+} signaling in brain neurons via a non-conducting function that is dependent on their ability to organize EPJs.

Title: Neuronal Kv2 channel-associated endoplasmic reticulum-plasma membrane junctions are sites of localized spontaneous Ca(2+) entry

Authors: *N. VIERRA, M. KIRMIZ, J. S. TRIMMER
Neurobiology, Physiol. & Behavior, Univ. of California, Davis, Davis, CA

Abstract: Endoplasmic reticulum-plasma membrane junctions (EPJs) have long been assumed to serve critical roles in modulating neuronal Ca^{2+} handling, as sites with enhanced expression of Ca^{2+} channels and pumps. The voltage gated K^+ channels Kv2.1 and Kv2.2 are prominent constituents of neuronal EPJs, facilitating the spatial concentration of L-type Ca^{2+} channels (LTCCs), ryanodine receptors (RyRs), and Ca^{2+} store-regulated PM Orai1 channels (Kirmiz et al., 2018. bioRxviv 10.1101/296731). Although these observations suggest a role for Kv2 channel-associated EPJs in neuronal Ca^{2+} handling, their participation in Ca^{2+} signaling events has not been demonstrated. This is an important question, as autosomal dominant *de novo* mutations in Kv2.1 that disrupt Kv2.1 clustering at EPJs are associated with severe neurological disorders. Here, we have visualized distinct Ca^{2+} signaling events at neuronal Kv2 channel-mediated EPJs. We used genetically encoded Ca^{2+} indicators (GECIs) fused to conducting and nonconducting Kv2 channel isoforms or to the Kv2 auxiliary subunit AMIGO1 to image Ca^{2+} at these sites in cultured rat hippocampal neurons. We found that Kv2 channel-mediated EPJs are

sites of Ca^{2+} entry during global Ca^{2+} influx events. We found that in addition to these global events, Ca^{2+} transients consisting of rapid and often stochastic spikes occurred at a subset of individual Kv2-containing EPJs. These transients at individual Kv2-containing EPJs occurred independent of one another, even at junctions located <1 µm away from one another, such that the spatial extent of the Ca^{2+} transients was confined within individual Kv2 channel clusters. The frequency and amplitude of these local Ca^{2+} transients were sensitive to membrane potential depolarization, nimodipine, caffeine, and thapsigargin, implicating the involvement of LTCC and RyR-mediated Ca^{2+}-induced Ca^{2+} release. Moreover, following global Ca^{2+} entry, Ca^{2+} was cleared more quickly within a Kv2 channel cluster than in regions outside of clusters. Importantly, we determined that Kv2.1 channel conductance was not necessary for the occurrence of Kv2 channel cluster-associated spontaneous Ca^{2+} transients, as neither their frequency nor their amplitude differed between neurons expressing the "wild-type" Kv2.1-GECI or a non-K^+-conducting Kv2.1 pore mutant (P404W)-GECI. Together these findings demonstrate that Kv2-channel mediated EPJs are sites of distinct and compartmentalized neuronal Ca^{2+} signaling events with unique Ca^{2+} handling properties. Our findings further support a critical role for EPJs in neuronal Ca^{2+} handling and demonstrate an important function for Kv2 channels in this process.

Title: Activation of Slack potassium channels (KCNT1) triggers an increase in mRNA translation

Authors: *T. J. MALONE[1], P. LICZNERSKI[2], E. A. JONAS[2], L. K. KACZMAREK[3]
[1]Cell. and Mol. Physiol., [2]Intrnl. Medicine/Section of Endocrinol., [3]Cell. and Mol. Physiology/Pharmacology, Yale Univ. Sch. of Med., New Haven, CT

Abstract: The Slack ion channel is a member of a family of large conductance sodium-activated potassium channels. It is expressed predominantly in neurons of the central nervous system where it regulates neuronal excitability. FMRP, an important regulator of mRNA translation, binds both Slack mRNA and the Slack protein. The association of Slack with FMRP stimulates

channel activity, raising the possibility that activation of Slack channels may also regulate the function of FMRP. Our laboratory has previously identified Slack as required for a protein translation-dependent recovery from an extended period of inhibition in Aplysia neurons following stimulation, further suggesting that Slack may play a role in the regulation of mRNA translation. Here we provide the initial evidence for such a role. We transfected cells with a fluorescent reporter for mRNA translation, which contains the 5' and 3' sequences of the mRNA for β-actin, but with the coding region replaced with that for the irreversibly-photoconvertible fluorescent protein dendra2. We were able to visualize real-time translation in HEK cell cultures and in mouse cortical neurons. Based on the observed translation levels in a stable Slack-expressing HEK cell line along with pharmacological manipulation and silencing RNA knockdowns, we propose a mechanism whereby Slack activation causes an increase in translation that is enhanced in the absence of FMRP. This increase in translation persists in the presence of the Slack channel blocker quinidine, indicating that it does not require ion flux through the channel. Experiments on cultured neurons from wild-type, Slack knockout, and FMRP knockout mice show that Slack-stimulated translation also occurs in native neurons. Additional experiments in HEK cell culture suggest that the Slack binding partners CYFIP1, another FMRP binding protein; and Phactr-1, a PP1 binding protein, may also modulate this channel-dependent translation. This mechanism of Slack-dependent translation potentially represents the first instance of the direct modulation of mRNA translation by activation of an ion channel.

Title: Interactions of Slack (KCNT1) channels with Phactr1 are altered by a human disease-causing mutation

Authors: *S. R. ALI[1], T. MALONE[2], Y. ZHANG[1], L. KACZMAREK[1]
[1]Dept. of Pharmacol., [2]Cell. and Mol. Physiol., Yale Univ., New Haven, CT

Abstract: The Slack gene encodes sodium-activated potassium channels that are abundantly expressed in the central nervous system. Human mutations alter the function of Slack channels, resulting in epilepsy and intellectual disability. Most of the disease-causing mutations are located in the extended cytoplasmic C-terminus of Slack channels and most result in increased Slack current. Previous experiment using a yeast two-hybrid system indicate that the C-terminus of Slack channels binds a number of cytoplasmic signaling proteins. One of these is Phactr1, a protein that is believed to target protein phosphatase 1 (PP1) to its phosphoprotein substrates. Phactr1 is also known to be an actin-binding protein. We have now found by co-immunoprecipitation that all three components, Phactr1, PP1 and actin exist in a complex with Slack channels. We then investigated the role of disease-causing Slack mutations in the modulation of the Slack-Phactr1 complex and found, using FRET and coimmunoprecipitation experiments that residue R1085 modulates the formation of Slack-Phactr1 complex and that the disease-associated mutation R1085A increases the affinity of the channel for Phactr1. In patch clamp experiments, however, the amplitude of both wild type and $Slack^{R1085A}$ currents was suppressed by co-expression of Phactr1. It has been proposed that activation of Slack channels could stimulate mRNA translation and preliminary experiments suggest that the $Slack^{R1085A}$ mutation may alter this aspect of channel function. Our data support the hypothesis that, in addition to regulating electrical excitability directly, Slack channels participate in intracellular signaling pathways via PP1 or actin. In this regard, targeting Slack-Phactr1 interactions may be helpful in developing novel therapies for brain disorders associated with the malfunction of Slack channels.

Title: Role of kv1.3 potassium channels in the auditory function

Authors: *L. EL-HASSAR[1], L. SONG[2], V. R. GAZULA[1], D. NAVARATNAM[3], J. SANTOS-SACCHI[2], L. K. KACZMAREK[1]
[1]Pharmacol. department SHMB 309, Yale Univ. Sch. of Med., New Haven, CT; [2]Surgery, New Haven, CT; [3]Neurol., New Haven, CT

Abstract: Kv1.3 is a low threshold voltage-dependent potassium channel expressed in both excitable and non-excitable cells. In non-excitable cells, Kv1.3 channels are involved in various functions including cell volume regulation, proliferation, and insulin signaling. Within the central nervous system, deletion of Kv1.3 gene from mitral cells of the olfactory bulb dramatically increased the sensitivity of the olfactory system. Our group has previously shown that Kv1.3 channels are also present in the presynaptic terminals of the medial nucleus trapezoid body (MNTB) within the auditory brainstem (also called Calyx of Held). More specifically, they were found to be expressed along the plasma membrane and in internal vesicular structures of the calyx of Held. Whether these Kv1.3 channels with distinct localization in the presynaptic terminals can regulate the synaptic transmission and contribute to the auditory function is unknown. To examine the functional role of Kv1.3 channels in the auditory system, we used *in-vitro* and *in-vivo* approaches in Kv1.3 knockout (KO) and Bl6 Wildtype (WT) mice. Our preliminary results from *in-vitro* whole cell patch-clamp recordings in young mice (P13-17) show that lack of Kv1.3 channels significantly increases the spike firing frequency of the presynaptic calyx in response to square pulses of injected currents. In contrast, no significant changes were detected in the postsynaptic MNTB neurons. We have also found aberrant evoked postsynaptic activity in MNTB neurons in response to presynaptic fibers stimulation in Kv1.3 KO mice, suggesting that kv1.3 channels regulate synaptic transmission between Calyx of Held and MNTB neurons. To further investigate their role in auditory function, we carried out *in-vivo* recordings of the Auditory Brainstem Responses (ABR) of Kv1.3 KO and found that the thresholds of ABR are elevated in young (P13-17) and old (2-4 months) Kv1.3 KO mice over those in WT mice. Latencies of peaks I, II and IV are prolonged in Kv1.3 KO mice. In addition, mice lacking Kv1.3 potassium channels show a desynchronization of ABR waves suggesting an alteration of synaptic transmission and changes in spike fidelity within auditory pathways. Altogether, our data suggest that loss of Kv1.3 potassium channels primarily influences the properties of presynaptic terminals, alters synaptic transmission between Calyx of Held and MNTB neurons, and impairs auditory function. Ongoing experiments are now characterizing the dynamic of Kv1.3 channels distribution in response to presynaptic fibers stimulation.

Title: A mutant SK channel that is hypersensitive to Ca^{2+}

Authors: *A. VIEGAS[1], Y.-W. NAM[1], S. BASKOYLU[3], R. O. ORFALI, 92866[2], A. HART[3], M. ZHANG[1]
[1]Chapman Univ. Sch. of Pharm., Irvine, CA; [2]Chapman Univ. Sch. of Pharm., Orange, CA; [3]Brown Univ., Providence, RI

Abstract: Small-conductance Ca^{2+}-activated K^+ (SK) channels mediate medium afterhyperpolarization in the neurons which limits the firing frequency of action potentials and, thus, play a key role in the regulation of neuronal excitability. Given their importance in neurons, SK channels are potential drug targets for movement disorders, including ataxia and Amyotrophic Lateral Sclerosis (ALS). The SK channels are activated exclusively by the Ca^{2+}-bound calmodulin. Previously, we identified an intrinsically disordered fragment that is essential for the mechanical coupling between Ca^{2+}/calmodulin binding and the channel opening. Here, we report that substitution of one amino acid residue in the intrinsically disordered fragment caused a ~6 fold increase in the Ca^{2+} sensitivity of SK2-a channels. Subsequent tests with equivalent substitutions in SK1 and SK3 channels also exhibited Ca^{2+} hypersensitivity. Additionally, an equivalent phenylalanine substitution in the *Caenorhabditis elegans* (*C. elegans*) SK2 ortholog *kcnl-2* partially rescued locomotion defects in an existing *C. elegans* ALS model, in which human SOD1G85R is expressed at high levels in neurons. This supports the idea that the phenylalanine substitution impacts SK channel function *in vivo*. This work confirms that the intrinsically disordered fragment plays a crucial role in SK channel regulation and - for the first time - provides a critical reagent for future studies: an SK channel that is hypersensitive to Ca^{2+} concentrations with increased activity *in vivo*.

Title: Distinct subsets of presynaptic K+ channels modulate frequency-dependent synaptic transmission in excitatory and inhibitory hippocampal neurons independent of net calcium influx

Authors: *I. CHO, S. ALPIZAR, M. HOPPA
Dartmouth Col., Hanover, NH

Abstract: Presynaptic terminals are fundamental computational units in the brain, and their dysfunction is associated with several neurological diseases. They mediate the transduction of incoming electrical signals (action potentials) into chemical signals (neurotransmitter release), and the efficiency of conversion determines the strength of circuits underlying memory and behavior. Many synapses in the hippocampus display frequency-dependent changes in transduction efficiency. The shape of the presynaptic action potential is of fundamental importance in determining the timing and magnitude of neurotransmitter release. However, the plasticity of action potential waveform shape during frequency dependent stimulation and a role in transduction efficiency is unknown. This is largely due to the fact that the *en passant* synapses that are prevalent in the hippocampus are difficult to measure with classic electrophysiology owing to their small size. To overcome these limitations in our current study we combine a genetically encoded far-red voltage indicator named QuasAr with quantitative measurements of presynaptic calcium and vesicle fusion by GCaMP and vGlut-pHluorin imaging, respectively. We found significant frequency-dependent changes in presynaptic action potential shape even from paired pulse stimulation in primary cultured rat hippocampal neurons. Namely, a significant broadening of action potentials at excitatory synapses and narrowing at inhibitory synapses were shown. We determined that these changes were due to unique molecular identities and functional role of K^+ channels that can modulate the electrogenic properties of the presynaptic membrane at excitatory and inhibitory terminals. Our results indicate that voltage-dependent inactivation of $K_v1.1/1.2$ channels underlies the broadening, while calcium-gated potassium channels underlie narrowing of the action potential for excitatory and inhibitory neurons respectively. Furthermore, while the changes in AP shape are strongly correlated with vesicle fusion probability, however they are independent of net calcium influx as classically predicted, suggesting a role for calcium-microdomain signaling. Taken together, these results suggest that variability in presynaptic K^+ channels may play a fundamental role in controlling frequency-dependent changes in synaptic strength.

Title: Proteomic and functional analysis of presynaptic actin regulation during synaptic transmission

Authors: *S. DUBE[1], T. BRADSHAW[1], A. UEZU[2], E. SODERBLOM[3], B. RÁCZ[4], S. H. SODERLING[1,2]
[1]Neurobio., [2]Cell Biol., [3]Proteomics Core, Duke Univ., Durham, NC; [4]Anat. and Histology, Univ. of Vet. Med. Budapest, Budapest, Hungary

Abstract: Proper nervous system function requires dynamic remodeling of the actin cytoskeleton, which is highly enriched at both presynaptic terminals and postsynaptic spines. Although actin dynamics and regulation have been well-characterized at postsynapses, studies on actin in mature presynapses have been limited by difficulties in visualizing presynaptic terminals and purifying them by biochemical fractionation. Here, we show the Arp2/3 complex, a nucleator of branched actin filaments, is present at presynaptic terminals *in vivo*. We also use electron microscopy, electrophysiology, and optical methods to probe the effects of its presynaptic disruption on synaptic transmission. Finally, we used *in vivo* BioID to identify 47 additional actin regulatory proteins that reside in presynaptic terminals in the mouse brain. We are currently using stimulated emission depletion (STED) microscopy to verify the localization of these proteins and CRISPR/Cas9-based approaches paired with electrophysiology to determine their functions during synaptic transmission. We expect to uncover several lines of genetic evidence for the functions and regulation of presynaptic actin, creating a framework for how presynaptic terminals may be structurally altered during synaptic plasticity. Additionally, since defects in actin regulation are associated with many neurological disorders (including autism spectrum disorders, intellectual disability, and schizophrenia), our findings may help inform potential presynaptic pathologies in these diseases.

Abstract: Synaptic vesicles (SVs) are accumulated at active zones in clusters, which are comprised of ready-releasable and reserve pools. Phosphoprotein synapsin I plays critical role in organizing SVs in the reserve pool in many central synapses. SVs in the reserve pool replenish the ready-releasable pool to sustain neurotransmission during high-rate activity and are rapidly reclustered after stimulation. How these SV trafficking events are regulated is largely unknown. Using the giant reticulospinal model synapse in lamprey we show that the scaffolding protein intersectin 1 (ITSN1) regulates the synapsin 1 function during synaptic activity by forming a dynamic complex with synapsin. Like in mammalian synapses ITSN1 is a component of an extravesicular matrix of the reserve pool of SVs in giant lamprey synapses. The complex formation with synapsin 1 is mediated by SH3A (Src-homology 3 A) domain of ITSN1, which binds to the D domain of synapsin I. An intramolecular switch within ITSN1 regulates the interaction between the proteins. Microinjection of antibodies against SH3A domain into giant synapses at rest does not perturb SV organization, while during stimulation it disrupts the vesicle clustering in the reserve pool thus supporting that ITSN1 and synapsin 1 come into interaction during synaptic activity. Our data suggest that the SH3A domain of ITSN1 serves to sequester synapsin 1 within the reserve pool when it dissociates from SV during stimulation and promotes efficient reclustering when stimulation ceased by releasing dephosphorylated synapsin within the reserve pool. Thus, our experiments uncover the molecular mechanism regulating vesicle reclustering within the reserve pool of SVs.

Title: MAP kinase phosphorylation gates regulation of SV trafficking and neurotransmitter release by J domain of synapsin III

Authors: *S.-H. SONG, G. J. AUGUSTINE
Lee Kong Chian Sch. of Medicine, NTU, Singapore, Singapore

Abstract: Among the 3 mammalian synapsin genes, synapsin III is unique because it regulates neurotransmitter release in a neurotransmitter-specific manner (J. Neurosci. 28:10835; 30:9762; 36:6742). These effects must be caused by the J domain, a motif found only in synapsin III. To examine the function of the J domain, we first injected a peptide from the J domain of synapsin III into squid giant presynaptic terminals. This peptide reversibly inhibited synaptic transmission, while a scrambled version did not; thus, the inhibitory effect is sequence-specific. Analysis of the kinetics of synaptic depression during high-frequency stimulus trains (50 Hz) revealed that J domain peptide inhibits synaptic transmission both by reducing the size of the readily-releasable pool (RRP) and by slowing mobilization of vesicles from the reserve pool (RP) to the RRP. This effect is regulated by phosphorylation: pseudophosphorylating the J domain peptide at a MAPK phosphorylation site (S470D) inhibited synaptic transmission, while a non-phosphorylatable version (S470N) did not. To further clarify J domain function, we examined excitatory synapses of microisland-cultured mouse hippocampal neurons. Expressing recombinant J domain did not affect the amplitude of autaptic EPSCs. However, during repetitive stimulation (10 Hz), J domain expression slowed the time constant of synaptic depression and increased RRP size. Further, a phospho-null mutant J domain (S470A) further slowed depression and increased RRP size, while pseudophosphorylated J domain accelerated the rate of synaptic depression and reduced RRP size. Thus, in both squid and mouse neurons, phosphorylation of the J domain controls the ability of synapsin III to regulate mobilization of RP vesicles. In summary, our results indicate that interactions mediated by the J domain of synapsin III determine the dynamics of both RRP and RP vesicles, thereby regulating neurotransmitter release. Further, this regulation is gated by MAPK phosphorylation.

Title: Neurexins mediate clustering of voltage-gated Ca^{2+} channels at presynaptic active zone

Authors: *F. LUO[1,2], M. JIANG[2], T. L. SÜDHOF[2]
[1]Guangzhou Univ., Guangdong, China; [2]Mol. and Cell. Physiol., Stanford Univ., Stanford, CA

Abstract: The spatial organization of voltage-gated Ca^{2+} channels and synaptic vesicles at the presynaptic active zone are tightly regulated and play essential role in synaptic function. However, the molecular mechanisms underlying the tight regulation remain much unknown. Here we examined the function of neurexins, the central organizer of synapse formation and function, at the calyx of Held synapse. We found that deletion of all neurexins remarkably reduces synaptic strength at the calyx of Held. The functioning of Ca^{2+} channels and release machinery remain intact; however, the coupling between Ca^{2+} channel and synaptic vesicle was surprisingly impaired. These results together suggest a novel function of neurexins in organizing presynaptic active zone by facilitating tight coupling between Ca^{2+} channels and readily-releasable synaptic vesicles.

Title: Nanoscale organization of RIM-BP2 at the mammalian active zone

Authors: *T. B. TARR, T. A. BLANPIED
Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Effective communication within neural circuits requires the precise control of neurotransmitter release in response to a presynaptic action potential. Indeed, perturbation of release can trigger circuit malfunction that leads to cognitive and psychiatric disorders. Functional precision arises from the proper subsynaptic organization of the proteins involved in synaptic transmission. Previous work from our lab has established that evoked vesicle fusion preferentially occurs at subdomains of the AZ with the highest density of Rab3-interacting molecule (RIM), a protein that is necessary for synaptic vesicle priming and for the recruitment of Ca^{2+} channels to the AZ. These RIM "nanoclusters" are also aligned with postsynaptic nanoclusters of receptors and PSD-95, suggesting this presynaptic organization helps maximize synaptic strength by aligning sites of release with high density clusters of receptors. Considering the importance of subsynaptic protein organization, we sought to determine the nanoscale organization of RIM-binding protein 2 (RIM-BP2), another functionally relevant presynaptic protein that is crucial for the reliability and fidelity of synaptic transmission. Like RIM, RIM-BP2 binds Ca^{2+} channels, particularly P/Q-type Ca^{2+} channels, and thus is suspected to localize them close to vesicles through this direct interaction as well as indirectly through its binding to RIM. Using super-resolution STORM imaging of cultured hippocampal neurons, we have observed that RIM-BP2 is tightly clustered within small AZ subdomains that bear a striking resemblance to the RIM nanoclusters. Since the overall clusters of RIM-BP2 are similar to the nanoclusters of RIM, RIM-BP2 may be playing an important role in synaptic function by influencing the nanoscale organization of RIM. To test this, we are currently performing STORM imaging of RIM and PSD-95 at synapses that are expressing RIM-BP2 mutants that cannot bind to RIM, and at synapses in which RIM-BP2 has been knocked down. Not only will these experiments help determine the influence of RIM-BP2 on the nanoscale organization of RIM, but they will also provide insight into the effect, or lack thereof, of presynaptic perturbations on postsynaptic protein organization.

Title: RIM4γ deficiency causes alterations in cerebellar Purkinje cell function

Authors: *E. M. SCHÖNHENSE, K. MICHEL, H. T. KIM, A. J. BECKER, D. DIETRICH, S. SCHOCH
Univ. Clin. Bonn, Bonn, Germany

Abstract: RIMs (Rab3-interacting molecules) are multidomain proteins, enriched at presynaptic active zones. The large isoforms (RIM1α/β, RIM2α/β) have been shown to be important for mediating presynaptic active zone function by coupling synaptic vesicles to voltage-gated calcium channels (VGCCs) and by regulating neurotransmitter release as well as presynaptic plasticity. The functional role of the small RIM isoforms, RIM3γ and RIM4γ, in particular in vivo has so far remained unresolved. To address this open question we have generated constitutive RIM4γ knock-out (KO) mice. Starting after weaning these RIM4γ KO mice exhibit spontaneous episodes of strong hind limb impairments with rapid uncontrolled movements accompanied by weight loss. In order to uncover if this phenotype resulted from dysfunction in the cerebellum, we crossed conditional RIM4γ KO mice with a Purkinje-cell specific Cre-driver line (Pcp2-Cre) resulting in Pcp2-cre(Mpin)-RIM4γ KO mice. Behavioral experiments with these mice confirmed deficits in fine motor coordination and less exploration in a novel environment found in the constitutive KO line. Furthermore, it was also possible to induce the motor phenotype by injections of ethanol or caffeine.
Interestingly, morphological analyses of the cerebellum and of individual Purkinje cells revealed changes in size and branching of the dendritic tree. Juxtacellular recordings of Purkinje cells in the presence of blockers of synaptic transmission revealed in Pcp2-RIM4γ KO mice an overall reduced spontaneous firing frequency of Purkinje cells and an almost complete lack of bursting cells. In addition, a population of Purkinje cells firing tonically at 10-15 Hz is strongly diminished in Pcp2-RIM4γ KO mice.
Taken together, our data for the first time reports that RIM4γ in cerebellar Purkinje cells is required to maintain normal electrophysiological properties and to establish proper dendritic morphology. In turn, RIM4γ deficiency results in a phenotype resembling human dyskinesias.

Title: Acute homeostatic challenge induces a rapid active zone cytomatrix-dependent increase in synaptic calcium channel levels

Authors: *S. J. GRATZ[1], J. J. BRUCKNER[2], R. X. HERNANDEZ[3], K. KHATEEB[5], G. T. MACLEOD[4], K. M. O'CONNOR-GILES[5]
[1]Univ. of Wisconsin Madison, Madison, WI; [2]Univ. of Oregon, Eugene, OR; [4]Wilkes Honors Col., [3]Florida Atlantic Univ., Jupiter, FL; [5]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Communication in neural circuits depends on neurotransmitter release at specialized domains of presynaptic terminals called active zones. Neurotransmitter release properties vary significantly, even between neighboring active zones of the same neuron. To investigate the role of voltage-gated calcium channels in determining diverse release properties, we combined endogenous tagging of the sole *Drosophila* Ca_V2 channel Cacophony with functional imaging at motor synapses. We find that calcium channels levels vary between individual active zones and robustly predict synapse-specific release probability. We next turned to a well-studied paradigm to investigate calcium channel clustering during homeostatic plasticity. Upon exposure to the glutamate receptor antagonist philanthotoxin, *Drosophila* presynaptic motorneurons increase neurotransmitter release to precisely offset reduced glutamate receptor function. It has previously been shown that increased presynaptic calcium influx is required for this homeostatic response. However, how this occurs has remained an open question. Surprisingly, we find that active zone calcium channel levels are increased in as little as 10 minutes during acute presynaptic homeostatic potentiation. Rapid channel accumulation depends on the core active zone cytomatrix protein ELKS/CAST/Bruchpilot, whose levels increase in parallel. Thus, the active zone cytomatrix is dynamically reorganized to cluster more calcium channels and maintain circuit function in response to homeostatic challenge.

Title: Role of serine arginine protein kinase 2 (SRPK2) on composition and function of the active zone

Authors: *J. BETZIN[1], J. A. MÜLLER[1], A. OPRIŞOREANU[1], E. M. SCHÖNHENSE[1], K. ENGHOLM-KELLER[2], M. GRAHAM[2], A. J. BECKER[1], D. DIETRICH[1], S. SCHOCH[1]
[1]Univ. Clin. Bonn, Bonn, Germany; [2]Childrens's Med. Res. Inst., Westmead, Sydney, Australia

Abstract: The presynaptic active zone (AZ) is composed of multiple proteins mediating the release of synaptic vesicles (SVs). One major presynaptic scaffolding protein is RIM1α, the most abundant isoform of the RIM family. RIM1α is involved in the regulation of SV exocytosis, the recruitment of voltage-gated Ca^{2+}-channels and synaptic plasticity. Posttranslational modifications, like phosphorylation, play a role in controlling protein-protein interactions and thereby synaptic transmission and plasticity. RIM1α has been identified as a phosphoprotein, however, it is still unresolved how phosphorylation affects RIM1α function. As a first step in this direction new phosphorylation-dependent binding partners of RIM1α were identified using affinity chromatography/mass spectrometry. This screen identified the SR protein kinase 2 (SRPK2) as a novel RIM1α interacting protein. The homolog of SRPK2 in *D. melanogaster* (SRPK79D) plays an important role for T-bar assembly and the transport of the AZ protein Bruchpilot to the presynapse, however its role in mammalian synapse function is to date still unresolved. Here, we analyzed the role of SRPK2 in murine AZ formation and function. Overexpression (OE) and knock-down (KD) of SRPK2 was induced in hippocampal neuronal cultures by transduction with rAAV particles. To study the influence of SRPK2 expression on AZ components, we established a method to quantify the abundance of synaptic proteins in bead units based on immunofluorescence labeling. Overexpression of SRPK2 resulted in increased levels of RIM1 within synapses. Furthermore, the impact of SRPK2 on AZ formation and structure at the nanoscale was analyzed using direct stochastic optical reconstruction microscopy (dSTORM). Functionally, the effect of SRPK2 expression on synaptic release was investigated using the genetically encoded glutamate sensor iGluSnFr and FM4-64 dye-release assays. Overexpression of SRPK2 resulted in a two-fold increase in release probability. Intriguingly, OE of SRPK2 could not potentiate release probability in RIM1/2 knock-out cells, indicating that the release stimulating effect of SRPK2 requires RIMs. In addition, a phosphoproteomic analysis was used to identify novel SRPK2 target proteins at the presynapse and the specific phosphorylation sites of these proteins. Amongst other targets, this analysis revealed several putative phosphorylation sites in RIM1. Our data identifies SRPK2 as a kinase that by phosphorylating multiple presynaptic proteins affects AZ composition and synaptic transmission.

Title: Synaptic maintenance in the absence of synaptic activity in the auditory brainstem

Authors: *C. KÖRBER[1], L. EBBERS[2], S. HOPPE[1], H. G. NOTHWANG[2]
[1]Univ. of Heidelberg, Heidelberg, Germany; [2]Univ. of Oldenburg, Oldenburg, Germany

Abstract: The maintenance and integrity of synapses are thought to rely on the presence of neuronal activity. This includes the release of synaptic vesicles (SVs) at presynaptic active zones (AZs), either in response to an action potential or spontaneously. SV release is inhibited by bacterial neurotoxins which cleave neuronal SNARE proteins thereby preventing the assembly of the crucial SNARE complex. One of these neurotoxins is tetanus toxin (TeNT), which cleaves the SNARE protein synaptobrevin/VAMP2. We expressed TeNT in the bushy cells of the ventral cochlear nucleus (VCN) in the auditory brainstem using a specific Cre-driver mouse line (Math5). The globular bushy cells of the VCN give rise to the calyx of Held in the contralateral medial nucleus of the trapezoid body (MNTB), a giant axo-somatic synapse that comprises 300-700 individual AZs. The expression of TeNT at this specific synapse led to a gradual decrease of SV release with the virtual absence of neurotransmission by P15. However, we did not observe any alterations in the MNTB, neither on the number and size of the MNTB principal cells, nor on the morphology of calyx of Held synapse. Moreover, TeNT expression did not lead to a reduction in AZ number or a loss of SVs from AZs, albeit the number of "docked" SVs close to the plasma membrane was strongly reduced. We therefore conclude that synaptic activity is not necessary for the maintenance of this synapse but rather contributes to the remodeling of synapses in order to meet the current requirements of the neuronal circuit.

Title: A potential mechanism for locus coeruleus-dependent dopamine signalling

Authors: *A. SONNEBORN, R. W. GREENE
Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: The dorsal hippocampus is essential for the consolidation of episodic memories, a process that is highly dependent on the activation of dopamine D1/D5 receptors. Initially the source of dorsal hippocampal dopamine (DA) was thought to be the ventral tegmental area (VTA), but several recent studies have established that the majority of this dopamine is actually released from locus coeruleus (LC) terminals. By selectively activating or suppressing LC terminal activity in CA1, these studies also determined a physiologically relevant role of LC DA in learning and memory. However, the mechanisms by which this dopamine can be released have not yet been explored. Here we combine optogenetics, electrophysiology, and pharmacology in order to show that one possible release mechanism is by reverse transport through the norepinephrine transporter. We also provide evidence that DA release in the dorsal hippocampus is mediated by presynaptic NMDA receptors on the terminal boutons of catacholaminergic projections. Since the LC is known to be involved in arousal, attention, and multiple types of memory, these experiments will provide new insight into how attentional processes can influence circuit-level memory formation

Title: Structural correlates of transmitter release and readily releasable pool at hippocampal mossy fiber synapses

Authors: *C. BORGES-MERJANE, O. S. KIM, P. JONAS
Inst. of Sci. and Technol. (IST) Austria, Klosterneuburg, Austria

Abstract: The readily releasable pool (RRP) is a key parameter that determines efficacy and dynamics of synaptic transmission. However, the structural correlate of this pool remains unclear. It is often thought that the RRP is identical to the pool of docked vesicles. However, it has been also suggested that the RRP represents only a subset of docked vesicles, or that it may include also vesicles added by rapid recruitment (Kaeser and Regehr, 2017). In order to test whether the docked vesicle pool can be fully depleted, we implemented and further developed on the recently described "Flash and Freeze" technique (Watanabe *et al*, 2013, Nature 504:242-247). "Flash and Freeze" combines optogenetics with high-pressure freezing (HPF): a light pulse activates genetically expressed channelrhodopsin (ChR2) in targeted cells, leading to action potential (AP) initiation and vesicle fusion at the active zone (AZ) membrane. During light stimulation, the tissue is kept at physiological temperature, and subsequently frozen by HPF with a pre-set timed delay after onset of stimulus, thus allowing for capture of events at different time points after synaptic transmission onset. We applied "Flash and Freeze" to assess docked vesicle pool dynamics at the mossy fiber-to-CA3 pyramidal cell synapse in organotypic slice culture and acute slices of mouse hippocampus. We expressed ChR2-H134R in granule cells and characterized direct light-evoked responses, as well as postsynaptic responses from CA3 pyramidal neurons. We tested different frequencies (0.1-100 Hz) and pulse duration (1-10 ms) to characterize granule cell AP initiation probability. We found that with 1-5 ms (n = 5) pulses, APs fire reliably, with up to 1-ms delay from stimulus onset. We also found stable postsynaptic responses; with a maximum reliable frequency of 20-30 Hz and median delay 4.6 ± 0.14 ms from stimulus onset. Analysis of AZ reconstruction from serial sections showed that the average area of AZs in putative mossy fiber boutons is 0.10 ± 0.01 μm^2 (n = 7) and mean number of docked vesicles is 67 per μm^2, corresponding to ~8 docked vesicles per AZ. After brief trains of stimuli at moderate frequency we observed vesicle pits, similarly to those described during ultrafast endocytosis and at the same time-scale, between 50-250 ms after stimulus. Furthermore, AZ profile analysis of light-stimulated tissue showed a significant decrease in the number of docked vesicles after a prolonged stimulus (1.6 in control to 0.2 vesicles per profile after 100x 20 Hz, $p < 0.00001$), presumably fully depleting the docked pool. Depletion of docked vesicles during activity suggests that docked vesicles represent the releasable vesicle pool.

Title: Single-cell RNA-seq data reveals developmental specification of alternative splicing profiles of synaptic molecules

Authors: *D. LUKACSOVICH, J. WINTERER, W. LUO, L. QUE, C. FOLDY
Lab. of Neural Connectivity, Brain Res. Institute, UZH, Zurich, Switzerland

Abstract: Synaptic cell adhesion molecules (CAMs) are responsible for the complex and varied connectivity properties of cells. Understanding the pattern of CAM expression can help us to understand the logic of neural connectivity in the brain. While most recent studies utilizing RNA-seq focus on gene expression levels, alternative splicing has a large impact on the properties of many synaptic molecules. Therefore we looked at alternative splicing at the cell type level to develop a deeper and more fundamental level of understanding of the logic of CAM expression. Here, we utilized single cell RNA-seq data from the NCBI GEO online database to generate a dataset of over 1,600 cells from 45 cell types and, after quality control, performed statistical analysis to explore alternative splicing in hippocampal and cortical cell types. Searching for broad and encompassing trends in the logic of alternative splicing, we found a strong developmental origin-dependent pattern of alternative splicing of CAMs. As an example, while Neurexin genes were not differentially expressed across different cell types, they exhibited significant developmental origin-dependent alternative splicing. Alternative splicing may mute the effect of disorder related genetic mutations that are located on alternatively spliced exons. In this manner our results potentially identify which cell types may be rendered into a pathological state by such mutations. Scaling and automatization of our approaches and pipeline will make it possible to simultaneously analyze a multitude of molecules across vast cellular networks.

Title: Architectural heterogeneity among ribbon synapse complexes in utricular hair cells

Authors: *L. F. HOFFMAN[1], I. LOPEZ[1], R. SCHIALEK[2], M. TERASAKI[3], J. W. LICHTMAN[2], F. E. SCHWEIZER[4]
[1]Head & Neck Surgery, Geffen Sch. of Med., Los Angeles, CA; [2]Harvard Univ., Cambridge, MA; [3]Univ. of Connecticut, Hartford, CT; [4]Neurobio., UCLA, David Geffen Sch. of Med., Los Angeles, CA

Abstract: Presynaptic complexes within inner ear sensory epithelia hair cells are characterized by synaptic ribbons, which are electron-dense structures exhibiting various morphologies surrounded by neurotransmitter vesicles. Ribbon synapses are also found in retinal rods and cones, lateral-line neuromast hair cells, and pinealocytes. The architectures of ribbon complexes exhibit diversity across the cells in which they are found, and some evidence suggests this heterogeneity may have physiologic correlates. However, the 3D ultrastructure of ribbon complexes in any sensory epithelia have not been extensively explored, and therefore a comprehensive understanding of ribbon architypes represents an important step in understanding potential contributions to processing within sensory epithelia. We addressed this problem through serial ultrastructural analyses to elucidate the 3D architecture of ribbon complexes in murine utricular hair cells. Utricles from C57Bl/6 mice were harvested, fixed (4% paraformaldehyde, 2% glutaraldehyde), and prepared for ATUM SEM (automatic tape-collecting ultramicrotomy and scanning electron microscopy) as previously described (Terasaki et al. 2012, Kasthuri et al. 2014). Sections were obtained at 30 or 50 nm thickness, respectively, and were imaged at either 4 or 3 nm/pixel, respectively. Ribbon complexes in utricular hair cells conformed to two general architectures. As previously described, individual micrographs revealed simple architectures characterized by a single ribbon body that exhibited spheroid, ellipsoid, or bar morphologies surrounded by clear vesicles. While some spheroid or ellipsoid ribbons conformed to the “expected” structure in serial reconstructions, ribbons that appeared as bars in 2D were, in fact, sections of a plate, resembling ribbons found in retinal rods. Such plates extended more than 0.5µm along the presynaptic membrane. In one case the plate extended approx. 1µm into the hair cell cytoplasm. Cluster architectures were formed by multiple ribbons exhibiting mixed morphologies (bar/plates or spheroid/ellipsoids). Neighboring ribbons were separated by a single “sheet” of vesicles. Ribbon clusters were distinguished by the regions of

close presynaptic membrane apposition. For some clusters the regions were very limited, but in others it was extensive. In most cases presynaptic contact was made by only 1-2 ribbons of a cluster, implying the existence of mechanisms to shuttle vesicles from distal ribbons to the active zone. The heterogeneity in ribbon architectures in vestibular hair cells may underlie differential contributions to the dynamic diversity exhibited by afferent neurons.

Title: Molecular anatomy of the average hippocampal neuron

Authors: *S. JÄHNE[1], M. HELM[2], H. WILDHAGEN[2], S. MANDAD[2], M.-T. WEIL[3], W. MÖBIUS[4], S. O. RIZZOLI[2]
[2]Neuro- and Sensory Physiol., [1]Univ. Med. Ctr. Göttingen, Goettingen, Germany; [4]Dept. of Neurogentics, [3]Max-Planck-Institut für Experimentelle Medizin, Göttingen, Germany

Abstract: Neuronal function has been analyzed extensively both *in vivo* and *in vitro*, in the form of primary cultures. Cultured hippocampal neurons have served for decades as tools for the neurosciences, and are the primary *in vitro* tool for neuronal physiology studies. Nevertheless, their detailed molecular anatomy is still poorly understood. We aim here to increase our knowledge of neuronal morphology and physiology by using an integrative approach to study the physical parameters, compartmentalization, and molecular composition of hippocampal neurons. We employed large-field fluorescence microscopy in combination with genetically-encoded fluorescent membrane proteins to determine the average number of neurites, their branching, length, diameter, and volume. Using confocal microscopy, we determined the volume of the neuronal soma, as well as the distribution and proportion taken up by the organelles of the secretory pathway, by mitochondria, peroxisomes, and ribosomes. Finally, focused ion beam scanning electron microscopy and direct stochastic optical reconstruction microscopy (STORM) were used to determine the exact volumes and shapes of the aforementioned organelles, allowing for an accurate description of the cellular compartmentalization. We also determined the copy numbers of 3000 proteins per average neuron, and we are currently integrating super-resolution microscopy and comparative imaging to map the distribution of the most important neuronal proteins (around 200).

Combining the experimentally-generated parameters we aim to produce a 3D model of an average hippocampal neuron and its functional compartments. We will be able to explore this model to increase our knowledge on the organization of functional pathways, such as synaptic vesicle biogenesis. The model also serves as an ideal basis for a molecular nanomap that comprises the numbers and localizations of the most important neuronal proteins.
The resulting molecular nanomap of an average hippocampal neuron will be a comprehensive structural description of a neuronal cell that can function as a database, which colleagues in the field will be able to use as a basis for comparing different cell types, for unraveling functional pathways, and for studying structural differences caused by neurodegenerative diseases, such as Alzheimer's disease.

Abstract: While recent evidence highlighted that distinct molecular machineries are segregated into functionally different nanodomains to mediate anterograde neurotransmission, the nanoarchitecture of retrograde synaptic signaling has remained elusive. Endocannabinoid signaling is a canonical retrograde pathway, and regulates synaptic transmission and plasticity at most synapse types throughout the brain. Notably, CB_1 cannabinoid receptors can control neurotransmitter release in both tonic and phasic manner. To determine the nanoscale organization of the underlying mechanisms behind these forms of synaptic cannabinoid

signaling, and retrograde synaptic signaling in general, we developed a novel approach, which makes the direct correlation of nanoscale molecular imaging data with the respective morphological and physiological synaptic parameters possible even at the single synapse level in brain circuits. First, paired whole-cell patch-clamp electrophysiological recordings were made between presynaptic CB_1-positive GABAergic interneurons and postsynaptic CA1 pyramidal cells in the mouse hippocampus. After anatomical reconstruction of both cells, pairs linked with one or two synaptic connections were further analyzed by correlated confocal and 3-D Stochastic Optical Reconstruction Microscopy (STORM). The nanoscale molecular distribution of presynaptic CB_1 receptors in relation to the active zone visualized by bassoon immunolabeling was quantified at the identified synaptic connection and the molecular data were correlated with the electrophysiologically and anatomically measured synaptic parameters. Our data revealed that the success rate of synaptic events was inversely correlated with the ratio of intra/perisynaptic CB_1 receptors/bassoon-positive voxels, but not with extrasynaptic CB_1/bassoon ratio. The correlation was not observed in the presence of the CB_1 receptor inverse agonist AM251. There was also no correlation between intrasynaptic CB_1/bassoon ratio and phasic endocannabinoid signaling. These observations indicate that tonic cannabinoid signaling fine-tunes GABAergic neurotransmission primarily via the intra/perisynaptic CB_1 receptor pool.

Title: Large volume dSTORM imaging of presynaptic active zones

Authors: M. PAULI[1], M. M. PAUL[1], S. PROPPERT[1], F. REPP[1], P. KOLLMANNSBERGER[2], M. SAUER[3], M. HECKMANN[1], *A.-L. SIREN[4]

Abstract: Active zones (AZs) are complex molecular machineries that mediate and regulate neurotransmitter release from presynaptic terminals. Among different neuronal tissues AZs display a large variety and variability in size ranging e.g. in mice from about 100 nm at endplates to several hundred nanometers in hippocampal mossy fiber boutons. The architecture of synaptic

sub-compartments has been revealed by EM with serial sectioning or array tomography studies. Superresolution light microscopic imaging of synaptic protein distributions has been restricted to cultured cells or to tissue sections less than a few micrometers from the coverslips. So far imaging of AZs in intact tissue blocks at nanoscopic resolution remained challenging.
Here we present a novel superresolution light microscopic method using 3D *direct* stochastical optical reconstruction microscopy (*d*STORM) that allows mapping AZs with molecular resolution in intact tissue blocks without mechanical or optical cutting.
We applied 3D *d*STORM with a custom-built microscope, a high NA water immersion lens and optimized staining procedures in standardized sections to map protein distributions. In up to 25 µm thick cryosections we recorded *en bloc* thousands of neuronal sub-compartments aberration-free in volumes up to 28 x 30 x 9.5 μm^3. Using highly specific anti-Bassoon antibodies we measured protein clusters with distinct size, number and density in mouse hippocampus. Sequential imaging with the fluorophore Alexa 647 in brain sections of Thy1-mEGFP (Ls1) mice identified a total of 8826 Bassoon clusters in the imaged tissue volume of 5701 μm^3; 185 clusters could be localized in 8 identified CA3-mossy fiber boutons. The volume (0.0102 ± 0.0204 μm^3) of Bassoon clusters in individual mossy fiber boutons was larger than the volume (0.0058 ± 0.0152 μm^3) of all Bassoon clusters recorded in the imaged tissue volume.
3D single-molecule localization microscopy using *d*STORM with far red fluorophores opens new possibilities for quantitative tissue imaging at the molecular level. Because imaging can be assumed to be free of depth-dependent spherical aberrations, it is feasible to stack through a complete presynaptic terminal, count the number of AZs, and map their architecture with molecular resolution.

Title: Characterization of the role of *Drosophila melanogaster* Vwa8 in the regulation of synaptic growth and transmission

Authors: *D. BEELER[1], F. L. LIEBL[2], J. E. RICHMOND[3], D. E. FEATHERSTONE[4]

Abstract: Proper function of excitatory synapses is necessary for learning and memory formation and misregulation of these synapses is common in several neurological disorders. Thus, understanding the mechanisms that regulate excitatory synaptic function is critical. Using the neuromuscular junction (NMJ) of *Drosophila* as a model excitatory synapse, a novel, highly conserved protein, VWA8, was identified as a regulator of synaptic growth and transmission. VWA8 is the founding member of a novel protein family, most closely related to midasins and dyneins, and contains three ATPase domains and a von Willebrand factor A domain. SNPs in the human homolog of this gene have been linked to bipolar disorder, autism spectrum disorders, and migrane disorders through genome-wide human disease association studies. To further characterize this gene a *Vwa8* null mutant was generated using CRISPR genome editing. Additionally UAS-VWA8 flies were made for studying the effects of targeted overexpression of VWA8. Analysis of VWA8 expression in *Drosophila* third instar larvae determined the presence of protein presynaptically at the NMJ and in the larval brain. Electrophysiology studies of *Vwa8* null mutants display a decreased evoked amplitude and quantal content as well as increased mini frequency, suggesting a presynaptic deficit. Additionally, locomoter studies revealed *Vwa8* null mutant larvae crawl more slowly than controls, travel less distance, and have a higher angular velocity. Current results have shown that both the knockout and overexpression of *Vwa8* show a synaptic overgrowth phenotype. An increased number of both synaptic and ghost boutons is observed at the mutant NMJs. Continuing studies will examine the affects of VWA8 reduction and overexpression on presynaptic vesicle release proteins and further explore interacting partners.

Title: Analysing the 3D nanotopolgy of active zones at the *Drosophila* neuromuscular junction

Authors: *N. EHMANN[1], J. SCHERBEL[2], M. PAULI[2], P. KOLLMANNSBERGER[3], F. REPP[2], S. PROPPERT[2], M. M. PAUL[2], R. J. KITTEL[1], A.-L. SIRÉN[4], M. HECKMANN[2]

Abstract: Communication between neural cells relies on accurate neurotransmitter release at special sites termed active zones (AZs). Here, tightly packed proteins provide the platform for the spatially and temporally precise fusion of transmitter-laden synaptic vesicles (SVs) with the

presynaptic membrane. Bruchpilot (Brp) is an integral component of *Drosophila* AZs that helps to tether SVs to the AZ cytomatrix and cluster AZ calcium channels [1–3]. Using super-resolution microscopy, previous work has contributed to resolve Brp's elongated conformation at the AZ and to clarify how its copy number and spatial arrangement impacts synaptic short-term plasticity [2–5]. Ehmann et al. (2014) studied the 2D nanotopolgy of Brp in wildtype and brp^{nude}. Lacking merely the last 1 % of the C-terminal amino acids (17 of 1740) of Brp, these mutants show altered SV tethering and enhanced synaptic depression. To gain further clarification on structure, function and diversification of the Brp protein we now compare wildtype and brp^{nude} in 3D.

To this end an approach was established to maintain the 3D organisation of AZs within their native environment. Employing *d*STORM [*direct* stochastic optical reconstruction microscopy; [6]], we were able to reconstruct super-resolved 3D images up to 10 µm depth that cover whole individual boutons.

By visualising the localizations, molecules were grouped into clusters and assigned to specific structures based on their spatial arrangement. To analyse larger fields of view, which can easily contain millions of localizations, automated clustering methods are used to perform detailed analyses of Brp at different levels of organisation.

Title: Super-resolution microscopy analysis of neuromuscular junction reveals degeneration of active zones in ALS model mice

Authors: Y. BADAWI[1], K. SHIGEMOTO[2], *H. NISHIMUNE[1]
[1]Anat. & Cell Biol., Univ. of Kansas Sch. of Med., Kansas City, KS; [2]Geriatric Med., Tokyo Metropolitan Inst. of Gerontology, Itabashi, Japan

Abstract: Presynaptic active zones play an essential role as synaptic vesicle release sites for synaptic transmission. We used stimulated emission depletion (STED) microscopy to reveal the molecular architecture of active zones at sub-diffraction limited resolution. We identified an unexpected finding of non-overlapping localization of the active zone proteins Bassoon and Piccolo in mouse neuromuscular junctions (NMJs). Piccolo puncta sandwiched a Bassoon punctum in a side-by-side pattern, which could not be resolved using conventional confocal microscopy. P/Q-type voltage-gated calcium channel (VGCC) puncta colocalized with Bassoon puncta. We aimed to reveal the distribution patterns of additional key active zone proteins in mouse NMJs using STED nanoscopy. We demonstrate that Munc13 and RIM2 active zone proteins distribute in discrete, punctate patterns at the active zone units formed by Bassoon and Piccolo in NMJs of adult wild-type mice. Based on the knowledge obtained from wild-type NMJs, we also aimed to elucidate how active zone proteins are altered in amyotrophic lateral sclerosis (ALS). ALS is a neurodegenerative disorder in which denervation occurs before the death of neuronal cell bodies in the spinal cord, suggesting a “dying-back” neuropathy. The mechanisms underlying NMJ denervation in ALS remain unknown. Changes in protein levels, which are important for the maintenance of NMJ active zones and regulation of neurotransmission may play a role in the pathogenesis of ALS. For this purpose, we analyzed active zone proteins in NMJs of a rodent ALS model $SOD1^{G93A}$ mice at an early, pre-symptomatic stage (P85) and a symptomatic stage (P140). Interestingly, we found that the quantity of active zone proteins Bassoon, Piccolo and PQ- type VGCC decreased in innervated NMJs of ALS mice. Bassoon and PQ-VGCC puncta intensity and density decreased in NMJs of P85 $SOD1^{G93A}$ mice compared to age- and sex-matched wild-type mice. This decrease became more significant as the disease progressed to the P140 symptomatic stage. Decreases in Piccolo quantity in active zones became significant at P140 in $SOD1^{G93A}$ mice NMJs. Impairments in presynaptic function are likely to contribute to NMJ denervation. In summary, this study revealed the distribution of previously unresolved active zone proteins in wild-type mice and described the progressive degeneration mechanism of active zone proteins in NMJs of $SOD1^{G93A}$ mice.

Title: Complexin regulates spontaneous synaptic transmission in a sub-population of active zones

Authors: *H. R. ASTACIO[1], A. VASIN[2], M. BYKHOVSKAIA[2]
[1]Anat. and Cell Biol., [2]Neurol., Wayne State Univ., Detroit, MI

Abstract: Neuronal transmitters are released via the fusion of synaptic vesicles with the neuronal plasma membrane at specialized sites termed active zones (AZs). Vesicle fusion can occur in response to action potentials or spontaneously, and the latter component is important for neuronal development and homeostasis. We took advantage of the transgenic *Drosophila* line expressing the Ca^{2+} - sensitive fluorescent marker GCaMP5 tagged to the postsynaptic reticulum to investigate spontaneous fusion at individual AZs at the larval neuromuscular junction (NMJ). We were able to detect optical events corresponding to spontaneous vesicle fusions at individual AZs at a spatial resolution of 0.2-0.3 μm. Statistical analysis enabled us to subdivide the entire AZ ensemble into two distinct sub-populations: low activity AZs (LAZs) which obeyed the Poissonian statistics and constituted over 90% of the entire AZ population, and a small sub-population of AZs with the activity which was higher by an order of magnitude (HAZs). Since spontaneous transmission in *Drosophila* is drastically elevated by the deletion of a protein complexin (*cpx*), which was implicated to serve as a fusion clamp, we asked whether all the AZs are equally sensitive to *cpx* deletion. To address this question, we generated a heterozygous $cpx^{+/-}$ line postsynaptically expressing the GCaMP5 sensor. The overall spontaneous activity in this line was approximately twice higher than in the control line. Strikingly, we found that only the activity of HAZs was selectively increased at the $cpx^{+/-}$ NMJ, while the activity of LAZs remained unchanged. This result suggests that spontaneous synaptic transmission is controlled by a heterogeneous ensemble of AZs, with a smaller population being regulated by *cpx* and having prominent activity, and a larger population representing a Poissonian ensemble, which is not sensitive to *cpx*.

Abstract: Exposure to organophosphorus nerve agents like soman (GD) can elicit severe neurological responses, including initial *status epilepticus* (SE) that progresses to persistent epileptiform activity and latent spontaneous recurrent seizures (SRS). Many studies have examined the progression and treatment of acute nerve agent-induced SE, but ensuing chronic neurological abnormalities are poorly understood. Our lab has begun a study to evaluate the therapeutic effectiveness of clinically approved antiepileptic drugs in treating SRS in adult male C57BL/6 mice following GD exposure. This study utilizes long-term cortical electroencephalogram (EEG) recordings to characterize SRS in adult male mice following GD-induced SE.
Twenty C57Bl/6J male mice, age 12-14 weeks, were used in this study. Three weeks prior to GD exposure, mice were implanted with telemetry transmitters to record EEG activity. The mice were then exposed to GD and given a drug regimen and supportive care to promote survival for ~42 d. The mice were observed for onset of convulsions, and the EEG was monitored for SE onset.
Custom automated analysis was developed using Neuroscore and verified against trained manual scoring, and used to quantify the duration and average spike rate of abnormal neurological manifestations. Two principal events were identified: SRS, defined as spiking with a rate greater than 5 Hz for at least 10 s; and low-frequency epileptiform events (LFE), defined as at least 10 spikes occurring with 2-59 s between spikes.
Ten of twenty GD-exposed mice survived the study. Each demonstrated both SRS and LFE, with large inter- and intra-animal variability in the number and duration of each event. Seven mice showed significant increases in SRS duration over time, and two showed significant changes in SRS spike rates. The longest LFE lasted for 10 d, though analysis of cumulative LFE activity is

still ongoing. Sex differences were not assessed. These data suggest that abnormal neurological effects arise shortly after acute SE and can persist for months. Automated characterization of SRS and LFEs is currently being used to evaluate the efficacy of FDA-approved antiepileptic drugs in mitigating chronic neurological symptoms in GD-exposed mice.

Title: A predictive epilepsy index based on probabilistic classification of interictal spike waveforms

Authors: J. A. PFAMMATTER[1], *R. A. BERGSTROM[3], E. P. WALLACE[1], R. K. MAGANTI[2], M. V. JONES[1]
[1]Dept. of Neurosci., [2]Dept. of Neurol., Univ. of Wisconsin, Madison, WI; [3]Biol., Beloit Col., Beloit, WI

Abstract: Automated algorithms for the analysis of interictal spikes (IISs) aim to standardize and speed detection. Still, wide-scale application of these algorithms is limited by lack of a universal definition of spikes, thereby potentially biasing each algorithm based on assumptions about what constitutes a spike. Ideally, algorithms should be fast, bias-free and reveal aspects of IISs that are predictive and guide mechanistic studies. Here, we developed a principal components (PC)-based algorithm that is agnostic in classification of events, provided that they 'stand out' from the background. We applied the algorithm to EEG records from mice treated with saline (SA, i.p., n=7) or with an epileptogenic stimulus (KA, kainate i.p., n=15 mice). First, we detected events using a two-threshold-crossing method to define event start and end. Detected waveforms were projected onto the first three PCs and clusters of spike morphologies were identified by a Gaussian mixture model. Probability scores were assigned to clusters based on the odds-ratio of events from KA versus SA within each cluster. Some spike morphologies were more frequent in KA, whereas others occurred in both groups. We created a novel index by assigning each event its probability score, summing these values and dividing by the record duration to yield "equivalent epileptic spikes per second". This index predicted whether an

animal received an epileptogenic treatment (i.e., KA) even if a convulsive seizure was never observed. We used this method to define and track different spike morphologies in five KA animals monitored for ~1 month. The magnitude of the predictive index increased over time in a subset of animals and revealed longitudinal changes in the prevalence of spikes with specific morphologies. Importantly, in both the longitudinal data and in our development data, the three animals that had convulsive seizures also had a relatively high predictive index. This analysis is fast (i.e., minutes per 24-hour EEG record), unbiased and provides information regarding the salience of different spike morphologies for disease progression. Future refinement will allow a better understanding of how exactly interictal spikes should be defined in quantitative and unambiguous terms.

Abstract: Objective: Rodent models of epilepsy are indispensable for probing disease circuits and testing novel therapies due to their genetic and structural similarities to the human brain. However, chronic epilepsy models utilize prolonged EEG recordings that generate substantial amounts of data, resulting in a time-intensive manual labelling process. Previously published automated detectors yield a prohibitively low positive predictive values (PPV), with a false discovery rate (FDR) on the order of 0.5/hour. To address this challenge, we introduce a

generalized seizure detection model for automated evaluation of large EEG data sets.
Methods: Young male SD rats (2-3 mo, n = 12) were implanted with surface electrodes, EMG pads and intrahippocampal depth electrodes bilaterally. Unilateral intrahippocampal injections of kainic acid were administered to induce epilepsy, while video and EEG recordings were recorded continuously for 3 months. Three-channel EEG data was analyzed by computing standardized features in time, frequency, and synchronization domains for 5-second windows, and seizure segments were also manually labelled by an expert. PCA was used for dimensionality reduction and maximally discriminating features identified by computing Fisher scores. Generalized linear classifiers were built with lasso regularization using these features to classify seizures versus interictal EEG segments.
Results: The generalized and individualized classifiers all achieved an AUROC > 0.99 on test data, and at a threshold of 0.1, the classifier had a sensitivity of 0.99, specificity of 0.83 and an overall PPV of 0.37 with an FDR of 0.08/hour. The mean AUROC of our leave-one-out general classifier, in which no data from the test subject was included in training, was 0.88. Our PCA visualizations reflect the separability of the features along the axes constructed.

Title: Optimizing a mouse model of severe nerve agent intoxication for long-term survivability, incidence of neuropathology, and emergence of spontaneous recurrent seizures

Authors: *H. S. MCCARREN, C. ARDINGER, P. BODNER, P. DUBEE, E. N. DUNN, M. R. EISEN, K. M. HAINES, D. L. NGUYEN, A. SANTORO, P. M. MCNUTT
US Army Med. Res. Inst. of Chem. Def, Aberdeen Proving Ground, MD

Abstract: Recently, nerve agents have been used in both widespread and targeted attacks on individuals. These deadly chemicals inhibit acetylcholinesterase, leading to signs of cholinergic

crisis such as excessive secretions, convulsions, and seizures that progress to generalized status epilepticus (SE). Research into nerve agent antidotes has largely focused on the acute phase of intoxication, but latent neurological defects resulting from brain damage sustained during SE can follow. The goal of this study was to optimize a mouse model of SE induced by the nerve agent soman (GD) for long-term survivability and development of neuropathology. Male C57Bl/6J mice (n=80) received 50 mg/kg HI-6, followed five minutes later by 172 µg/kg GD. Animals were assigned to one of five experimental paradigms: saline (SAL) one minute post-GD, 2 mg/kg atropine methyl nitrate (AMN) one minute post-GD, or 2 mg/kg AMN one minute post-GD followed by 5 mg/kg diazepam (DZP) at 30, 60, or 120 minutes post-onset of convulsions. Survival, weight, and nesting behavior were observed for 14 days, followed by H&E neuropathological scoring. Animals in the AMN group displayed the highest survival rate (81% survival), while other groups ranged from 56-63% survival. All groups except the SAL group returned to baseline body weight by the end of the experiment, but required supplemental care. There was an inverse relationship between nesting and severity of neuropathology. The AMN group displayed the highest incidence of neuropathology (76%), followed by the SAL and 120 min DZP groups (70% and 67%). Given the high survival rate and high incidence of neuropathology, the AMN paradigm was then applied to mice that had been implanted with EEG telemetry units (DSI, ETA-F10), with the ultimate goal of observing and characterizing spontaneous recurrent seizures (SRS) in these animals. Survival was substantially poorer in implanted animals, with only 40% survival at Day 14 and 13% survival at Day 28. Alternately, implanted animals that received DZP 120 minutes after SE onset had a Day 14 survival rate of 65% and a Day 28 rate of 55%, which was similar to that in non-implanted animals. All animals in both groups that survived to the end of the study demonstrated SRS, and the incidence of pathology among survivors was 100% for AMN and 72% for 120 minute DZP. Thus, continued efforts will use the 120 min DZP paradigm to characterize SRS after GD-induced SE and test the efficacy of FDA-approved antiepileptic drugs in preventing and treating them.

Title: Electrographic changes in the brain after trauma in wild-type and aquaporin-4 knockout mice

Authors: *J. SZU, D. PATEL, C. JONAK, S. CHATURVEDI, J. LOVELACE, D. BINDER
Univ. of California, Riverside, Riverside, CA

Abstract: Posttraumatic epilepsy (PTE) refers to the development of recurrent spontaneous seizures after a traumatic brain injury (TBI). Current models of PTE have focused on testing seizure susceptibility pharmacologically and injured animals were shown to be more predisposed to generalized seizures. These studies, however, lack chronic detailed EEG analysis. Here, we aim to detect electrographic changes in the posttraumatic brain in wildtype (WT) and aquaporin-4 knockout (AQP4 KO) mice to determine the role of AQP4 in the development of PTE.
TBI was induced in the right frontal cortex using controlled cortical impact (CCI) injury device. Sham animals received a craniotomy only and naïve mice did not receive an injury or a craniotomy. 10 days before each experimental endpoint (14, 30, 60, and 90 days) mice were implanted with an indwelling electrode in their ipsilateral hippocampus. After 3 days of recovery, mice underwent continuous video-EEG recording to monitor for spontaneous seizures and *in vivo* electrical intrahippocampal stimulation was performed for the quantitative assessment of electrographic seizure threshold (EST) and duration (ESD) at each experimental endpoint.
Spontaneous non-convulsive seizures were observed in injured animals only. A significant increase in delta, theta, and alpha powers were observed 14 days after TBI in WT mice and a significant increase in delta and theta powers were observed 14 days after TBI in AQP4 KO mice. Electrical stimulation revealed a significant increase in ESD in AQP4 KO mice compared with WT mice in both sham and TBI groups.
Our data suggest that AQP4 plays a critical role in epileptogenesis after TBI. The increase in EEG power at 14 days after TBI in both genotypes suggests that mice may be more excitable at this time point after injury. Additionally, increased ESD after injury alludes to impaired water homeostasis which prolongs seizure activity suggesting impaired seizure termination in AQP4 KO mice. Histological studies for AQP4 and Kir4.1, astrocyte molecules known to modulate excitability, are also performed to correlate protein expression levels with electrographic changes at each time point. Furthermore, studies utilizing a 30-channel multi electrode array (MEA) after TBI are currently underway to localize seizure onset, propagation, and termination.

Title: Kindled seizures accelerate forgetting of previous context fear memory

Authors: L. E. BRANDT, C. COLE, A. KALININA, H. LEHMANN, *N. M. FOURNIER
Dept. of Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Epilepsy is associated with a range of cognitive impairments, includes those related to memory. One type of memory deficit that has received increasing attention is accelerated forgetting, which is characterized by impaired recall of newly acquired information over long-delays (e.g., days, weeks) despite normal recall following short delays. Despite the prevalence of memory retention deficits in patients with epilepsy, the neurobiological mechanisms contributing to these problems remain obscure. There is strong evidence that high rates of neurogenesis can promote forgetting of hippocampal-dependent memories acquired at earlier time points. One explanation for this phenomena is that the continual maturation and synaptic integration of new neurons remodel hippocampal circuits thereby reducing the probability that information stored in these circuits can be easily accessed. Several studies have shown that epileptic seizures dramatically increase rates of neurogenesis in the rat hippocampus. A significant proportion of seizure generated neurons develop and function abnormally thereby contributing to the formation of faulty circuits that promote hyperexcitability and interfere with hippocampal function. Based on these observations, we hypothesize that seizure-induced neurogenesis promotes aberrant remodeling of hippocampal circuits that can interfere with the retrieval of previously acquired memories. To test this possibility, rats were trained in a contextual fear memory task. Following training, one group of rats underwent chemical kindling for 2-weeks with the chemoconvulsant pentylenetetrazole (PTZ). PTZ kindled rats showed significantly less freezing compared to saline-treated controls when re-exposed to the training context 4 days after their last seizure suggesting that seizures induced forgetting of the fear memory. Importantly, PTZ seizures did not induce markers of neuronal degeneration or gliosis in the hippocampus, but increased immature neuronal (DCX) and proliferation (Ki67) markers. Similar behavioural findings were observed with a low dose treatment with kainic acid. These experiments offer support that aberrant remodelling of hippocampal circuits can interfere with the retrieval of previously acquired fear memory. <!--EndFragment-->

Title: Tracking brain state changes during epileptogenesis with seizure dynamics and probing

Authors: *D. N. CRISP[1], W. CHEUNG[3], A. LAI[4], D. R. FREESTONE[4], D. B. GRAYDEN[3,4,5], M. J. COOK[4], W. C. STACEY[1,2]

Abstract: Our recent work has demonstrated that seizures can be classified according to the dynamics of their onset transitions (Saggio & Crisp et al., Under Review). However, the direct practicality of this taxonomy is still being explored. One analytical approach, analyzing evoked responses from periodic electrical probing, enables the collection of more robust features to assist in brain state tracking and seizure prediction frameworks (Freestone et al. 2011). Our objective is to begin delineating the potential clinical impact of this seizure dynamics taxonomy by pairing its seizure onset classifications with independent evoked response analysis. This was performed by analyzing seizure onsets and evoked responses from periodically perturbed, long-term (~10 weeks), DC coupled, epidural EEG recordings from an intrahippocampal tetanus toxin rat model of temporal lobe epilepsy. This model produces frequent, stereotyped, electro-clinical events that spontaneously remit after some weeks. Six rats were studied, each of which exhibited thousands of seizures, providing ample data for robust analysis. To track the evolution of epileptogenesis, we also investigated cumulative seizure duration as a function of time since toxin administration. In all cases, the distribution of cumulative seizure duration was sigmoidal in shape, characterized by an initial period of increasing seizure frequency, an inflection point, and finally leveling out as seizure freedom was achieved. In all six rats, seizure dynamics and features of the evoked responses underwent major alterations at the inflection point (~week 3), demonstrating correlation between the underlying seizure dynamics and the system's response to perturbing stimuli. This suggests that these methods may be uncovering novel biomarkers of ictogenesis, and could lead to further insights into underlying mechanisms.

Title: Glucose metabolism but not neuroinflammation during epileptogenesis correlates with chronic seizure outcome in a rat model of temporal lobe epilepsy

Authors: *I. JAHREIS[1,2], P. BASCUÑANA[1], A. POLYAK[1], T. L. ROSS[1], W. LÖSCHER[2], F. M. BENGEL[1], J. P. BANKSTAHL[1], M. BANKSTAHL[2]
[1]Dept. of Nuclear Med., Hannover Med. Sch., Hannover, Germany; [2]Dept. of Pharmacology, Toxicology and Pharm., Univ. of Vet. Med. Hannover, Hannover, Germany

Abstract: The lithium-pilocarpine rat model is well-established to evaluate insult-induced epileptogenesis. Effective multi-target termination of status epilepticus (SE) results only in a proportion of chronically epileptic rats. Here, we aimed to evaluate the value of positron emission tomography (PET) imaging for prediction of epilepsy after SE.
SE was terminated by a combination of diazepam, phenobarbital, and scopolamine. Female Sprague-Dawley rats (22 post SE, 6 sham) underwent PET scans with the glucose analogue ^{18}F-fluordeoxyglucose (FDG) and the TSPO ligand ^{18}F-GE180 targeting neuroinflammation at 5d and 12-14d post SE, respectively. Video/EEG seizure monitoring was performed during weeks 22-24 after SE. Regional neuronal loss or astrocytosis were assessed by histological analysis. Potential correlations were evaluated using statistical parametric mapping (SPM) analysis.
Compared to sham, post-SE rats showed decreased FDG uptake (-9%, $p=0.033$) and increased ^{18}F-GE180 volume of distribution (V_t ,+37%, $p=0.046$) in the hippocampus. Lower hilar neuronal density (-25%, $p=0.001$) and mild astroglial activation were found 26 weeks post SE. Chronic epilepsy was present in 72% of the rats. SPM (Student's t-test, $p<0.05$) indicated a decrease in hippocampal FDG uptake in non-epileptic vs. epileptic animals. SPM did not reveal differences in TSPO V_t. Additionally, SPM (linear regression, $p<0.05$) demonstrated a correlation between chronic hippocampal neuronal loss and higher ^{18}F-GE180 signal during epileptogenesis in multiple epilepsy-associated brain regions, but not the hippocampus. By contrast, chronic astrogliosis correlated with early TSPO expression mainly in the hippocampus and piriform cortex.
Although glucose hypometabolism discriminates epileptic from non-epileptic rats, it may not be suitable as a clinical predictive biomarker since epileptic animals did not deviate from controls. Early inflammation is associated with reduced neuronal density and scar formation but is not correlated to seizure development.

Title: The possible role of spontaneous seizures on epileptogenesis

Authors: P. M. LAM, *M. I. GONZALEZ
Dept. of Pediatrics Sch. of Med., Univ. of Colorado, Denver, Aurora, CO

Abstract: Spontaneous recurrent seizures (SRS) are characteristic of epilepsy. Temporal lobe epilepsy (TLE) is a subtype of acquired epilepsy that might develop after stroke, traumatic brain injury or *status epilepticus*. Current hypotheses propose that a brain injury can trigger the transformation of a normal brain into an epileptic one in a complex process known as epileptogenesis. A less explored alternative is that SRS themselves might promote epileptogenesis. Pathologic activation of calpain, a calcium dependent protease ubiquitously expressed in neurons, has been observed in epilepsy. Calpain activation after a brain injury triggers a series of neurotoxic signaling cascades that results on the cleavage of proteins that negatively affect neuronal function and promote neuronal death. Here, we investigated if calpain activation can be detected after occurrence of SRS and if recurrent calpain activation might

contribute to epileptogenesis. To investigate if SRS themselves promote calpain activation and to evaluate if calpain activation exacerbates cellular and molecular abnormalities typically found in epileptic tissue, we used continuous EEG/video to monitor occurrence of seizures and evaluated if calpain activation can be detected in rats enduring SRS. We were able to detect both calpain activation and the loss of proteins required to maintain inhibitory drive. These studies aim to uncover the molecular mechanisms promoting occurrence of SRS and the possible role of SRS on epileptogenesis.

Title: Involvements of tryptophan metabolism in the pathogenesis of epilepsy

Authors: *S. HASHIMOTO[1,2], J. MAEDA[3], Y. TAKADO[3], H. TAKUWA[3], M. SHIMOJO[3], M. TAKAHASHI[3], T. URUSHIHATA[3], K. KUMATA[3], Z. MING-RONG[3], T. SUHARA[3], M. HIGUCHI[3]

Abstract: Objective: Despite a long history of nonclinical and clinical research on the significance of tryptophan metabolism in epilepsy, the mechanistic implication of this amino acid in the pathogenesis of epilepsy is still unclear. In this study, we assessed tryptophan metabolisms in EL mice modeling genetic epilepsy by in vivo positron emission tomography (PET) with a radiolabeled tryptophan analog and mass spectrometry of brain tissues to pursue the kinetics and metabolism of tryptophan. Mechanistic associations of tryptophan with the epileptogenesis were also examined by treating these mice with tryptophan. **Method:** Male EL and age-matched control ddY mice were used. PET scans with [^{11}C]1-methyl-L-tryptophan([^{11}C]1-MT) were conducted in EL mice (n=6) in an interictal state and control ddY mice (n=10) during the period from 5 weeks (prior to the seizure onset) to 6 months (long after the seizure onset) of age. We also preformed mass spectrometry to measure concentrations of tryptophan, serotonin and related metabolites in the hippocampus of EL and ddY mice at 9 weeks of age antecedent to the seizure onset (n=8 in each group). Furthermore, we treated EL mice with either standard diet containing 0.1% tryptophan or diet containing 5% tryptophan from 5 weeks of age prior to the seizure onset. Epileptic seizures of EL mice were stimulated by tail suspension once a week, and we determined the latency to the first seizure and frequency of

seizures in these mice. **Results:** The uptake of [^{11}C]1-MT in the EL mouse brain significantly increased (by 70%) compared to control ddY mice from 5 weeks to 6 months of age. The content of tryptophan in the EL mouse hippocampus was significantly higher than the control level. Increased levels of serotonin and other related metabolites were also observed in EL mice. The diet containing 5% tryptophan induced seizures in EL mice at an earlier age than the standard diet. **Conclusion:** Our results indicate that an enhanced uptake of tryptophan in the brain provokes initiation of the epileptogenesis in EL mice. PET imaging with [^{11}C]1-MT potentially offers a means for diagnosing and subtyping epilepsy on a pathophysiological basis.

Title: Inhibition of seizure-induced hippocampal neurogenesis by the chemotherapy drug temozolomide rescue cognitive deficits after kindling

Authors: *T. J. FRANCIS, B. S. REIVE, K. BLEWETT, K. POST, J. REID, H. LEHMANN, N. M. FOURNIER
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Cognitive impairments, such as memory loss, are a frequent and devastating co-morbidity associated with epilepsy. The neurobiological mechanisms through which recurrent seizures induce cognitive impairments are not well understood. Recent studies have shown that seizure activity stimulates the birth of new neurons in the adult hippocampus. Many of these new neurons develop abnormal morphological and functional characteristics that promote network hyperexcitability and hippocampal dysfunction. Previously, we found that kindling dramatically increases the rate of neurogenesis at early stages of seizure development, followed by a long-term suppression at later stages. These changes in the rate of cell proliferation coincides with aberrant modifications in the migration, excitability, and functional integration of these new neurons. It has been suggested that the long-term consequences of seizure-induced neurogenesis contributes to the development of cognitive impairment seen in chronic epilepsy. However, direct experimental evidence has been limited. To explore this question, we inhibited neurogenesis by administering the DNA-alkylating agent temozolomide (TMZ) in rats that

underwent long-term amygdala kindling. Kindled rats began treatment with TMZ (25 mg/kg, i.p.) after their 30th stimulation—a time point that corresponds with increased neurogenesis—and kindling proceed until 99 stimulations were delivered. We found that TMZ reversed seizure-induced deficits in contextual fear learning and context discrimination. In addition, we found that TMZ did not adversely impact exploratory behaviour, anxiety, and contextual discrimination learning in non-epileptic rats. Our findings suggest that suppressing neurogenesis improves memory impairments seen after kindling, and helps to further establish that targeting aberrant neurogenesis can serve as a novel approach for reducing cognitive deficits associated with epilepsy.

Title: Diving responses elicited by nasopharyngeal irrigation compared to seizure-associated central apneic episodes in a rat model

Authors: *M. G. STEWART[1], S. MOONEY[1], B. CHIN[1], S. VILLIERE[1], S. KIM[1], R. KOLLMAR[2], K. SUNDARAM[3], J. B. SILVERMAN[4]
[1]Physiol. & Pharmacol., [2]Cell Biol., [3]Otolaryngology, SUNY Downstate Med. Ctr., Brooklyn, NY; [4]Otolaryngology, Northwell Hlth. LIJ Med. Ctr., New Hyde Park, NY

Abstract: Epileptic seizures spreading to respiratory and autonomic regions in the brainstem of rats can elicit episodes of obstructive apnea or central apnea. These episodes can be associated with significant oxygen desaturation (Nakase et al., Epilepsy Res. 128: 126-139, 2016). Obstructive apnea in these animals is due to intense adduction of laryngeal muscles as a result of seizure spread to the recurrent laryngeal nerve, a branch of the vagus nerve that controls both abduction and adduction of the vocal folds, and is lethal (ibidem). Central apneic events in the same animals, in contrast, are typically brief (1-30 seconds) and transient. Central apneic events are concomitant with (1) respiratory rhythm reset and (2) suppression of breathing behavior, which, we argued, was due to seizure spread into brainstem regions to activate the efferent limb of the diving reflex (Villiere et al., Neurobiol. Dis. 101: 8-15, 2017). In this study, we sought to explore the similarities of seizure-induced central apneic episodes to apneic episodes occurring as part of the diving reflex. We induced the diving response in urethane-anesthetized animals with or without kainic acid-induced seizure activity to (1) demonstrate diving-reflex properties in our rat model and (2) form a basis for comparison with spontaneous seizure-induced central

apneic events. Nasopharyngeal irrigation with cold water or mist elicited the typical diving response with apnea and significant bradycardia. When evoked during ongoing seizure activity, bradycardia was associated with decreased seizure activity. Repeated irrigations led to a dissociation of the apneic episodes (which always occurred) from the bradycardia (which became less pronounced with repetition). This dissociation of apnea from the cardiovascular components of the diving response supports the idea that seizure-associated central apnea and the diving response share a common neural basis. Further, the coupling or uncoupling of respiratory and cardiovascular elements of the diving response is dependent on the physiological state of the animal (e.g. levels of autonomic tone at baseline or set by ongoing seizure activity, recent history of similar episodes, etc.) at the onset of the diving response or a seizure-associated central apneic episode.

Title: Calbindin immunoreactivity may be related to cognitive dysfunction in the epileptic brain

Authors: *L. E. KALYNCHUK[1], N. NOGOVITSYN[2], J. J. BOTTERILL[3], H. CARUNCHO[1]
[1]Univ. of Victoria, Victoria, BC, Canada; [2]Dept. of Psychiatry, Univ. of Calgary, Calgary, AB, Canada; [3]Ctr. for Dementia Res., The Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY

Abstract: Although temporal lobe epilepsy is primarily characterized by recurring seizure activity, it can also include profound interictal behavioral and cognitive comorbidities, such as anxiety, depression, and cognitive impairments. The neural mechanisms that contribute to these behavioral comorbidities are largely unknown. Interestingly, recent studies have suggested that alterations in expression of the calcium-binding protein calbindin within the dentate gyrus may be important for hippocampal plasticity and cognitive dysfunction. In this experiment, we used the kindling model of temporal lobe epilepsy to investigate the relationship between cognitive function and calbindin expression following repeated seizure activity. Kindling refers to the gradual development and intensification of elicited motor seizures resulting from electrical

stimulation of a discrete brain site. We kindled 25 male rats over a 6.5 week period, with a total of 99 stimulations delivered 3 times per day, 5 days per week. We delivered electric stimulations into two limbic brain regions — the basolateral amygdala and dorsal hippocampus-- and one non-limbic brain region - the caudate nucleus. Following kindling, rats were subjected to a trace fear conditioning paradigm to assess cognition. Rats were then sacrificed and their brains collected for immunohistochemical analyses of calbindin and Arc, which is an immediate early gene that signals neuronal activation. We found that kindling had no effect on the acquisition of hippocampal-dependent fear conditioning, but the amygdala- and hippocampal- kindled rats showed impaired retrieval of fear memories. This was accompanied by decreased Arc expression in both the subgranular zone/granule cell layer and hilus and reduced calbindin in the subgranular zone and granule cell layer. Our results provide the first demonstration of a relationship between kindling-induced cognitive deficits and reduced calbindin expression and suggest that novel therapeutics that normalize calbindin may be effective against the behavioral comorbidities associated with temporal lobe epilepsy.

Title: Brain-derived neurotrophic factor may contribute to ictogenesis in a mouse model of viral infection-induced temporal lobe epilepsy

Authors: *D. C. PATEL[1], E. G. THOMPSON[1], H. SONTHEIMER[2]
[1]Virginia Tech. Carilion Res. Inst., Roanoke, VA; [2]Sch. of Med. and Res. Inst., Virginia Tech. Sch. of Neurosci., Roanoke, VA

Abstract: Epilepsy resulting from CNS infection is often refractory to established anti-seizure drugs. C57BL/6J mice infected with Theiler's murine encephalomyelitis virus (TMEV) show acute behavioral seizures between 3-7 days post-infection (dpi), exhibit clinically relevant pathological and physiological changes in the hippocampus, survive the infection and later develop chronic epilepsy after approximately two months of infection. Therefore, this is an appropriate model to study mechanism(s) underlying epileptogenesis for infection-induced limbic epilepsy. Numerous studies have implicated brain-derived neurotrophic factor (BDNF)

signaling in the development of epilepsy. BDNF is released from neurons in an activity-dependent manner, but reactive glia, which are prevalent in the TMEV-infected mice, can also contribute to its synthesis and release. In addition to its effects on the expression and cellular trafficking of excitatory and inhibitory receptors, BDNF may cause hyperexcitation by impairing chloride homeostasis and GABAergic inhibition by downregulating K^+-Cl^- cotransporter (KCC2). Therefore, we hypothesized that increased BDNF signaling impairs GABAergic inhibition via cation chloride cotransporters that may underlie network hyperexcitability and seizures following viral infection. Mice were injected with either TMEV or PBS (sham) and monitored for acute seizures. In one group of mice, the hippocampi were dissected at 1, 3, 5, 14 and 60 dpi (n=5-6) and the protein expression of BDNF was quantified by ELISA and that of KCC2, phosphorylated KCC2 and NKCC1 by gel electrophoresis and western blot. In a second group of mice, the membrane expression of KCC2 was measured with a cell surface biotinylation assay in acute hippocampal slices (n=5-6) at 5 dpi. The BDNF level in the hippocampus from TMEV-infected mice with seizures was increased at the onset of acute seizures compared to the sham group. BDNF continued to increase during the peak acute seizure, latent and chronic phases of epilepsy and more than doubled at 60 dpi. We found no change in the expression of NKCC1, whereas the expression of KCC2 and phosphorylated KCC2, as well as the surface level of KCC2, were significantly decreased at 5 dpi in the hippocampi from TMEV-infected mice. Therefore the ratio of NKCC1 to KCC2 was reduced, which may favor accumulation of chloride intracellularly and may contribute to hyperexcitability by reversing GABA-mediated inhibition. Further investigation will seek to probe the causal relationship between BDNF signaling and epileptogenesis following viral infection.

Title: Epistatic interaction between Stxbp1 and Snap25 genes produces super-additive effects on synaptic transmission and epileptic seizures

Authors: *J. KOVACEVIC[1], K. D. B. WIERDA[2], J. B. SORENSEN[3], M. VERHAGE[1,4]
[1]Vrije Univ. Amsterdam, Amsterdam, Netherlands; [2]VIB-KU Leuven Ctr. for Brain & Dis. Res., Leuven, Belgium; [3]Univ. of Copenhagen, Copenhagen, Denmark; [4]Dept. of Clin. Genet., CNCR, Vrije Univ., Amsterdam, Netherlands

Abstract: De novo, heterozygous mutations in *STXBP1/Munc18* and *SNAP25* genes cause largely overlapping symptoms: neurodevelopmental delay, intellectual disability and epilepsy. Because these two genes work together in neurosecretion, the pathogenic mechanisms for mutations may also be similar. We tested this hypothesis at the synaptic, system and behavioral level using single and double heterozygous *Stxbp1*$^{+/-}$ and *Snap25*$^{+/-}$ mice. Epistatic interactions were observed at the synaptic and system level, but not behavioral level: Patch clamp recordings of synaptic transmission in single neuron micro dot cultures revealed 70% reduced evoked and 80% reduced spontaneous excitatory synaptic transmission in *Stxbp1*$^{+/-}$*Snap25*$^{+/-}$ neurons, while synaptic transmission was (virtually) normal in single *Stxbp1*$^{+/-}$ and *Snap25*$^{+/-}$ neurons. *Stxbp1*$^{+/-}$ *Snap25*$^{+/-}$ mice showed a variety of behaviorally- and EEG- detected seizures, including clonic seizures and generalized epileptic attacks, that were not observed in *Stxbp1*$^{+/-}$and *Snap25*$^{+/-}$ mice. Excessive cortical cFos activity was detected in *Stxbp1*$^{+/-}$*Snap25*$^{+/-}$ mice and it was higher than previously detected cFos activity in *Stxbp1*$^{+/-}$ mice. At the behavioral level, *Stxbp1*$^{+/-}$*Snap25*$^{+/-}$ mice mimic phenotypes of single *Stxbp1*$^{+/-}$ mice. Double heterozygous mice showed impairment in several cognitive domains: impaired contextual and cued learning in fear conditioning and impaired behavioral flexibility. Additionally, *Stxbp1*$^{+/-}$*Snap25*$^{+/-}$ mice showed lower spontaneous activity during the light phase in the home cage and anxiety-related behavior in the elevated plus maze test. All these behavioral phenotypes were similar to single *Stxbp1*$^{+/-}$ mice and were not observed in single *Snap25*$^{+/-}$ mice. Taken together, these results provide clear evidence for epistatic interactions between *Stxbp1* and *Snap25* genes, at least at the synaptic and systems level, suggesting that the pathogenic mechanisms for patients carrying mutations in these genes have shared, but also unique features. This presynaptic gene set, not only *Stxbp1* and *Snap25* but also *Stx1b* and *Syt1*, may be considered together for future treatment design.

Title: Focal motor seizure model in mouse

Authors: *T. SINGH, A. BRODOVSKAYA, J. M. WILLIAMSON, J. KAPUR
Dept. of Neurol., Univ. of Virginia, Charlottesville, VA

Abstract: Focal motor can cause injury and secondarily generalized tonic clonic seizures are associated with sudden unexpected death in epilepsy (SUDEP). However circuits underlying these seizure have not been delineated. In order to get insight into neuronal circuits and plasticity underlying focal motor seizures, we translated cobalt model of focal motor seizures from rats to mice. We implanted cobalt wire in supplementary motor (M2) area of the right prefrontal cortex (AP, 2.6 mm; ML, 1.8 mm) of mice. Four doses were administered 0.44 mg, 0.66 mg, 0.88 mg, and 1.75 mg. Animals were monitored by video and EEG, 30 min after the surgery continuously for 7 days. Seizure frequency, latency to first and last seizure, and total number were characterized. After 7 days, animals were sacrificed, and brains were sectioned and processed for nissl staining to evaluate the lesion size. Also, to understand layer specific activation of neurons in the cortex due to cobalt induced seizures two kinds of transgenic mice were used. Transgenic mice that express EGFP under the control of tetracycline repressor and early immediate gene, cfos (Mayford) were maintained on high doxycycline diet until 24 hours prior cobalt implantation. We also used TRAP (targeted recombination in activated population of neurons) mice. Immunohistochemistry was performed on the brain sections with different cortical layer-specific antibodies (Brn2, Tbr1, and Ctip2) in transgenic mice after peak occurrence of seizures. All doses triggered motor seizures, which were first observed within 8 to 12 h; the peak seizure frequency was at 24 h (0.44 mg, n=8), 28 h (0.66 mg, n=13), 36 h (0.88 mg, n=12), and 24h (1.75 mg, n=12). Seizures dissipated by 72 h in all animals. Total seizures increased as a function of Cobalt dose. Mean seizure ranged from 3.9±0.29 (0.44 mg, n=8) to 13.91±2.22 for four doses. Histological examination also depicted increased lesion size with increased cobalt dose. Initial studies of transgenic mice indicate activation of principally layers II/III and also of V/VI in the motor and somatosensory cortices. Further studies to map the seizure propagation employing combination of imaging and electrophysiology to elucidate the cortical seizure spread pathway are in progress.

Title: Pharmacological augmentation of on-demand 2-arachidonoylglycerol (2-AG) signaling in the brain modulates epileptic seizures in rodents

Authors: *A. VIADER, J. L. BLANKMAN, A. R. COPPOLA, R. A. HERBST, A. KNIZE, J. S. WARBURG, C. GRICE, G. O'NEIL, A. EZEKOWITZ, J. R. CLAPPER
Abide Therapeut., San Diego, CA

Abstract: Epilepsy is a common, debilitating neurological disease, comprising a spectrum of syndromes with diverse etiologies, and often categorized as acquired forms of epilepsy (e.g. temporal lobe epilepsy), those with genetic origin (e.g. Dravet syndrome), and status epilepticus. Despite etiological diversity, epilepsy is unified by the spontaneous occurrence of seizures caused by excessive and hypersynchronous neuronal activity in the brain. The endocannabinoid system (ECS) is now recognized as a ubiquitous, retrograde lipid signaling system, central to activity-dependent synaptic modulation and able to prevent excessive network excitability. 2-arachidonoylglycerol (2-AG), a principal ligand for the ECS, is produced and released from postsynaptic neurons in an activity-dependent manner to act retrogradely on presynaptic cannabinoid receptors (CBRs) and dampen aberrant neurotransmitter release. As such, modulators of the ECS and of 2-AG represent promising novel antiepileptic therapies. 2-AG signaling is tightly regulated by this lipid's principal biosynthetic and degradative enzymes in the nervous system, diacylglycerol lipase-α (DAGLα) and monoacylglycerol lipase (MGLL), respectively. In the present study we leverage recently-developed pharmacological inhibitors of DAGLα and MGLL to examine whether modulation of 2-AG signaling can regulate seizure activity in preclinical rodent models of epilepsy. We found that PTZ-induced seizures were exacerbated in mice with depleted brain 2-AG levels through pharmacological inhibition of DAGLα. Remarkably, the observed seizures were more severe following DAGLα inhibition than CB1 inverse agonism, emphasizing the importance of on-demand 2-AG production in suppressing abnormal brain network activity. Conversely, enhancement of 2-AG signaling through inhibition of MGLL, significantly decreased the occurrence of PTZ-induced seizures in rats. Together, these results highlight a critical role for 2-AG as a natural brake to excessive neuronal excitability and support the potential use of MGLL inhibitors for the treatment of epilepsy syndromes.

Title: Effects of the type 1 cannabinoid receptor positive allosteric modulator GAT211 on absence seizures and the anxiety-like phenotype of Genetic Absence Epilepsy Rats from Strasbourg

Authors: *A. J. ROEBUCK[1], M. ALAVERDASHVILI[1], Q. GREBA[1], M. ANDERSON[1], W. N. MARKS[2], S. M. CAIN[3], T. P. SNUTCH[4], S. GURAI[5], G. A. THAKUR[5], R. B. LAPRAIRIE[1], J. G. HOWLAND[6]

Sci., Northeastern Univ., Boston, MA; [6]Physiol., Univ. Saskatchewan, Saskatoon, SK, Canada

Abstract: Absence epilepsy is characterized by recurring seizures that lead to brief lapses of awareness and a variety of comorbid complications. The most widely accepted treatments for absence epilepsy are ethosuximide, which can produce drowsiness and confusion; and valproic acid, which displays hepatotoxicity. The type 1 cannabinoid receptor (CB1R) is considered a potential therapeutic target for many forms of epilepsy, including absence seizures. In a series of experiments, we tested the effects of the CB1R positive allosteric modulator (PAM) GAT211 (10 mg/kg; i.p.) for its potential to reduce absence seizures and behavioural comorbidities in the

Genetic Absence Epilepsy Rats from Strasbourg (GAERS). Using a within-subjects design adult males (n = 3) were implanted with recording electrodes in sensorimotor cortex and hippocampus and treated with both GAT211 and a vehicle treatment. In the hour following GAT211, the number of cortical-recorded seizures decreased from an average of 65 seizures per hour to an average of 45 seizures per hour. Spike frequency was also decreased from an average of 7.5 Hz to an average of 6.5 Hz after GAT211. In the second experiment, male and female GAERS and non-epileptic controls (NECs; total n = 76) were treated with either vehicle or GAT211 in a between-subjects design using an acoustic startle task. Both sexes of GAERS demonstrated a significantly higher startle response than NECs. Treatment with GAT211 reduced the startle response in female GAERS and NECs. Results from these experiments suggest that GAT211 may be effective in reducing seizure severity and may also reduce the anxiety-like phenotype previously identified in GAERS and NEC animals. However, potential interactions between strain and sex must be further investigated. In conclusion, these results suggest that CB1R PAMs may be a therapeutically effective target for ameliorating absence seizures, as well as their comorbidities such as anxiety.

Title: Anticonvulsant effect of cannabidiol in female rats during two phases of estrous cycle on a PTZ-induced convulsive seizure model

Authors: *N. L. JANISSET[1], B. M. LONGO[2]
[2]Physiol., [1]Univ. Federal de Sao Paulo, Sao Paulo, Brazil

Abstract: Cannabidiol (CBD) is one of the major cannabinoids present in *Cannabis sativa* with great therapeutic potential. According to evidence from preclinical and clinical studies, CBD was shown to have anticonvulsive effect and has recently been proposed for the treatment of epileptic seizures. Approximately 70% of women with epilepsy face additional challenges on seizures exacerbation due to hormonal changes that occur during the menstrual cycle. Given the impact of hormonal influences on seizure activity and potential complications of treatments, the goal of the present study was to investigate the anticonvulsive effect of CBD in seizures induced by PTZ in two phases of the estrous cycle of female rats. Rats in the estrus (E) and diestrus (D) phases were treated with vehicle (CTRL) or CBD (50mg/kg). One hour after CBD treatment, acute

generalized seizures were induced by administration of PTZ (100mg/kg), and the following parameters were recorded: mortality, latency, duration and frequency of seizures. After 24h, half of animals from each group were perfused and their brains processed by immunohistochemistry for the microglial marker Iba-1. In the other half of animals, blood was collected for the analysis of the pro-inflammatory interleukin *IL-1β levels*. CTRL animals from estrus and diestrus groups presented a 12.5% and 50% of mortality rate, respectively, whereas there was no mortality in groups treated with CBD. Microglial quantification was reduced in the hippocampus (P= 0.05), and *IL-1β blood levels* decreased in CBD-E group when compared with CTRL-E group (P= 0.05). Our preliminary data suggest that CBD has an anticonvulsive effect in catamenial epilepsy, reducing the inflammatory response that occurs after an acute seizure. The present results indicate that, this protective effect is influenced by hormonal variations, showing prominent effect during the estrus phase. Our study may help to clarify some issues related to the therapeutic potential of CBD in catamenial epilepsy and may contribute to the development of new therapies in the future.

Title: Seizures frequency modifies cardiovascular responses *ex vivo* and cardiac tissue in rats submitted to electric amygdala kindling model of epilepsy

Authors: *A. P. PANSANI[1], P. P. GHAZALE[3,1], E. G. DOS SANTOS[1], K. S. BORGES[1], K. P. GOMES[1], C. Q. DE LIMA, Jr.[1], P. P. P. BRAGA[1], B. P. DE SOUZA[1], C. H. DE CASTRO[1], C. H. X. Abstract: Cardiovascular alterations have been identified as the main cause of sudden unexpected death in epilepsy. We aimed to evaluate the impact of the number of seizures on heart function and morphology and on aortic vascular reactivity in rats submitted to the electrical amygdala kindling model. Male Wistar rats were fitted with electrodes on the right amygdala for stimulation and two surface electrodes for recording cortical EEG. The amygdala was stimulated

electrically once a day, and seizure evolution was classified according to Racine's scale (R1-R5). Kindled rats were submitted to 5 seizures R5 (Low Seizure - LS) or to 10 seizures R5 (High Seizure - HS). At the end of this protocol, rats were decapitated, and heart and aortic rings were dissected. The heart was submitted to Langendorff technique and challenged by ischemia/reperfusion protocol. Vascular reactivity of aortic ring (with and without endothelium) was assessed by organ bath technique. After *ex vivo* analysis, the heart was fixed and histologically processed. Cardiomyocyte size, interstitial fibrosis, perivascular fibrosis, and ventricular mass index were evaluated. Compared to sham group (rats with implanted electrodes without stimulation), LS group presented decreased basal values of the following parameters: intraventricular systolic pressure, positive and negative dP/dt. During ischemia, all groups had a reduction on developed intraventricular pressure and positive and negative dP/dt, but with less magnitude in LS group. During reperfusion, only LS group did not recover its basal parameters. There were no alterations among groups in both intrinsic heart rate and ventricular fibrillation after reperfusion. The aortic ring with endothelium had higher contraction induced by phenylephrine (PHE) in LS group than in both SHAM and HS group. The PHE-induced contraction curve of aortic rings without endothelium was shifted to the left in HS group. Concerning morphological analysis, LS group had larger cardiomyocyte size and percentage of interstitial fibrosis than both sham and the HS groups. The perivascular fibrosis was also higher in LS group than in HS group, which in turn has a smaller fibrotic area compared to the sham group. No alterations were observed on the ventricular mass index. So, rats with low seizures frequency had worst ventricular function and cardiac tissue alterations than those with high seizures frequency. Epileptic rats had greater aortic contraction reactivity, regardless of the number of seizure. Therefore, seizure frequency interferes with cardiovascular parameters.

Title: Validity of post traumatic epilepsy outcome following lateral fluid percussion injury

Authors: *S. M. TATUM[1], Z. Z. SMITH[2], A. BERNIER[2], D. POULSEN[3], D. BARTH[2]
[1]Univ. of Colorado-Boulder, Boulder, CO; [2]Univ. of Colorado, Boulder, CO; [3]Univ. at Buffalo, Buffalo, NY

Abstract: Post-traumatic epilepsy (PTE) is characterized by recurrent spontaneous nonconvulsive or convulsive seizures, typically emerging after a "latent period" of months to years following injury. Presumed epileptogenesis during the latent period may provide a therapeutic window for intervention. Yet, the successful exploration of potential anti-epileptogenesis compounds and intervention strategies relies directly on valid animal models of PTE. For the past 10 years, a leading rat model of PTE has used lateral fluid percussion injury (LFPI) to simulate closed head injury. This model has been reported to result in frequent and brief (seconds) bouts of spike-wave discharges (SWDs) that are claimed to reflect spontaneous complex partial non-convulsive seizures (CPSs) within weeks of injury. Yet, except for the distinction of focal onset near the injury site, the SWDs characterizing CPSs are indistinguishable from absence-like (genetic) seizures recordable in both injured and control rats. We hypothesized that if post-injury, focal-onset CPSs are in fact distinct from absence-like seizures, they should be resistant to the established anti-absence medication, ethosuximide, which is ineffective in treating human CPSs. We performed chronic video/EEG recording in rats with severe LFPI for 6 months post-injury. A subset of rats displayed SWDs of focal onset ipsilateral and not contralateral to injury. These were intermixed with bilaterally synchronous SWDs typically characterizing absence-like seizures in the rat model. Ethosuximide transiently (4-6 hr) but completely suppressed all SWDs (focal or bilaterally synchronous). Conversely, carbamazepine, used to effectively treat CPSs in humans, had no effect on either focal or bilaterally synchronous SWDs. These results suggest that SWDs, whether focal or generalized, do not present a viable outcome measure for exploration of the mechanisms or treatment of PTE in the rat LFPI model.

Paulista, Sao Jose do Rio Preto, Brazil; [6]Inst. do Cérebro - Hosp. Israelita Albert Einstein, Sao Paulo, Brazil

Abstract: Introduction: Temporal lobe epilepsy (TLE), the most common adult human pharmacoresistant epilepsy, involves limbic networks and is progressive. Systemic application of pilocarpine in rodents, a model of TLE, induces epilepsy with variable efficiency and mortality. The main goal of this study was to detect limbic seizures and their evolution after induction of status epilepticus (SE) by intra-amygdala application of pilocarpine in rats. **Methodology:** Following ARRIVE standards, pilocarpine (0.9mg/μL; 1μL) or sterile saline solution (0.9%; 1μL) were injected into the right amygdala of experimental (n=7) and control (n=6) groups of male Wistar rats, respectively. Anticonvulsant therapy was applied four hours after the SE-onset or the intra-amygdala injection of saline solution. Beginning at the time of the intracerebral injection, animals were individually monitored by a CCTV video system during the SE-day and along a period from the 30th to the 120th days. Rat's behavior was qualified in a blinded way using the Racine's scale. **Results:** Along the experiment, the behavior was normal in control rats while all experimental group rats displayed SE followed by spontaneous recurrent seizures (SRS). Limbic seizures corresponding to the SE, with a total duration of more than 120 min, were mainly generalized in three animals, partial in two animals and one rat showed generalized and partial seizures with similar duration. Additionally, one rat died during the SE. In the chronic period, all experimental rats displayed spontaneous recurrent seizures (SRS). However, frequency of seizures occurred with two profiles: 1) rats with frequent seizures (total number of seizures > 80) and 2) rats with few seizures (less than 80 seizures). The frequency of SRS was directly associated with severity of SE. Two months after SE, rats with frequent seizures showed higher proportion of partial than generalized seizures. This proportion was inverted by the fourth month. In contrast, rats with few seizures presented similar proportion of partial and generalized seizures throughout the analyzed period. **Conclusion:** Generalized limbic SE, induced by intra-amygdala application of pilocarpine, is associated to progressive limbic epilepsy. In contrast, partial SE seems to be followed by non-progressive and less severe epilepsy. Additionally, animal mortality associated to this experimental paradigm is low.

Title: Combination intramuscular allopregnanolone and perampanel in the treatment of acute diisopropylfluorophosphate (DFP)-induced status epilepticus in rats

Authors: *A. DHIR[1], D. J. TANCREDI[2], M. A. ROGAWSKI[1]
[1]Neurol., [2]Pediatrics, Univ. of California, Davis, Sacramento, CA

Abstract: Organophosphate (OP) nerve agent intoxication may cause lethal status epilepticus (SE) in animals and humans. These seizures are often refractory to first line, standard-of-care benzodiazepines, especially when therapy is delayed. In this study we assessed the combination of the neurosteroid allopregnanolone, a positive allosteric modulator of synaptic and extrasynaptic GABA-A receptors, and perampanel, an AMPA receptor antagonist, in the treatment of status epilepticus induced by the OP nerve agent surrogate DFP. AMPA receptors, the main mediators of excitatory glutamate neurotransmission, were considered a potential treatment target since excessive glutamate levels are believed to be a mechanism of toxicity in OP poisoning. The combination was studied as we previously found that AMPA receptor block alone does not terminate DFP seizures. To mimic a typical clinical treatment scenario, the combination treatment was administered following the benzodiazepine midazolam, which was administered at a time of benzodiazepine resistance. For comparison, we studied valproate, a marketed antiseizure agent available in a parenteral formulation, that could be used in the treatment of benzodiazepine-refractory OP intoxication. Status epilepticus was induced in male SD rats with DFP (4 mg/kg, SC). One minute later, animals were injected with atropine (2 mg/kg, IM) and pralidoxime chloride (25 mg/kg, IM) to avoid peripheral side effects. Forty min after DFP, animals received midazolam (1.8 mg/kg, IM) followed by either (a) allopregnanolone (6 mg/kg, IM) plus perampanel (2 mg/kg, IM) or (b) valproate (200 mg/kg, IP). High-amplitude epileptiform discharges occurred within a few minutes after DFP treatment that were resistant to midazolam. Treatment with the combination of allopregnanolone and perampanel resulted in rapid cessation of behavioral and electrographic status epilepticus. Valproate reduced the EEG power but did not eliminate spikes and electrographic seizures in the EEG. The results indicate that allopregnanolone/perampanel combination treatment is more effective than valproate in terminating benzodiazepine-refractory OP-induced SE.

Title: Effects of sleep deprivation on tonic GABAergic inhibition in the hippocampus

Authors: *E. WALLACE[1,2,3], R. MAGANTI[3], M. V. JONES[1]
[1]Neurosci., Univ. of Wisconsin - Madison, Madison, WI; [2]Cell. and Mol. Pathology Grad. Training Program, [3]Neurol., UW-Madison, Madison, WI

Abstract: Sleep is critical for effective homeostasis. Disturbances in sleep patterns can impact cognition and memory. For people with epilepsy, for whom problems with sleep are common, sleep deprivation is one of the most potent triggers for seizures. However, the mechanisms for these detrimental effects remain poorly understood. Having been implicated in memory as well as seizure generation in some epilepsies, and displaying specific sleep-related activity, the hippocampus may be involved in mediating numerous detrimental effects of sleep disruption. Pathologies in the hippocampal trisynaptic circuit are common in temporal lobe epilepsy. We hypothesized that brief disruptions in sleep may affect hippocampal neurotransmission, increasing excitability, which may heighten susceptibility for epileptiform activity in individuals with epilepsy.

Here, we evaluated the effect of 4-hour sleep deprivation (4SD) on GABAergic neurotransmission. Building on evidence that hippocampal mRNA expression of alpha-5 and delta subunits of $GABA_A$ receptors (that mediate tonic inhibition) decrease after acute sleep disruption, we used whole-cell voltage-clamp (-70 mV, room temp.) to investigate GABAergic currents in CA1 and DG of hippocampal slices prepared from sleep-deprived and control C57bl/6 mice (P37±4). Total sleep deprivation occurred ZT0-4 using novel object methods, ensuring continuous locomotion and exploration. Tonic current density was measured as the change in holding current upon application of 100 µM bicuculline methiodide, divided by membrane capacitance. Sleep deprivation significantly decreased tonic current density in both CA1 pyramidal cells (control: 0.25±0.02 pA/pF, n=14, 4SD: 0.13±0.03 pA/pF, n=11, $p<0.01$, unpaired t test) and DG granule cells (control: 0.44±0.08 pA/pF, 4SD 0.17± 0.03 pA/pF, $p<0.01$). In both cell types, we saw no significant alteration of miniature inhibitory postsynaptic current amplitude or frequency.

Sleep deprivation could therefore contribute to hyperexcitability and seizure susceptibility, in part, by reducing tonic inhibition. Future experiments will aim to determine the underlying mechanisms by evaluating changes in GABA receptor expression and function, as well as regulation of ambient GABA concentration, after acute sleep deprivation.

Title: Abnormal hypersynchrony of neuronal activity and its relation to neuroinflamation, number and location of cysts in rats with neurocysticercosis

Authors: *A. D. DELGADO[1], R. P. CARMEN[2], R. H. GILMAN[3], F. ANCAJIMA[2], L. E. BAQUEDANO[2], R. H. CELIZ[2], D. G. DAVILA[2], M. R. VERASTEGUI[2]

Abstract: Neurocysticercosis (NCC) is caused by the larva of the taenia solium located in the central nervous system (CNS). In endemic countries as Peru, it is the main cause of late epilepsy. Our group has developed a rat model to study the electrophysiology of the waveforms of seizures in neurocysticercosis. In preliminary studies we have observed that our model allows the development of viable cysticerci in the brain, and the presence of generalized tonic clonic seizures, which allows us to have a model similar than humans. Our objective is to relate changes in the electroencephalogram recording with neuroinflammation, number and location of cysts in rats with neurocysticercosis. Male Holtzman rats received intracranial infection with activated T. solium oncospheres between 12-15 days of birth, after 3 months of infection MRI T2 were performed in order to detect the presence of the cysticercus in the rat brain. Selected Infected rats (n=14) and not infected rats (n=8), were continuously recorded by telemetric electroencephalography (tEEG) to monitor the brain activity and detect seizures for five weeks. Abnormal hypersynchrony of neuronal activity was observed in the tEEG recording associated with generalized tonic clonic seizures in 15% (n = 2), with an average duration of 120 seconds per seizure. These rats had the highest number of parenchymal cysts in the group of infected rats, immunohistochemistry studisn were performed to observe neuroinflammation.

Title: Carbamazepine and lamotrigine revert cardiovascular alterations in rats submitted to the pilocarpine model of epilepsy

Authors: *D. B. COLUGNATI[1], B. P. DE SOUZA[1], K. P. GOMES[1], P. P. P. BRAGA[1], C. Q. DE LIMA, Jr[1], F. C. A. DOS SANTOS[1], M. F. BIANCARDI[1], P. P. GHAZALE[1,2], E. P. MENDES[1], C. H. DE CASTRO[1], F. A. SCORZA[2], A. P. PANSANI[1]
[1]Physiological Sci., Univ. Federal De Goiás, Goiânia, Brazil; [2]Univ. Federal de São Paulo, São Paulo, Brazil

Abstract: Sudden Unexpected Death in Epilepsy (SUDEP) is responsible for approximately 15% of all deaths in individuals with epilepsy and 50% in refractory epilepsy, presenting an incidence among young epileptic population between 1:500 and 1:1000 patient-years. In fact, cardiovascular alterations have been often demonstrated in association with epilepsy. Therefore, it is believed that cardiovascular alterations may be one of the main causes for SUDEP. Regarding risk factors for SUDEP the antiepileptic drugs (AEDs) has been extensively evaluated. With respect to specific AEDs, sodium channel-blocking drugs such as carbamazepine (CBZ) and lamotrigine (LTG) may be related with heart rhythm alterations. So, we sought to evaluate cardiovascular parameters in epileptic rats treated with CBZ or LTG. The epilepsy was induced by pilocarpine model in male Wistar rats. After the first spontaneous recurrent seizure, the rats were treated with CBZ (150mg/day) or LTG (150mg/day) or vehicle for 60 days. Than, systolic blood pressure (SBP); Diastolic blood pressure (DBP); Mean arterial pressure (MAP) and heart rate (HR) were recorded. We also performed a baroreflex test with *bolus* administration of phenylephrine (PHE - 5μg) and sodium nitroprusside (NPS - 10μg) via cannulation of femoral vein. After *in vivo* protocols the animals were euthanized and the heart were prepared for histological analyzes. The epileptic rats treated with vehicle (EP) had higher HR, SBP, DBP and MAP when compared to control rats (CNT) and epileptic rats treated with CBZ (EP-CBZ). Also, the treatment with LTG reduced resting HR. No differences were observed regarding the baroreflex. Furthermore, we observed that the EP rats had a greater cross-sectional area of cardiomyocytes when compared to the other groups and an increased deposition of perivascular collagen compared to both CNT and EP-CBZ groups. It is important to note that neither CBZ nor LTG reduced the seizure frequency compared to EP. However, both CBZ and

LTG had a beneficial effect on cardiovascular parameters and cardiac remodeling of rats with epilepsy. So, CBZ and LTG at doses studied were cardioprotective, with no modification of seizure frequency.

Title: Hippocampal oxygen levels during the development and expression of epilepsy in two status epilepticus models: Intrahippocampal kainate and perforant path electrical stimulation

Authors: *M. D. WOLFF[1], M. H. SCANTLEBURY[2], G. C. TESKEY[3]
[2]Dept. of Pediatrics, [3]Cell Biol. & Anat., [1]Univ. of Calgary, Calgary, AB, Canada

Abstract: We determined that following the cessation of brief focal seizures, a long-lasting severe hypoperfusion/hypoxic event occurs in the brain regions involved in the seizure. We reasoned that there might also be changes in local oxygen levels during and following focal status epilepticus (SE). Current animal models of epilepsy employ the use of either the infusion of a chemoconvulsant or electrical stimulation to induce an epileptic state in rodents. We aimed to compare both models with the goal to prevent generalized SE, limit lethality, and ultimately produce self-generating seizures. We hypothesized that; 1) during SE there will be drastic changes in hippocampal oxygen levels and 2) following the termination of SE spontaneous hippocampal seizures will produce episodes of postictal hypoxia.
A dose of urethane was administered to induce sedation before the induction of SE to sequester electrical activity and prevent generalized SE. In the intrahippocampal kainic acid model, kainic acid was infused directly into the rat ventral hippocampus. In the electrical stimulation model, a 24-hour stimulation protocol of the performant path was used. In both groups oxygen levels and EEG were recorded in dorsal hippocampus throughout the first 24 hours. Immediately after the 24-hour induction period, rats were transferred to a 24/7 video-EEG monitoring unit. Hippocampal EEG was monitored continuously for 4-6 weeks. We have found that prolonged stimulation of the performant pathway results in a long-lasting severe hyperoxia in the hippocampus during the 24-hour stimulation period. Animals infused with kainic acid on the other hand experience mild hyperoxia during bouts of seizure activity that lasts for approximately 2-4 hours. Following epilepsy induction, both groups experience immediate epileptiform activity during the first week, which eventually matures into self-generating

seizures. We have also found that these self-generating seizures are followed by severe postictal hypoxia. This study advances our current understanding of epilepsy models in relation to local oxygen levels. These discoveries may lead to the development of new treatments or preventative strategies for people with epilepsy.

Title: A noninvasive screening method for seizures and related behaviors in small animal models

Authors: A. AJWAD[1], H. WANG[1], F. YAGHOUBY[1], D. M. HUFFMAN[1], *B. F. O'HARA[2], S. SUNDERAM[1]
[1]Dept. of Biomed. Engin., [2]Univ. of Kentucky, Lexington, KY

Abstract: Animal models of epilepsy and other seizure disorders require careful monitoring to characterize phenomena and assess the effect of experimental therapies. Some contributing factors are: latency to development of spontaneously recurring seizures (in models of acquired epilepsy); types of seizures & the spectrum of behaviors associated with them; the difficulty in distinguishing seizures from baseline behavior; and the sporadic & unpredictable nature of seizure recurrence. Invasive EEG is often required to detect & verify seizures, with associated costs and need for skilled personnel. Visual observation or retrospective video analysis is labor-intensive and potentially inaccurate. Thus, convenient noninvasive automated methods of seizure analysis are needed to remove some of these limitations. In prior work, we demonstrated how a piezoelectric motion sensor (Signal Solutions LLC) placed on the cage floor can be used to discriminate sleep-wake states. In the present study, we examine the use of this sensor for noninvasive seizure detection in rodent disease models. C57BL/6 mice were injected with pilocarpine i.p. to induce acute seizures. Seizures subsided in 1-2 hrs and after a latent period of weeks led to spontaneously recurring seizures, a sign of chronic epilepsy. Animals were surgically instrumented for EEG recording & monitored for 4-5 weeks. Overt seizures (grade 4-5 on the Racine scale) were detected from EEG and used as test data to assess feasibility of noninvasive seizure detection from the piezo signal. 160 seizures were identified in 5 mice. A

simple algorithm based on comparison of instantaneous line length in a moving window of the piezo signal with a threshold, after adaptive correction for changes in baseline state, was used for seizure detection. The performance of the algorithm was evaluated against previously accumulated seizure data using conventional metrics of sensitivity & precision. Analysis of the data using a 5-fold cross-validation scheme showed that the piezo seizure detection algorithm had a sensitivity of 88% and precision of 29% on average. This implies that only 1 in 10 seizures are likely to be missed while about 1 in 3 are likely to be true events. The performance in this preliminary study gives confidence that the piezo sensor method will enable significant savings in time and effort with only a moderate proportion of candidate events that may need to be reviewed retrospectively on video. Our ongoing studies are focused on expanding the range of events to include more subtle seizures in both mouse & rat models and finer characterization of seizure-related motion and respiratory distress, which is also enabled by the piezo sensor.

Title: Effect of the gut microbiome on seizure susceptibility in murine models of epilepsy

Authors: *A. F. BOUSLOG[1], L. CHAUNSALI[2], H. SONTHEIMER[3], S. CAMPBELL[4]
[1]Translational Biology, Medicine, and Hlth., [2]Virginia Tech., Roanoke, VA; [4]Animal Poultry Sci., [3]Virginia Tech., Blacksburg, VA

Abstract: Epilepsy is a devastating neurological disorder that currently affects over 3 million Americans. Although multiple anti-epileptic drugs (AEDs) with diverse mechanisms of action are available, over 30% of patients suffering from epilepsy experience seizures that do not respond to AED treatment. Ketogenic diets are administered as alternatives to AEDs for seizure management in patients with drug-resistant epilepsy, but the anti-epileptic mechanism of action of ketogenic diets remains to be elucidated. Over the past decade, an increasing body of evidence has grown to support the idea that the trillions of bacteria residing in the gut, termed the gut microbiome, have widespread effects on neural functions. Given that ketogenic diets lead to marked changes in the composition of the gut microbiome, we hypothesize that alterations in the

gut microbiome can affect seizure susceptibility. To address this hypothesis, we altered the microbiomes of several murine models of epilepsy with a cocktail of antibiotics chronically administered through drinking water. The electrophysiological properties of neurons from microbiome-altered and un-altered mice will be evaluated. Additionally, continuous recordings of electroencephalography (EEG) activity in microbiome-altered mice and un-altered mice will be evaluated to determine whether alteration of the microbiome affects seizure activity. Elucidating specific changes in gut microbes that alters seizure susceptibility in epilepsy models could lead to potential therapies for patients with epilepsy that do not respond to currently available treatments.

Title: A comprehensive investigation of human hippocampal mossy fiber transmission and plasticity

Authors: K. A. PELKEY, D. CALVIGIONI, R. CHITTAJALLU, K. A. ZAGHLOUL, *C. J. MCBAIN
Lab. Cell/Molec Neurosci, NIH, Bethesda, MD

Abstract: Computational models, based primarily on evidence from rodents, predict that synaptic connections between hippocampal dentate gyrus (DG) granule cells and CA3 pyramidal cells are essential for encoding contextual memories. In support of this, disruption of the mossy fiber (MF) pathway connecting DG and CA3 impairs spatial memory encoding while false memories can be generated by optogenetically driving MF transmission through memory engram-bearing granule cells of one context in a novel context. The ability of MF-CA3 synapses to support memory encoding is considered to relate to their somewhat peculiar specialized synaptic properties. Indeed a rich literature describes several unique structural/functional properties of MF-CA3 synapses including sparse innervation by large multi-release site presynaptic terminals supporting a remarkable frequency-dependent dynamic range of transmission onto the most proximal dendrites of CA3 pyramids, dramatic susceptibility to presynaptic modulation (particularly cAMP levels), rapid AMPAR dominated kinetics with minimal NMDAR-mediated contribution, “detonator” capabilities, and presynaptically expressed

NMDAR-independent long-term plasticity. Ultimately, the goal of examining synaptic function in experimental models to such exquisite detail is to gain insight into how a given circuit may function in the human brain. Thus, the translation and relevance of rodent MF findings to their role in human hippocampal function demands validation that human MF transmission displays similar unique properties. We comprehensively evaluated the basic synaptic properties of MF-CA3/4 pyramidal cell connections within the human hippocampus obtained from tissue resected for treatment of epilepsy. Remarkably, human MF-CA3/4 pyramidal cell transmission exhibits the same hallmark features described in the rodent including AMPAR dominated synapses with small contributions from NMDARs and KARs, large dynamic range with strong frequency-facilitation, NMDAR-independent presynaptically expressed long-term potentiation, strong cAMP sensitivity of presynaptic release engaged by group II mGluRs. While interpretation of our findings could be confounded by the diseased nature of the resected tissue the astonishing congruence of core features shared between rodent and human MF synapses argues that the basic properties of MF transmission reported in animal models (including studies in non-human primate) are also critical to human MF function. Further investigation will compare/contrast human MF transmission with other "model" hippocampal synapses such as Schaffer collateral-CA1 pyramidal cell synapses.

Title: Multiparametric screening of compound-induced seizure risk

Authors: *J. KANERVA[1], Y. CHEN[1], C. CARROMEU[2], O. GUICHERIT[2], J. MCDUFFIE[1]
[1]Janssen Res. & Develop., San Diego, CA; [2]Stemonix, San Diego, CA

Abstract: Approximately 30% of candidate drugs are attrited in Phase I clinical trials due to seizure liability. The assessment of compound seizurogenic activity is currently limited to functional measurements such as electroencephalography, observation of clinical signs and brain histopathology in animal models, which are often called into question due to limited translatable evidence of neurotoxicity. To address this issue, we have developed *in vivo* and *in vitro* approaches to screen compounds for seizure risk associated with perturbed glia-neuron interactions. First, we developed different kainate-, 4-aminopyridine-, pentylenetetrazole-, and undisclosed proprietary compound-induced rat seizure models to identify candidate genomic/proteomic biomarker panels for neuronal/astrocytespecific toxicities. Second, we

characterized two human induced pluripotent stem cell (hiPSC)derived neuronal models (microBrain® 2D and 3D), which are comprised of cortical neurons (GABAergic and glutamatergic) and astrocytes, exhibit sustained viability, and possess functionalities comparable to the human brain. Functionally, the microBrain® 2D platform shows spontaneous firing on lowthroughput microelectrode array (MEA), while the microBrain® 3D platform shows spontaneous synchronized calcium transient oscillations on highthroughput Fluorescent Imaging Plate Reader (FLIPR™). Third, we examined MEA and FLIPR™ responses from the two physiologicallyrelevant hiPSC models post-exposure to seizurogenic or non-seizurogenic compounds, as well as the *in vitro* context of use for astrocyte toxicity biomarkers that were first detected following recurrent seizures in rats. Elucidating the mechanistic role of astrocytes in compound-induced seizures in rat as well as the 2D/3D human microBrains® may help bridge the gap in species translatability. These data support the use of a novel, integrated, multiparametric *in vitro*/*in vivo* screening paradigm for de-risking compound seizurogenicity.

Title: Limbic seizures depress cortical activation via subcortical pathways

Authors: J. POK[1], L.-A. SIEU[1], L. FENG[1], C. MA[1], C. W. ZHAO[1], J. CARDIN[1], *H. BLUMENFELD[1,2,3]
[1]Dept. of Neurol., [2]Neurosciences, [3]Neurosurg., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Temporal lobe epilepsy is the most common type of focal seizure disorder and is usually accompanied by loss of consciousness in its complex partial form. Despite its prevalence however, the specific neural pathways by which this occurs are still poorly understood. Previous intracranial EEG studies have shown that focal limbic seizures depress cortical activity, as marked by deep sleep-like slow wave activity in cortex and reduced cholinergic arousal. In addition, electrostimulation of the lateral septum (LS), a subcortical region with connections to

the hippocampus, was found to induce slow waves in cortex and reduce choline release. Given this knowledge and understanding that the nucleus basalis (NB) has cholinergic outputs to cortex, we propose that partial limbic seizures arising from the hippocampus could potentially inhibit cholinergic neurotransmission from NB to cortex through subcortical pathways. First, we examined any potential functional pathways between the NB and LS to better understand how partial seizures arising from the hippocampus could result in cortical deactivation. To this end, we developed an optogenetic rat model to restore cholinergic arousal in NB neurons during electrically-induced hippocampal seizures. Our results showed that the delta wave oscillations (0.5-2 Hz) found in cortex during seizure were converted to fast waves following optogenetic stimulation of the cholinergic neurons, suggesting that cholinergic arousal from NB plays a role in cortical arousal. To confirm any neuronal connections between the two regions, we did neuroanatomical retrograde and anterograde tracing studies. Our histology showed evidence of direct connections between the aforementioned regions. Moreover, we observed connections from NB and LS to midline thalamic nuclei; specifically, the paratenial region of the thalamus. To better understand what role, if any, this region has in the circuit, we recorded multiunit activity (MUA) and local field potentials (LFP) during electrically induced hippocampal seizures. Our recordings showed that during seizure, multiunit activity in PT was suppressed. These findings suggest that a possible pathway by which cortical depression occurs may be that PT receives inhibitory inputs from LS, thereby decreasing excitatory output to NB, leading to decreased cholinergic arousal. More thematically, our findings show that partial seizures arising from the temporal lobe affect several subcortical networks to induce loss of consciousness, suggesting that further investigation into these networks may bring about novel therapeutic targets aimed at improving cortical arousal during and after seizures.

Title: Mouse model of electrically inducible focal seizures with impaired consciousness

Authors: *L.-A. SIEU[1], S. SINGLA[1], C. MCCAFFERTY[1], M. VALCARCE-ASPEGREN[1], A. NIKNAHAD[1], Q. PERRENOUD[2], J. CARDIN[2], H. BLUMENFELD[1,2,3]
[1]Neurol., [2]Neurosci., [3]Neurosurg., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Focal temporal lobe seizures impair cortical function and often result in a loss of consciousness. Clinical studies showed that temporal lobe seizure is accompanied by an increase in cortical slow-waves activity in intracranial EEG recordings and a decreased cerebral blood flow (CBF). These results are replicated in a previous anesthetized rat model where partial limbic seizures are induced electrically. Further work in this model revealed increased CBF in lateral septum (LS), and reduced cholinergic input to cortex from subcortical arousal systems during seizures. Electrostimulation of LS resulted in both cortical slow oscillations and a decrease of cholinergic neurotransmission as seen during seizures suggesting that limbic partial seizures cause impaired cortical function through depressed subcortical arousal, possibly via LS. While the rat model provides insight to potential networks responsible for impaired consciousness, it is limited by the poor availability of genetic tools and the impossibility to assess behavior due to its anesthetized state. Therefore, mechanisms underlying depressed subcortical arousal, e.g. inhibition or removal of excitation, have not been investigated. The genetic techniques available and the possibility to do awake head-fixed experiments makes a mouse model much more desirable. However, most mouse models of chronic temporal lobe epilepsy develop spontaneous seizures, which limit the use of optogenetics and calcium imaging techniques. Here, we present a model of electrically inducible focal seizures in awake, behaving mice. Partial seizures were unilaterally induced and recorded from the dorsal hippocampus with a 60 Hz 2 s bipolar stimulus, while local field potential signals (LFP) were recorded from lateral orbitofrontal cortex (LO). Focal seizures were 5-10s in length, were repeatable for several weeks (n=40 seizures, 7 animals) and were associated with increased slow wave activity in the frontal cortex as observed in patients and rats. To assess behavioral responses during seizures, water-restricted mice were trained to lick a spout in response to a sound (0-50kHz noise, 12ms) every 10-15s while head-fixed on a running wheel. Response to sound decreased during seizures with reduced number of licks (n=7 animals) with increased lick latency (n=7 animals). Interestingly, response to sound was often normal during seizures suggesting consciousness was not always impaired as seen in patients. Overall, this mouse model shares characteristics seen in both human and in rat while offering new possibilities to investigate the mechanisms underlying loss of consciousness.

Title: *In vitro* anticonvulsant activity of pterolobium stellatum extracts

Authors: *S. S. SALILE[1,2], H. J. LEE[2], J. V. RAIMONDO[2], T. A. ORJINO[1]
[1]Dept. of Pharmacol., Addis Ababa University, Sch. of Pharm., Addis Ababa, Ethiopia; [2]Div. of Cell Biology, Dept. of Human Biol., Neurosci. Inst. and Inst. of Infectious Dis. and Mol. Medicine, Fac. of Hlth. Sciences,University of Cape Town, Cape Town, South Africa

Abstract: Though there are conventional antiepileptic drugs in use ,one third of cases are refractory to treatment which underscores the need for new anticonvulsant agent. While four-fifths of the potential market for antiepileptic drugs is in the developing world, up to 90% of people with epilepsy in developing countries receive no treatment at all. In Ethiopia, many diseases are treated using traditional medicines. *Pterolobium stellatum* is often used to treat epilepsy. The whole plant juice is given orally for one month. The aim of this study is to investigate the anticonvulsant activity of *P. stellatum* extracts using the *in vitro* 0 Mg^{2+} model of seizures in mouse hippocampal brain slices.

Methods

Plant material was collected and extracted using standard methods. The crude hydroalcholic extracts of *P. stelatum*: petether, chloroform, butanol and water extracts with 0.7 mg/ml concentration were tested for anticonvulsant activity. Extracellular field potential recordings were performed in coronal hippocampal slices from P14-P21 of C57BL16 mice.The $0Mg^{2+}$model of seizures was utilized. Baseline recordings were made for 600s with normal artificial cerebrospinal fluid(aCSF) before $0Mg^{2+}$aCSF was washed in for 3000s in order to induce seizure-like activity. The 0 Mg^{2+} solution either contained plant extract or solvent as a control. The presence of seizure-like events was compared in treated versus untreated control. The Chi square test with $P<0.05$ was used to determine statistical difference between groups.

Results

The crude extract had a statistically significant anticonvulsant activity compared to control($P=0.0153$). The chloroform and water extracts were also shown to have significant anticonvulsant activity as compared to control ($P=0.0008$ and $P= 0.0001$ respectively). The petether and buthanol extract activity was not statistically significant compared to control ($P=0.4760$ and $P=0.4637$ respectively). A positive control using the known anticonvulsant diazepam(3µM), showed significant anticonvulsant activity ($P= 0.0118$).

Discussion and recommendations

Our results demonstrate that *P. stellatum* has anticonvulsant activity. Active compounds are likely in both the water fraction and the chloroform fraction of the extracts as these both demonstrated good anticonvulsant activity. Further chemical studies are required to isolate the active compounds from these fractions. The mechanism of action of the active compounds in terms of their targets will also require further elucidation. This work demonstrates the utility of harnessing Africa's indigenous knowledge and rich biodiversity to identify novel anticonvulsant therapies based on natural compounds.

Abstract: Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels and the I_h current they generate contribute to the pathophysiological mechanisms of absence seizures, but their precise role in neocortical and thalamic neuronal populations, the main components of the network underlying absence seizure generation remains controversial. In diverse genetic absence seizure models, I_h amplitude is smaller in neocortical neurons and either larger or unchanged in thalamocortical neurons compared to non-epileptic strains. A lower expression of neocortical

HCN subtype 1 channels is present in genetic absence seizure-prone rats and HCN2 Knock-Out mice exhibit absence seizures. Furthermore, whereas many studies have characterized I_h contribution to "absence-like" paroxysmal activity *in vitro*, no data is available on the specific role of cortical and thalamic HCN channels in behavioural seizures.
We have now performed experiments showing that the pharmacological block of HCN channels with the antagonist ZD7288 applied via reverse microdialysis in the ventrobasal thalamus of freely moving male Genetic Absence Epilepsy Rats from Strasbourg decreases TC neuron firing and abolishes spontaneous absence seizures. A similar effect is observed on γ-hydroxybutyric acid-elicited absence seizures in normal male Wistar rats. Moreover, thalamic knockdown of HCN channels via virally-delivered shRNA into the ventrobasal nucleus of male Stargazer mice, another genetic model of absences, decreases spontaneous absence seizures and I_h-dependent electrophysiological properties of ventrobasal nucleus thalamocortical neurons.
Overall, these findings provide the first evidence that the block of HCN channels of thalamocortical neurons prevents absence seizures. Moreover, they suggest that any potential anti-absence therapy that targets HCN channels should carefully consider the opposite role for cortical and thalamic I_h in the modulation of absence seizures.

Abstract: Absence seizures, the most common form of generalized seizure, are periods of apparent impaired consciousness accompanied by distinctive spike-and-wave discharges on the electroencephalogram (EEG). Syndromes for which these seizures constitute the primary symptom (include the archetypal Childhood Absence Epilepsy (CAE)) feature significantly decreased quality of life, with developmental and psychosocial impairments common. Furthermore, current first-line pharmacological treatments have approximately 50% efficacy and non-seizure symptoms may persist even after seizure suppression. To better understand the neuronal and network mechanisms of absence seizures, we investigated the cortical and thalamic mechanisms of seizure synchrony using ensemble extracellular unit recordings and delivery of T-type Ca2+ channel (T-channel) blockers by reverse micro dialysis in a freely behaving polygenic rat model of absence. In contrast to previously prevailing hypotheses of seizure generation, we found that somatosensory thalamocortical (TC) neurons rarely expressed T-channel dependent burst firing during seizures, and that the pharmacological antagonism of these T-channels prevented neither seizure expression nor synchronous thalamic output during seizure. Rather, we found that the firing times of TC neurons appeared to be determined by a combination of strong inhibition from reticular thalamic (NRT) neurons, which persisted through the majority of each spike-and-wave cycle, and rhythmic cortical excitation, which preferentially elicited tonic (rather than burst) TC firing. This cortical excitation, in fact, was also the primary driver of the NRT neurons, thus expressing a novel form of feed-forward inhibition of TC cells. Despite this strong inhibition, and the relative paucity of T-channel dependent bursts, somatosensory TC neurons still provided synchronous and reliable reciprocal excitation of the cortex at the population level, potentially contributing to seizure perpetuation.

Title: Audiogenic seizure modeling SUDEP (sudden and unexpected death in epilepsy): comparative study between four inbred strains of mice

Authors: *B. MARTIN[1], G. DIEUSET[1], N. COSTET[1,2]
[1]LTSI - INSERM U1099, Rennes, France; [2]Inserm, EHESP, Irset, UMR_S 1085, Rennes, France

Abstract: Sudden and Unexpected Death in Epileptic Patients (SUDEP) rate is about three times that of the general population. Several hypothesis are suggested to explain the mechanisms of SUDEP, most of them underlying a post-ictal respiratory dysfunction secondary to affecting cardiac functions. Mouse models of SUDEP use audiogenic seizures (AGS), which are seizures induced with a sound stimulation. Immediately after the sound presentation, the mouse manifests a stereotyped behavior for which one can identify successively a wild running, clonic seizures, a tonico-clonic seizure when the mouse falls on its flanks and a tonic seizure with an extension of the limbs toward the tail, followed or not by death. AGS in mice represents one of the greatest models for SUDEP since one can observe death after respiratory arrest and a cerebral shutdown as observed in SUDEP. Moreover, the seizure is the consequence of a non-invasive induction without any pharmacologic or electric component. Only a few inbred strains of mice are AGS prone and the vast majority of studies involve DBA/2 or DBA/1 strains. These strains are ideal for basic experiments but, due to their fragile constitution, it remains very difficult to use them for experiments requiring surgery. With the goal to offer a larger panel of mice available for AGS studies, we performed a comparative study of the variability in AGS responses in four inbred strains of mice, DBA/1, DBA/2, BALB/c and 129/SvTer. The experiments were conducted on independent groups of mice at different ages, from week 3 to week 17, and for each week, we scored the percentages of mice 1/ presenting no seizure or just the wild running, 2/ presenting clonic seizures without a tonic seizure, 3/ presenting a tonic seizure without death, 4/ presenting a tonic seizure and death. As mentioned previously, the tonic seizures can be followed by death or not, even in the same inbred strain. Hence, in a second experiment, we addressed the "determinism" component in death. In other words, if some mice present a determinism to die after a tonic seizure or not. Since one can "resuscitate" mice with a respirator after a lethal tonic seizure in AGS, we addressed the question of the determinism in testing mice during 5 consecutive days and we scored for each of the five days, the lethal versus non-lethal tonic seizures.

Title: Sleep-like slow-wave oscillations can drive epileptic spike-wave discharges in an idiopathic generalized epilepsy model with GABAR γ2 Q390X mutation

Authors: *C. ZHOU[1], L. DING, 37221[2], M. J. GALLAGHER[3], R. L. MACDONALD[4]
[1]Neurol., [2]Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Neurol., Vanderbilt Univ. Sch. of Med., Nashville, TN; [4]Professor & Chair, Dept Neurol, Vanderbilt Univ., Nashville, TN

Abstract: Idiopathic generalized epilepsy(IGE) influences large percentage of epileptic patients (2/3 of almost 3 million people in US). In patients epileptic activity is preferentially present during sleep or non-motion quiet-wake period, implying that sleep-related cortical activity may contribute seizure initiation. Thus we hypothesized that sleep-like slow-wave oscillations(SWOs) can drive epileptic spike-wave discharges (SWD) and seizure onset. Here we used heterozygous(het, GABAR $\gamma 2^{Q390X}$) IGE mice expressing halorhodopsin in cortical neurons by crossing het mice with Thy1-eNpHR2.0-EYFP mice (012332, Jackson laboratory). Following the Vanderbilt IACUC approved animal protocol, mouse surgery was performed for EEG headmounts, and cannula implantation(optic fiber (200 μm)(Thorlabs, Newton, NJ, USA) within somatosensory cortex. Tungsten electrodes were positioned in cortical layer V and the tips were below the cannula optic fiber ending. Animal behaviors were video-recorded and synchronized with EEG (band filtered 0.1~100 Hz)/multi-unit recordings (band filtered 300~2K Hz) (two Multiclamp 700B amplifiers and one DigiData1200, current clamp mode, sampling frequency 20K Hz). Sleep-like SWOs(0.5 Hz for 5~10 min) were induced by optogenetically activating halorhodopsin (590 nm, around 1.5 s)(DPSS Laser MGL-III-589-50) and intracortical stimulation (400~500pA, 20 ms, tungsten electrodes). In WT littermate mice (n=3), spontaneous SWOs(1~3 Hz) were present except a few spontaneous SWDs (16.33±4.51 per hour, 1.72±0.14s 4~10 Hz). In contrast, in het mice (n=4), spontaneous atypical slow-SWDs (4~5 Hz) and typical SWDs(6~10 Hz) were present (53.50±7.62 per hour, duration 2.13±0.22s). Moreover, in WT mice, sleep-like SWOs by optogenetic induction in cortex did not cause any epileptic behaviors and only SWOs and short multi-unit burst were present, and SWDs were slightly increased (24.67±8.60 per hour). However, in het mice, sleep-like SWOs by optogenetic induction in cortex caused dramatically increased slow-SWDs/SWDs (110.25±13.57 per hour, paired t-test $p=0.01$ pre *vs* post) and longer duration (3.28±0.15s, paired t-test $p<0.001$) (particularly after several repeats of sleep-like SWO induction in same mice) while mice exhibited behavioral rest/pausing. Moreover, accompanied with some slow-SWDs and SWDs, multi-unit activity in cortex layer V was also increased with longer duration. In conclusion, sleep-like SWOs *in vivo* could drive epileptic SWDs in het mice, suggesting one potential mechanism (due to hemostatic potentiation impairment of GABAergic currents) which can initiate seizures in this idiopathic generalized seizures model.

Abstract: Mesio-temporal lobe epilepsy is characterized by recurrent spontaneous seizures and extensive cell loss in the CA1, CA3 and hilar regions of the hippocampus. Granule cells and CA2 pyramidal cells, however, are mostly spared from cell death but their interconnection is pathologically altered. Dentate mossy fibers sprout within the dentate gyrus (DG) and into the pyramidal cell layer of CA2. How CA2 pyramidal cells are integrated into the hippocampal network after they lose their target neurons in CA1 and whether they participate in the generation of epileptic and non-epileptic activity patterns remained unclear. To investigate connectivity and activity of the surviving CA2 pyramidal cells in MTLE we unilaterally injected kainate (KA) into the hippocampus of Amigo-cre/ERT2 mice which express cre-recombinase in CA2 pyramidal cells and in littermates. NaCl injections served as controls. One subgroup of mice received an ipsilateral injection of a cre-dependent adeno-associated virus (phSyn1(S)-FLEX-tdTomato-T2A-SypEGFP-WPRE) into CA2 to trace axons of ipsilateral CA2 pyramidal cells. We found strong projections to CA1 and to the contralateral hippocampus in controls. While the projection to CA1 was lost in chronic epileptic mice in agreement with the loss of CA1 pyramidal cells, the projection to contralateral CA2 was preserved. A second subgroup of chronically epileptic and control mice was implanted either with wire electrodes bilaterally into the DG and CA2 or with a silicon probe into the ipsilateral CA2 region. Local field potentials recorded while mice were freely behaving showed alternating epileptic and non-epileptic activity patterns in the DG and CA2 of both hippocampi. Current source density analysis of epileptic activity patterns revealed that, analogous to dentate granule cells, CA2 pyramidal cells

participate in the generation of epileptic activity. Likewise, we found sinks/sources that were alternating at theta frequency in the somatic regions of CA2 during periods free of epileptic activity. Interestingly, the frequency of these theta oscillations was decreased bilaterally in CA2 of epileptic animals when compared to controls. This is in line with the theta frequency reduction reported for the entire DG and the MEC. We conclude that CA2 is an active part of the epileptic network and might contribute to the propagation of epileptic activity towards the contralateral hippocampus by its bilateral connection.

Abstract: Remodeling of neuronal circuits is known to be largely activity-dependent. However, the relationship between neuronal activity and synaptic plasticity during the development of mesial temporal lobe epilepsy (mTLE) remains poorly understood. Therefore, the present study aimed to provide an integrated view on epileptic activity, activity-dependent gene expression and synaptic plasticity in the hippocampus during kainic acid-induced epileptogenesis in mice.We show that shortly after status epilepticus, seizure activity is present and persists throughout epileptogenesis in both, sclerotic and non-sclerotic regions of the hippocampal formation. The sclerotic hippocampus differed from non-sclerotic regions by displaying milder paroxysmal discharges, which increased in their severity over time. This increase was paralleled by the upregulation of the activity-related cytoskeleton protein (Arc) gene expression exclusively in dentate granule cells (DGCs) residing in the sclerotic hippocampus. Importantly, we found that Arc mRNA-upregulating DGCs exhibited an increase in their spine density and size within the

terminal field of entorhinal afferents. But at the same time the density of AMPA-type glutamate receptors decreased. In order to probe its functional significance in mTLE, we performed optogenetic stimulation of entorhinal synapses on DGCs in vivo and showed that seizure activity was evoked with higher probability under epileptic conditions. Moreover, optogenetically-induced seizures failed to induce dendritic translocation of Arc mRNA and further AMPAR attenuation only in sclerotic regions of the hippocampus, supporting the notion of a local breakdown of the dentate gate in mTLE. We conclude that during epileptogenesis epileptic activity emerges early and persists in the whole hippocampus, however, only the sclerotic part shows modulation of seizure severity accompanied by plasticity of DGC synapses. In this context, we identified *Arc* as a putative mediator between seizure activity and synaptic plasticity.

Title: Molecular and structural characterization of inhibitory innervation of the CA2 region in experimental epilepsy

Authors: *S. TULKE[1,2,3], M. JOHNSTON[1], C. A. HAAS[1,2], U. HÄUSSLER[1,2]
[1]Exptl. Epilepsy Research, Dept. of Neurosurgery, Univ. Med. Ctr., Fac. of Medicine, Univ. of Freiburg, Freiburg Im Breisgau, Germany; [2]BrainLinks-BrainTools, Cluster of Excellence, Univ. of Freiburg, Freiburg Im Breisgau, Germany; [3]Fac. of Biology, Univ. Freiburg, Freiburg Im Breisgau, Germany

Abstract: Mesial temporal lobe epilepsy (MTLE) is often associated with extensive loss of excitatory neurons in the regions CA1, CA3 and hilus and inhibitory neurons throughout the hippocampus. In contrast, the majority of granule cells and CA2 pyramidal cells (PCs) survive and contribute to epileptic activity. We have shown before that sprouted mossy fibers not only induce recurrence between granule cells but also form aberrant synapses on CA2 PC somata (Häussler et al., 2016, Hippocampus). The molecular nature of synaptic inputs (mossy fibers and other terminals) innervating the CA2 region in MTLE is, however, still unclear. To characterize synaptic inputs to the CA2 region we induced MTLE with a unilateral injection of kainate (KA)

into the hippocampus of transgenic Thy1-EGFP mice which intrinsically express EGFP in a subset of adult granule cells and mossy fibers and in Rbp4-Cre mice expressing Cre-recombinase in granule cells. Rbp4-Cre mice received an adeno-associated virus (phSyn1(S)-FLEX-tdTomato-T2A-SypEGFP-WPRE) injection inducing tdTomato expression in somata and EGFP in mossy fiber synapses. At 21d after injection we performed *in situ* hybridization for glutamic acid decarboxylase 67 (GAD67) and immunohistochemistry for GAD65, both key enzymes for GABA production, vesicular GABA transporter (vGAT) and potassium-chloride-cotransporter 2 (KCC2) and localized CA2 PCs with PCP4 or RGS14, followed by Imaris-based reconstruction of synapses. We show only slight variations in somatic GAD67 mRNA expression in granule cells but strongly upregulated expression of GAD65 in mossy fiber terminals innervating CA2 and an increased fraction of EGFP+GAD65-expressing mossy fiber boutons contacting CA2 PC somata. Importantly, we did not detect any co-expression of GAD65 with vGAT in mossy fiber terminals, indicating that in case GABA is produced by GAD65 it is not loaded into synaptic vesicles, rendering classical synaptic GABA release unlikely. Yet, we found a substantial plexus of vGAT-positive fibers which did not express EGFP (neither intrinsically in Thy1-EGFP mice, nor AAV-driven in Rbp4-Cre mice) in CA2 indicating preservation of inhibitory nerve terminals. KCC2 was persistently expressed after KA injection indicating intact postsynaptic prerequisites for inhibition of CA2 PCs. Altogether, we hypothesize that despite expressing GAD67, sprouted mossy fiber synapses do not contribute to GABA-ergic transmission. Instead, CA2 PCs are still innervated by other GABAergic fibers and express KCC2 which might contribute to their resilience towards epileptogenicity.

Abstract: Absence seizures, characterized by behavioral impairment and a distinct rhythmic spike-and-wave electrographic signature, are associated with attentional deficits and developmental difficulties that have a major impact on quality of life. While clinical symptoms have been largely described, the mechanisms of how absence seizures impair cognition and behavior remain unknown, and therapy often fails. Human studies suggest that the degree of behavioral impairment varies, with accompanying hemodynamic and electrographic changes. Early data from our lab provide evidence that undrugged conditions may be necessary for the preservation of electrophysiology and hemodynamics during absence seizures in Genetic Absence Epilepsy Rats from Strasbourg (GAERS). This awake, non-medicated animal model of absence seizures provides the opportunity to investigate the neuronal mechanisms underlying behavioral impairments. Hemodynamics, electrophysiology and behavioral components of absence seizures were studied in awake adult female GAERS, aged 4-8 months. Rats were trained for awake body and head restraint, and were implanted with frontoparietal epidural EEG electrodes to electrically detect spike-and-wave discharges (SWDs). EEG was recorded with simultaneous local cerebral blood flow (CBF) and multi-unit activity (MUA). Rats were also trained on one of two behavioral tasks of increased complexities: a repetitive spontaneous licking task and a goal-oriented sensory detection task. For the spontaneous licking task, rats were encouraged to lick a spout intermittently by the presentation of a 20% sucrose water reward at varying intervals. In the sensory detection task, an 8KHz tone was used to signify reward availability. There were significant increases in CBF and MUA seen in deep layers of multiple regions of the cortex for the first 2 seconds of seizure activity, followed by a reduction from baseline for the remainder of the seizure duration. Larger CBF and MUA increases were associated with longer seizures. The increase in MUA appeared to be more dependent on seizure frequency than intensity of neural firing. SWDs in GAERS were accompanied by impaired performance in behavioral paradigms - repetitive spontaneous licking decreased upon SWD initiation, while stimulus responses were less reliable during SWDs. The degree of impairment varied significantly between seizures and was associated with electrographic changes. These findings may lead to better understanding of cellular mechanisms for variable severity in absence epilepsy and potentially guide improved therapy options.

Abstract: Absence epilepsy is the most common form of epilepsy in children and raises significant challenges for learning and quality of life. Current pharmacological therapies frequently fail to fully treat this condition or lead to side effects. Therefore, it is important to understand the underlying neural mechanisms towards the development of better therapeutic options. Such mechanistic investigation requires validated animal models. Previous work has focused on sedated animals, but has not replicated the behavioral components or hemodynamics of human absence seizures. We hypothesize that seizure hemodynamics and behavior in awake, drug free animals will be more consistent with those of human seizures. Here, we report head-fixed, awake, drug free functional magnetic resonance imaging (fMRI) of Genetic Absence Epilepsy Rats from Strasbourg (GAERS), an established rat model of absence epilepsy, with simultaneous electroencephalography (EEG) recordings. Animals were incrementally acclimated to the head-fixed apparatus and to a recording of sounds from the high field magnet (9.4T) over 3 weeks. They were then scanned in a total of 117 sessions across 18 animals, during which we monitored 1719 seizures. Echo-planar imaging (EPI) was used to acquire fMRI; T1- and T2-weighted anatomical images were obtained for signal localization. Preprocessing included estimation of motion, realignment, removal of motion and artifact epochs, functional to structural registration, registration of animals to a template, and spatial smoothing. Two analyses were performed: first, a voxel-wise general linear model comparing seizure to non-seizure periods and second, a region of interest (ROI) based time-course analysis. In the voxel-wise analysis seizures were associated with a decrease in blood oxygen level dependent (BOLD) signal in the primary somatosensory cortex and an increase in thalamic nuclei. This resembles the cortical decreases and thalamic increases seen in human fMRI during absence seizures. In the ROI based analysis, we also find different time-courses in the cortex vs thalamus for BOLD fMRI both during and

after seizures. We conclude that the hemodynamics of seizures in GAERS are like those in humans with absence epilepsy, supporting the application to humans of findings of electrophysiological recordings and behavioral testing from GAERS. We also conclude that like in human patients the BOLD signal in GAERS seizures has significant regional heterogeneity. This suggests that mechanistic investigations should take place in awake, drug free animal models to ensure translational validity and facilitate development of new therapies.

Title: Increase of seizure activity by picrotoxin in thalamic reticular nucleus of the rat

Authors: *V. M. MAGDALENO-MADRIGAL, F. J. HIDALGO-FLORES, G. CONTRERAS-MURILLO, S. ALMAZÁN-ALVARADO

Abstract: The deep brain stimulation (DBS) is used for the control of refractory epilepsy. In our laboratory we reported that DBS in the thalamic reticular nucleus (TRN) protects against seizures caused by Pentylenetetrazol (PTZ). The TRN contains inhibitory neurons that release GABA and is involved in the generation and control of spike-wave (SWD) and generalized tonic-clonic seizures (GTCS). The goal of this study was to analyze the behavioral and electroencephalographic (EEG) changes of the low-frequency stimulation (LFS) and the microinjection of picrotoxin (PTX) in the TRN. Wistar rats were implanted with a tripolar electrode and a cannula guide in the left TRN. The animals were randomly assigned to four groups: SS group, they received an ICV microinjection of saline solution (SS) and PTZ; PTX group, received an ICV microinjection of PTX and PTZ; SS/LFS group, received SS plus LFS and PTZ; PTX/LFS group, received PTX plus LFS and PTZ. Meantime, EEG recordings were done. The SWD number and latency were analyzed. In addition, the GTCS number, duration, latency, and severity. The results showed an increase in the number and duration of the GTCS of the groups PTX and PTX/DBS. The groups that received LFS showed a significant increase in the frequency of SWD and the amplitude. Our preliminary results suggest that the picrotoxin in

the TRN show a tendency to increase the GTCS effect that is facilitated with the LFS. Suggesting that the probable mechanism of the protective outcome of the DBS in the TRN it may be an increase in intrareticular inhibition.

Title: Experimental febrile status epilepticus increases seizure susceptibility in developing mice: A powerful experimental model?

Authors: *A. M. HALL[1], G. A. SANCHEZ[1], M. M. CURRAN[4], H.-S. MUN[2], L. A. LUCERO[2], J. DAGLIAN[3], T. Z. BARAM[4]

Abstract: Premise: Prolonged fever-invoked seizures (febrile status epilepticus; FSE) during infancy increases risk for epilepsy and cognitive deficits later in life, but the underlying mechanisms are incompletely understood. Experimental febrile status epilepticus (eFSE) in rats has successfully modeled human FSE, recapitulating epilepsy and cognitive problems seen in a subset of humans, yet rats do not enable the use of many genetic tools developed in mice. **Methods:** We used mice on the C57BL/6J background strain and examined if eFSE can be generated in immature mice and promote vulnerability to subsequent convulsant drugs. For eFSE, mice age P14-15 were maintained at temperatures between 40ºC to 40.9ºC for more than 30 minutes. We exposed naïve and eFSE-experiencing adult mice to subthreshold kainic acid dose (15 mg/kg) intraperitoneal. In a separate cohort, we assessed if eFSE induces epileptogenesis. We implanted electrodes into the hippocampus of control and eFSE experiencing mice and then recorded 24/7 video electroencephalogram and analyzed for seizures and spike series. **Results:** eFSE in immature mice increased susceptibility to kainic acid induced seizures, apparent from reduced latency and increased propagation, indicating an enduring change in the brain networks that are involved in limbic seizures. Studies of overt epileptogenesis are ongoing. **Conclusion**: EFSE is feasible in mice and provokes enduring pro-epileptogenic changes in the underlying brain circuits.

Title: Hippocampal deletion of sodium channel Nav1.1 causes thermally evoked seizures and spatial learning deficits in a mouse model of Dravet Syndrome

Authors: *R. E. STEIN, J. S. KAPLAN, W. A. CATTERALL
Univ. of Washington, Seattle, WA

Abstract: Dravet Syndrome is a severe epileptic disorder with many debilitating comorbidities caused by haploinsufficiency of the *Scn1a* gene, which encodes the alpha-subunit of Nav1.1 voltage-gated sodium channels. Dravet Syndrome is characterized by treatment-refractory epileptic seizures that present before one year of age, followed by symptoms that include developmental delays, autism, and severe cognitive impairment. Mouse models of Dravet Syndrome closely mirror the mutations and phenotypes present in humans. Previous work has demonstrated that reduced sodium current due to heterozygous loss-of-function of Nav1.1 channels causes hypoexcitability of GABAergic interneurons, which is responsible for the core disease phenotypes of epilepsy, cognitive impairment, and social interaction deficits. However, the impact of reduced Nav1.1 expression in specific brain regions on epileptiform activity and co-morbidities is unknown. To elucidate this question, we used a floxed *Scn1a* mouse line and the Cre-Lox method to delete Nav1.1 in the hippocampus of C57BL/6 mice using targeted viral injections. The frequency of spontaneous inhibitory postsynaptic currents from GABAergic synapses onto dentate granule cells was impaired by this local gene deletion. Mice with local deletion of Nav1.1 experienced thermally evoked behavioral and electrographic generalized tonic-clonic seizures, which were similar in intensity to seizures in mice with global mutation of Nav1.1. Local gene deletion in the hippocampus also caused impairments in spatial learning and memory in the Barnes maze, but had no effect on novel object recognition or social interaction behaviors. Our results provide evidence that local Nav1.1 deletion in the hippocampus is sufficient to induce generalized tonic-clonic seizures and deficits in spatial learning and memory that are characteristic of Dravet Syndrome in mice and humans.

Title: Characterization of kindled VGAT-Cre mice as a new animal model of pharmacoresistant epilepsy

Authors: J. STRAUB, A. GAWDA, P. RAVICHANDRAN, C. BURKE, J. KANG, I. VITKO, M. M. SCOTT, *E. PEREZ-REYES
Dept Pharmacol, 800735, Univ. of Virginia, Charlottesvle, VA

Abstract: Our long-term goal is to develop novel gene therapies for temporal lobe epilepsy (TLE) patients whose seizures are not controlled by drugs. Due to a lack of suitable animal models, there has been little progress in developing therapies for TLE. While testing the hypothesis that "inhibiting inhibitory neurons" was sufficient to induce seizures, we discovered that hippocampal kindling of VGAT-Cre mice leads to spontaneous seizures (protocol: twice a day, every day, @1.5x after-discharge threshold, ADT). Control experiments demonstrate electrical kindling was required to induce the epileptic phenotype. Spontaneous seizures developed ~10 days after kindling was complete (3 tonic-clonic seizures). These seizures resemble those in post-status epilepticus models of TLE in terms of both electrographic and behavioral components (tonic-clonic seizures). In contrast to post-status models, seizures in VGAT-Cre mice occur in the absence of neuronal death, absence of ectopic dentate granule cells, and with only a small increase in aberrant granule cell axon sprouting. These findings rule out changes that are commonly postulated as the cause of limbic seizures in post-status models. These mice express Cre recombinase under the control of the vesicular GABA transporter (VGAT), a gene that is specifically expressed in GABAergic inhibitory neurons. Loss or dysfunction of hippocampal GABAergic neurons has been linked to the development of TLE. Accordingly, we hypothesize Cre expression impairs the function of GABAergic neurons, leading to increased seizure susceptibility. Spontaneous seizures in kindled VGAT-Cre mice occur 1-2 seizures/day with little sign of clustering. We conclude kindled VGAT-Cre mice are an ideal model for screening novel anti-seizure and anti-epileptogenic drugs.

Title: Development of a zebrafish model to study childhood epileptic encephalopathy caused by dynamin 1 (DNM1) mutations

Authors: *G. C. MILLS, E. FRANKEL, J. DODSON, L. LLACI, R. GUPTA, B. GERALD, M. STRINGER, V. NARAYANAN, S. RANGASAMY
Translational Genomics Res. Inst., Phoenix, AZ

Abstract: Next generation sequencing (NGS) technology has led to the identification of causal genes in epileptic encephalopathies. Recently, mutations in the DNM1 gene encoding dynamin 1 (OMIM: 602377) have been recognized to cause early infantile epileptic encephalopathy-31 (OMIM: 616346). While recent studies have provided insights into dynamin-1 structure and function, it is still unclear how the *de novo* missense mutation in DNM1—a core component of postsynaptic endocytosis machinery—leads to early epileptic encephalopathy (EE). It is critical to use valid animal models in our effort to understand the pathophysiology of EE caused by *DNM1* mutations. The zebrafish is an alternative model system with substantial benefits which is now widely used to study the pathophysiology of human Mendelian disorders, develop cost-efficient breeding, and practice *in vivo* drug discovery. Zebrafish Dnm1 is structurally similar (88%) to human DNM1 at the gene and protein levels. In this study, we utilized the zebrafish model to analyze the role of DNM1 in epilepsy and characterize disease-specific phenotypes using a reverse genetics approach. To create the animal model, wildtype AB zebrafish between six and 24 months old were bred to produce embryos which were then randomly assigned to treatments of the dynamin inhibitor (n = 417), the vehicle treatment, DMSO (n = 306), or left untreated (n = 376). At 72 hours post fertilization (hpf), zebrafish locomotion was captured through videography and behavior was analyzed for seizures and curvature. By creating a 2d-trace map (path length) of zebrafish motion, we were able to evaluate convulsant-like locomotor behaviors in the zebrafish. We found a significant increase ($p<0.001$) in locomotor pathlength between treatment and both the vehicle treatment and the untreated zebrafish at the same time interval. Two-tailed, heterozygous t-tests showed a significant increase ($p<0.001$) in seizure and curvature expression in 72 hpf zebrafish. Seizures were classified in this study as quick and involuntary movements in accordance to previous research. By targeting *dnm1a* using Morpholinos (Gene Tools, LLC.), we recapitulated the seizure-like activity in 48 hpf embryos

seen using DNM1 inhibitors, but the seizures were less severe than those produced by chemical inhibition of dnm1 in the zebrafish. Our preliminary data indicates that the disruption of Dnm1 leads to seizure like-activity in zebrafish, suggesting that this is a promising model system. This approach can potentially lead to the identification of novel therapies and treatment of epileptic encephalopathy caused by DNM1 mutation in humans.

Title: Deletion of a key Scn1a regulatory element causes severe phenotypes in mice

Authors: *A. S. NORD[1], T. W. STRADLEIGH[1], I. ZDILAR[1], M. SRAMEK[1], A. NGUYEN[1], A. ADHIKARI[2], N. COPPING[3], J. L. SILVERMAN[4]

Abstract: Dravet Syndrome (DS) is understood to be a disorder driven primarily by loss-of-function mutations in *SCN1A*, a gene encoding the $Na_V1.1$ sodium channel. We hypothesize that mutations to non-coding DNA regulatory elements (REs) represent a secondary causal mechanism in *SCN1A*-associated pathology. Changes to REs can produce strong phenotypes, and there are instances of in patients of large genomic deletions affecting the *SCN1A* without impacting coding sequence, yet the role of gene regulation in DS is not well understood. We used the Cas9/CRISPR system to generate a mouse model harboring a deletion of the h1b non-coding RE of *Scn1a*. Three genotypes were investigated at all developmental time points: wild type (WT), deletion carrier (*Scn1a*-REdel$^{+/-}$), and homozygous deletion (*Scn1a*-REdel$^{-/-}$). Mice expressing a homozygous deletion of RE demonstrated severely reduced survival after P28. No early lethality effects have been noted in heterozygous deletion carrier mice. *Scn1a* was the most significant differentially expressed gene identified via RNA-seq, with dosage-sensitive down-regulation in h1b deletion brain. We did not identify a strong global signature of differential expression at P7, but did find suggestive evidence of pathology-related changes even at this early stage of life. We are currently evaluating *Scn1a* transcription and global expression changes via

RNA-seq at later ages. WB analysis and IHC indicates Na_V1. 1 expression follows a dose-dependent relationship, with expression differences most pronounced at the later developmental time points (P21, P28). We demonstrate that targeting the h1b element with dCas9-p300 can drive increased *SCN1A* mRNA levels in human cells. These data suggest we have created a novel alternative mouse model of DS and *SCN1A*-associated developmental disorders that relies upon deletion of a non-coding regulatory element associated with *SCN1A*. This work and extension of the approach to characterize other *Scn1a* REs has the potential to generate new insights about pathology and guide diagnosis and treatment of DS and *SCN1A*-associated disorders in the future.

Title: A novel zebrafish model of GABRB3-linked childhood epilepsy

Authors: *C. A. CARPENTER, B. P. GRONE, S. C. BARABAN
Neurolog. Surgery, Univ. of California, San Francisco, San Francisco, CA

Abstract: Epilepsy is a debilitating, chronic neurological disorder, where individuals experience spontaneous and recurrent seizures. Although a variety of anti-epileptic drugs (AEDs) are available, 20-30% of patients, many suffering with genetic childhood epilepsies, remain classified as pharmaco-resistant. To address this problem, there is need for further elucidation of the causative elements of epilepsy and improvements in the current AED discovery process. Reduced expression or function of $GABA_A$ receptor β3 subunit (GABRB3) is linked to the pathogenesis of a collection of early-onset epilepsies. *GABRB3* null mice exhibit seizures, impaired learning, poor motor performance and hyperactivity. Nonetheless, rodents are not an ideal species for drug discovery. Through this study we aim to establish the first zebrafish model of GABRB3 deficiency. Using CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats)/Cas9 system, we generated mutant *gabrb3* zebrafish and our goal is to validate whether this model accurately recapitulates salient features of the human epileptic disorder. Here we describe our initial characterization of the behavioral, electrophysiological, pharmacological and morphological phenotypes of mutant *gabrb3*$^{-/-}$ zebrafish. In vivo electrophysiology experiments

at 5 days postfertilization (dpf) indicate that *gabrb3*$^{-/-}$ larvae exhibit spontaneous electrographic seizure events characterized by brief high-frequency interictal-like events and rare larger, long duration multi-spike discharges, which are absent in recordings from the wild-type control larvae. In locomotion assays, freely swimming *gabrb3*$^{-/-}$ larvae are hyperactive compared to age-matched wild-type control larvae at 5 dpf. We are also testing the effect of various AEDs in these behavioral and electrophysiological assays including, but not limited to, carbamazepine, valproate, ethosuximide, topiramate and diazepam. Taken together, our results already point to similarities between our *gabrb3*$^{-/-}$ zebrafish larvae and GABRB3-linked human epilepsies. We are therefore excited by the prospect of generating a novel, translational model that will help us better understand childhood epilepsies and discover new effective AEDs.

Title: Status epilepticus induced in the infant rat by pentylenetetrazol and lithium pilocarpine promotes similar c-Fos expression in the hippocampus and the cerebellum

Authors: *L. LOPEZ-MERAZ[1], J. VELAZCO-HERNÁNDEZ[2], E. VELAZCO-CERCAS[1], L. BELTRÁN-PARRAZAL[1], C. MORGADO-VALLE[1]
[1]Cice, Univ. Veracruzana, Xalapa, Mexico; [2]Cice, Univ. Veracruzana, XALAPA, Mexico

Abstract: Consequences of *status epilepticus* (SE) in the developing brain can be assessed through different experimental models. SE can be induced by pentylenetetrazole (PTZ) characterized by clonic-tonic seizures, or by lithium-pilocarpine (Li-Pilo) characterized by complex partial seizures with secondary generalization. The goal of this study was to compare the effect of SE induced by PTZ (PTZ-SE) or LI-Pilo (Li-Pilo-SE) in infant rats on c-Fos protein expression in the hippocampus and cerebellum. SE was induced in fourteen-days-old Wistar rat pups (both sexes). PTZ-SE was produced by 55mg/kg of PTZ (n=6); Li-Pilo-SE was induced by 3mEq/kg of LiCl (on the day before the induction of SE) and 100mg/kg of pilocarpine hydrochloride (n=7). Control animals were given an equal volume of saline or LiCl followed by saline, respectively (n=6). 90 to 120 min after SE or control conditions, rats were anesthetized and transcardially perfused with 4% paraformaldehyde; the brain and the cerebellum were removed, cryoprotected in 30% sucrose and cut to obtain 40-µm-thick coronal (dorsal

hippocampus) or sagittal (medial vermis of cerebellum) sections. Colorimetric immunohistochemistry was performed to detect c-Fos immunoreactive (Fos-IR) cells in the hippocampal CA1, CA2 and CA3 pyramidal layer and dentate gyrus (DG) granular layer, as well as in the cerebellar granular layer of lobules I-X (ROI 30,000 um^2). Differences between SE models were analyzed with the U Mann Whitney test (data are expressed as the median); a multivariate clustering analysis was performed to identify similarities in neuronal activation after SE. Scarce or null c-Fos immunoreactivity was detected in controls. There was a higher number of Fos-IR cells in the CA2 area after Li-Pilo-SE (185) than after PTZ-SE (82; p=0.0082); no additional differences were observed in the hippocampus (PTZ-SE: CA1=49, CA3=85, DG=139; Li-Pilo-SE: CA1=146, CA3=113, DG=125). The number of Fos-IR cells after PTZ-SE (I=130, II=150, III=127, IV=137, V=114, VIa=130, VIc=137, VII=125, VIII=177, IX=186, X=147) or Li-Pilo-SE (I=119, II=116, III=122, IV=128, V=129, VIa=126, VIc=162, VII=191, VIII=185, IX=180, X=163) was similar in all the cerebellar lobules. The clustering analysis showed three brain regions with different c-Fos expression after SE (PTZ and Li-Pilo SE; Cohen coefficient=0.8586): 1) Hippocampus (including CA1, CA2 and DG), 2) Anterior lobe of cerebellum (including lobules I-V and VIa) and 3) Posterior lobe of cerebellum (including lobules VII-X). In conclusion, SE induced in the infant rat by two different experimental models promotes similar neuronal activation in the hippocampus and the cerebellum.

Neurosci. and Dept of Cell Biology, Physiol. and Immunol., Univ. Autonoma De Barcelona, Bellaterra, Spain

Abstract: Epilepsy and premature mortality are common and prominent features of Leigh syndrome (LS) (OMIM: #256000). Leigh Syndrome (LS), or subacute necrotizing encephalopathy, is a debilitating, progressive, and neurodegenerative mitochondrial disorder of childhood. Mouse models of LS, generated by global or CNS-specific Knock-out (KO) of *Ndufs4* recapitulate several key clinical features of the disease in humans, including spontaneous seizures and premature death.
We examined the contribution of excitatory and inhibitory neurons to the development of epilepsy and sudden death phenotypes in the mouse model of LS.
Methods: Control mice and mice with *Ndufs4* knocked out selectively in either GABAergic interneurons (Gad2-specific KO mice) or in Vglut2-positive glutamatergic neurons (Vglut2-specific KO mice) were generated by crossing the *Ndufs4* floxed mice with the Gad2Cre or Vgut2Cre driver mice respectively. Thermal seizure susceptibility test, plethysmography, and video-EEG assessment of the mice were conducted as described in our previous work.
Results: All Gad2-specific KO (not control) mice exhibited spontaneous behavioral seizures and died prematurely. Series of myoclonic seizures, often preceding and following a generalized tonic-clonic seizure, were observed beginning on postnatal day (P) 32. Premature death occurred starting at P49, with none of the mice surviving past P82. All witnessed deaths occurred immediately following a Racine 5 generalized spontaneous seizure, suggesting they are precipitated by a seizure. Combined video-EEG recordings revealed generalized interictal epileptiform spikes during resting behavior or sleep as well as spontaneous and thermal seizures, marked by high-voltage spike and wave EEG discharges closely associated with hypermotor behaviors lasting 31 ± 9 seconds. In a striking contrast, Vglut2-specific KO mice did not show any behavioral or electrographic sign of predisposition to spontaneous or thermal seizures. Interestingly however, they develop respiratory disturbances and succumb to non-epilepsy related premature death, starting at ~P50, with none of the mice surviving past P200.
Conclusion: These results suggest for the first time that LS can lead to fatality via sudden unexpected death in epilepsy (SUDEP) or non-SUDEP. *Ndufs4* KO in GABAergic neurons is critical for the development of epilepsy and SUDEP in LS. Whereas the same mutation in excitatory neurons is central in the pathogenesis of respiratory abnormalities and non-SUDEP phenotype.

Title: Using Dravet Syndrome mice to trace the progress of Dravet-associated comorbidities

Authors: *M. RUBINSTEIN[1], S. FADILA[2], Y. ALMOG[2], K. ANDERSON[2]
[1]Sackler Sch. of Med., Tel Aviv Univ., Tel Aviv-Yafo, Israel; [2]Goldschleger Eye Res. Institute, Sackler Sch. of Med., Tel Aviv Univ., Tel Aviv, Israel

Abstract: Dravet syndrome (Dravet) is an infantile epileptic encephalopathy with ominous course. Children develop normally during the first year of life but subsequently exhibit unusually severe febrile seizures that progress to prolonged refractory seizures and frequent episodes of status epilepticus. Following the onset of epilepsy, developmental delay becomes evident with cognitive decline, appearance of autistic features, hyperactivity and motor deficits. Importantly, while toward adolescence the epilepsy improves, the invalidating comorbidities persist. The onset of Dravet-associated comorbidities and its relationship to the recurrent seizure are unclear. Here, we conducted combined electrophysiological and behavioral studies of the Dravet mouse model in order to characterize developmental changes in Dravet phenotypes, examining neuronal changes and the presentation of Dravet-associated comorbidities. Electrophysical brain slice recordings from hippocampal interneurons demonstrated that at P14, prior to the onset of spontaneous seizures in mice, the excitability of wild-type and Dravet interneurons is similar. However, at P21, when spontaneous seizures appear and premature death is frequent, the excitability of hippocampal inhibitory neurons is reduced. These recordings suggest that the onset of epilepsy correlates with the onset of reduction in inhibition, supporting the view of disinhibition as the cause of Dravet. In contrast, motor deficits, characterized by lower performances on the rotarod and wider base of support in both front and hind paws, are evident already at P14, before the onset of epilepsy. Surprisingly, these deficits were improved at the onset of seizures. Thus, motor dysfunction precedes the onset of seizures, with transient improvement at the onset of seizures, and further decline at adulthood. However, hyperactivity assessment in the open field showed a different progression profile with later onset; while no changes were observed at P14 and P21, hyperactivity was evident at P35, after the period of instance seizures and frequent death. Together, these results indicate that Dravet-associated comorbidities change thorough development, with some appearing before the onset of epilepsy and others that are evident only later in life.

Title: Vasoactive intestinal peptide-expressing interneurons are impaired in a mouse model of Dravet syndrome

Authors: *K. GOFF[1], E. M. GOLDBERG[2]
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Dravet syndrome (DS) is a severe neurodevelopmental disorder defined by intractable epilepsy and a high rate of autism spectrum disorder. It is caused primarily by *de novo* mutations in *SCN1A* which codes for the voltage gated sodium (Na+) channel alpha subunit Nav1.1. Nav1.1 is prominently expressed in GABAergic interneurons, and it is hypothesized that selective dysfunction of interneurons leads to impaired inhibition in the developing brain, which in turn leads to DS pathology. Both parvalbumin (PV-INs) and somatostatin expressing interneurons (SST-INs) are impaired in DS; however, the function of the third major group of interneurons - the vasoactive intestinal peptide (VIP) expressing interneurons (VIP-INs) - has yet to be specifically investigated. Here, we used *Scn1a*$^{+/-}$ mice crossed to VIP-Cre.tdTomato reporter mice to perform targeted whole cell recordings from VIP interneurons in layer 2/3 primary somatosensory cortex of acute brain slices prepared from male and female mice across development. We demonstrated that VIP-INs from *Scn1a*+/- mice exhibit evidence of hypoexcitability relative to age-matched wild-type littermate controls, with a depolarized action potential threshold, reduced steady state firing frequency, and prominent spike height attenuation in both post-natal day (P) 18-21 and P35-56 age groups, consistent with the presence of Nav1.1 in VIP-INs. Partial block of Na+ channels in VIP-INs with low concentrations of TTX mimics the *Scn1a*$^{+/-}$ phenotype. We then used single-cell PCR to investigate the expression of Nav1.1 isoforms, as well as other neural Na+ channels, in VIP interneurons. Finally, as VIP-INs are considered to serve a predominantly disinhibitory role in cortex via inhibition of SST-INs, we tested the function of this microcircuit in DS by optogenetically stimulating corticocortical motor afferents in the superficial layers of barrel cortex while measuring activation of VIP-INs and disynaptic inhibition of SST-INs. Our results show that VIP-INs express Nav1.1 and, along with PV and SST-INs, are dysfunctional in DS. This is an important step towards understanding how loss of Nav1.1 gives rise to the circuit abnormalities that underlie epilepsy and cognitive

dysfunction in DS. As VIP-INs are presumed to be disinhibitory, VIP-IN dysfunction may contribute to non-epilepsy comorbid conditions in DS.

Title: Interictal dentate gyrus hyperexcitation in a mouse model of Dravet syndrome

Authors: *I. AIBA, J. L. NOEBELS
Baylor Col. of Med., Houston, TX

Abstract: Dravet syndrome is an infantile onset genetic epilepsy that involves a variety of comorbidities including autonomic and cognitive dysfunction and an extremely high risk of premature sudden death (SUDEP). The majority of DS cases are caused by loss of function mutations in the SCN1A gene which reduces the excitability of inhibitory neurons and contributes to network hyperexcitability. Apart from this well characterized cellular mechanism, the neuroanatomical basis of the seizures and comorbidity of DS is not well understood. While the SCN1A gene is widely expressed in the CNS, it is not known which brain regions are particularly vulnerable to the mutation and whether specific single brain regions could contribute to epilepsy and individual comorbidities of the DS.
To address this question, this study screened for hyperexcitable brain regions in a mouse model of Dravet Syndrome (Scn1a+/R1407X) using the FosTRAP system which genetically labels neuronal populations during a ~12 hour time window after activation by tamoxifen administration. Scn1a mutant mice (P20-30) were crossed with FosTRAP as well as a tdtomato reporter line to fluorescently label the activated population during a period while cortical EEG activity was continuously recorded. In a series of such experiments, we detected robust and reproducible labeling within the dentate gyrus (DG) of juvenile Scn1a mutant mice. The same labeling pattern could be detected even in animals which did not show visible generalized convulsive seizures, suggesting the activation was likely due to localized subcortical hyperexcitation. Remarkably, this DG hyperexcitation pattern was restricted to a juvenile developmental stage when SUDEP incidence is high; thus DG activity labeling was most reliably detected in mutant mice younger than P30 when the majority of SUDEP cases are detected, but was never detected in animals older than P60 when SUDEP incidence is extremely rare.
These preliminary results suggest the presence of age-dependent, spatially restricted

hyperexcitation patterns in the hippocampal formation of DS mice. Because of the involvement of the DG in seizure gating, cognitive functions, and limbic output, this localized DG activation may define an early and reversible interictal network excitability defect contributing to epilepsy and comorbidities in this DS model.

Title: BRAFV600E expression in mouse neocortical progenitors is sufficient to induce glial activation, elevate neuronal excitability, and cause seizures in mice

Authors: *R. GOZ[1], J. J. LOTURCO[2]
[1]Physiol. and Neurobio., [2]PNB, UCONN, Storrs, CT

Abstract: The mechanisms by which low-grade neuroepithelial tumors (LNETs) associated with epilepsy cause hyper-excitability and hyper-synchrony of cortical tissue are not completely understood. Hypotheses include somatic mutations transforming the physiology of neurons, and mutations altering the physiology of astrocyte networks and function. BRAFV600E mutations have now been identified as a common somatic mutation in pediatric low grade glioma, and the most common mutation in ganglioglioma, two focal lesions that cause seizures. We found that introducing human BRAFV600E mutations into mouse neocortical progenitors by *in utero* electroporation and piggyBac transposition resulted in focal cortical developmental disruptions and behavioral and electrographic seizures in mice. The developmental alterations included a several fold increase in astrocytogenesis relative to neurogenesis in Glast+ progenitors and an opposite effect in Nestin+ progenitors, astrocytes activation, increased gene expression related to inflammatory responses including elevated expression in genes in the classic complement pathway. In whole-cell patch clamp recordings of cortical neurons in slices we found that BRAFV600E mutant neurons showed marked changes in intrinsic excitability relative to neighboring control pyramidal neurons. Elevated excitability in the current-clamp included more hyperpolarized threshold to Action Potential (AP) firing, and increased AP firing frequencies in response to depolarizing current pulses. Some BRAFV600E neurons also showed a distinct type of bursting behavior that was not observed in control pyramidal neurons. In addition, BRAFV600E expressing neurons had increased rebound excitation, and increased voltage

hyperpolarization induced SAG. In voltage clamp experiments, BRAFV600E neurons had increased Ih currents, and reduced sustained potassium currents. Early activation of potassium currents contributing to the sustained currents with retigabine decreased the AP firing frequencies. Unlike the effects of BRAFV600E, neurons induced to over-express human BRAF wild type (wt) displayed no significant changes in intrinsic excitability compared to controls. Based on these results we propose that the same somatic mutation arising in neocortical progenitors can both increase pyramidal neuron excitability cell autonomously and increase the numbers and activation of astrocytes.

Title: Transcriptomic and proteomic profiling in an epilepsy fly model reveals cell non-autonomous downregulation of synaptic proteins

Authors: *K. A. HOPE[1], D. JOHNSON[2], D. KAKHNIASHVILI[3], L. REITER[1,4,5]

Abstract: Duplication 15q syndrome (Dup15q) is caused by maternally inherited duplications of chromosome 15q11.2-q13.1 and has a high rate of treatment resistant epilepsy. Previous research in mice focused on the neuronal overexpression of *UBE3A,* which is located within 15q11.2-q13.1, yet seizures were not observed in any of these models. Our lab recently generated a novel fly model that recapitulates the Dup15q seizure phenotype when *UBE3A* is overexpressed in glial cells, not neurons, implicating glia in Dup15q epilepsy. To investigate the effects of *UBE3A* overexpression in glia compared to neurons we employed proteomic analysis through liquid chromatography coupled to high-resolution mass spectrometry and transcriptome analysis through RNA-sequencing of whole fly head extract in glial *Dube3a* (fly *UBE3A* homolog) vs neuronal *Dube3a* overexpression. We measured approximately 2,500 proteins at both the transcript and protein level, allowing us to identify genes that were altered only at the transcript level, only the protein level, or both the transcript and protein level in glial or neuronal overexpressing lines. Gene ontology analysis revealed enrichment in synaptic proteins downregulated at both the transcript and protein level following overexpression of *Dube3a* in

glia (*repo>Dube3a*), including *synapsin, Sap47, Syx1a,* and *Nwk*. These synaptic proteins were relatively unchanged in neuronal *Dube3a* overexpression (*elav*>Dube3a), indicating synaptic proteins in neurons change in a cell non-autonomous manner upon glial overexpression of *Dube3a*. Additionally, we identified an upregulation of glutathione s-transferase (GST) genes in *repo>Dube3a* flies. GSTs are known to metabolize xenobiotics and may underlie the treatment resistant nature of Dup15q epilepsy. We are currently investigating whether downregulation of synaptic proteins and upregulation of GSTs is specific to our Dup15q epilepsy seizure model or if this is common across multiple "gliopathic" epilepsy types. In summary, cell non-autonomous downregulation of synaptic proteins may play a key role in Dup15q epilepsy, and an upregulation of GSTs may be common across multiple seizure types driven by glial abnormalities.

Epileptology, Fndn. Inst. di Ricerca e Cura a Carattere Scientifico Neurolog. Inst. Carlo Besta, Milano, Italy; [4]CNRS Inst. Mol. & Cell. Pharmacol., Valbonne, France

Abstract: Eukaryotic Elongation Factor 2 Kinase (eEF2K) is a ubiquitous Ca2+/Calmoduline-dependent kinase that regulates protein translation by catalyzing the phosphorylation of eEF2 at Thr56. In neurons, eEF2K is activated by Ca2+ influx mediated by glutamate stimulation leading to an increased the expression of certain proteins involved in synapse formation and plasticity, whereas the general protein translation is decreased. We recently demonstrated that eEF2K activity regulates excitation/inhibition ratio in the brain. In particular, eEF2K-/- mice display enhanced GABAergic transmission and tonic inhibition by the upregulation of proteins involved in inhibitory synapses functioning and are less susceptible to epileptic seizures. Accordingly, to

these data, we propose eEF2K/eEF2 pathway as a possible target for antiepileptic therapies (Heise et al., 2017). We studied the effect of eEF2K deletion in Scn1a+/- mice, through a genetic approach. We generated a mouse model by crossing Scn1a+/- mice with eEF2K-/- mice. First, we found that eEF2K deletion protected Scn1a+/- mice from the onset of epileptic seizures either under basal condition or under thermal stress, a condition known to trigger seizures in Dravet syndrome patients as well as in Scn1a+/- mice. Also, motor coordination defect, memory impairments, and stereotyped behavior are reverted by eEF2K depletion. The analysis of spontaneous inhibitory postsynaptic currents (sIPSCs) suggested that the rescue of the pathological phenotype was driven by the potentiation of the GABAergic synapses. In addition, the analysis of eEF2 phosphorylation in samples from cerebral cortex and hippocampus of Scn1a+/- mice revealed that eEF2K/eEF2 pathway might play a role in the progression of the pathology. Title: The comparison of high-frequency oscillations in three types of limbic seizures

Authors: *H. SUN[1], C. R. STEPHENSONS, 71103-4228[2]
[1]Neurosurg., Louisiana State Univ. Hlth. Sci. Ctr., Shreveport, LA; [2]Louisiana State Univ. Hlth. Sci. Ctr. Shreveport, Shreveport, LA

Abstract: High-frequency oscillations (HFO) are involved with seizure genesis and spread. It has been demonstrated that different HFO patterns detected on intracranial electroencephalogram (EEG) are associated with different mechanisms of seizure onset. Here, we analyzed HFO patterns among three types of limbic seizures in mice: 1. Seizures induced by optogenetic stimulation of glutamnergic neurons in the hippocampus, 2. Spontaneous seizures detected in Kv1.1 knockout (KO) breeds, and 3. Seizures induced by systemic administration of 4-Aminopyridine (4-AP).In optogenetics-induced seizures, wild-type mice were injected with adeno-associated virus (AAV) in order to achieve hippocampal channelrhodopsin (ChR2) expression. Glutaminergic neurons were targeted using a CaMKIIA promotor. A custom, single-channel optic fiber-electrode (optrode) assembly was stereotactically implanted into the dorsal

hippocampus for stimulation and EEG recording. For Kv1.1 KO and 4-AP recordings, an EEG recording electrode was stereotactically implanted into the same location of the hippocampus. Each animal was then recorded for at least 30 minutes for possible seizure activities with multiple recording sessions. Custom MATLAB software, combined with an open-source software package, was used to perform analyses of HFO patterns on hippocampal recordings from each group. For reliable detection of an HFO, we set a minimum requirement for oscillatory event duration of 30 milliseconds.For this study, we included one mouse for each seizure induction method. Each mouse has undergone at least 4 recording sessions. In optogenetics-induced seizures, the ictal event is more likely preceded by appearance of fast ripple (250-500Hz) activity, while the spontaneous activity induced by 4-AP and associated with Kv1.1 KO animals are more likely preceded by gamma ripples (40-120Hz) and ripples (120-240Hz). It appears that optogenetics-induced seizures had the hypersynchronous (HYP) onset pattern, while both seizures from Kv1.1 KO animal and seizures induced by 4AP had low-voltage fast (LVF) onset pattern. These findings suggest that different neuronal types may be responsible for these different types of limbic seizures.

Title: Hippocampal GLT1 regulation in the intrahippocampal kainic acid model of epilepsy

Authors: *A. R. PETERSON[1], D. BINDER[2]
[2]Biomed. Sci., [1]Univ. of California, Riverside, Riverside, CA

Abstract: Temporal lobe epilepsy (TLE) is the most common form of epilepsy worldwide. Current antiepileptic drugs (AEDs) primarily target neurons which can lead to cognitive slowing, incoordination and behavioral disorders. Therefore, new drugs for non-neuronal targets are an attractive alternative for the treatment of TLE.
Astrocytes are an essential component of the tripartite synapse playing an important role in the clearance of extracellular glutamate using Na^+-dependent transporters. Glutamate transporter-1 (GLT1) is responsible for the largest proportion of total glutamate clearance. GLT1 is downregulated in various neurological diseases which can lead to glutamate neurotoxicity. Extracellular glutamate homeostasis is essential to decrease neurotoxicity.
Previous results have shown reduced total expression of GLT1 in the hippocampus following an

intrahippocampal kainic acid injection model. Here we aim to characterize expression of GLT1 at the tripartite synapse using crude synaptosomal fractionation. In addition, we hope to investigate the therapeutic capacity of adeno-associated virus type 8 (AAV8)-Gfa2 vectors in the kainic acid model of temporal lobe epilepsy. The ability to increase the expression of GLT1 could attenuate the effects of glutamate neurotoxicity.

Title: Are planarians a useful model organism for high throughput genetic and toxicological investigations of neurodevelopment?

Authors: *S. GUARIGLIA[1], J. GOTIANGCO[2], S. NARVAEZ[3]
[1]New York State Inst. for Basic Reserch, Staten Island, NY; [2]St. Joseph by the Sea High Sch., Staten Island, NY; [3]CUNY Col. of Staten Island, Staten Island, NY

Abstract: Toxicological studies in intact organisms are often time consuming and expensive. Modeling gene and environmental interactions become increasingly complex and take long periods of time to complete. Here, we discuss our work in standardizing high throughput assays to utilize planarians as an alternative model for such investigations. The genome of Schmidtea mediterranea has been characterized and is publically available, which facilitates the capacity of any small lab to create RNAi knockdown organisms using cost-effective commercially synthesized dsRNA constructs to target genes of interest that are introduced by simple feeding with meals. Although transgenic manipulations through feeding can be performed in Caenorhabditis elegans models, planarians offer an additional advantage as they regenerate an entirely new brain after head amputation within seven days, thus expediting neurodevelopmental studies. Furthermore, planarians can be made transparent using RNAi manipulations (albino), thus allowing for studies of cell proliferation, reactive oxygen species production and other manipulations in live animals. In combining these techniques with toxicology, there are endless combinations of genetic and environmental interactions that could be modeled, thus providing the groundwork for more guided studies in higher organisms. Additionally, we have worked to standardize behavioral assays that are robust and highly reproducible using behavioral paradigms from rodents that have been amended to planaria. Such assays include a locomotor assay for hyperactivity and anxiety using the rodent tracking software ANYmaze, an active avoidance memory task in combination with ANYmaze tracking and a three-chambered social, behavioral assay. We have standardized our assays in pharmacologically manipulated models for

hyperactivity using nicotine exposure, and we created scopolamine models for learning and memory. The results of our work provide evidence and highly reproducible protocols for examining cell proliferation and reactive oxygen species generation in intact organisms, as well as protocols for studying behaviors that are important in neurodevelopmental and neurodegenerative studies.

Title: Myeloid-macroglial crosstalk as a motor for optic nerve regeneration

Authors: *I. BOLLAERTS, J. VAN HOUCKE, L. ANDRIES, A. BECKERS, S. VANHUNSEL, L. DE GROEF, L. MOONS
KU Leuven, Leuven, Belgium

Abstract: Appropriate modulation of acute neuroinflammation upon central nervous system (CNS) damage is known to trigger a regenerative response, yet, the underlying cellular and molecular mechanisms remain largely elusive. In contrast to mammals, zebrafish retain high regenerative capacities into adulthood. As such, zebrafish form a powerful model to study the contribution of neuroinflammation to successful regeneration.
Firstly, we characterized the inflammatory response after optic nerve injury in zebrafish, using the transgenic fish lines *Tg(mpeg:GFP)* and *Tg(coro1a:eGFP; lyz:dsRed)*, to label microglia, macrophages and neutrophils. During the regenerative process, a timed induction and resolution of microglia/macrophages was observed in the retina, optic nerve and optic tectum. Secondly, we studied the effect of inflammatory stimulation on the course of optic nerve regeneration. Intravitreal injection of zymosan induced additional retinal inflammation and accelerated tectal reinnervation, as revealed by biocytin tracing. These data indicate that induced acute inflammation can stimulate optic nerve regeneration in fish, similar to what is observed in mammals. Interestingly, we disclosed that inflammatory stimulation also induces macroglial reactivity and proliferation of Müller cells ($GFAP^+/PCNA^+$), in both naive and injured retinas. As such, our data are suggestive for crosstalk between myeloid and macroglial cells in the retina, and it is conceivable that zebrafish Müller glia mediate an important part of the beneficial effect

of inflammatory stimulation to optic nerve regeneration, similar to their mammalian counterparts. We are currently performing pharmacological depletion of microglia/macrophages and/or inhibition of Müller glia, in order to disentangle the interactions between these cell populations, and gain insight into their respective contributions to successful optic nerve regeneration.
Conclusively, our data indicate that inflammatory stimulation is beneficial for optic nerve regrowth in the spontaneously regenerating adult zebrafish, and suggest a role for crosstalk between different neuroglial cell populations herein. Further characterization of the underlying cellular and molecular mechanisms might unveil new targets for the development of novel regenerative strategies in the mammalian CNS.

Title: Inflammatory stimulation as motor for axonal regeneration: Elucidating the underlying cellular and molecular players

Authors: *L. ANDRIES[1], L. DE GROEF[1], M. SALINAS-NAVARRO[1], I. BOLLAERTS[1], K. MOVAHEDI[2], L. MOONS[1]
[1]KU Leuven, Leuven, Belgium; [2]VUB, Brussels, Belgium

Abstract: Despite intensive research, induction of long-distance axonal regeneration and functional recovery of the damaged central nervous system (CNS) remain a challenge. The ever-innovating insights into the dichotomous role of neuroinflammation sprouted the idea that, instead of suppressing the inflammatory machinery, directing and instructing it may be a better therapeutic objective to trigger axonal regrowth. The overarching goal of this project is to unravel the underlying cellular and molecular players that link inflammation to axonal regeneration using optic nerve crush (ONC) (degeneration model) and ONC combined with inflammatory stimulation (IS) (regeneration model).
The responses of resident glia and invading macrophages during neurodegenerative and -regenerative processes are still controversial and insufficiently described. Therefore, we investigated the kinetics and ontogeny of myeloid cell influx in the retina and optic nerve, at

different time points after ONC and ONC+IS, in wild-type and *Cx3Cr1.CreERT2xR26.STOP.YFP* transgenic mice combining flow cytometry and immunohistochemical stainings. From 2dpi onwards, there was a large influx of monocytes, monocyte-derived macrophages (MDMs) and neutrophils after ONC+IS in both tissues, which was not found after ONC. In both injury models, we detected a significant increase in the number of microglia at 6 and 8dpi, but microglia became larger and more internally complex after ONC+IS, a sign of augmented activation. Later time points showed long-term engraftment of the infiltrating inflammatory cells in the microglia population, indicating an altered resident cell population. In addition, we investigated the expression profile of pro- and anti-inflammatory cytokines in the retina and optic nerve after ONC and ONC+IS. In the retina, the expression of TNFα, IFNγ, iNOS, IL-1β, ArgI, IL-10 and Ym1 was upregulated after ONC+IS compared to ONC alone, correlating to the huge influx of inflammatory cells. However, in the optic nerve, these genes, upregulated after ONC, showed a lower expression after ONC+IS compared to ONC only. To further clarify these expression data and disentangle the expression profile of the specific inflammatory cell populations, we are currently performing single-cell RNAseq. We also initiated experiments in *Ccr2*$^{-/-}$ mice to specifically define a role for MDMs in axonal regeneration.
Taken together, these data combined with a comprehensive transcriptomics approach will enable us to pinpoint the inflammatory cell populations and processes that are specific to a pro-regenerative response.

Title: Paracrine effects of multiple sclerosis donor-derived mesenchymal stem cell-neural progenitors (MSC-NP) on glial cells

Authors: G. CARLING, S. ZANKER, S. A. SADIQ, *V. K. HARRIS
Tisch MS Res. Ctr. of New York, New York, NY

Abstract: Multiple sclerosis (MS) is an autoimmune-mediated demyelinating disease of the CNS. Patients with progressive MS experience a steady worsening of neurologic function attributed to chronic demyelination and axonal loss. A novel regenerative therapy utilizing autologous mesenchymal stem cell-derived neural progenitors (MSC-NP) is currently under

clinical investigation in patients with progressive MS. Recent results from a phase I trial demonstrated reversal of established disability after repeated intrathecal MSC-NP injections. Pre-clinical studies suggest that the mechanism of action of MSC-NPs occurs through the paracrine release of trophic and immunomodulatory factors. The objective of this study was to investigate the MSC-NP-associated factors that influence glial cell types in the CNS (microglia, astrocytes, and oligodendrocytes), all of which play a role in the pathogenesis and progression of MS. We utilized an *in vitro*co-culture approach with MS patient bone marrow-derived MSC-NPs (n=5) and the following: (1) M1-polarized BV-2 mouse microglial cells, (2) activated mouse primary astrocytes, and (3) spontaneously differentiated rat neural stem cells (rNSC). The degree of activation or differentiation was determined by quantitative PCR and/or by immunofluorescence, and secreted protein levels were determined by ELISA. We observed a dose-dependent decrease in M1 (Nos2) and increase in M2-specific markers (Arg1) in microglial cells in response to co-culture with MSC-NPs, which correlated with increased release of IL-10 and decreased CCL2. Primary astroglial cells co-cultured with MSC-NPs demonstrated reduced expression of activation markers including GFAP and TNF-alpha. Finally, we found a significant increase in the degree of spontaneous oligodendrocyte differentiation from rNSCs in the presence of MSC-NPs, which correlated with an increase in mature oligodendrocyte markers including PLP, along with an increase in pro-myelinating factors. These results suggest that MSC-NPs promote a beneficial shift in activation and differentiation of glial cells with relevance to MS. These studies form the basis of cell-based potency assays that may be used to better predict the therapeutic efficacy of individual batches of autologous MSC-NPs administered to patients during clinical trials.

Title: An estradiol mediated sensitive period in cerebellar development is disrupted by Poly I:C induced inflammation

Authors: *A. HOLLEY[1], M. M. MCCARTHY[2]
[1]Physiol., Univ. of Maryland Baltimore, Baltimore, MD; [2]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Although the cerebellum is one of the first brain regions to develop, it is one of the last to fully mature. Purkinje neurons, the primary cells of the cerebellum, are present at birth and mature over the first three postnatal weeks, with the second week being particularly important for cytoarchitectural changes. Over the course of their maturation, Purkinje neurons are particularly susceptible and their developmental trajectory can be easily altered by perturbation. Previous work in our lab identified the second postnatal week in the rat as a sensitive period during which there is a natural increase in aromatase expression and estradiol production. Prostaglandin E2 (PGE2) stimulates aromatase expression in the cerebellum and the high levels induced during inflammation results in excessive estradiol within the cerebellum which then stunts Purkinje neuron growth. Both the naturally occurring sensitive period and the magnitude of perturbation are the same in males and females, however enduring consequences are observed in males in the form of a a disruption in social play during the juvenile period, some three weeks later (add reference). We hypothesize that inflammation induced in the second postnatal week is sustained within the cerebellum for several weeks following the initial insult in males and thereby disrupts social play. To test this hypothesis we are treating 2-week old rat pups with poly I:C , a viral mimetic, and measuring the impact on the PGE2-E2 pathway as well as Purkinje neuronal morphology. We used 3 different doses of poly I:C and analyzed both, peripheral and central inflammation at short and long term time points and results will be reported.

Abstract: Dysregulation of the cellular antioxidant response has recently been implicated in inflammatory disorders like multiple sclerosis (MS) and its animal model experimental autoimmune encephalomyelitis (EAE). This pathway is regulated by a family of transcription factors that include the nuclear factor erythroid like-2 proteins (Nrf). One of these factors (Nrf2)

binds to antioxidant response elements (AREs) increasing the transcription of antioxidant and phase II xenobiotic genes, while Nrf1 antagonizes the effects of Nrf2. This study was designed to investigate the role of pro-inflammatory cytokines, present in MS and EAE, on Nrf1 and Nrf2 signaling in an astrocyte cell line. Incubation of astrocytes for 24 h with a combination of interferon γ, interleukin-1β and tumor necrosis factor α (CIII) reduces Nrf2 protein levels by 28% and increases the amount Nrf1 protein by 14%, suggesting an impaired antioxidant response. Indeed, expression of target genes, p62 and GCLc, is diminished in CIII-treated cells, indicating that the decrease in the Nrf2/Nrf1 ratio has functional consequences. We then sought to investigate whether low levels of Nrf2 are caused by increased protein degradation, reduced mRNA translation and/or low transcription. We found that the half-life of Nrf2 protein, measured upon exposure to cycloheximide, in control and CIII-treated cells are identical (~20 min). This is supported by the finding that Nrf2 degradation by the proteasome via Keap1-dependent and GSK-3β dependent mechanisms is not altered in CIII-treated cells. Moreover, in both conditions, Nrf2 protein is localized to the nucleus, with only small amounts present in the cytoplasm. The rate of mRNA translation, determined in the presence of proteasome inhibitors, is unaltered by the cytokine treatment. Furthermore, the proportion of the total Nrf2 mRNA that is bound to polysomes as well as the level of phosphorylated eIF2α, which is involved in cap-independent translation, are unaffected in CIII-treated cells. Finally, we discovered that the relative amount of Nrf2 mRNA, determined by RT-qPCR, is decreased in the CIII condition. Altogether, these studies indicate that the cytokine-induced Nrf2 depletion in astrocytes may result from dysregulation at the transcriptional or post-transcriptional level. Studies are underway to distinguish between these two possibilities. The identification of how cytokines affect the Nrf1/Nrf2 balance in inflammatory conditions is essential for understanding the pathophysiological processes that underlie tissue damage in neuroinflammatory disorders.

Title: Neuroprotective effect of sirt1 in EAE

Authors: *M. I. ARVAS, F. MUBARIZ, A. KATURI, S. ANDHAVARAPU, C. BEVER, Jr., T. MAKAR
Neurol., Univ. of Maryland, Baltimore, MD

Abstract: Multiple sclerosis (MS) is a chronic and inflammatory, demyelinating disease associated with axonal loss and gliosis of the central nervous system (CNS). This study aimed to investigate the effect of Sirt1, a NAD linked enzyme on mice with experimental autoimmune encephalomyelitis (EAE), a widely used MS model, and its potential mechanism underlying the action of anti-oxidative stress. Female C57BL/6 Sirt1 neuron specific overexpressing mice were injected with MOG35-55 peptide to set up the EAE model, and to detect the effect of Sirt1 on the progression of EAE. A total of 24 female C57Bl/6 mice were randomized to a control group (N = 6) or EAE (N = 10) and Sirt1 overexpressing EAE mice (N=10). All the mice were sacrificed 30 days (endpoint) after EAE induction. EAE severity score was observed using EAE scale and myelin content was assessed by immunostaining for MBP and Luxol fast blue, lymphocyte and monocyte infiltration and Sirt1 expression. Furthermore, through the immunohistochemical approaches; the potential molecular mechanism of Sirt1 on EAE was evaluated as the levels of oxidative stress and the expression of (nuclear factor erythroid 2-related factor 2) Nrf2 /HO-1 (heme oxygenase-1) signal pathway. Nrf2 regulates HO-1 gene in several cell types. HO-1, a member of inducible cytoprotective protein family regulated by Keap1/Nrf2/ARE pathway, and small molecular antioxidants such as glutathione provide the cell powerful means to counteract oxidative stress. Our experiments showed a change of oxidative stress and Nrf2/HO-1 pathway expression in normal control group, only EAE group and Sirt1 over expressing EAE group, demonstrating that oxidative stress is associated with the pathophysiology of EAE and Sirt1 suppresses oxidative stress by upregulating Nrf2/HO-1 signaling. The overexpression of Sirt1 exerts neuroprotective effects against EAE, notably in suppressing the progression of EAE and pathological changes, cellular infiltration, inflammation, neuronal loss and demyelination. Furthermore, the effect of Sirt1 was probably related to decrease of the levels of oxidative stress, by activation of Nrf2 and increased levels of anti-oxidant enzymes HO-1 and Catalase expression. Therefore, the present study suggests that Sirt1 possesses significant protective effects against in vivo oxidative stress in EAE. So, Sirt1 may be a promising target for developing MS drugs.

Title: Inhibition of autophagosome-lysosome fusion by ginsenoside Rk1 induces apoptosis in neuroblastoma cells

Authors: *J. OH[1], S. CHUN[2]
[2]Physiol., [1]Chonbuk Natl. Univ. Med. Sch., Jeonju, Korea, Republic of

Abstract: Autophagy can results in cellular adaptation, as well as cell survival or cell death. Modulation of autophagy has been increasing regared as a promising cancer therapeutic approach. In this study, we screenced several ginsenosides extracted from *Panax ginseng* and showed that Rk1 inhibit late stage autophagy (autophagosome and lysosome), possibly through changes in autophagy regulator protein expression. Rk1 treatment dose dependently increased the p62 protein expression and GFP-LC3. Also, Autophagy flux inhibitor, chloroquine treatment further enhanced the effect of Rk1 induced apoptosis. These results suggest that minor ginsenosides Rk1 is a novel autophagy inhibitor and could function as a potent anti-cancer agent, and that combination therapy with classical chemotherapeutic drugs might be promising compounds to have therapeutic effect on neuroblastoma cell lines.

Title: Adult neurogenesis in the dentate gyrus induced by minor ginsenoside compound K

Authors: *S.-H. YU[1,2], S. CHUN[1]
[1]Dept. of Physiol., [2]BrainKorea21 PLUS, Chonbuk Natl. Univ. Med. Sch., Jeonju-si, Korea, Republic of

Abstract: Adult neurogenesis, a process of generation of new neurons in adulthood, occurs in both subventricular zone and dentate gyrus. Adding new neurons into the dentate gyrus has been linked to learning and memory, and it can be influenced by stress, exercise, and others. It is reported to be reduced in several neurodegenerative disorders including Alzheimer's disease

(AD). Therefore, it might be great value to identify positive regulator of adult neurogenesis. Ginsenosides, one of natural products, have been known to have anti-cancer, anti-metastatic, anti-inflammatory and neuroprotective effects without cell toxicity. In addition, major ginsenoside Rb1 have been known to promote neurogenesis in DG, but the effect of minor ginsenosides is still unknown. Here, we injected Compound K (CK), one of minor ginsenosides, to aged mice intraperitoneally during 5 days (30mg/kg per day). Then mice were injected with BrdU (50mg/kg per day) during 3 days and sacrificed. Through the immunohistochemistry (IHC) method, we examined whether CK enhance the proliferation of newly generated progenitor cells in the granular zone (SGZ) of the adult hippocampus or not. As a result, we found that the number of $BrdU^+/GFAP^+$, $BrdU^+/Ki\text{-}67^+$, $BrdU^+/DCX^+$ cells in the SGZ was increased compared to control. These findings suggest that ginsenoside CK can be used as a positive regulator of adult neurogenesis in the SGZ and this effect could be used as one of tolerable agents underlying its anti-aging actions.

Title: Minor ginsenoside promotes strongly progenitor cell proliferation in the dentate gyrus of hippocampus

Authors: *B. KIM[1,2], S. CHUN[1]
[1]Dept. of Physiol., [2]BrainKorea21 PLUS, Chonbuk Natl. Univ. Med. Sch., Jeonju-si, Korea, Republic of

Abstract: Adult neurogenesis is the adding process of new neurons from neural stem cells at the dentate gyrus in hippocampus and the subventricular zone in striatum. It consists of several stages including stem cell proliferation, differentiation, migration and integration. During aging, newly generated neurons continuously decline in most mammals, and it causes the weakness of neuronal plasticity and loss of cognitive memory. Recent studies suggest that promoting neurogenesis in adult mammalian brain might provide a therapeutic way to treat aging-induced neurodegenerative disease such as Alzheimer's disease. Therefore, it might be great value to

identify positive regulators which can increase the proliferation of new neurons in the hippocampus. There are some natural products regarded as regulators for adult neurogenesis. Among them we investigated the effect of minor ginsenoside Rh2, extracted from Korean ginseng, on proliferation of neural progenitor cells. Intraperitoneal Rh2 (30mg/kg) administration to aged mice (4-month old) led to enhance newly generated progenitor cells in the dentate gyrus. Rh2 injection (3 times a week) resulted in increased the number of $BrdU^+/GFAP^+$, $BrdU^+/PCNA^+$, $BrdU^+/DCX^+$ cells compared to control mice. These findings suggest that ginsenoside Rh2 can be used as a regulator of progenitor cells proliferation in the hippocampus and this effect could be used as one of non-toxic methods underlying its anti-aging actions.

Title: Modulating microglial phenotypes via colony stimulating factor-1 receptor (CSF1R) inhibition for therapeutic benefit in multiple sclerosis

Authors: *N. A. HAGAN, L. WOODWORTH, A. MAHAN, M. ZELIC, D. OFENGEIM
Neurosci., Sanofi, Framingham, MA

Abstract: Microglia serve as the innate immune cells of the central nervous system (CNS) by providing continuous surveillance of the CNS microenvironment and initiating defense mechanisms to protect CNS tissue. Upon injury, microglia transition into an activated state altering their transcriptional profile, transforming their cell morphology, and producing pro-inflammatory cytokines. These activated microglia initially serve a beneficial role, but their continued activation drives neuroinflammation and neurodegeneration. Multiple sclerosis (MS) is a chronic, inflammatory, demyelinating disease of the CNS and activated microglia and macrophages play a significant role in mediating disease pathophysiology and progression. We hypothesize that modulating microglia and infiltrating macrophages through the inhibition of a class III receptor tyrosine kinase, colony stimulating factor-1 receptor (CSF1R) will attenuate deleterious CNS inflammation and inhibit subsequent demyelination and neurodegeneration. In our human credentialing experiments, we observed an increase in CSF1R signaling components in CNS tissue derived from MS patients. This finding provided sufficient rationale to generate a novel CSF1R inhibitor for preclinical testing. *In vitro* assays utilizing primary microglia and macrophages demonstrated that our CSF1R inhibitor successfully blocked receptor phosphorylation and downstream signaling and ultimately altered cytokine production. *In vivo*,

our CSF1R inhibitor decidedly improved the neurological impairments observed in the MOG peptide-induced experimental autoimmune encephalomyelitis model of secondary progressive MS (NOD-EAE). Together, these data suggest that CSF1R inhibition should be explored further as a strategy to modulate microglia phenotypes in the context of neuroinflammation and for therapeutic use in MS.

Title: Epigenetics of Cpt1, the key gene in the new paradigm of multiple sclerosis pathogenesis

Authors: *J. LICHOTA, K. JØNSSON, J. D. NIELAND
Dept. of Hlth. Sci. and Technol., Aalborg Univ., Aalborg Ost, Denmark

Abstract: Multiple Sclerosis (MS) is a disabling and multifactorial disease of the central nervous system (CNS), characterized by degradation of the myelin sheath surrounding the axons, followed by neurological symptoms, such as vertigo, loss of vision, tremor, weakness, and spasms. MS is characterized as an autoimmune disease that is affected by both molecular mimicry and bystander activation. In MS, the blood brain barrier (BBB) is disrupted. One of the major factors contributing to MS symptom development is demyelination of neurons. Demyelination of neurons might be caused by an autoimmune reaction, although it is tempting to speculate in a link between fatty acid metabolism and demyelination or remyelination of neurons. One of the major players in fatty acid metabolism is the rate limiting enzyme carnitine palmitoyl transferase 1 (CPT1). It was demonstrated, that blockage of CPT1 reduces both disease severity and demyelination in a mouse EAE model. Hence, CPT1 and fatty acid metabolism might play a role in the development of the disease. The regulation of Cpt1 genes and the mechanism behind the possible increased expression of Cpt1 in MS patients is yet unknown. We present the evidence that Cpt1 a and c genes are epigenetically regulated, thus presenting an attractive target for pharmaceutical intervention.

Title: Novel molecular marker DJ-1 indicates role in cognitive dysfunction in multiple sclerosis

Authors: N. FAVRET, *A. IACOANGELI, S. A. SADIQ
Tisch MS Res. Ctr., New York, NY

Abstract: DJ-1 is a key protein associated with mitophagy processes and mitochondrial dysfunctions. Acting as a redox-sensitive protein, DJ-1 promotes neuroprotection by translocating to the mitochondrial membrane upon oxidative stress. DJ-1 has been linked to early onset and progression of Parkinson's disease, a neurodegenerative disease that frequently leads to cognitive impairment. Patients with multiple sclerosis (MS) will also often experience cognitive impairment including deficits in attention, memory and executive functions. We hypothesized that dysregulation of DJ-1 led to cognitive impairment in MS, and specifically examined whether this protein was involved in severe cognitive dysfunction (SCD) of MS patients. We also investigated whether neuronal DJ-1 was translocated to the mitochondrial membrane after a stress paradigm, using cerebrospinal fluid (CSF) from MS patients. With immunoblotting and ELISA techniques, we quantified levels of DJ-1 in CSF samples of (1) subjects with no MS, (2) MS patients without cognitive dysfunction, and (3) MS patients with SCD. Moreover, using a xenogeneic approach, we applied CSF samples from these three groups to hippocampal neurons in culture and assessed DJ-1 relocalization to the outer membrane of mitochondria. Our results revealed that, compared to the unaffected control group, the levels of DJ-1 were significantly reduced in CSF samples of MS patients with SCD. There was no significant reduction of DJ-1 levels between CSF from MS patients without SCD and CSF from the control group. At the cellular level, we observed that in neurons, after oxidative stress-inducing treatments with CSF of MS patients, DJ-1 was localized to the mitochondrial membrane.These results identified DJ-1 as a promising molecular marker of cognitive impairment in MS patients. Furthermore, the translocation of DJ-1 to the mitochondrial membrane occurring in neuronal cultures exposed to CSF from MS patients suggested that this protein may play a role in mitochondrial homeostasis and dysfunction in neurons of MS patients.

Title: β-Chemokine Ccl5 deficiency preserves retinal ganglion cells in a murine model of optic neuropathy

Authors: *R. L. WEINER[1], W. M. MCLAUGHLIN[2], M. G. DUBNER[2], C. R. FORMICHELLA[2], R. M. SAPPINGTON[1,2,3]
[1]Dept. of Pharmacol., Vanderbilt Univ., Nashville, TN; [2]Vanderbilt Eye Inst., [3]Dept. of Ophthalmology and Visual Sci., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Proinflammatory chemokine, CCL5 (C-C motif ligand 5), is constitutively expressed in retina and is associated with inflammatory and neuroprotective responses in diseases such as HIV-dementia, Alzheimer's Disease and Multiple Sclerosis. As in other neurodegenerative disorders, CCL5 and its receptors are differentially expressed in a murine model of chronic retinal ganglion cell (RGC) degeneration. Here we examined the role of CCL5 signaling in an inducible model of RGC degeneration. We induced unilateral glaucoma for 6 weeks in age-matched, 8 month old C57Bl/6 (WT) and ccl5-/- mice, using the Microbead Occlusion Model. Intraocular pressure (IOP) was monitored by tonometry. To assess RGC degeneration, we quantified axon transport facility and RGC soma and axon structure in both the retina and optic nerve. To determine how Ccl5 signaling may impact these disease outcomes, we quantified expression of Ccl5 and its high affinity receptors CCR3 and CCR5 as well as key elements of the downstream signal transduction pathways. We found that Ccl5 deficiency did not alter baseline or experimental IOP (22-25% increase), as compared to WT mice ($p>0.05$ for both). In WT mice, elevated IOP resulted in a 28-36% decrease in Brn3a+ RGCs in the retina and RGC axons in the optic nerve ($p<0.05$), as compared to saline-injected controls. In ccl5-/- mice, the density of RGC soma and axons did not differ between saline- and microbead-injected eyes ($p>0.05$). Immunohistochemistry also revealed reorganization of beta-tubulin+ processes in the inner plexiform layer of microbead-injected WT mice. This reorganization was significantly less appreciable in microbead-injected ccl5-/- mice. Anterograde transport of the neural tracer cholera toxin beta subunit (CTB) to the superior colliculus decreased by almost 40% in WT mice six

weeks after IOP elevation ($p<0.01$), but not in ccl5-/- mice ($p>0.05$). IOP-dependent pathology noted in WT mice was accompanied by increased expression of pro-apoptotic mediators FADD and Bax and downregulation of anti-apoptotic mediator Bcl-2. CCR5 anti-apoptotic activities are linked to AKT/PI3K and MEK/ERK activity. This is also downregulated in the Microbead Occlusion Model with the exception of MEK which is significantly increased ($p<0.01$) as determined by RNAseq mRNA expression. These data implicate Ccl5 as a potential therapeutic target in retinal ganglion cell degeneration. However, further analysis of downstream signaling and differential receptor activity is needed to understand Ccl5/CCR5 and Ccl5/CCR3 roles in inflammation and neurodegeneration.

Title: GABAergic synapses and tonic inhibition are upregulated by the HIV protein gp120 via pathways that diverge downstream of the interleukin-1 receptor

Authors: *M. GREEN[1], X. ZHANG[2], S. A. THAYER[3]
[1]Univ. of Minnesota, Minneapolis, MN; [2]Pharmacol., Univ. of Minneasota, Minneapolis, MN; [3]Dept Pharmacol., Univ. of Minnesota Med. Sch., Minneapolis, MN

Abstract: Inhibitory signaling is altered in many neurodegenerative diseases and is upregulated in models of neuroinflammation. Here, we show how the inflammatory HIV envelope protein gp120 upregulates two types of GABAergic inhibition in neurons via microglial release of interleukin-1beta (IL-1β). Tonic inhibition produced by extrasynaptic GABARs was measured using patch clamp electrophysiology to record bicuculline-sensitive shifts in holding current. The number of inhibitory synapses were quantified by counting fluorescent puncta labelled with a GFP-tagged intrabody targeting the scaffolding protein gephyrin. Both types of inhibition increased following exposure to gp120 by a mechanism dependent on microglial release of IL-1β and activation of the IL-1 receptor (IL-1R) on neurons. However downstream of the IL-1R the mechanisms diverged. The increase in the number of inhibitory synapses was dependent on Src activation of GluN2A-containing NMDARs and protein synthesis. This is likely an activity dependent change in synaptic function that may be a homeostatic scaling response to compensate for the excitotoxic effects of gp120. However, the increase in tonic inhibition during exposure to gp120 was not dependent on these signaling steps and resulted from the activation of p38. Thus,

these two types of inhibition were regulated through a mechanism that was dependent on microglial activation and diverged downstream of the IL-1R. The viral protein HIV gp120 likely plays a role in HIV-associated neurocognitive disorders (HAND) which affect nearly half of the 37 million patients with HIV. There is no current treatment available. Importantly, we found that the increase in the extrasynaptic tonic current following exposure to gp120 was due to α5-containing GABARs selectively. Drugs that target the α5-containing GABARs are well tolerated and have been shown to rescue cognitive function in other models of neurodegenerative disease. Additionally, these drugs do not affect synaptic inhibition, thus sparing what may be a homeostatic response. Understanding the mechanisms that regulate distinct populations of GABARs following neuroinflammation may guide selective therapeutic agents to better target the inhibitory system. Extrasynaptic GABARs may be a promising target for the treatment of HAND.

Title: Antiviral acute phase response induces neuronal generation of the chemokine CXCL10 in the hippocampus and cortex

Authors: *T. J. PETRISKO, G. W. KONAT
Biochem., West Virginia Univ., Morgantown, WV

Abstract: Peripheral viral infections are known co-morbid factors for major neuropathological conditions. Additionally, peripheral infections can exacerbate these conditions. We are able to mimic this comorbidity in a murine model by inducing an antiviral acute phase response (APR) to the dsRNA viral mimetic polyinosinic: polycytidylic acid (PIC) via injection into the intraperitoneal (i.p.) cavity of mice. Previous analysis demonstrated that PIC renders the brain hypersusceptible to kainic acid (KA)- induced seizures and increases basal synaptic transmission in the hippocampus, the ictal site of KA-induced seizures. At the molecular level, PIC challenge results in hippocampal production of the chemokine CXCL10, a known modulator of neuronal activity. The aim of the current study was to identify cells that generate CXCL10 in response to a

peripheral PIC challenge. Eight-week-old female C57BL/6 mice were i.p. injected with 12 mg/kg of PIC and the brains were analyzed with confocal microscopy using CXCL10 and cell specific antibodies to label neurons (NeuN), astrocytes (GFAP), and microglia (Iba1). 24 hours after PIC injection, intense CXCL10 staining was was observed in the neuronal perikarya of the hippocampus. A strong CXCL10 stain was also evident in some, but not all, astrocytes. Microglia did not express CXCL10, but did undergo hypertrophy. Additionally, the number of microglia cell bodies present in the visual field was increased at 24 compared to control brains, indicating migration of microglia toward neuronal cell bodies. The same features were observed in the cortex. Based on these results, we hypothesize that CXCL10 secreted from neurons in response to an antiviral APR recruits microglia to home onto neuronal cell bodies and uncouple inhibitory axosomatic synapses, leading to hyperexcitability of the neuronal circuitry. The augmentation of neuronal hyperexcitability by the APR may underlie the observed exacerbations in neuropathologies accompanied by peripheral infections.

Title: Neurobehavioral and immunohistochemical alterations in immunocompetent mice with congenital zika virus infection

Authors: *P. J. VIG[1], A. PAUL[2], M. LOPEZ[1], B. NEUPANE[3], F. BAI[3]
[1]Neurol., Univ. Mississippi Med. Ctr., Jackson, MS; [2]NASA Ames Res. Ctr., Moffett Field, CA; [3]Univ. of Southern Mississippi, Hattiesburg, MS

Abstract: Zika virus (ZIKV) infection during pregnancy can result in a spectrum of neurodevelopmental defects including vision and hearing loss, seizures, and microcephaly. Recent reports indicate that congenital ZIKV infection could manifest as more subtle cognitive and/or behavioral effects in children who were seemingly unaffected at infancy. However, it may take years before such effects could be well-documented in humans. In the present study we used an immunocompetent model of congenital ZIKV infection in which pregnant wild-type mice are

infected (ip) with ZIKV. To determine if these postnatal deficits were associated with neuron function, we assessed various neurodevelopmental behaviors in ZIKV- and mock-pups. These assessments included balance, motor coordination, forelimb strength, and cognitive development. The results showed that the ZIKV-pups exhibited poor balancing skills and weak fore-limb strength, along with a significant increase in passivity, decrease in locomotion, and cognitive memory decline compared to mock-pups at selected time points. In addition, immunostaining of midsagittal brain sections showed cellular disarrangement and a thinner cortical layer 1 in the brains of ZIKV-pups at D19, a feature associated with microcephaly in human babies. Apart from cortical layer 1 thinness in ZIKV-pups at D40, the density of neurons within L1-6 of the cortex were also reduced. Furthermore, midsagittal brain sections were immunostained with GFAP to identify astrogliosis, a hallmark feature of human and mouse newborns with microcephaly. The GFAP immunostaining exhibited progressive astrogliosis near CA1 neurons of the hippocampus and within the white matter of the cerebellum of ZIKV-pups at D12, D19 and D60, along with enlarged astrocytes surrounding motor neurons within cervical spinal cords, while only minimal reactivity to GFAP was detected in these regions in mock-pups. Reactive astrogliosis in the hippocampus and cerebellum has been linked to defective memory and motor coordination in mice, which were observed in our behavioral studies of ZIKV-pups. Collectively, these observations suggest that a transient and mild ZIKV infection in immunocompetent mice during pregnancy could cause postnatal brain developmental deficits, providing a novel animal model to study congenital ZIKV syndrome.

Abstract: Trigeminal lesions, dysfunction and sensory disturbances (e.g. hypoesthesia, pain) are well-recognized, but poorly understood, complications of Multiple Sclerosis (MS). We have previously shown that the animal model experimental autoimmune encephalomyelitis (EAE)

could be a useful tool for understanding MS-related trigeminal pathology and dysfunction. In particular, we found that mice with EAE exhibit facial hypersensitivity as well as inflammation and demyelination at several points along the trigeminal primary afferent pathway. The objective of this study was to further investigate EAE-related changes to the trigeminal primary afferent pathway. We show here that in mice with EAE, immunoreactivity (IR) for amyloid precursor protein (APP), a marker of axonal injury, increases significantly at the trigeminal root entry zone (TREZ) (B, E in Image 1). Interestingly, APP-IR is entirely restricted to the central nervous system (CNS) aspect of the TREZ. Additionally, APP-IR only appears in sections where glial fibrilary acidic protein (GFAP)-IR is disrupted (A, D in Image 1). Preliminary comparisons between sexes suggest that GFAP disruption and APP-IR is significantly greater in female mice. Preliminary data also suggest that APP-IR at the TREZ is not related to the presence of reactive microglia/macrophages or T cells in both sexes. In contrast to previous studies that have used APP as a marker for axonal injury, we do not find that APP co-localizes with the pan-axonal markers SMI-311 or SMI-312. We do however find that APP colocalizes with damaged myelin as well as oligodendrocytes. We are currently examining how GFAP disruption and APP-IR at the TREZ relates to facial sensitivity in mice with EAE. We are also assessing the relationship between APP and GFAP in the brainstem regions involved in trigeminal processing. In summary, we have extended our previous findings to show that disruption of GFAP at the TREZ is associated with the presence of APP in mice with EAE. Taken together, our data suggest that TREZ astrocytes are protective in an inflammatory demyelinating environment.

Title: GP91 deficiency ameliorates oxidative stress associated neural damage and dysfunction in an experimental autoimmune encephalomyelitis mouse model

Authors: *C.-F. HU[1], S.-J. CHEN, Senior[2], J.-S. HONG[3]
[1]Pediatric Dept., Tri-Service Gen. Hosp., Taipei, Taiwan; [2]Pediatric department, Tri-Service Gen. Hosp., Taipei City, Taiwan; [3]NIEHS, Rtp, NC

Abstract: The roles of reactive oxygen species (ROS) contributing to the pathogenesis of experimental autoimmune encephalomyelitis (EAE) is not yet totally understood. Recent strategies of multiple sclerosis treatment center on T cell based interventions that work successfully on a subset of patients. In this study, we focus roles of innate immunity in the pathogenesis of EAE. We hypothesized that dysregulated ROS production by both macrophage and microglial NADPH oxidase (NOX2) contributes to neural inflammation, damage and demyelination after EAE induction.
We found that *Nox2* deficient mice are more resistant to EAE induced neural damage compared with control mice (C57). *Nox2* deficiency results in reduced disease severity scores, less body weight loss, less leukocytes infiltration, lower grades of demyelination, decreased oxidative stress markers 3-NT , and lower levels of genes encoded for proinflammatory cytokines IL-1beta, IL-4, IL-6, IL- 17α, IFNɣ and TNFα as well as T cell regulatory cytokines and T cell regulatory factors IL-10 and TGFβ in the spinal cords in comparison with control. Our findings suggest that NOX2-mediated ROS in macrophage and microglia plays an important role in EAE-induced neuronal damage. Roles of NOX2 in macrophage and microglia in the pathogenesis of EAE are being investigated using a various of NOX2 inhibitors. Further studies on the function of dendritic cells and macrophages in *Nox2* deficient mice after EAE induction.

Title: Potential role of estrogen in maintaining the proNGF/NGF and Bax/Bcl2 ratio in hippocampus of aged female rat

Authors: *P. KUMAR[1], P. KAUSHAL[2], P. DHAR[3]
[1]Anat., AIIMS, New Delhi, India; [2]Anat., All India Inst. of Med. Sciecnes, New Delhi, India; [3]Anat., All India Inst. of Med. Sci., New Delhi, India

Abstract: Immunosenescence contributes to the cascade of events leading to neurodegeneration in old age. Immune system undergoes a dynamic change induced by declining levels of estrogen in women during age progression. The dynamic changes in different brain areas including hippocampus might be associated with the progressive decline of estrogen in females as decreased levels of estrogen are reported to alter nerve growth factor status in the hippocampus. ProNGF contributes in activating inflammatory pathway and increasing the production of inflammatory cytokines (Minnone G. et al., 2018). Our aim was to study the role of estrogen on proNGF/NGF and Bax/Bcl2 ratio, expression of the complement system and the status of pro and anti-inflammatory cytokines in female rat hippocampus during age progression. Immunohistochemistry and Western blot techniques were used for proteomic analysis. The observations revealed altered levels of ERs, proNGF/NGF and Bax/Bcl2 ratio, microglial and astrocytes activation, expression of complement proteins and pro- and anti-inflammatory cytokines, decreased synaptic activity, in the hippocampus of middle-aged and aged female rats. Long-term estrogen (E2, 17β estradiol) and tamoxifen (TAM) therapy to these animals could maintain synaptic plasticity (synaptophysin) and regulate microglial and astrocytes activity, nerve growth factor and Bax/Bcl2, complement proteins and pro-inflammatory cytokines. Taken together, these data indicate that estrogen and SERM act as potent modulators in maintaining proNGF/NGF and Bax/Bcl2 balance in the hippocampus of the aging rat, thereby highlighting the multi-faceted regulatory effects of exogenous estrogen and SERM.
(National Postdoctoral Fellow award (PDF/2016/000060) from Department of Science and Technology, Government of India.
Our study add a new perspective to the neuroprotective and neuromodulatory effects of estrogen based on its role in complement system and pro-inflammatory cytokines on one hand and modulation of apoptosis associated proteins on the other.

Title: Environmental enrichment benefit on visual pathway damage induced by neurinflammation of the optic nerve

Authors: *M. L. ARANDA[1], M. F. GONZALEZ FLEITAS[1], P. H. SANDE[1], D. DORFMAN[2], R. E. ROSENSTEIN[3]

Abstract: Optic neuritis (ON) is an inflammatory, demyelinating, neurodegenerative, and presently untreatable condition of the optic nerve which might induce blindness. We analyzed the effect of environmental enrichment (EE) on visual pathway damage provoked by experimental ON induced by a microinjection of bacterial lipopolysaccharide (LPS) into the optic nerve. For this purpose, LPS was microinjected into the optic nerve from male Wistar rats. After injection, one group of animals was submitted to EE, and another group remained in standard environment (SE) for 21 days. EE prevented the decrease in pupil light reflex (PLR), visual evoked potentials, retinal anterograde transport, phosphorylated neurofilament immunoreactivity, myelination (luxol fast blue staining), and axon (toluidine blue staining) and retinal ganglion cell (Brn3a-immunoreactivity) number. EE also prevented microglial/macrophage reactivity (Iba-1- and ED1-immunoreactivity), and astrocytosis (glial fibrillary acidic protein-immunostaining) induced by experimental ON. LPS-injected optic nerves displayed oxidative damage and increased inducible nitric oxide synthase, cyclooxygenase-2, and interleukin-1b and TNFa mRNA levels which were prevented by EE at 1 day pos-injection. EE increased optic nerve brain-derived neurotrophic factor levels. When EE started at 4 (but not 7) days post-injection of LPS, a preservation of the PLR was observed at 21 days post-LPS, which was blocked by the daily administration of ANA-12 (a Trk-b antagonist) from day 4 to day 7 post-LPS. Moreover, EE from day 4 to day 7 post-LPS significantly

preserved the PLR at 21 days post-injection. Taken together, our data suggest that EE preserved visual functions and reduced neuroinflammation of the optic nerve.

Service, Hôpital St. Antoine-HUEP, Paris, France

Abstract: Multiple sclerosis (MS) is a neurological disease in which immune cells invade the central nervous system and destroy myelin. A regenerative process, called remyelination, can occur. The extent and efficacy of remyelination is highly variable among patients but efficient remyelination is critical for a favorable disease evolution. Macrophages contribute to demyelination but also orchestrate the remyelination process, and their role in each process depends on their phenotype, or “activation state”, achieved in response to external signals. We hypothesize that a failure in remyelination in patients could be caused by a dysregulated macrophage function, possibly due to intrinsic capacities of macrophages to correctly respond to

signals.
To test this hypothesis, CD14+ monocytes from MS patients and healthy controls (HC) were differentiated into macrophages. After applying for 24h or 72h pro-inflammatory (LPS and IFNγ) or pro-regenerative (IL-4 or IFNβ) stimuli, we evaluated macrophage (dys-) functionality in different steps essential for efficient myelin repair: their phagocytic capacities when exposed to human myelin and their effect on oligodendrocyte precursor cells (OPC) proliferation and differentiation. In parallel, we established their transcriptomic (RNA sequencing) and secretory profile (Luminex assays).
Our preliminary results provide evidence that among MS patients, there are deficits in macrophages function that appear to be patient specific. For example, macrophages of some patients exhibited a deficit in phagocytic activity in response to pro-regenerative stimuli. At the transcriptomic level, principal component analysis separated transcriptomes of patient samples from controls across all activation states. Among genes differentially expressed between patients and controls, a significant number are involved in molecular pathways important for the pro-regenerative activation state. We next plan to correlate macrophages functionality to specific transcriptomic signatures and identify which molecular pathways to correct in order to steer macrophages biological networks into a specific regenerative state.
Our results highlight a dysfunction in MS patient monocytes, before encountering the inflammatory environment of an MS lesion that might affect their capacity to instruct the remyelination process. In a translational step, we will also include in our analysis patients genotype and clinical data in order to create a full model describing how different defects in macrophage activation can influence the disease course.

Title: Effect of anti-VEGF treatment on the innate immune response in a mouse model of multiple sclerosis

Authors: *C. CARAVAGNA[1,2,3,4], A. JAOUËN[1,2,3,4], G. ROUGON[1,2,3,4], F. DEBARBIEUX[1,2,3,4]

Abstract: Multiple sclerosis is an inflammatory disease, characterized by infiltration of immune cells into the central nervous system leading to myelin and axonal damages. Although this disease was previously thought to be led by adaptive immune cells, e.g. T cells, recent findings lead us to focus on innate immune cells, such as monocytes, neutrophils and microglial cells. We used Thy1-CFP/LysM-EGFP/CD11c-EYFP triple transgenic mice induced for EAE. In these mice Thy1-CFP is expressed by axons, LysM-EGFP by peripheral innate immune cells, CD11c-EYFP by activated microglial cells and both LysM-EGFP and CD11c-EYFP by monocyte-derived dendritic cells. These markers allowed us to precisely study the spatial and temporal recruitment of these cells in the spinal cord of EAE mice, in relation with axonal loss and clinical signs. First on day 10 after induction, EGFP neutrophils and monocytes invade the meninges, then (day 13) they enter into the spinal cord parenchyma through the meninges, rather than by extravasion. Axonal losses occur in the white matter concomitantly with immune cell infiltration. Once in the parenchyma, monocytes mature into EGFP/EYFP monocyte-derived dendritic cells whose density is maximal on day 17 when the axonal degradation and clinical signs stabilize. Meanwhile, microglia is progressively activated in the entire spinal cord and subsequently recruited to plaques. As a direct effect of VEGF on immune cell has been demonstrated in other diseases, we examined the effects of VEGF blockade (with bevacizumab) on the innate immune response in triple fluorescent EAE mice. In animals treated with bevacizumab from disease onset, we found no significant difference in the numbers of fluorescent cells recruited to the spinal cord, compared to controls. We are now focussing on the phenotypes and movements of these cells.

Title: Granulocyte-macrophage colony-stimulating factor (GM-CSF) improves mouse peripheral nerve regeneration following axotomy

Authors: *A. L. BOMBEIRO, B. T. N. PEREIRA, A. L. R. OLIVEIRA
Dept. of Structural and Functional Biol., Univ. of Campinas, Campinas, Brazil

Abstract: Peripheral nerve injuries severely impair the life quality of the patient since full recovery is seldom achieved. Upon axonal disruption, distal nerve stump undergoes fragmentation and myelin breaks down, being regeneration progression dependent on cell debris removal. Besides tissue clearance, macrophages release angiogenic and neurotrophic factors that contribute to axon growth. Based on the importance of macrophages for nerve regeneration, especially during the initial response to injury, we stimulated the proliferation and infiltration of those cells in the sciatic nerve by treating male mice with granulocyte-macrophage colony-stimulating factor (GM-CSF, 50 μg/Kg) or PBS (control) at zero, 24h and 48h following nerve crushing. Sciatic nerves were histologically analyzed (3, 7, 14 and 28 days; n=5/group/day) regarding the presence of macrophages and the regenerative stage, being intact nerves (n=5) used as the baseline control. Functional recovery was followed up by an automated walking track test (CatWalk system, Noldus). According to our data, GM-CSF potentiated early axon growth, as evidenced by the enhanced expression of growth-associated protein (GAP-43) at 7 days post-injury (83% more than PBS, $P < 0.05$). Inducible nitric oxide synthase (iNOS) expression increased in the beginning and at the end of the regenerative process for both PBS and GM-CSF groups, suggesting nitric oxide is involved in axon growth and pruning. As expected, GM-CSF treatment stimulated macrophage infiltration, which was increased at 7 days (60% more than PBS, $P < 0.0001$) and 14 days (23% more than PBS, $P < 0.01$). Curiously, myelin quantification revealed no difference between PBS and GM-CSF groups at any of the analyzed time points. However, GM-CSF anticipated in one week the brain-derived neurotrophic factor (BDNF) production peak, which occurred at 7 days (56% more than PBS, $P < 0.0001$). Ambulation recovery pattern was not improved by GM-CSF treatment. Overall, the present results indicate that GM-CSF has beneficial effects on early axon regeneration, and its use brings new perspectives regarding PNS regeneration.

Title: The regulatory effect of a multiple sclerosis drug candidate on macrophages

Authors: B. LIN, B. KOFFMAN, *J. DU
Univ. of Toledo, Toledo, OH

Abstract: Multiple sclerosis (MS) is a central nervous system (CNS) disease in which the myelin sheath in brain and spinal cord is damaged. This damage disrupts the communications network resulting in physical, mental, and/or psychiatric problems. Pathogenesis of MS involves autoreactive T cells and pro-inflammatory macrophages (e.g. monocyte-derived macrophages and microglia). We previously reported that BBR3378, a novel aza-anthrapyrazole structurally similar to an FDA-approved MS drug mitoxantrone, can ameliorate experimental autoimmune encephalomyelitis (EAE), a clinically relevant mouse model of MS, without cardiotoxic effects often associated with this family of drugs (i.e. anthracyclines). BBR3378 inhibited production of the pro-inflammatory cytokine IFN-γ both in recently activated T cell blasts and established Th1 effectors via suppressing T-bet regulated gene expression, while sparing the activities of IL-13-producing Th2 cells. In this study, the effect of BBR3378 on macrophages was investigated. BBR3378 inhibited cell proliferation of human brain microglia HMC3 in a concentration-dependent manner (IC_{50}: 429.5 ng/ml), demonstrated by MTT cell viability assays, and 8h treatment of BBR3378 (100 ng/ml) reduced expression of CD68, a typical marker of activated macrophage, as quantified by qRT PCR. Compared to mouse fibroblast L292 (IC_{50}>1000 ng/ml), mouse macrophage RAW 264.7 (IC_{50}: 181.1 ng/ml) was shown more susceptible to BBR3378-mediated inhibition of cell proliferation. LPS-induced inflammation was measured by qRT PCR analysis of expression of TNFα and IL-1α and by using a luciferase reporter construct with NF-κB promoter to assess NF-κB activation. Pre-treating RAW 264.7 cells with BBR3378 (100 ng/ml) did not affect the early response cytokine TNFα expression after 1h LPS stimulation (100 ng/ml) but significantly accelerated decay of TNFα mRNA after 8h. In contrast, the peak IL-1α mRNA level appeared after 8h LPS stimulation but was significantly down-regulated by BBR3378. In addition, BBR3378 inhibited activation of NF-κB, the major cellular event leading to inflammatory cytokine production in response to LPS. Furthermore, BBR3378 blocked COX-

2, an enzyme catalyzing the production of prostaglandin, another critical inflammatory mediator. These preliminary observations together have implicated BBR3378's regulatory activity on macrophages which can potentially contribute to its therapeutic effect on EAE and MS.

Title: Novel combinatory treatment for experimental ischemic stroke

Authors: *L. S. BELAYEV[1], S. HONG[1], L. KHOUTOROVA[1], A. OBENAUS[2], N. A. PETASIS[3], N. G. BAZAN[1]
[1]Neurosci. Ctr., LSUHSC, New Orleans, LA; [2]Dept Pediatrics, Univ. of California, Irvine, Irvine, CA; [3]Chem., USC, Los Angeles, CA

Abstract: Acute ischemic stroke triggers complex neurovascular, neuroinflammatory, and synaptic alterations. Our study aimed to test the prediction that blocking pro-inflammatory platelet-activating factor-receptors (PAF-Rs) plus administering selected docosanoids after middle cerebral artery occlusion (MCAo) would lead to sustained neurological recovery. Two different types of bioactive small molecules were investigated. The first was LAU-0901, an antagonist of PAF-R that blocks activated pro-inflammatory signaling and has been shown to have promising efficacy in a stroke model. The second, products of DHA, a novel synthetic docosanoid (Aspirin-triggered neuroprotectin D1 methyl-ester; AT-NPD1-ME), which activates cell-survival pathways and possesses potent anti-inflammatory and neuroprotective activity in the brain. Sprague-Dawley rats were anesthetized with isoflurane/nitrous oxide and received 2h MCAo by intraluminal suture. Neurological status was evaluated at 3h and 4h, and on days 1, 2, and 3; a grading scale of 0-12 was employed. Animals were treated with LAU-0901 (i.p. 60mg/kg, 2h after onset of stroke), AT-NPD1-ME (i.v. 333mg/kg, 3h after onset of stroke) and vehicles (cyclodextran and saline). There were four groups: LAU-0901+AT-NPD1; LAU-0901+saline; Cyclodextran+AT-NPD1; and cyclodextran+saline. On day 3, *ex vivo* MRI of the brain was conducted using 11.7 T MRI. LAU-0901 and AT-NPD1 treatments alone improved behavioral scores compared to vehicle groups by 22-32%. The neuroprotective effect was enhanced using the LAU-0901+AT-NPD1, which resulted in improved behavioral scores up to 50% on day 3. Total lesion volumes, which were computed using T2WI, were significantly reduced by 80% with LAU-0901+AT-NPD1 treatment compared to vehicle-treated groups. We

concluded that combination treatment of the PAF-R antagonist, LAU-0901, plus AT-NPD1-ME affords synergistic neuroprotection in the post-ischemic brain and might provide the basis for future therapeutics in patients suffering from ischemic stroke. We are currently exploring the molecular mechanisms involved.

Title: Mesenchymal stem/stromal cell delivery through cardiopulmonary bypass modulates systemic inflammation and reduces microglia activation in a juvenile porcine model

Authors: T. MAEDA[1], K. SARKISLALI[1], C. LEONETTI[1], F. A. SOMAA[1], G. R. STINETT[1], Z. DHARI[1], B. K. LEWIS[5], M. M. NUSZKOWSKI[2], K. PANCHAPAKESAN[3], K. GRECCO[4], P. VYAS[4], P. J. HANLEY[6], R. ULREY[6], J. A. FRANK[5], R. A. JONAS[1], *N. ISHIBASHI[1]
[1]Children's Natl. Heart Inst. and Ctr. for Neurosci. Res., [2]Children's Natl. Heart Inst., [3]Ctr. for Genet. Med., [4]Radiology and Nuclear Med., Children's Natl. Hlth. Syst., Washington, DC; [5]Frank Lab. and Lab. of Diagnos. Radiology Research, Radiology and Imaging Sci., NIH, Bethesda, MD; [6]Div. of Blood and Marrow Transplantation, Ctr. for Cancer and Immunol. Res., Children's Natl. Hlth. Syst., Washington, DC

Abstract: Neurodevelopmental impairment is emerging as one the most important current challenges for survivors after pediatric cardiac surgery. Cardiopulmonary bypass (CPB) can cause substantial systemic inflammation and trigger prolonged microglial activation in the brain. Mesenchymal stem/stromal cells (MSCs) have significant immunomodulatory properties and regulate microglia activation. We hypothesize that intra-arterial MSC delivery through CPB is neuroprotective by modulating systemic and neuro-inflammatory responses. Two-week old piglets (n=16 total) were randomly assigned to one of 3 groups: (1) Control, (2) Deep hypothermic circulatory arrest (DHCA), (3) DHCA followed by MSC administration. In group 3, ^{18}F-FDG or superparamagnetic iron oxide (SPIO)-labeled MSCs ($10x10^6$ per kg) were delivered through CPB during the rewarming period. Positron emission tomography (PET) was performed 1hr after MSC delivery to determine the whole body distribution of cells with ^{18}F-FDG. Animals

were sacrificed 3hrs after CPB for analysis with magnetic resonance imaging (MRI) and immunohistochemistry. Plasma cytokine/chemokine levels were determined by multiplex immunoassay. Clinically-relevant physiological biomarkers determined the effect of MSC delivery on multi-organ function. It has been well demonstrated that intra-venous injection of MSCs results in high accumulation of cells primarily in the lungs. In contrast our PET study showed that intra-arterial delivery through CPB uniformly distributed MSCs to most of the organs analyzed including brain, heart, and kidney. The lungs and intestine showed lower uptake. T2* weighted brain MRI showed diffuse distribution of hypointense voxels (SPIO particles) throughout the entire brain with large clusters along the lateral and third ventricles. Immunohistochemistry revealed an even distribution of SPIOs within the cortex and white matter. We have previously demonstrated an increase in permeability of the blood-brain barrier after DHCA. Consistent with this we identified SPIOs located in the extra-vascular space. MSC delivery through CPB modulated plasma cytokine/chemokine expression following surgery. In the brain MSC treatment reduced microglia expansion/activation and inhibited caspase activation resulting from CPB. Various physiological biomarkers after MSC delivery did not differ compared with CPB group. No evidence of either embolic events or microstrokes was observed by MRI and histology. MSC delivery during CPB has the translational potential to minimize systemic inflammation and reduce microglial expansion and caspase activation in children undergoing CPB.

Abstract: Stroke survivors often suffer from disability, including motor, psychiatric, and cognitive deficits. Early therapeutic intervention with the clot-busting agent TPA can indeed be effective, but the few who receive this treatment still suffer from neurological deficits. We hypothesize that neuroprotective adjunct therapy is required to reduce post-stroke adult disability. The potential non-invasive stroke treatment involving low field magnetic stimulation (LFMS) is under investigation, and we are delineating the cellular mechanisms involved in the therapeutic benefits of this novel treatment in our animal model of post-stroke depression. Using an established focal cortical pial vessel disruption (PVD) stroke model in Sprague-Dawley rats, we studied the efficacy of gamma burst stimulation or LFMS (40 Hz, <0.1 Tesla) in reducing hippocampal neuronal damage and associated behavioural deficits. Levels of anxiety, depressive and cognitive behavioural deficits were measured using the open field test (OFT), forced swim test (FST) and Y-maze, respectively. In vitro electrophysiological recordings were performed to correlate cognitive deficits with changes in hippocampal synaptic plasticity. Various tissue staining methods followed by confocal microscopy were employed to visualize the effects of PVD and LFMS on hippocampal protein and cell expression. Western blotting was then used to quantify these expressions. PVD treatments produced hippocampal-dependent spatial memory deficits, which were associated with decreased long-term potentiation in hippocampal brain slices. Increased anxiety and depressive behaviours were observed in PVD-treated animals but not in sham animals (similar surgical procedures but with pial vessels left intact). Increased neuronal damage was confirmed using propidium iodide and Fluro-jade C labeling followed by confocal imaging. In contrast, all animals that received daily LFMS (20min, 3d) showed significant improvements in their depression, anxiety, and spatial memory impairments. The results showed that restoring gamma oscillations with LFMS counters the damaging effects of pro-neurotoxicity pathways after stroke. Clinical implications of this non-invasive therapy include potential treatments of post-stroke depression and dementia, and other neurodegenerative diseases.

Title: The effect of sodium ozagrel, edaravone, or heparin on the development of infarcted lesions in our three-vessel occlusion (3-VO) model

Authors: *K. YAMATO[1], Y. NAKAJO[1,3], J. C. TAKAHASHI[2], H. YANAMOTO[1,4]
[1]Lab. of Neurol. and Neurosurg., [2]Dept. of Neurosurg., Natl. Cerebral and Cardiovasc. Ctr., Suita, Japan; [3]Res. Lab., Rakuwa-kai Otowa Hosp., Kyoyo, Japan; [4]Dept. of Cardiovasc. Science, Div. of Surgical Med., Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Ischemic stroke, which may seriously affect the quality of life for a prolonged period, involved 10.3 million patients worldwide in 2013. Sodium Ozagrel (SO) is a thromboxane A_2 (TXA_2) synthase inhibitor developed as an antiplatelet drug, which has been used for the treatment of neurological deficits (motor functions) associated with cerebral thrombosis, since Mar. 1998, or for the prevention of cerebral vasospasm (delayed ischemic symptoms) after subarachnoid hemorrhage (SAH), since Jun. 1995. Edaravone is a free radical scavenger developed as a neuro/vascular protectant, which has been approved for the treatment of ischemic stroke in Japan (for this particular purpose), since Apr. 2001. Here, we examined the effect of SO, Edaravone, or heparin (a potent anti-coagulant that has been used clinically) on the development of cerebral infarction, using our original three-vessel occlusion (3-VO) model (Yang et al., Eur Neurol, 2014). Male C57BL/6J mice received either SO; 10 mg/kg, Edaravone; 3 mg/kg, heparin; 600 U/kg, or saline (as the vehicle control), i.v., at 5 min and 3 h (twice) after the induction of ischemia (N= 8 in each treated group, or 12 in the control). Infarcted lesion volumes and neurological deficits were analyzed 24 h after ischemia, using the TTC stain or the tail suspension test, respectively. Regional cerebral blood flow (rCBF) was monitored before, during and after ischemia, using laser Doppler flowmetry. In the results, SO or Edaravone, significantly reduced the infarcted lesion volumes (12.4 $mm^3 \pm 4.5$, or 13.7 $mm^3 \pm 6.5$, respectively), compared to the control (20.2 $mm^3 \pm 5.1$). The treatment with SO or Edaravone did not affect the levels of rCBF during ischemia, indicating that reduced lesion sizes were not due to increased rCBF (i.e. there was no reduction in the ischemic stress applied by the 3-VO method). The anti-platelet agent, SO may protect the brain after focal ischemia. The treatment with heparin did not improve the rCBF or infarcted lesion volumes, but induced hemorrhagic transformation as a side effect in some cases. The neurological deficits were relatively less in the SO or Edarabone groups compared to the control, but without a significant difference. It was possible to reduce the anatomical lesion sizes using the anti-platelet agent, or the neuro/vascular protectant, but these methods failed to improve neurological deficits after the induction of 3-VO. Although there is a possibility of type II error in the present functional assessment, it is mandatory to find an agent that can reduce infarcted lesion volumes and improve neurological functions, by acute administrations after the onset of ischemic stroke.

Title: Injury site-targeted complement inhibition improves motor & cognitive recovery after murine ischemic stroke

Authors: *A. TOUTONJI[1], S. TOMLINSON[2]
[1]Neurosci., [2]Immunol., Med. Univ. of South Carolina, Charleston, SC

Abstract: Introduction: Ischemia induces the expression of surface epitopes (Danger Associated Molecular Patterns), which upon return of blood flow (reperfusion), bind circulating self-reactive natural IgM antibodies These bound IgM antibodies activate complement and drive secondary ischemia reperfusion injury. From an IgM mAb hybridoma that recognizes a post-ischemic stroke neoepitope, we derived a single chain antibody (scFv) for use as a targeting vehicle to deliver a complement inhibitor specifically to the post-ischemic brain.
Methods: We linked the murine complement inhibitor, Crry, to a scFv that specifically binds to neoepitopes (a subset of phospholipids) expressed in the post-ischemic brain. The construct, termed C2scFv-Crry, was administered intravenously 90 minutes after ischemia in a 1-hour middle cerebral artery occlusion (MCAO) mouse stroke model. Mice were then tested for recovery over 21 days using neurological severity score (NSS) for symmetry, corner test for forelimb laterality, and passive avoidance task for fear memory. All personnel involved in conduct & analysis of experiments were blinded, and behavior was scored separately by two researchers.
Results: Compared to control mice (vehicle treated), mice that received C2-Crry performed significantly better on motor and cognitive tasks. C2-Crry treated mice had significantly lower scores on NSS both acutely and at 21 days (using non-parametric t-tests), lower magnitudes of laterality on corner test, and longer latency to enter the dark room on passive avoidance task (using student t-tests & two-way ANOVA to compare groups at single & at multiple time points, respectively).
Conclusion: Targeted-complement inhibition using C2-Crry improves motor and cognitive recovery after 1-hour MCAO in mice. This can be attributed to neuroprotection by reducing inflammation and cellular death, investigation of which is currently underway and which will be reported on.

Title: Neuroprotective effects of palmitic acid methyl ester against cerebral ischemia

Authors: *A. DO COUTO E SILVA[1], R. H.-C. LEE[2], C. Y.-C. WU[2], H. POSSOIT[2], C. T. CITADIN[1], P.-Y. CHEN[2], T.-H. HSIEH[2], R. AZIZBAYEVA[3], J. T. NEUMANN[3], H. W. LIN[2]
[1]Cell. Biol. and Anat., LSU Hlth. Sci. Ctr. Shreveport, Shreveport, LA; [2]Neurol., LSU Hlth. Sci. Ctr., Shreveport, LA; [3]Biomed. Sci., West Virginia Univ. Sch. of Osteo. Med., Lewisburg, WV

Abstract: Cardiopulmonary arrest (CA) affects more than 350,000 people each year in the USA. Disruption of cerebral blood flow (CBF), more specifically CA-induced hypoperfusion (decrease in CBF), results in severe and selective brain damage contributing to neuronal cell death, which leads to cognitive impairment. Functional neuroprotective therapies remain few and ineffective. Our goal is to identify novel neuroprotective therapies which could modulate CBF and provide neuroprotection after ischemia. Previously, we discovered a saturated fatty acid, palmitic acid methyl ester (PAME), as a novel vasodilator/neuroprotective agent. PAME is released from the superior cervical ganglion (sympathetic nervous system), which innervates major cerebral arteries and is enhanced in the presence of arginine derivatives. Furthermore, arginine is a substrate for protein arginine methyltransferases (PRMTs). PRMTs can methylate various biological targets causing pre or post-transcriptional/translational modifications. Therefore, our hypothesis is that methylation of palmitic acid (PA) to form PAME via PRMTs is essential to enable PAME's therapeutic actions against ischemia, providing enhancements in CBF, neuroprotection, and functional recovery. To characterize the therapeutic properties of PA vs PAME, we subjected organotypic hippocampal slices to oxygen glucose deprivation (OGD) and visualized total cell death via propidium iodide staining. Our results suggest that treatment with PAME after OGD, but not PA, enhances neuroprotection in the CA1 region of the hippocampus [vehicle OGD (0.538 ±0.022) and PAME OGD (0.232 ±0.055)]. To investigate if the methylation of PA is needed for CBF enhancement after ischemia, we utilized a global model of cerebral ischemia [asphyxial CA (ACA, 6min)]. The rat skull was thinned to visualize red blood

cell speed (an indicative measure of CBF) in microvessels of the neocortex via intra-vital two-photon laser scanning microscopy. Our results suggest that PAME enhances cortical CBF while maintaining systemic blood pressure *in vivo.* Additionally, histopathological analyses suggest that treatment with PAME, but not PA enhances neuronal survival after ACA. Functional cognitive outcomes were tested post-ACA via spontaneous alternation test (T-maze). Treatment of PAME improved functional outcomes after ACA [improvements in both alternation ratio ACA (0.261±0.049), ACA+PAME (0.487±0.039) and side-bias preference, ACA (0.821±0.046), ACA+PAME (0.641 ±0.025)]. Overall, our results suggest that methylation of PA to form PAME, enhances CBF, neuroprotection, and functional outcomes after CA.

Title: Outcomes in mild acute ischemic stroke treated with intravenous thrombolysis

Authors: *R. ZHANG, H. WEI, X. QIN
The First Affiliated Hosp. Of Chongqing Med., Chongqing City, China

Abstract: Background
Stroke is a leading cause of death and disability in the world. Minor stroke, a subtype of stroke, accounts for about two-thirds of stroke approximately. Intravenous thrombolysis by recombinant tissue plasminogen activator (rt-PA) has been widely confirmed to be an effective and safe therapy for minor stroke patients. However, the cost of rtPA is too expensive to afford for many poor patients. At this time, urokinase, another drug for intravenous thrombolysis becomes their choice because of its cheap price. In fact, urokinase is being widely used in poor areas of China to treat poor minor stroke patients as a substitute of rtPA. However, the use of urokinase is lack of clinical study, and the safety and efficacy of it remains unclear. Therefore, it is of high significance to explore the safety and efficacy of urokinase treatment for acute minor stroke patients.
Methods
Minor stroke was defined as the baseline NIHSS score is ≤ 5. Of 610 acute ischemic stroke patients underwent urokinase thrombolysis ≤ 6 hours we collected in 22 hospitals at Chongqing

and Sichuan Province of China, a total number of 126 minor stroke patients was included into this study. Outcomes were the 3-months favorable functional outcome (modified Rankin Scale score 0-1), mortality and bleeding. Results were compared among different thrombolysis time window groups (< 3 hours, 3-4.5 hours, 4.5-6 hours). SAS9.2 was used for data analysis. Values of $p < 0.05$ were regarded as statistically significant.
Results
Of the 126 minor stroke patients, 4 cases (4/126, 3.2%) died during 3 months. 1 case (1/126, 0.7%) had symptomatic cerebral hemorrhage. 2 cases (2/126, 1.6%) had asymptomatic hemorrhaging. 12 cases (12/126, 9.5%) have oral
mucosal bleeding. The MRS scores of 105 cases (105/126, 83.3%) were 0 or 1 at 3 months. Furthermore, when grouped the patients by thrombolysis time window, the death and bleeding rates of the different groups were low and were not statistically significant ($p > 0.05$). The favorable functional outcomes in each time window groups were as follows respectively: 37 cases (37/41, 90.24%), 35 cases (35/42, 83.33%) and 33 cases (33/43, 76.74%), while there is no significance among them ($p > 0.05$). But when using logistic regression analysis, we found that for the 3 thrombolytic time window level, the poor prognosis risk is 2.486 times higher when the time window adds a level.
Conclusions
For thrombolysis of minor stroke, it is safe and effective to use urokinase within 6 hours of the disease onset. But the longer the time of treatment start, the higher rate of poor prognosis is.

Title: Protective and restorative effects of stem cell factor and granulocyte-colony stimulating factor on brain repair through VEGF-mediated angiogenesis in a mouse model of CADASIL

Authors: *S. PING
SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Cerebral autosomal dominant arteriopathy with subcortical infarct and leukoencephalopathy (CADASIL), a NOTCH3 gene mutation-induced cerebral small vascular disease, is characterized by progressive degeneration of vascular smooth muscle cells (VSMCs) in cerebral small arteries. Our earlier studies have revealed increases in angiogenesis and

improvements in spatial learning and memory by stem cell factor and granulocyte colony-stimulating factor (SCF+G-CSF) treatment in a transgenic moue model of CADASIL (TgNotch3R90C). This study aimed to determine how SCF+G-CSF promotes angiogenesis and whether SCF+G-CSF-enhanced angiogenesis is a key mechanism involved in brain repair and cognitive improvement in TgNotch3R90C mice. Avastin, a FDA-approved drug for preventing angiogenesis by neutralizing VEGF's biologic activity, was used for blocking SCF+G-CSF-increased angiogenesis. SCF+G-CSF, SCF+G-CSF-Avastin, Avastin or an equal volume of vehicle solution were injected (s.c.) at 9 and 10 months of age in TgNotch3R90C mice. Age-matched C57BL/6J mice served as wild type (WT) control. After neurobehavioral testing mice were sacrificed at 15 months of age for pathological examination. Our data showed that SCF+G-CSF-improved spatial learning and memory was eliminated by Avastin. Decreased blood vessel density and impaired VSMC structure in the brains of TgNotch3R90C mice was restored by SCF+G-CSF treatment, whereas the SCF+G-CSF-enhanced angiogenesis and VSMC protection were completely abolished by Avastin. Avastin also blocked the SCF+G-CSF-enhanced neural network remodeling (by MAP2 and SMI312 immunostaining), neurogenesis (by Doublecortin), and synaptogenesis (by Synaptophysin) in the brains of TgNotch3R90C mice. VEGF expression was decreased in the cerebral VSMCs and the whole brain of TgNotch3R90C mice. SCF+G-CSF treatment significantly increased VEGF expression in both cultured cerebral VSMCs and brain tissue of TgNotch3R90C mice. These findings suggest that SCF+G-CSF-increased angiogenesis via VEGF plays a key role on brain repair in a mouse model of CADASIL. This study provides novel insights into how hematopoietic growth factors restrict CADASIL pathology.

Title: SC411 improves cerebral blood cell flow after ischemia in the Townes mouse model of sickle cell disease

Authors: *C. Y.-C. WU[1], A. DAAK[2], M. A. LOPEZ-TOLEDANO[2], A. L. W. RABINOWICZ, 33137[2], H. LIN[1]

[1]Neurol., LSU Hlth. Sci. Ctr. Shreveport, Shreveport, LA; [2]Sancilio & Company, Inc, Riviera Beach, FL

Abstract: Background: Sickle cell disease (SCD) is an inherited blood disorder caused by a gene mutation that results in abnormal hemoglobin S (HbS). Under low oxygen tension, HbS polymerizes to form rigid/deformed red blood cell (RBC). RBC of SCD patients are characterized by enhanced expression of adhesion molecules and increased propensity to adhere to the endothelial wall causing episodic vaso-occlusion. Ischemic stroke is one of the major complications, leading to physical and/or cognitive impairments. SCD patients present a deficit in docosahexanoic acid (DHA). DHA is known to have potent anti-inflammatory, anti-adhesion, and anti-oxidant properties. DHA treatment may reduce RBC adhesion and enhance cerebral blood cell flow (CBF). The effect of SC411, a novel highly purified DHA ethyl ester formulation with a proprietary delivery platform (Advanced Lipid Technology® (ALT®), on CBF was investigated.
Objective: To investigate the effect of two oral doses of SC411 on reversing DHA deficiency and to improve cerebral blood cell in the HbSS-Townes SCD mouse model.
Methods: Transgenic sickle cell mice (HbSS-Townes) were fed with two doses of SC411 (36 mg DHA /kg/day or 180 mg DHA /kg/day) or control (soybean oil) for 56 days and subjected to 3 hrs of hypoxia (10% O_2) at days 28 and 56. RBC flow was measured in real-time using two-photon laser scanning microscopy at 0, 28, 56 days.
Results: HbSS-Townes mice presented with lower DHA and EPA levels as compared to healthy HbAA controls. DHA levels were higher in Townes mice as compared to controls in SC411-treated groups after 4 weeks of intervention. RBC flow was also enhanced in HbSS-Townes mice treated with 180 mg DHA/kg/day, challenged with repeated bouts of hypoxia, on both 28 and 56 days.
Conclusions: Preliminary findings from this ongoing study suggest that treatment with SC411 improves RBC flow in the HbSS-Townes SCD mouse model.

Title: Impact of therapeutic hypothermia on cerebral autoregulation and neuroglial protection in an asymmetric ischemia-reperfusion model

Authors: *E. CHOI[1], G. PARK[1], H. SHIN[1], S.-J. LEE[2], M. CHOI[2], J. HONG[2]
[1]Dept. of Neurology, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [2]Sch. of Med., Ajou Univ., Suwon, Korea, Republic of

Abstract: BACKGROUND: Cerebral autoregulation (CA) is the ability to maintain sufficient and stable cerebral blood flow (CBF) despite changes in cerebral perfusion pressure (CPP). It is a biological marker of cerebrovascular reserve and its impairment can lead to subsequent brain damage in the setting of stroke, traumatic brain injury, and global cerebral ischemia. Therapeutic hypothermia (TH) is a promising neuroprotection strategy in numerous experimental and clinical situations. Therefore, we are to investigate CA function as a biological change of cerebrovascular reserve after TH in an asymmetric ischemia-reperfusion model. **METHODS:** We made asymmetric ischemia-reperfusion model "chimeric model" with different ischemic mode in each hemisphere for mimicking global ischemia and for obtaining asymmetric ischemia-reperfusion contrast between two hemispheres. This model was established in male Sprague-Dawley rats through combination with transient middle cerebral artery occlusion (tMCAO) in for 30 minutes the right side and transient four-vessel occlusion (4-VO) for 8 minutes. Temperature management [hypothermia (33℃), normothermia (37℃), and hyperthermia (39℃)] was maintained in a temperature controller for 120 minutes after 4-VO. We sequentially measured cerebrovascular reserve capacity (CVRC) with acetazolamide (ACZ, 50mg/kg), modified neurological severe score (mNSS), cell death, endothelial cell and mitochondrial functions at 1, 2, 3, 5, and 7 days after procedure. We also analyzed histological and molecular characteristics amongst different temperature conditions. **RESULTS:** (vs. contralateral CVRC), ipsilateral CVRC was significantly decreased until 3 days and gradually recovered to normal level from 5 days after injury. (vs. normothermia or hyperthermia), hypothermia showed the restoration of CVRC with enhancement of endothelial functions (eNOS and tight junction proteins) at 3 days after injury. They also showed neuroprotective effects by decreasing inflammatory responses, oxidative stress, and pro-apoptosis (Bax and cytochrome C) and by increasing anti-apoptotic protein (Bcl-2) at 3 days after injury. Consequentially, they led to a decrease in infarct volume, neurological deficit scores, blood brain barrier (BBB) damage at 7 days after injury. **CONCLUSIONS:** Our data indicate that TH alleviates CA failure and subsequent cerebral damage in asymmetric ischemia-reperfusion model as restoring endothelial function. Rapid monitoring and management of CA would be a therapeutic target in certain ischemia-reperfusion injuries such as cardiac arrest and embolic stroke.

Title: Backward directional arteriogenesis by cranial burr hole and erythropoietin pretreatment in ischemic rat model with cerebral perfusion impairment

Authors: *G. PARK[1,2], E. CHOI[1,2], H. SHIN[1,2], K.-E. LEE[1], M. CHOI[1], S.-J. LEE[1], J. HONG[1]
[1]Dept. of Neurology, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [2]Dept. of biomedical science, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: BACKGROUND: Cranial burr hole procedure can be a potential revascularization strategy even in acute stroke patients with perfusion impairment, however, it cannot guarantee stable revascularization from the extracranium. Erythropoietin (EPO) is an attractive candidate with an angiogenic potential with proven safety in high-dose administration to promote successful revascularization. We investigated the efficacy and safety of a combined treatment by cranial burr hole with erythropoietin (EPO) pretreatment in severe ischemic rat model with cerebral perfusion impairment. We also evaluated its cellular mechanism. **METHODS:** Severe ischemia with cerebral hypoperfusion was established in male Sprague-Dawley rats (250 to 270g) through permanent bilateral internal carotid artery ligation (bICAL) and transient middle cerebral artery occlusion (tMCAO) for 30 minutes. Experimental models received intraperitoneal injection of recombinant human erythropoietin (EPO, 5,000 U/kg) or saline for 3 consecutive days at 7 days after ischemic injury. Cranial burr hole and cracking dura mater as a mechanical barrier disruption (MBD) from extracranium to intracranium were performed on the right hemisphere. We sequentially evaluated modified neurological severe score (mNSS), infarct volume, revascularization take rate, hemodynamics, BBB breakdown, histology and molecular analysis up to 2 months. **RESULTS**: Our modified tMCAO model with bICAL (vs. original tMCAO model) showed a prolonged reduction of CBF and increased expression of hypoxia-related factors in ipsilateral hemisphere. Hemisphere with MBD (vs. hemisphere without MBD) had inflammatory responses such as glial activation and upregulations of pro-inflammatory factors, while EPO-combination group suppressed inflammatory responses. Combination treatment group (vs. no treatment group or MBD-only group) had a successful transdural anastomosis with the upregulation of pro-angiogenic factors, vessel maturation (PDGF-beta, TIE-2, alpha-SMA), and endothelial cell proliferation (BrdU). They also showed the induction of cell survival pathways (pAkt and eNOS) through activation of erythropoietin receptor. Finally, transdural revascularization and neuroprotection in combination group made reduction of the infarct volume and improvement of the neurological outcome. **CONCLUSIONS:** Our finding indicate that a combination therapy of MBD and systemic EPO pretreatment resulted in a

successful revascularization as well as neuroglial protection in ischemia rat model with cerebral hypoperfusion.

Title: The calcium binding protein apoaequorin alters cytokine expression following direct hippocampal brain infusion in a rat model

Authors: *C. W. SMIES, J. R. MOYER, Jr
Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: As the aging population continues to grow, the number of individuals that experience a stroke will continue to rise. Thus, it is important to study the cellular and molecular mechanisms by which the negative effects of stroke can be ameliorated. Ischemic strokes are the most prevalent type of stroke and induce excitotoxicity via calcium dysregulation (Choi, 1999). Several molecules exist that are able to assist in calcium buffering and sequestration, including the calcium binding protein apoaequorin (AQ; Toma et al., 2005). Using an in vitro stoke model, an intra-hippocampal infusion of AQ is neuroprotective for up to 1 or 2 days later, whereas changes in cytokine mRNA expression (e.g. IL-10, TNF-α) are observed as early as 1 h following an AQ infusion (Detert et al., 2013). This disconnect between when neuroprotection is observed and when cytokine mRNA is expressed demonstrates the need to further investigate the cellular and molecular neuroprotective mechanisms of AQ. Ischemic preconditioning is a small insult that does not cause damage on its own, but proves to protect against major insults that occur at a later time. In addition to the neuroprotection gained from preconditioning, ischemic preconditioning has also been shown to alter anti-inflammatory cytokine expression, such as TNF-α (Wang et al., 2000), thus RT-qPCR is used to explore if AQ-induced cytokine mRNA expression is similar to that of ischemic preconditioning. To further elucidate the connection between AQ and cytokine expression it is important to know if and when cytokine mRNA is translated. Given that AQ infusion induces cytokine mRNA expression 1 h later, but requires a delay of 1 d to produce a neuroprotective effect (Detert et al., 2013), the timing of cytokine translation may be contributing to the delay of neuroprotection observed following an infusion of AQ. A combination of RT-qPCR and Western blotting techniques are used to determine if and

when cytokines induced by AQ are translated. This research will further explore the cellular mechanisms and temporal relationship between AQ-induced neuroprotection and ischemia.

Abstract: Retinal ischemia is a major cause of vision impairment/loss and a common underlying mechanism associated with diseases such as glaucoma, diabetic retinopathy, and central retinal artery occlusion. The regenerative capacity of the diseased human retina is very limited (Jorstad et. al 2017). Our previous studies have shown the neuroprotective effects of intravitreal injection of mesenchymal stem cells (MSC) and MSC conditioned media in retinal ischemia (Mathew et. al 2017, Roth et. al 2016). We hypothesize that the neuroprotective effects of MSCs are largely mediated by extracellular vesicles (EVs), approximately 30nm -150nm in size secreted by most cells and involved in cell-to-cell communication. EVs were isolated from MSC conditioned media using a centrifugation and precipitation process. EVs were characterized using immunoblotting (CD63, CD9, HSP70), Nanosight analysis, and Transmission Electron Microscopy. MSC derived EVs were tested in our in-vitro oxygen-glucose deprivation (OGD) model of retinal ischemia in the R28 cell line, a well-characterized retinal precursor line consisting of neuronal and glial cells. We found that pre-treatment of R28 cells with MSC derived Evs 24 hours prior to OGD significantly reduced cell death, apoptosis and increased cell proliferation compared to the OGD control condition. Further, we studied the uptake of extracellular vesicles in our R28 cell line using fluorescent labelled EVs. Our results indicate that EV uptake is dependent on Heparin Sulfate Proteoglycans (HSPGs), and immuno-localization

studies indicated that EV uptake in retina depends on the caveolar endocytic pathway. Using our in vivo rat model of retinal ischemia, we have demonstrated EV induced functional recovery from retinal ischemia (ERG), increased neuroprotection as evidenced by decreased retinal inflammation(IL-6,TNF-a and Il-1b), apoptosis (TUNEL), and increased RGC count (IHC and flat mount).Taken together, MSC derived EVs play a key role in neuro-protection and offer potential in treating retinal ischemic injury.

Title: Autophagy and retinal ischemic post-conditioning

Authors: *M. CHENNAKESAVALU, B. MATHEW, C. STELMAN, M. SHARMA, L. TORRES, S. ROTH
Anesthesiol., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Retinal ischemia is a major cause of vision impairment and a common underlying pathology associated with diseases such as glaucoma, diabetic retinopathy, and central retinal artery occlusion that currently affect millions worldwide. Our previous studies have demonstrated the potent neuroprotection conferred in retina by post-conditioning (post-C), a brief period of ischemia given 24 hours following prolonged and damaging initial ischemia in rat. Currently, the mechanisms guiding the remarkable protection induced by post-C are largely uncharacterized. Based on ischemic preconditioning studies in heart and brain, we hypothesize that autophagy, an intracellular catabolic “recycling” system, plays a key role in facilitating post-C induced neuroprotection in retina. Using our rat in-vivo model of retinal ischemic injury, we observed significant increases in the expression of autophagy proteins LC3-II and Beclin-1 and a

significant decrease in the expression of P62 in the post-C group vs. sham post-C group. Similar results in LC3-II, P62, and Beclin-1 were observed in the in-vitro model of retinal ischemia. Changes in expression of LC3-II, P62, and Beclin-1 in our in-vivo and in-vitro models were consistent with increased levels of autophagy in post-C. To further study the involvement of autophagy in post-C, we blocked two key proteins involved in autophagosome formation (Atg5 and Atg7) using small interfering RNA (siRNA). Blockade of Atg5/7 attenuated the functional protective effect of post-C (measured by electroretinography) and increased histological damage compared to treatment with non-silencing siRNA in-vivo. Blockade of Atg5 in-vitro similarly attenuated post-C induced protection measured by cell proliferation and viability. Utilizing tandem RFP-GFP-LC3B in-vitro, we visualized greater levels of autophagic flux with post-C. Further, induction of autophagy via TAT-Beclin attenuated cell death and increased cell proliferation in retinal neurons subjected to oxygen-glucose deprivation, suggesting the key role of autophagy in protection from retinal ischemic injury. Taken as a whole, our results suggest that autophagy is a key underlying mechanism in the post-C induced neuroprotection in retina, and that the supplementation of autophagy offers promise in the treatment of retinal ischemic injury.

Title: Neuroprotective effects of astrocyte-specific overexpression of Nrf2 in a mouse model of stroke

Authors: *J. H. FOWLER[1], M. AIMABLE[2], L. HEGARTY[2], K. NAGASSIMA[2], J. A. JOHNSON[4], G. E. HARDINGHAM[3], K. HORSBURGH[1]
[2]Ctr. for Discovery Brain Sci., [3]Dementia Res. Inst., [1]Univ. of Edinburgh, Edinburgh, United Kingdom; [4]Sch. of Pharm., Univ. of Wisconsin Madison, Madison, WI

Abstract: Cerebrovascular pathology such as that caused by stroke increases risk of cognitive decline and dementia by mechanisms including inflammation and oxidative stress. Nrf2 is a transcription factor and master regulator of a battery of antioxidant and anti-inflammatory genes. Nrf2 activation in astrocytes has previously been shown to confer protection in models of neurodegeneration. We hypothesised that overexpression of Nrf2, specifically in astrocytes,

would attenuate neuronal damage following stroke by reducing oxidative stress and inflammation. GFAP-Nrf2 male mice (2 to 3 fold increase of Nrf2 expression in GFAP-astrocytes) and C57Bl/6J (wild-type; WT) littermates controls (3-4 months old) underwent ischaemia (transient middle cerebral artery occlusion for 60 mins) (n=7-15/group) or control sham surgery and brains were collected at 24 hours. Indices of cellular neuroinflammation (Iba1, microglia; GFAP, reactive astrocytes) and oxidative stress (3-Nitrotyrosine) were quantified in the peri-infarct area using immunohistochemistry. Neuronal damage was assessed histologically. Gene expression for Nrf2 and Nrf2-related genes *hmox1*, *nqo1* and *slc7a11* were analysed by qRT-PCR (n=7-11/group). All surgeries and analyses were carried out blinded to experimental groups. There was a significant reduction in neuronal damage in GFAP-Nrf2 mice compared with WT mice following ischaemia (p=0.048). 3-Nitrotyrosine immunostaining was increased after ischaemia but there was a marked reduction in GFAP-Nrf2 compared with WT mice after ischaemia (p=0.003). Microgliosis was increased following ischaemia but not altered between WT and GFAP-Nrf2 mice. Reactive astrocytes were increased in the peri-infarct area after ischaemia, and furthermore were significantly increased in GFAP-Nrf2 compared with WT stroke mice (p=0.0007). Nrf2-related gene expression was unchanged after ischaemia in WT mice compared to shams but significantly increased in GFAP-Nrf2 mice following ischaemia. We have shown that the overexpression of Nrf2 in astrocytes reduces neuronal damage and oxidative stress following stroke and this was paralleled by increased reactive astrocytosis and expression of Nrf2-related genes. We are currently investigating if boosting Nrf2-signalling in astrocytes exerts long-term protection after stroke.

Abstract: Between 1.5 and 2 percent of live births in the United States are classified as very preterm with 5 to 20 percent of these infants diagnosed with spastic cerebral palsy. Neonatal white matter injury (NWMI) remains the predominant cause of brain injury in this population. During injury, early inflammatory cascades result in cell death and maturation arrest in oligodendrocytic lineage cells, and previous work demonstrates that transplanted glial restricted precursors (GRP) can facilitate short term recovery though long-term survival of these exogenous cells is low. Hydroxyl polyamidoamine dendrimer therapy successfully targets injured and activated cell types in the brain with low toxicity and high specificity. Acute administration of dendrimer conjugated to N-Acetyl-Cysteine (D-NAC) has been successful in other animal models. Mitigation of the inflammatory response using D-NAC following NWMI in conjunction with GRP transplantation may result in the improved survival of both endogenous and transplanted glial cells, resulting in healthy oligodendrocytes capable of typical myelination patterns in the long term. GRPs were obtained from embryonic day 13.5 mouse embryos. To establish the dynamics of dendrimer with GRPs, cells were exposed to dendrimer conjugated CY5 (D-CY5) *in vitro*, then analyzed to determine uptake. Preterm equivalent CD-1 mice underwent right common carotid artery ligations or a sham surgery at post-natal day (P)5. At P10, a treatment group received a single dose of D-NAC intraperitoneally. Those mice went on to receive either vehicle or an intracallosal injection of 100,000 green fluorescent protein (GFP) expressing GRPs at P22. A second group received a vehicle injection at P10, followed by GFP GRP intracallosal injection at P22. To interrogate the effect of administration time and localized delivery on transplanted cell survival, cells were loaded with D-NAC prior to transplantation. The D-NAC treated GRPs were then transplanted at P22 into ligated animals not previously exposed to D-NAC. D-CY5 successfully colocalizes to GRPs *in vitro* suggesting that transplanted GRPs pretreated with D-NAC may be efficacious *in vivo*. Furthermore, preliminary results at 4 and 8-week post-transplant indicate behavioral recovery to be both treatment and sex dependent. These results show, for the first time, that GRPs incorporate dendrimer conjugated therapies. Dendrimer-drug uptake *in vivo* may allow for a combined effect, reducing NWMI related inflammation while enhancing survival of GRPs for long term recovery. This multi-tiered approach can result in long term efficacy, expanding upon the acute successes each treatment has seen individually.

Title: Using structural equation modeling to investigate predisposition of regional tetrahydrobiopterin for hypertonia following antenatal hypoxia-ischemia

Authors: *S. TAN[1], Z. SHI[1], J. JEONG-WON[1], K. LUO[1], K. THIRUGNANAM[2], J. VASQUEZ-VIVAR[2]
[1]Pediatrics, Wayne State Univ., Detroit, MI; [2]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Background: Tetrahydrobiopterin (BH4) levels in brain are low in prematurity. Without any insult, the rabbit fetuses mature and develop normally. Our previous hypothesis was that normally low BH4 levels in prematurity would fall below a threshold defining injury during hypoxia-ischemia (H-I) to cause critical brain injury. We have previously shown that MRI biomarkers can predict which fetuses will develop postnatal hypertonia following antenatal H-I.Objective: Our new hypothesis was that there is a combination of regional BH4 levels that determine which fetuses are predisposed to developing hypertonia following antenatal H-I.Methods: In vivo global HI of fetuses was induced in pregnant New Zealand white rabbits at 25 days gestation with a 4F Fogarty balloon catheter in a 3T magnet. Using MRI patterns of change in brain apparent diffusion coefficient (ADC, four patterns), we categorized fetuses predicted to get hypertonia based on criteria of ADC decrease below a nadir of 80% and presence of evidence of reperfusion-reoxygenation injury (patterns III and IV) and compared to those that were Non-hypertonia (Patterns I and II). Enough animals were enrolled to have a power of 80%. BH4 concentrations were assayed using HPLC-electrochemical detection. Statistical analyses used were ANOVA, t-test, logistic regression, correlation, structural equation modeling and path analysis. Results: Thalamus and cerebellum BH4 levels immediately after H-I were decreased in Hypertonia group vs Non-hypertonia (t-test) as well as different between patterns of MRI and sham (ANOVA). No differences were found for the cerebral cortex or basal ganglia alone using t-test and ANOVA. The interaction of all four regions was found to be significantly influencing Hypertonia on ANOVA and logistic regression. Interactions of two regions showed Cortex and Cerebellum correlations and Cortex and Basal ganglia correlations to be different between Hypertonia and Non-hypertonia. Additional analyses using structural equation modeling indicate that all four brain regions contribute to causing hypertonia. The best model obtained with path analysis shows thalamus to affect hypertonia the most. The error of the path to Hypertonia in this

model is 0.15. Conclusions: Only some fetuses will become hypertonic with a certain fetal insult. There is a combination of regional brain BH4 that predisposes to hypertonia following antenatal H-I. Our findings may explain prematurity by itself could be a risk factor for cerebral palsy in other studies.

Title: Neonatal anoxia in rats: Protein levels of hippocampal interneurons and spatial memory in adult rats

Authors: *J. M. IKEBARA, D. S. CARDOSO, N. M. M. DIAS, S. H. TAKADA, A. H. KIHARA
Univ. Federal do ABC, São Bernardo do Campo, Brazil

Abstract: The neonatal anoxia is one of the most common causes of morbidity and mortality in neonates. This injury in early life corresponds to 23% of neonatal deaths in all the world being an important issue for public health. The longlasting sequelae include motor deficits, behavioral and sensory and /or cognitive impairments, such as memory and learning deficits. The hippocampus is a vulnerable structure to oxygen deprivation due its high metabolic demand and capacity for synaptic plasticy. The presente model of neonatal anoxia has showed, in previous work, cell death in hippocampus 24 hours after oxygen deprivation, and in adult life, it was observed decrease of neurogenesis and impairments in spatial and working memory (Takada et al. 2015; Takada el al. 2016). In this work, we hypothesize that important interneurons population related to memory consolidation and electrophysiologic modulation can be altered by oxygen deprivation in neonatal rats. In this way, the aim of this study was to performe memory task and characterize the population of distinct hippocampal interneurons, such as parvalbumin, calretinin and calbindin, and proteins related to synapsis, synapsin I and synaptophysin of adult rats submitted to neonatal anoxia. P1/P2 neonates Wistar rats (Rattus norvegicus) were divided in anoxia and sham groups. Anoxia was performed according to described system of neonatal anoxia, composed by 25 minutes of 100% nitrogen gas exposure at 37°C (Takada et al., 2011).

At P60, the rats were euthanized and the hippocampi removed for western blotting analysis. In spatial reference memory and working memory task, the Barnes maze apparatus was used. Our preview results showed an increase of synapsin I protein levels in anoxia group ($p<0.05$). However, we detected no difference in protein levels to parvalbumin, calretinin, calbindin and synaptophysin. In spatial memory task, we observed that anoxia groups presented a higher escape latency compared to control group in spatial reference memory task. The Barnes Maze protocol used to test working memory was not sensible to detect alterations. These data suggest that neonatal anoxia can cause alterations in hippocampus of adult rats in synaptic proteins, but not in protein levels of interneurons, and also causes an impairment in spatial memory task.

Title: Neonatal anoxia in rats: Decrease of parvalbumin hippocampal interneurons during development of rats

Authors: *D. S. CARDOSO, J. M. IKEBARA, N. M. M. DIAS, S. H. TAKADA, A. H. KIHARA
Univ. Federal do ABC, Santo André, Brazil

Abstract: Neonatal anoxia is an important public health concern worldwide, once it may lead to hypoxic-ischemic encephalopathy, composed by serious permanent sequels (memory and learning deficits, cerebral palsy, hyperactivity, hearing deficiencies and others). The brain is one of the most susceptible organs to oxygen deprivation, since it demands high energy rate. Among the brain structures, the hippocampus (HPC), important to mnemonic processes, is one of the most sensitive areas to anoxia and it is characterized by a well-known morphology and neuronal circuits. Its cell variety is largely composed by interneurons, inhibitory cells that form local circuits through synapses with the main cells of the HPC, thereby promoting harmonization to hippocampal oscillations, such as theta and gamma, and controlling the activity and local rhythmicity. Anoxia results in numerous events leading to injury and neuronal death in the HPC and can alter the connectivity and hippocampal function. However, the impact of anoxia in the balance of excitatory and inhibitory neurons is not well known. Thus, the aim of this study was investigate the parvalbumin (PV)-positive population of cells, an important class of interneurons

with a well-defined fast-spiking electrophysiological signature. These interneurons have a crucial role in the process of learning and memory during development of rats submitted to neonatal oxygen deprivation. Briefly, P1-P2 neonate Wistar male rats (Rattus novergicus) were maintained in a semi hermetic chamber for 25 minutes, at 37°C, saturated by 100% nitrogen gas (Takada et al., 2011); control groups were exposed to room air. In P30, the rats were transcardial perfused and their brains were processed for PV immunohistochemistry. Hippocampal PV-positive cells were count using stereological analysis. Results revealed PV population decrease in hippocampus of rats from anoxia group (P=0.007), specifically in CA3 region (P=0.007), and a tendency in CA1 region (P=0.072). It suggests that neonatal anoxia reflects in PV population long term susceptibility. The decrease of this population was identified in CA3, which is involved in process of integration of hippocampal information; and CA1, principal output pathway of the hippocampal information. This important finding might reflect in primordial control of the excitability and oscillations that could contribute to the better understanding of the pathophysiology of neonatal anoxia sequelae and provide subsidies for future therapeutic approaches related to cognitive and learning deficits caused by neonatal anoxia.

Title: Molecular mechanism of action of galantamine in reducing hyperoxia-induced brain injury in neonatal mice

Authors: *K. R. AYASOLLA[1], N. ZAGHLOUL[2], N. S. COHEN[2], M. N. AHMED[2]
[1]Feinstein Inst. for Med. Res., Manhasset, NY; [2]Pediatrics, Cohen's Children Med. Ctr., Manhasset, NY

Abstract: Background: Hyperoxia affects brain development in premature infants leading to excess free radical production with subsequent inflammation, astrogliosis, microgliosis and apoptosis. Galantamine, an acetyl cholinesterase inhibitor, showed a protective role in hypoxic brain injury by its anti-inflammatory effects. **Objective:** To explore the mechanism by which galantamine reduces hyperoxic brain injury in neonatal mice. **Design/Methods:** WT mouse pups were housed in a hyperoxia chamber (FiO2 95%) for 7 days. Half the control as well the test group, were injected daily with galantamine intraperitoneally (IP) (5mg/kg/dose) and the other half were injected with saline. After exposure, brain tissue was studied for : IF staining for ChAT, NeuN, Iba-1, CD68, CNPase and GFAP; multiplex ELISA for Pro-inflammatory markers

and HMGB1; western immunoblot for NF-κB activity; fluorometric assay for Caspase 3, ROS assay and acetyl cholinesterase activity. MicroRNA profile panel was studied using a custom designed microarray plate. All results were compared to control group housed in room air (RA). **Results:** IF staining showed a significant increase of ChAT expression accompanied by a significant reduction in acetylcholinesterase activity in the hyperoxia groups treated with galantamine vs. saline group. In galantamine treated hyperoxia group, oligodendrocytes were preserved and thus the myelination. Also, CD68 was decreased, indicating less microglial activation which leads to a reduction of neuronal apoptosis (caspase 3). Both inflammatory markers (HMGB1, IL 12p70, IL6, KC GRO and IL10, pP65), and ROS, showed a significant decrease among hyperoxia galantamine treated group compared to the saline group. MicroRNA profile showed a significant >3 fold increases of the following: mir181a-3p; mir185-3p and mir146a-5p; and a significant reduction by >5 fold decrease for both mir21a-3p and mir494-5p among saline treated hyperoxia group in comparison to control RA. All these findings were reversed in galantamine hyperoxia treated group: mir181a-3p; mir185-3p and mir146a-5p were significantly downregulated and mir21a-3p and mir494-5p were upregulated as compared to saline group. **Conclusion(s):** Galantamine shows a potent anti-inflammatory and antioxidant activity in hyperoxia-induced brain injury in neonatal mice. Hyperoxia exposure has a specific impact on microRNA profile expression in neonatal brain tissue. Treating neonatal animals exposed to hyperoxia with galantamine leads to a specific modification of microRNA expression which could be a new therapeutic target.

Title: Impact of sildenafil on vasculature, gliosis and inflammatory cytokine expression on retinal injury secondary to hypoxia-ischemia

Authors: *P. BALIAN[1,2], A. YAZDANI[2], A. BÉLANGER[2], V. BLEAU[2], Z. KHOJA[2], P. WINTERMARK[2]
[1]Res. Inst. of the McGill Univ. Hlth., Montreal, QC, Canada; [2]McGill University, Montreal Children's Hospital, Div. of Newborn Med., Montreal, QC, Canada

Abstract: Background: Birth asphyxia often leads to long-term neurological consequences including visual impairments. These impairments are associated to hypoxic-ischemic injuries to visual pathways in the brain, but also injuries to the neuroretina itself. Treatment with sildenafil has been shown to ameliorate retinal function in a rat model of term neonatal asphyxia, however, the underlying cellular mechanisms explaining this amelioration remain to be elucidated. Our goal is to determine the impact of sildenafil on retinal neurons, inflammation and vasculature following hypoxia-ischemia (HI).
Methods: Neonatal HI was induced in rat pups at P10 by left common carotid ligation followed by 2-hour exposure to 8% oxygen. Subsequently, animals were randomly administered a vehicle solution or 50 mg/kg of sildenafil for 7 days. At P12 and P17, ELISA was performed to measure inflammatory cytokine IL1B levels. At P30, immunohistochemistry on radial sections of the retina was performed to examine retinal ganglion cells (Brn3a), bipolar cells (Chx10), astrocytes (GFAP), as well as activated (Nestin) and non-activated (GS) Muller glia. Immunohistochemistry on flatmount preparations of the retina was performed to assess retinal vasculature (Lectin).
Results: At P12, IL1B levels increased with HI compared to sham, but normalized by P17. At P30, HI caused a decrease in the number of retinal ganglion cells and bipolar cells, as well as persistent inflammation marked by an increase in the number of astrocytes and an increase in the number of activated Muller glia. HI also induced a loss of blood vessels in deeper layers of retinal vasculature. Sildenafil administration restored the number of retinal neurons, reduced inflammation by regulating gliosis and IL1B expression at P12, and improved retinal vascularization by increasing vascular branching in deep layers.
Conclusion: Sildenafil seems to improve retinal injuries by reestablishing retinal neuron numbers back to sham levels, modulating inflammation following HI and improving retinal vasculature.

Title: The effects of sildenafil on the suppression of RNF213(a susceptibility gene of Moyamoya disease) under hypoxia

Authors: *H.-S. SHIN[1], G. PARK[2], E. CHOI[2], M. CHOI[3], S. LEE[2], J. HONG[4]
[1]Dept. of Neurol., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [2]Dept. of Neurology,

Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [3]Dept. of Neuology, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [4]Sch. of Med., Ajou Univ., Suwon, Korea, Republic of

Abstract: BACKGROUND: Moyamoya disease (MMD) is a rare and progressive occlusive disorder of cerebral vasculature around the circle of Willis with abnormal compensatory collateral vessels so called ‘moyamoya’. Ring-finger protein 213 (RNF213, a specific susceptibility gene of MMD) was recently identified through genome-wide linkage analyses. Even if allelic variations of RNF213 are associated with the risk of MMD and intracranial stenosis in Asians, its role under hypoxic condition has still been unclear. Meanwhile, phosphodiesterase (PDE) 5 inhibitors including sildenafil increase the level of nitric oxide (NO) with the activation of cyclic guanosine monophosphate (cGMP) through intracellular signal processes. Therefore, we are to investigate that sildenafil can restore the endothelial function under hypoxia or normoxia with a suppression of RNF213 in a cell line. **METHODS:** We incubated Human Umbilical Vein Endothelial Cells (HUVECs) with chemical inducer of hypoxia [$CoCl_2$ (200 μM/ml)] for 1 hour. A cell line was treated with Sildenafil in a dose-dependent manner (1uM, 5uM, 10uM, 20uM). For physiological hypoxic insult, HUVECs transferred to an anaerobic chamber. The culture medium was replaced with the saturated with N_2 gas. After the incubation of the cells in hypoxic chamber, HUVECs were transferred to normoxic chamber and treated with Sildenafil in a dose-dependent manner. **RESULTS**: mRNA and protein levels of RNF213 expressed about 5-fold under $CoCl_2$-induced hypoxia. In addition, HUVECs treated with $CoCl_2$ were significantly decreased the angiogenic ability via the induction of RNF213. The administration of sildenafil mitigates a fragile endothelial tube formation with a downregulation of RNF213 and hypoxia-inducible factor-1 alpha (HIF-1α) in a dose-dependent manner. **CONCLUSIONS:** Our results suggest that endothelial function is closely related to a hypoxic stress condition under a suppression of RNF213 with the moyamoya susceptibility. In our data, sildenafil restored impaired endothelial function through angiogenic transduction pathway along with an attenuated RNF213.

Title: The effects of a one-year extensive exercise program on the progression of mild cognitive impairment

Authors: *S. SCHNEIDER[1], M. OLDE RIKKERT[2], B. LAWLOR[3]
[1]German Sport Univ. Cologne, Köln, Germany; [2]Radboud Alzheimer Centrum, Nijmegen, Netherlands; [3]Trinity Col. Dublin, Dublin, Ireland

Abstract: A lack of physical exercise plays a major role in the pathophysiology of vascular, metabolic, and metastatic diseases. Regular physical exercise has been successfully proven to counteract this deconditioning. Human and animal studies have demonstrated that regular physical activity targets brain function by increasing cognitive reserve. There is also evidence of structural changes caused by exercise in preventing or delaying the genesis of neurodegeneration. A considerable number of studies have targeted the effects of physical activity on functional and structural brain changes in patients at greater risk for Alzheimer's disease (AD). Epidemiological studies have shown that leisure-time physical activity at midlife is associated with a decreased risk of dementia and AD later in life. Although initial studies indicate enhanced behavioural performance in dementia patients after three months of exercise, little is known about the effect of an extensive, controlled and regular exercise regimen on the progressive neuropathology of cognitive impairment with and without dementia. This study aimed to determine the effects of an extensive exercise program in the prodromal phase of AD, known as mild cognitive impairment (MCI) with respect to the progression of the disease. 225 previously sedentary patients with diagnosed MCI underwent a standardized one-year extensive aerobic exercise intervention (3 units à 30-60min / week, according to WHO recommendations). Changes in the progression of cognitive impairment were monitored by means of cognitive testing (Cogstate, MoCA) and self-rated quality of Life (DemQOL) in comparison to a matched sedentary group as well as a group of subjects undergoing stretching and toning exercises. First results show an increase in physical fitness ($p < .05$) for participants attending sessions at least twice / week, which is mirrored by an increase in cognitive performance ($p < .05$) and self-rated quality of life ($p < .001$). No changes where obtained for participants attending only one session per week. Data of the sedentary control group revealed an ongoing decrease of physical fitness and cognitive performance in the course of the year. It is concluded that an extensive exercise program is able to decelerate further cognitive decline in MCI patients, even if they were following a sedentary life-style so far. Data emphasizes the importance of an active lifestyle and regular physical exercise for brain health in the context of an increasing sedentary society and is of high relevance for socio-economic and health-political decisions related to the increasing number of neurodegenerative diseases.

Title: Multimodal detection of spreading depolarization and repolarization during cardiac arrest and resuscitation: An ultra-early biomarker of neurological outcome

Authors: *Y. AKBARI[1], D. LEE[2], R. WILSON[2], C. CROUZET[2], D. DONGA[2], A. BAZRAFKAN[2], N. MAKI[2], M. MOSLEHYAZDI[2], N. NGUYEN[2], A. PATEL[2], M. AZADIAN[2], J. PHAM[2], J. ALCOCER[2], G. TIAN[2], B. TROMBERG[2], B. CHOI[2], O. STEWARD[2], B. LOPOUR[2]
[1]Neurol., UC Irvine, Irvine, CA; [2]Univ. of California at Irvine, Irvine, CA

Abstract: Intro: Spreading depolarizations (SD) are known to occur during acute and ongoing brain injury, such as ischemia and trauma. Most studies suggests that SD contribute to and exacerbate ongoing brain injury. Recent data from humans demonstrates SD occurring during cardiac arrest (CA), though the significance of SD is unknown. Using a rodent model of cardiac arrest and resuscitation, we have found that the timing of occurrence of SD during cardiac arrest is an early biomarker of neurological outcome.
Methods: Wistar rats (n=26) underwent asphyxial cardiac arrest followed by cardiopulmonary resuscitation (CPR) while monitoring electrocorticography (ECoG), cerebral blood flow (CBF), and brain metabolism. Neurological recovery was measured at various post-resuscitation time points with quantitative ECoG parameters and behavioral tests (i.e. Neurological Deficit Score; NDS). SD during CA and repolarization post-CPR was detected with ECoG after applying a 1-Hz low-pass filter, and onset was determined visually and confirmed algorithmically. Laser speckle imaging (LSI) and spatial frequency domain imaging (SFDI) were used to measure CBF, tissue oxygenation, and cerebral metabolic rate of oxygen (CMRO2).
Results: SD was captured directly by DC potential measurement and indirectly by ECoG. Earlier onset of SD during cardiac arrest is closely associated with better neurological recovery, with r value ranging 0.65-0.80 ($p<0.001$). During the SD period, we found a wave of decreasing CBF beginning 2.28 +/- 0.34 min post-asphyxia that lasted 1.05 +/- 0.29 min. Simultaneous spatio-temporal propagation of changes in tissue scattering were also detected and preceded by an inflection point in the CMRO2, suggesting a transient increase in cerebral metabolic activity. Post-CPR, a spreading repolarization (SR) was captured by DC potential measurement, ECoG, LSI, and SFDI, suggesting a mirror image phenomenon of SD during the CA phase. Earlier onset of SR was associated with better neurological outcome ($r= 0.5-0.6$, $p<0.01$). SR always preceded the initial EEG burst during the recovery phase.
Conclusion: Our findings demonstrate the first evidence for a unifying model of SD and SR occurring during CA and post-CPR, respectively, with earlier onset of SD and SR associated with better neurological outcome. Metabolic mechanisms underlying these findings are being explored. These data have important implications for prognostication, as they may be the earliest reported biomarker of outcome, and invoke various novel therapeutic interventions during CA.

Title: Roflumilast, a phosphodiesterase 4 inhibitor, prevents memory impairments and increases hippocampal neurogenesis after transient global cerebral ischemia in rats

Authors: *J. M. BONATO[1], E. MEYER[1], H. MILANI[1], J. PRICKAERTS[2], R. M. M. W. DE OLIVEIRA[1]
[1]State of Maringá Univ., Maringá, Brazil; [2]Maastricht Univ., Maastricht, Netherlands

Abstract: Background: Brain ischemic processes, such as the transient global cerebral ischemia (TGCI), is an immediate and severe outcome of reversible cardiac arrest. TGCI compromise the blood supply to the brain and causes neuropsychological, emotional, cognitive and physical deficiencies associated with neurodegeneration, reducing patients' quality of life. Phosphodiesterase inhibitors (PDE-I) may represent a novel therapeutic strategy for the treatment of cerebral ischemia sequelae. Rolipram, a PDE4-I, improved emotional and cognitive outcomes of TGCI. However, rolipram presents severe emetic effects which make impossible its clinical use. Roflumilast, a PDE4-I with less emetic effects than rolipram, has been approved for the treatment of chronic obstructive pulmonary disease. However, there are no reports of the effects of roflumilast on the sequelae of cerebral ischemia. The objective of this study was to evaluate the effects of roflumilast in rats with TGCI. **Methods**: Thus, Wistar rats (ethical committee approval 5529100517) underwent 4-vessel occlusion model of TGCI. Roflumilast (0.003 or 0.01 mg/Kg) or vehicle was administered for 21 days after ischemia. On day 7,14 and 21 the rats were tested in the aversive radial maze (AvRM), to evaluated retrograde memory. The parameters analyzed were: latency time and the number of reference and operational erros. After behavioral testing, on day 21, the rat brains were examined for hippocampal neurogenesis using immunohistochemistry for doublecortin (DCX). Neuronal specific nuclear protein (NeuN), brain derived neurotrophic factor (BDNF), growth associated protein 43 (GAP43), microtubule-2 associated protein (MAP-2), synaptophysin and post-synaptic density protein 95 (PSD95) were also evaluated using Western blotting. **Results**: TGCI caused persistent retrograde amnesia in this effect was prevented by roflumilast. Ischemic animals treated with roflumilast (0.003 and

0.01 mg/Kg) presented a decrease in the latency time ($F_{3,120}$=21.14, p<0.0001), number of reference errors ($F_{3,120}$=17.34, p<0.0001) and operational errors ($F_{3,120}$=13.68, p<0.0001) compared to controls. Roflumilast increased the number of DCX ($F_{3,21}$=13.68, p<0.0001) but did not change the hippocampal levels of NeuN BDNF, MAP-2, GAP-43, PSD-95 and synaptophysin, in ischemic animals compared to controls (p>0.05). **Conclusions**: Roflumilast prevented memory impairments and increased hippocampal neurogenesis in TGCI animals. The protective effects of roflumilast seem to be independent of increasing synaptic plasticity.

Title: Aberrant network activities in neural cultures from patients with chronic mountain sickness

Authors: *H. YAO[1], H. W. ZHAO[1], W. WU[1], J. WANG[1], P. D. NEGRAES[2], A. R. MUOTRI[2], G. G. HADDAD[1,3,4]
[1]Dept Pediat, UCSD, LA Jolla, CA; [2]Pediatrics/Cellular Mol. Med., [3]Dept Neurosci, UCSD, La Jolla, CA; [4]The Rady Children's Hosp., San Diego, CA

Abstract: Chronic mountain sickness (CMS) is manifested by neurological symptoms such as migraine headache, dizziness, and cognitive deficits. The underlying pathological mechanisms are not well understood. Since our previous work has shown alterations in Na^+ or K^+ currents in neural cells derived from CMS patients, we hypothesize that the neural network activities could also be altered in such cells derived from CMS patients. Skin biopsies were obtained from both CMS patients and healthy highlanders (non-CMS) who live in the Peruvian Andes (~14000 ft). Fibroblasts were grown and reprogramed into induced pluripotent stem cells (iPSCs) which then were differentiated into neurons in a 3D system. Cultures were characterized by typical neuronal markers, MAP2 or Tuj1, and showed positive staining to VGLUT2, suggesting that most of the cells are glutamatergic neurons although our patch clamp recordings have identified a small portion of glial cells. Using a multielectrode array system (Axion Biosystems), we studied the

neural network activity of these neural cells. Our results show that the network activity in non-CMS (normoxia) cultures increases overtime. The number of spikes (Ns) within a 5-min recording increased from 79±5 (n=6) at 5 weeks in culture (WIC) to 1125±58 (n=6, $p<0.05$) at 9 WIC, and plateaued thereafter. Under chronic hypoxia (5% O_2), the Ns increased from 102±6 (n=6) at 5 WIC to 478±19 (n=6, $p<0.05$) at 9 WIC. The difference between hypoxia and normoxia at 9 WIC was significant, suggesting that hypoxia hindered neuronal maturation in non-CMS cultures. In CMS neuronal cultures, the Ns changed from 849±54 (n=6) at 5 WIC to 1182±98 (n=6) at 9 WIC and, under hypoxia, the Ns increased from 923±65 (n=6) at 5 WIC to 3089±324 (n=6) at 9 WIC. Hence, hypoxia significantly enhanced the firing rate at 9 WIC in CMS neural networks. Furthermore, the Ns was significantly higher in CMS (849±54, n=6, $p<0.05$) than in non-CMS (79±5, n=6) at 5 WIC under normoxia. Our findings show that: a), under normoxia, CMS neural network exhibits a higher excitability than non-CMS counterparts; b), chronic hypoxia decreased the Ns in non-CMS neurons but increased the Ns in CMS neurons. Compared with CMS, non-CMS neural network show reduced activity under hypoxia which may suggest that an adaptation mechanism exists in the brain of healthy highlanders.

Title: A role of aryl hydrocarbon receptor in vasogenic brain edema

Authors: *M. TANAKA[1], Y. ISHIHARA[1], K. ITOH[2], C. VOGEL[3], A. ISHIDA[1], T. YAMAZAKI[1]
[1]Grad. Sch. of Integrated Arts and Sci., Hiroshima Univ., Higashi-Hiroshima City, Hiroshima, Japan; [2]Lab. for Pharmacotherapy and Exptl. Neurol., Tokushima Bunri University, Kagawa Sch. of Pharmaceut. Sci., Sanuki City, Kagawa, Japan; [3]Ctr. for Hlth. and the Envrn., Univ. of California, Davis, CA

Abstract: Vasogenic edema, a type of brain edema is a severe complication that accompanies ischemic stroke. We reported that neuroinflammation after ischemic stroke resulted in the aggravation of vasogenic edema. The aryl hydrocarbon receptor (AhR) is a cytosolic transcription factor which is involved in the metabolism of xenobiotic substances. Recently, it has been reported that AhR activation can regulate the inflammatory response. However, little is known about the effect of AhR on vasogenic edema. To that end, we investigated that a role of AhR in a mouse model of ischemic stroke.ICR mice underwent permanent middle cerebral artery

occlusion (pMCAO). Microglial activity was assessed by double immunostaining of Iba1-CD68 until 24 h after occlusion. MRI and TTC staining were conducted to visualize the vasogenic edema and infarct area, respectively, at the same time points with immunostaining. Minocycline, a tetracycline derivative with microglial activation inhibitor and CH223191, a potent and specific AhR antagonist, were intraperitoneally administrated before surgery.We clarified the non-ischemic area and ischemic area after pMCAO using 3-hydroxymethyl PROXYL during the MRI scans. Microglia were activated in the ischemic area 3 hours after ischemia and time-dependently activated in the non-ischemic area. Vasogenic edema subsequently occurred in the ischemic area and progressed to the non-ischemic area. This progression of vasogenic edema was prevented by inhibition of microglial activation. These results suggested that activated microglia after ischemia enhanced vasogenic edema. Next, we examined the involvement of AhR in edema progression. The expression of AhR mRNA increased 3 hours after ischemia in the striatum and cerebral cortex. The increase in the AhR expression was suppressed by the administration of Minocycline. Administration of CH223191 suppressed vasogenic edema progression and decreased the infarct size. These results indicate that AhR in activated microglia after ischemic stroke aggravate vasogenic edema.We revealed that AhR, which is upregulated in microglia after ischemia, can exacerbate vasogenic edema and increase the infarct size. We will also present the interaction of activated microglia and BBB using *in vitro* BBB model.

Title: Regional heterogeneity in consequences of spreading depolarization in metabolically compromised tissues

Authors: *K. M. REINHART[1], J. MENDEZ[2], P. D. PARKER[2], K. BRENNAN[2], C. W. SHUTTLEWORTH[1]
[1]Univ. of New Mexico Sch. of Med., Albuquerque, NM; [2]Dept. of Neurol., Univ. of Utah, Salt Lake City, UT

Abstract: Slowly-propagating waves of neuronal and glial depolarization (spreading depolarization; SD) can contribute to the progression of stroke and traumatic brain injuries. We are interested in cellular determinants that confer SD vulnerability in order to develop interventions that can limit glutamate-mediated excitotoxicity during SD. We used complementary *in vitro* and *in vivo* mouse models of metabolic compromise to assess differences in glutamate and Ca^{2+} signaling. Two photon imaging was used *in vivo* to examine neuronal intracellular Ca^{2+} (GCaMP) and extracellular glutamate with viral transfection of iGluSnFr. SDs were initiated with focal KCl microinjection and, in some animals, focal ischemia generated with distal middle cerebral artery occlusion or photothrombosis. After stroke, SD-associated glutamate and Ca^{2+} signals were prolonged in penumbral versus remote regions with better perfusion. In non-injured animals, we observed microheterogeneity in neuronal recovery after SD, related to vascular proximity. Thus, decay of Ca^{2+} signals was significantly delayed in regions more distant from penetrating arterioles. Consistent with metabolic microheterogeneity, NADH autofluorescence after SD increased with distance from arterioles. Complementary studies were conducted in brain slices, to model penumbral conditions. Moderate restriction of metabolic substrates did not alone cause damage, but rendered slices vulnerable to SD. The adenosine A1 receptor antagonist DPCPX increased EPSP amplitude and normalized paired pulse ratio, consistent with metabolic compromise and accumulation of extracellular adenosine. KCl-evoked SDs still propagated but resulted in prolonged inhibition of functional recovery. EPSP suppression after SD was partially due to A1R activation, but DPCPX did not fully restore EPSP amplitude, implying persistent dysfunction or injury. Glutamate and neuronal Ca^{2+} transients were significantly longer, consistent with a role of these mediators in extended dysfunction after SD in vulnerable tissues. The glutamate receptor antagonists memantine (100µM) and ketamine (30µM) did not prevent SD but reduced the duration of Ca^{2+} loading and significantly improved recovery after SD in vulnerable slices. These results demonstrate that penumbral regions have greater glutamate and neuronal Ca^{2+} loading after SD and also raise the possibility that subtle damage resulting from SD may occur first in neurons distant from arterioles. While improved vascular supply is expected to be helpful for SD recovery, results with the slice model indicate that targeting glutamate-mediated excitotoxicity can significantly improve recovery.

Title: Acrolein involvement in the aberrant presentation of alpha-synuclein post-mild blast traumatic brain injury

Authors: *S. HERR[1], G. G. ACOSTA[2], N. RACE[1], R. SHI[3]
[2]Basic Med. Sci., [3]Depat. Basic Med. Sci., [1]Purdue Univ., West Lafayette, IN

Abstract: Survivors of blast-induced traumatic brain injury (bTBI) have increased susceptibility to Parkinson's disease (PD), characterized by α-synuclein aggregation and the progressive degeneration of nigrostriatal dopaminergic neurons. Using an established blast-induced traumatic brain injury (bTBI) rat model, we evaluated the changes of α-synuclein and tyrosine hydroxylase (TH), known hallmarks of PD, and acrolein, a reactive aldehyde and marker of oxidative stress, aiming to reveal key pathways leading to PD post bTBI. Indicated in both animal models of PD and TBI, acrolein is likely a point of pathogenic convergence. Here we show that after a single mild bTBI, acrolein is elevated up to a week, systemically in urine, and in whole brain tissue,specifically the substantia nigra and striatum. Acrolein elevation is accompanied by heightened α- synuclein oligomerization, dopaminergic dysregulation, and acrolein/α-synuclein interaction in the same brain regions. We further show that acrolein can directly modify and oligomerize α- synuclein *in vitro*. Taken together, our data suggests acrolein likely plays an important role in inducing PD pathology following bTBI by encouraging α-synuclein aggregation. These results are expected to advance our understanding of the long-term post-bTBI pathological changes leading to the development of PD, and suggest intervention targets to curtail such pathology.

Title: Mechanisms of secondary injury and auditory deficits following mild blast induced trauma

Authors: *J. FERNANDEZ[1], E. X. HAN[2], N. RACE[2], J. LAI[3], E. L. BARTLETT[2], R. SHI[4]
[1]Purdue Univ., Lafayette, IN; [2]Weldon Sch. of Biomed. Engin., [3]Purdue Univ. Interdisciplinary Life Sci., [4]Depat. Basic Med. Sci., Purdue Univ., West Lafayette, IN

Abstract: Some of the most commonly reported functional deficits after (blast induced) traumatic brain injury (bTBI) in patients are auditory in nature. Although injury to the peripheral auditory system after bTBI has been thoroughly investigated, few studies have examined the effects of bTBI on the central auditory system. In particular, the underlying structural deficits within the auditory system and the effects of blast injury on the different auditory areas within the central auditory system are still poorly understood. Oxidative stress, along with inflammation, have been suggested as key players in secondary molecular damage in other models of CNS injury, including TBI. However, the role of this secondary pathway of damage on the auditory system following bTBI has yet to be examined thoroughly. Potentially, both mechanical and secondary oxidative injury to the central auditory system contribute to deficits in communication, memory, and learning seen among veterans, and thus warrants examination. Here, we present data showing increased levels of oxidative stress, combined with other biochemical changes, following bTBI in rats, suggesting a potential secondary mechanism for injury within the auditory system. In addition, an array of audiometric tests (DPOAE, ABR, EFR, IRN) were used to assess auditory deficits after mild primary bTBI. We show potential deficits in the auditory nerve/brain stem region, as well as temporal processing impairments, suggesting potential damage to the auditory nerve and/or inferior colliculus. Taken together, these data suggest key mechanisms of molecular damage that may play an important role in injury to the central auditory system following bTBI and subsequently in the behavioral and functional deficits commonly seen after blast-induced trauma.

Title: Chronic epigenetic changes in hippocampal neural stem cells in a rat fluid percussion injury model of traumatic brain injury

Authors: *E. BISHOP, D. R. BOONE, I. BOLDING, M. PARSLEY, D. DEWITT, D. PROUGH, M.-A. MICCI
Anesthesiol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Traumatic brain injury (TBI) results in a range of cognitive dysfunctions that significantly affect the quality of life for post-TBI survivors. Using a rat fluid percussion injury

(FPI) model, we have previously shown that, two weeks following injury, increased gliogenesis is coupled with reduced maturation and integration of new neurons in the hippocampus dentate gyrus (DG). The aim of this work was to build on our short-term studies and determine the chronic effect of TBI on the genetic and epigenetic regulation of neurogenesis in the rat FPI model, and in neural stem cells harvested and cultured from injured and control rats.
Adult male Sprague-Dawley rats were randomized to receive FPI or sham surgery. The brains were collected 6 months later and the DGs were collected by laser capture for gene expression analysis (Neurogenesis PCR array, Qiagen) and qRT-PCR analysis of miRNAs known to regulate neurogenesis. Additionally, neural stem cells (NSCs) were isolated from the hippocampus 5 weeks after FPI or Sham injury and cultured for one month under proliferating conditions.
We found that genes known to regulate neuronal differentiation, migration and survival were significantly altered in the hippocampus DG up to 6 months after FPI as compared to sham rats. Additionally, the expression of miRNAs known to regulate neurogenesis (miR9, miR24, miR124, miR132, miR134, miR184) was significantly increased. Interestingly, the same miRNAs were increased in NSCs isolated from the DG of FPI rats and cultured for an additional 30 days as compared to cultured NSC isolated from control rats. Our data strongly suggest that FPI produces chronic genetic and epigenetic changes in hippocampal NSCs. Furthermore, our results show that persistent epigenetic changes in hippocampal NSC are independent of the microenvironment as they are maintained even after the cells are removed from the brain and cultured under standard conditions. Understanding the mechanisms underlying impaired neurogenesis after TBI will aid the development of novel therapeutic interventions for the treatment of TBI survivors.

Title: Iron deposition and microglia activation in a rat model of chronic traumatic brain injury

Authors: *J. GUPTARAK, A. C. GRANT, M. O. PARSLEY, K. M. JOHNSON, I. J. BOLDING, D. S. DEWITT, D. S. PROUGH, S. L. SELL, M. A. MICCI
Anesthesiol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Activated microglia and iron accumulation have been shown to play a role in neurodegeneration and demyelination after traumatic brain injury (TBI) and in neurodegenerative disorders such as Parkinson's and Alzheimer's disease. Using a rat model of TBI our group has previously reported persistent behavioral deficits in working memory up to one year after injury. Such deficits could be associated with the presence of activated microglia and increased iron deposition, known to stimulate the generation of reactive oxygen species (ROS), in those brain areas involved in cognitive function (cortex and hippocampus). In this study we used the fluid percussion injury model (FPI) to investigate the distribution of activated microglia, iron deposition and demyelination in the rat brain at 6 and 12 months after injury. Adult male Sprague-Dawley rats were anesthetized and randomized to receive FPI or SHAM surgery (N=5-6/group). Microglia was identified by immunofluorescence analysis using a specific antibody against CD68 (a marker of activated microglia). Iron accumulation and myelin were identified using specific histological stains (Perl' Prussian blue and Weil respectively). A total of 6 sections/brain (bregma levels -1.92 mm to - 7.08 mm) were analyzed. An Investigator who was blinded to the experimental groups performed volume analysis and histological stain quantifications using Image J. Statistical analysis between two groups was performed using unpaired, two-tailed t-test. Cortical and hippocampal atrophy was observed at 6 and 12 months after FPI. Activated microglia (CD68 positive cells) and iron deposition were observed in the cortex (motor, sensory and auditory cortex) corpus callosum/deep cerebral white matter/external capsule, thalamic nuclei and hippocampus at 6 and 12 months after FPI. Myelin thickness was significantly reduced in the corpus callosum in the ipsilateral site to the injury as compared to both the contralateral site and uninjured SHAM brains at 6 months and 12 months after surgery. This study strongly suggests that TBI results in chronic microglia activation, demyelination and iron deposition leading to a progressive degenerative process possibly mediated by iron-induced oxidative damage in those brain areas involved in cognitive functions such as working memory.

Title: Traumatic brain injury causes chronic down-regulation of miR-124 in dentate gyrus

Authors: *N. VUOKILA[1], K. LUKASIUK[2], A. PITKANEN[1], N. PUHAKKA[1]
[1]A. I. Virtanen Inst. for Mol. Sci., Univ. of Eastern Finland, Kuopio, Finland; [2]Nencki Inst. Exptl. Biol, Warsaw, Poland

Abstract: Traumatic brain injury (TBI) induces molecular and cellular changes that can in time lead to the development of post-traumatic comorbidities such as hippocampus-related memory decline.
We hypothesize that TBI causes chronic changes in a hippocampal network that are regulated by microRNAs.
TBI was induced to adult rats with the lateral fluid-percussion method. Changes in gene expression were detected from the dentate gyrus at 3 months post-TBI using microarray. The data obtained was used to investigate molecular networks that could contribute to the development of post-TBI comorbidities. Differential expression of key molecules was validated with PCR, *in situ* hybridization and immunohistochemistry.
Ingenuity Pathway Analysis of microarray data indicated that TBI causes upregulation of 30 targets of microRNA-124-3p suggesting the downregulation of this microRNA. Text mining and bioinformatics analysis connected the miR-124 targeted networks with inflammation and proliferation. Both droplet digital PCR and *in situ* hybridization confirmed the chronic downregulation of miR-124 ($p<0.05$) in the dentate gyrus. The upregulation two targets of miR-124, *Plp2*, and *Stat3*, was validated with quantitative PCR ($p<0.05$). Immunohistochemical analysis of STAT3 revealed that the upregulation of *Stat3* extents also to protein level.
Our findings indicate that miR-124 is a chronic regulator of molecular networks relevant to post-traumatic hippocampal pathologies.

Title: Mechanisms underlying axonal swelling formation

Authors: *V. M. POZO DEVOTO, V. LACOVICH, M. NOVAKOVA, M. FEOLE, K. TEXLOVA, G. B. STOKIN
Fakultní Nemocnice U Sv. Anny V Brne, Brno, Czech Republic

Abstract: Axonal swellings (AxS) are focal enlargements of axons found post-mortem in a range of biological and pathological settings including traumatic brain injury, Alzheimer's disease and multiple sclerosis. Despite their description in a range of settings, the mechanisms involved in the formation of AxS remain poorly understood. Here we developed a novel *in vitro* experimental paradigm to test for mechanisms underlying AxS formation. Human neuronal progenitor cells were seeded into microfluidic chambers and terminally differentiated to neurons. In these chambers axons grow into microchannels, which are crossed by a perpendicular channel to which we connected a syringe pump. Syringe pump generates force, which subjects axons to bending stress. After full characterization of the channel fluid dynamics, we tested how axons respond to the stress. Detailed analysis of the kinetics by time-lapse imaging showed a significant increase in the number and size of axonal enlargements during and after stress as visualised by transducing neuronal culture with a membrane targeted Cherry. We have first studied these axonal enlargements by scanning electron microscopy to reveal and distinguish physiological versus pathological enlargements following axonal injury. We next performed super-resolution microscopy to demonstrate loss of Spectrin BII periodicity of the sub-axolemmal cytoskeleton. We then investigated whether enlargements form as a result of membrane leakage in response to shear stress. We incubated axons with fluorescent dextrans of different sizes at the time of injury and learned that enlargements do not form as a result of membrane leakage. Considering many reports found increased Ca^{2+} following axonal injury, we then asked whether Ca^{2+}concentrations increase in axonal enlargements. We found a significant increase in Ca^{2+} within the enlargements as visualised by the Fluo 4AM Ca^{2+}sensor. To confirm this finding further we also used the ratiometric Fura 2AM Ca^{2+} sensor in addition to imaging $Na^{+}$and K^{+}concentrations prior, during and after axonal injury with the aim of confirming the role and specificity of Ca^{2+} in axonal enlargements during injury. Furthermore, to understand the role of Ca^{2+}in enlarged axons following injury we next depleted Ca^{2+} from media and blocked different axonal membrane and ER/mitochondrial Ca^{2+}channels. In summary, we created a unique cell culture paradigm to study the response of axons to physical injury and provide novel insight into mechanisms responsible for the formation of axonal swellings.

Title: pH change-induced zinc release causes cell and tissue injury

Authors: *Z. WANG, Y. V. LI
Biomed. Sci., Ohio Univ. Dept. of Biomed. Sci., Athens, OH

Abstract: Intracellular pH (pH_i) is stringently regulated and varies greatly among different organelles. For example, the pH in lysosome, nucleus, and mitochondrial matrix are 4.7, 7.2 and 8, respectively. The pH in the cytosol is around 7.2. A stable pH is critical for normal neuronal function. However, pathological conditions, such as ischemic stroke, traumatic brain injury, and epileptic seizure are accompanied by a marked reduction of pH_i. The following reperfusion process brings pH_i back to physiological level. PH change affects metal ions homeostasis, such as zinc homeostasis. As an important trace element, zinc is required for normal cellular structures and functions. The concentration of zinc is tightly regulated in the cells. However, a number of studies have shown that a lowering of pH_i can interrupt zinc homeostasis by causing zinc release from loosely bound proteins and subcellular organelles. In the present study, we investigated the effect of zinc during pH_i change in both cell and animal model. We proposed a strategy to save cells and tissues by reducing intracellular zinc concentration. Sodium dithionite (DT) was used to induce intracellular acidification, and the following reperfusion with ACSF was used to bring pH_i back to normal. In the animal model, the traumatic brain injury (TBI) caused a fall in local pH in the beginning, followed by latterly pH recovery through reperfusion with ACSF. Zinc chelator was applied to reduce zinc concentration of cells and tissues. The specific zinc fluorescent indicator was used to detect zinc concentration change in both cells and tissues. TTC staining was used to measure brain infarction levels. Results showed that DT-induced intracellular acidification caused zinc release, which led to cell morphological changes, resulting in cell injury. The following reperfusion-induced pH_i recovery caused more damage than that of intracellular acidification. This injury was attenuated by the application of zinc chelator, suggesting the importance of zinc homeostasis in cell protection against pH recovery-induced cell injury. The similar results were also observed in TBI. TBI caused zinc release, resulting in tissue damage. Zinc chelation exhibited a neuroprotective effect on TBI-induced brain damage through reducing brain infarct volumes.

Title: Delayed effects of acute radiation exposure in BBT-059 treated survivors

Authors: *N. K. SHARMA[1], S. BISWAS[1], S. STONE[1], C. FAM[2], G. COX[2], V. KUMAR[1], S. GHOSH[1]
[1]SRD, Armed Forces Radiobiology Res. Inst., Bethesda, MD; [2]Bolder Biotech., Boulder, CO

Abstract: Introduction: BBT-059, developed by Bolder Biotechnology (BBT), is a long acting PEGylated IL-11 analog. Previously, we demonstrated that BBT-059 is effective as a radiation countermeasure in CD2F1 male mice when a single dose was administered either at -24 h pre- or 24 h post-total body irradiation (TBI). In this study, we show that surviving animals remain healthy up to 6 months post-TBI. Methods: Twelve to fourteen week old CD2F1/ male mice used in these studies. BBT-059 was prepared in formulation buffer (10mM sodium phosphate, 4% mannitol, 1% sucrose, pH 6.2) at the specific doses used in studies. Formulation buffer and saline (9%) were used as controls. Drug and controls were injected as a single dose (0.1 mL) subcutaneously (SC) at the nape of the neck. The experimental animals received a single exposure of ^{60}Co gamma TBI at an estimated dose rate of 0.6 Gy/min in the AFRRI radiation facility. Survived animals post-30 day after radiation were monitored up to 6 months. Blood and bone marrow analyzed for CBC counts, serum chemistry, and colony forming units (CFU) to understand the longterm effects of the survivors at 1 and 6 months post-TBI. Histopathological and immunohistochemical analysis of Brain and other major organs were performed. Results: Mortality was monitored up to 6 months post-TBI. There was an increase in the CBC counts and CFU in the 6 months post-TBI survivors compared to one month group. Mitochondrial damage in brain was seen in survivor of mice treated with higher radiation dose. Increased Glomerular with messangium and lung fibrosis was observed at 6 months post-TBI. In heart, after 6 months some vessels had evidence of smooth muscle hypertrophy of the arterial/ arteriolar wall as compared to naïve. Immunohistochemistry revealed an increase in the B- Catenin expression after 1 and 6 months in brain and kidney. Mice with higher radiation doses developed cataract after 6 Months. However, after six months serum biochemistry for blood urea nitrogen, creatinine, aspartate aminotransferase, alanine aminotransferase and alkaline phosphatase did not show any difference between naïve, untreated and treated groups. The results indicate that significant delayed effects of acute radiation exposure occur in Brain, lung, heart, and kidney in survivor animals. Conclusion: We have shown that BBT-059 treated animals survived up to 6 months post-TBI. Significant survival benefit with BBT-059 and as well as its long term effect suggests that the drug could be developed as a novel radiation countermeasure for civilians exposed in a fall out field for use after radiation in the aftermath of a radiation event.

Title: Cerebral blood flow and cognitive deficits following a single and multiple mild traumatic brain injuries

Authors: *R. A. MORTON[1], J. M. PACHECO[1], H. ZHANG[1], J. GUERIN[2], J. L. BRIGMAN[3]
[1]Neurosciences, [3]Dept. of Neurosciences, [2]Univ. of New Mexico, Albuquerque, NM

Abstract: It is estimated that there are approximately 3.8 million sports related concussions every year (Langlios, 2006). Many concussions do not result in emergency room visits but can result in a myriad of cognitive and behavioral deficits including: the inability to concentrate, feeling "foggy", headaches, and depression (Brent, 2017), and are referred to as post-concussion syndrome. The mechanisms of these symptoms remain unclear, however, cerebral blood flow has been implicated in mTBI. The objective of these studies is to identify the time course of CBF hypoperfusion immediately following a single impact and identify cortical mediated behavior deficits following a single mild traumatic brain injury (mTBI) versus multiple mTBIs. To achieve these objectives, we have used a closed skull impact model in wild type C57/Bl6 mice utilizing both male and female animals between the ages of 8 - 12 weeks. Mice were impacted at a speed of 4 m/s with a 5mm head deflection. These mTBIs did not result in significant tissue damage, hemorrhaging, or cell death. We used Laser Speckle Contrast Imaging to monitor CBF immediately following a single mTBI. Our preliminary data indicate that immediately following an impact the CBF is reduced to 46.87% baseline levels and remains significantly reduced after 90 minutes (69.45%; $p<0.0001$). To assess for cortical/striatal mediated behavioral deficits we have utilized a discrimination/reversal touchscreen-based task. Animals that received a single mTBI showed no significant differences in discrimination or reversal learning. However, animals that received a mTBI every day for four days had significantly more incorrect trials (Sham=112; mTBI=485.75, $p<0.0001$), correction trials (Sham=206; mTBI=1000; $p=0.0009$) and did reach the criteria of 85% correct within the 40 day cut-off. Overall, these data suggest that a single mTBI results in long-term reductions in CBF but does not impair cortical/striatal mediated cognitive behavior. However, multiple mTBIs results in significant impairment in discrimination learning that is largely mediated by the medial prefrontal cortex.

Title: In-vitro assessments of brain injuries and different neuronal network topologies on development of epilepsy

Authors: *S. GHIASVAND, Y. BERDICHEVSKY
Lehigh Univ., Bethlehem, PA

Abstract: Introduction: Post-traumatic epilepsy(PTE) is the most common form of acquired epilepsy. Following the injury, a cascade of molecular and cellular alterations leads to the epileptogenesis and the onset of seizures. Anti-epileptic drugs(AEDs) are the common treatment for PTE. However, a significant portion of patients are resistant to these drugs. This lack of efficacy cannot be alleviated in part due to an incomplete understanding of the changes that occur at the molecular and cellular levels following traumatic injury. Additionally, it is not clear what neuronal network topologies result in spontaneous epileptiform activity. Therefore, in order to describe the changes associated with various forms of injury we have employed *in-vitro* models of brain injury. Effects of chemically and mechanically induced injuries were investigated through electrical and optical recordings to assess seizure onset and propagation.
Materials and Methods: Organotypic hippocampal cultures(OHCs) were used as an *in-vitro* model of PTE. Two different neuronal network sizes of the hippocampal cultures, including whole hippocampal cultures and small portion of CA3 sub-region were cultured. Secondly, a brief pulse of 0.3% triton solution was used to kill a portion of cells in the OHC, thereby reducing the neuronal network density. Lastly, an *in-vitro* model of mechanical traumatic brain injury (TBI) was employed by dropping a 0.2g mass from a height of 2mm on the various regions of OHCs.
Results and Discussion: Contrary to our initial expectations the significantly smaller neuronal network from CA3 micro-cultures displayed significantly higher seizure rate and duration, suggesting that relative deafferentation might play the critical role in driving epileptogenesis. Reducing the density of the network by chemical injury resulted in significantly suppressed ictal activity. Preliminary results from mechanically induced TBI have demonstrated that we can selectively induce cell death in specific sub-regions of OHCs.
Conclusion: Our results indicate that the proportion of deafferentation can be the driving impetus of epileptogenesis. In future experiments we hope to prevent the consequent alterations of deafferentation at the cellular and network level to validate the centrality of deafferentation in PTE.

Title: Closed nest pre-weaning environment improves the development of physical characteristics and buffers hippocampal injury in neonatal hypoxic ischemic injury

Authors: *L. ROLLINS[1,3], B. M. MASON[2], T. DONALDSON[4]
[1]Univ. of Massachusetts Boston, Warwick, RI; [2]Univ. of Massachusetts Boston, Boston, MA; [3]Dept. of Psychiatry and Human Behavior, Brown Univ., Providence, RI; [4]Psychology, Univ. of Massachusetts, Boston, MA

Abstract: Term neonates with hypoxic-ischemic (HI) injury are at risk for devastating neurological sequelae. Maternal care taking behavior has been found to alter the trajectory of normal brain development and may also impact neurodevelopment with exposure to HI injury. Maternal care-taking behavior can be highly influenced by environmental stress and may, therefore, mediate the effects of such stressors on injury and repair for these neurologically high-risk neonates. In the present study, we investigated whether altering early environment for maternal care-taking impacts neurodevelopment and neuroprotection in HI rat offspring. The Rice-Vannucci model was used to induce HI in 26 postnatal day (PND) 7 Long-Evans pups. Dams and litters were randomized to a closed nest (CN) or normal standard housing (SH) condition. Performance on a neurodevelopmental battery and characteristics of physical development were assessed daily from PND8-PND21 to quantify effects of the CN condition on HI injury. Brains were harvested at PND 60 and analyzed for morphological differences. Results indicate that HI injured animals reared in the CN condition showed significantly earlier development of physical characteristics, exhibiting ear unfolding an average of 2.23 days earlier ($p<0.001$), eye opening 1.85 (L) and 1.07 (R) days earlier ($p<0.001$), left ear twitch 1.9 days earlier ($p<0.05$), and audible startle response 1.46 days earlier ($p<0.01$) than those in the SH condition. There was also a trend observed for earlier development of negative geotaxis ($p=.084$) in the CN condition by 2 days. In addition, animals in the CN condition were consistently found to have a significantly higher body weight than those in AF ($p<0.001$) throughout the pre-weaning period. Finally, CN animals had significantly greater hippocampal tissue ($p<0.001$) in the ipsilateral hemisphere than SH animals with no difference in ipsilateral cortical area ($p>0.05$), indicating potential neuroprotection for vulnerable white matter areas. These findings indicate that, in comparison to SH housing, CN housing during the pre-weaning period promotes

maternal care-taking behavior to increase weight gain, improves the development of reflexes, physical characteristics, and supports neuroprotection in pups exposed to neonatal HI.

Title: Alterations in the deep layer cortex of $SOD1^{G93A}$ rats throughout disease progression and following repetitive mild TBI

Authors: *M. ALKASLASI, N. CHO, N. DHILLON, N. LINAVAL, J. GHOULIAN, A. YANG, G. BARMPARAS, E. LEY, G. M. THOMSEN
Cedars-Sinai Med. Ctr., West Hollywood, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by a progressive loss of motor neurons leading to paralysis and death within 3-5 years of disease onset. Much of the etiology of ALS is likely rooted in complex interactions between genetic and environmental risk factors. Traumatic brain injury (TBI) is an environmental risk factor often linked to neurodegeneration. Populations prone to repetitive head injury, such as professional athletes and veterans are reported to have a higher incidence of neurodegenerative disease, including ALS. In this study, we assessed changes within layer V of the motor cortex of the $SOD1^{G93A}$ ALS rat model that occur over the time course of disease as well as following repetitive mild TBI.
$SOD1^{G93A}$ rats were administered mild, bilateral, closed-skull, controlled cortical impact (CCI) TBI at post-natal day (p) 60 once weekly for 5 weeks. Uninjured $SOD1^{G93A}$ sham controls were exposed to anesthesia only. Rats were euthanized at acute (p90), short (p165) or long (p235) timepoints, with $SOD1^{G93A}$ rats in the long group euthanized at disease endpoint (p150-235). TBI rats were classified as having “mild” or “severe” injuries based on rotorod performance within 6 days following the final injury. Brains were processed histologically to assess brain atrophy, microglial activation and health of layer V corticospinal motor neurons. RNA was also extracted and analyzed from brain tissue microdissected from layer V/VI of the motor cortex. Transcriptional profiling was performed to examine differentially regulated genes within this cortical region.
Following rTBI, $SOD1^{G93A}$ rats exhibiting initial severe symptoms showed exacerbated functional and pathological disease symptoms. These animals experienced earlier onset of forelimb paralysis and shortened survival relative to their sham counterparts (median onset: 150 vs 169 days, $p<.0001$; median survival: 168 vs 179 days, $p=.038$). Pathologically, $SOD1^{G93A}$ rats

in the severe group displayed increased cortical and corpus callosum atrophy, altered inflammation, and a reduction in large corticospinal motor neurons residing in layer V. RNA sequencing of brain tissue from layer V/VI revealed that $SOD1^{G93A}$ animals show significant alterations in genes associated with astrocyte activation and microglia development. Identifying and understanding changes in critical genes associated with ALS within the motor cortex will be important for developing therapeutic strategies targeting these relevant pathways.

Title: Transcriptional and epigenomic signatures identified via systems-based modeling of hippocampal pathology in a rat model of traumatic brain injury

Authors: *I. ZDILAR, K. TERCOVICH, B. LYETH, G. GURKOFF, A. NORD
Univ. of California Davis, Davis, CA

Abstract: Outcome following traumatic brain injury (TBI) is influenced by the initial mechanical insult, combined with secondary effects, including neuroinflammation, apoptosis, and altered neurotransmission. Rather than focusing on a single target for investigation we propose that measures of systems-level changes can provide a readout that allows us to comprehensively assay across processes related to pathology following TBI. Further, we hypothesize that epigenetic changes persist in the brain after initial recovery from TBI. Ipsilateral hippocampus was isolated either 1 or 14 days following lateral fluid percussion or sham injury and processed for RNA sequencing and genome-wide analysis of select histone post-translational modifications. At day 1 post-injury we observed a characteristic increase in expression and epigenetic modifications at genes related to inflammation apoptosis, metabolism, extracellular matrix receptor interactions, and calcium signaling, with neurotransmitter systems not profoundly altered. While still elevated as compared to sham at day 14, there was a reduction in expression of inflammatory genes, apoptosis, and altered metabolism as compared to 24 hours post-injury. Unique to the later two-week time point was a widespread decrease in transcription of neurotransmitter receptors and ion channels, a larger effect than would be explained by cell loss alone. Many of these perturbed molecules also play key roles in learning and memory,

processes highly relevant to the hippocampus and long-term outcome following TBI. Finally, there was an increase in coagulation cascades as well as a reduction in steroid synthesis at the later time point. Our data indicate that transcriptomic and epigenetic alterations persist in the brain long after the acute injury response. This systems-level analysis identified clear modulation of multiple systems over time following injury and demonstrate linked perturbation to gene expression and epigenetic state following TBI.

Med. Ctr., Loma Linda, CA; [6]Ctr. for Perinatal Biol., Loma Linda Univ. Sch. of Med., Loma Linda, CA; [7]Pediatrics, Univ. of California Irvine, Irvine, CA

Abstract: Traumatic brain injury (TBI) results in damage to the cerebral vasculature and is often associated with hypoperfusion, edema, hemorrhage, and cell death. While numerous studies have revealed that the cerebral vasculature is injured after TBI, there are scant studies looking at repair of the vessel network following brain injury. At present there are no studies that have comprehensively examined the molecular mechanism(s) underlying revascularization after TBI. One possible molecular mechanism may be the Wnt/β-catenin pathway, which promotes blood vessel formation during vascular development. We previously reported increased Wnt/β-catenin expression and activation of Wnt target genes in blood vessels after TBI which coincides with revascularization at 7 days post injury (dpi). The objective of this exploratory study is to investigate the role of β-catenin in revascularization after TBI. A controlled cortical impact mouse model was used to induce a moderate TBI in adult male C57BL/6J mice (8 weeks old) which leads to gross injury to cerebral vessels. To assess the role of β-catenin in revascularization, we utilized JW74 (tankyrase inhibitor) to inhibit β-catenin expression. JW74

or vehicle (dimethyl sulfoxide/polyethylene glycol 400) was administered orally for 6 consecutive days and underwent terminal vessel painting to label the entire cerebral vasculature at 7dpi (n=6-8/group). Innovative analysis methods were employed, including fractals to measure complexity along with a classical analysis to measure vessel features. Ex vivo T2-weighted imaging and susceptibility weighted imaging was undertaken to assess edema and hemorrhage. Sex differences were not assessed. All experiments and analyses were performed by investigators blinded to the treatment and subject. We report that JW74 treated mice showed a robust reduction in vessel features including vessel area, branch points, and average vessel length compared to vehicle treated mice. We observed a reduction in number of vessels and vessel complexity in JW74 treated mice. T2 and susceptibility weighted imaging of vessel painted brains at 7 dpi revealed an increase in hemorrhage and edema volumes following JW74 treatment. Our findings suggest that endogenous developmental programs, such as Wnt/β-catenin, likely become activated after TBI to initiate repair. Treatment regimens to enhance activation Wnt/β-catenin may contribute to the vascular repair process after TBI and represents a potential target for future therapeutics.

Abstract: Traumatic brain injury (TBI) accounts for more than 90,000 newly disabled persons annually in the USA with the upsurge in metabolic neuropathies increasingly recognized to worsen outcomes. The sequela of TBI includes acute and chronic effects, with marked alterations in metabolic, inflammatory and enteric function, affecting both brain and periphery. Accordingly, functional gastrointestinal disorder is a notable complication of TBI. Because gut function is greatly disrupted after brain injury, TBI may consequently disrupt the gut microbiota

and its products, contributing to central and peripheral complications in TBI. The microbiome is getting recognition as a key player in the gut-brain axis, exerting powerful effects on host metabolic and inflammatory status, and altering brain function and behavior. After brain injury, functional alterations in the brain-gut axis may also disrupt immune-mediated regulation of gut permeability, increasing the translocation of bacteria to the host. Bacteria may accumulate in host organs, including liver and brain, exacerbating metabolic and inflammatory effects of TBI on both the brain and periphery. We used fluid percussion injury in rats in order to examine neuroenteric alterations, the modulation of inflammatory mediators, and the subsequent disruption of tight junction proteins in the gut barrier. In addition, we tracked the changes in gut microbiota profiles at 24 hours, 6 and 21 days after injury, and assessed the accumulation of bacteria in the liver and brain. The potential role of the gut bacteria in mediating or moderating the bidirectional interactions between gut and brain after TBI presents an opportunity to elucidate underlying gut-brain axis mechanisms and to help develop novel application of probiotics, dietary therapeutics and pharmacological compounds in the prevention or reversal of secondary complications of TBI.

Title: Loss of pericyte impairs blood-brain barrier integrity following traumatic brain injury

Authors: S. BHOWMICK[1], V. D'MELLO[1], A. WALLERSTEIN[1], *P. ABDUL-MUNEER[2,1]
[1]Neurosci., Hackensack Meridian Hlth. JFK Med. Ctr., Edison, NJ; [2]Neurosci., JFK Med. Ctr., Edison, NJ

Abstract: Background: Blood-brain barrier (BBB) constitutes a neurovascular unit formed by microvascular endothelial cells, pericytes, and astrocytes. Disruption of BBB is a hallmark of many neurological disorders including traumatic brain injury. Loss of pericyte have been implicated in injury, however, how the crosstalk between pericytes, endothelial cells, and astrocytes ultimately leads to BBB dysfunction and subsequent progression in TBI remains elusive. In this study, we hypothesized that following TBI, loss of pericytes is a consequence of downregulation in the platelet derived growth factor B (PDGF-B)-platelet derived growth factor receptor β (PDGFR-β) signaling pathway that results in the impairment of BBB integrity and

leads to neurovascular dysfunction following TBI. **Method:** In this study, mice were subjected mild (7psi) and moderate (15 psi) fluid percussion injury (FPI) injury and tissue samples collected from the site of injury were analyzed for expression of proteins using western blotting, immunohistochemistry and ELISA approach. The integrity of the vasculature was analyzed by assessing the permittivity of small-molecular-weight sodium fluorescein (Na-Fl) (MW 376) and high-molecular-weight-tracer Evans blue (EB) (MW 961) across the BBB. Further, BBB permeability after FPI was analyzed by detecting peripheral S100β and NSE in blood serum samples. **Results:** Our data provide substantial evidence that expression of various pericyte markers such as PDGFRβ, NG2 and CD 13 reduces significantly following FPI injury with subsequent reduction in the expression of certain proteins such as N-cadherin and Connexin 43 that connect endothelium and pericyte and tight junction proteins such as Occludin, Claudin 5, ZO-1, and JAM-a. Loss of pericytes further results in the permeability of BBB marked by a significant increase in Aquaporin4 in injury groups and increase water leakage as compared to control animals. Similarly, FPI greatly increased the permittivity of small-molecular-weight Na-Fl (MW 376) and high-molecular-weight-tracer EB (MW 961) across the BBB compared with respective controls. Intriguingly, the injury inflicted animals also showed significantly higher levels of S100β and NSE in the blood samples compared with controls. In conclusion, our data provide an insight that brain trauma causes an early loss of pericyte function and results in BBB dysregulation that initiates pathological consequences associated with TBI. Thus, a therapeutic approach targeting restoration of pericyte function could lead to a better outcome in the treatment of TBI.

Title: Role of CXCR3 in astrogliosis after mild traumatic brain injury

Authors: M. FOURNIER[1], J. AUSSUDRE[1], M. TORRES-NUPAN[1], F. CASSE[1], C. BILLOTET[2], A. BIKFALVI[2], *J. BADAUT[1]

Abstract: Traumatic brain injury (TBI) is the first cause of disability among young adults and children. Mild TBI (mTBI) is defined to include no or transient loss of consciousness, no visible alterations on conventional medical imaging and no short-term cognitive deficits. Mild TBI represent most of TBI cases. Even with mTBI, clinical studies report long-term psychological and behavioral consequences. Those dysfunctions are not only caused by the local primary injury but also by the development of a chronic inflammation altering the brain properties. The chemokine receptor CXCR3 has been previously associated to microglia activation after injury but its role has been under-explored in the process of reactive astrocyte and cerebral blood vessels changes after mTBI. We hypothesized that activation of CXCR3 will contribute to promote astrogliosis after mTBI with consequences on blood-brain barrier (BBB) properties, synaptic plasticity and behavior outcomes. The role of CXCR3 after mTBI was investigated using a closed head injury (CHI) model and comparing behavior outcomes, neuroimaging (T2WI), neuronal plasticity, astrocytes and BBB properties between wild-type (WT) and CXCR3 knockout (CXCR3-KO) mice from 1 to 30 days after injury. T2WI did not show any gross brain morphological changes in all experimental groups, suggesting that CHI model mimics mTBI. Increase of foot-faults (230%) was observed 7d after injury compared to sham in the WT-group but not in CXCR3-KO group. In Morris Water Maze test, WT group with mTBI exhibited spatial learning and memory alterations compared to sham 30 days after injury. In contrast, CXCR3-KO group did not show memory alterations. In the WT group, the behavioral dysfunctions were associated to an increase of the GFAP staining in the hippocampus 7 days after injury, whereas no change in GFAP staining were observed in CXCR3-KO group after mTBI. However, no change in the BBB was observed using IgG extravasation staining in all experimental groups. In conclusion, absence of CXCR3 is beneficial for both locomotor and cognitive outcomes, associated to reduced astrogliosis 7 days to 1 month after mTBI. Our preliminary results suggest that CXCR3 pathway is an interesting target to treat memory and sensory motor dysfunctions associated to the inflammation occurring after a mTBI.

Abstract: Presently there are still no approved treatments for traumatic brain injury (TBI). This suggests that we still lack a full understanding of TBI mechanisms. Previously we reported acute changes in small non-coding microRNAs (miRNAs) after experimental fluid percussion brain injury (FPI). Our objective in this study was to examine TBI-induced miRNA changes up to a year after injury. Adult male, Sprague-Dawley rats (300-350 g) were subjected to either TBI or sham injury and survived for 24 hr, 2 wk, 3 mo, 6 mo, and 1 yr. We microdissected the hippocampus and cortex regions and isolated total RNA. cDNA libraries were prepared for miRNA sequencing and sequenced on a NextSeq550 Illumina platform. MicroRNA-sequencing data was analyzed using EdgeR. Ingenuity Pathway Analysis (IPA) was used to identify pathways regulated by significantly altered miRNAs at all post injury intervals. Expression of selected miRNAs was confirmed using digital PCR analysis. Bioinformatics analysis showed the majority of TBI-dysregulated miRNAs (i.e., miR-146a-5p, miR-142-3p, miR-17-5p, and miR-221-5p) are predicted to target genes involved in inflammation and neurodegeneration. Our data suggest that TBI- induced miRNAs may have dual effects on inflammation because some of these miRNAs are known to suppress gene expression. We have previously shown that knocking down individual TBI-induced genes does not result in altered functional outcomes. Because miRNAs coordinately regulate multiple genes in cell signaling pathways affected by TBI, we have identified specific miRNAs that regulate these genes as potential therapeutic targets for brain injury.

Title: Reversal of glutamate transport contributes to retinal zinc elevation and ganglion cell death after optic nerve injury

Authors: *N. HANOVICE[1], Y. LI[2], N. C. DANBOLT[3], L. I. BENOWITZ[1], P. A. ROSENBERG[1]
[1]Boston Children's Hospital/Harvard Med. Sch., Boston, MA; [2]State Key Lab. of Ophthalmology, Zhongshan Ophthalmic Center, Sun Yat-sen Univ., Guangzhou, China; [3]Univ. of Oslo, Oslo, Norway

Abstract: Glaucoma, a leading cause of blindness worldwide, is characterized by the progressive and irreversible loss of retinal ganglion cells (RGCs). Though mounting evidence shows that glaucoma initiates with an insult to RGC axons in the optic nerve head/lamina cribrosa, the precise mechanisms linking axonal injury to RGC apoptosis are unclear. Recently, we discovered that retinal interneurons play a critical and previously uncharacterized role in linking optic nerve crush (ONC) to RGC death in mice: namely, that ONC leads to a rapid increase of mobile zinc (Zn^{2+}) in amacrine cell (AC) terminals that is transmitted to RGCs, and that chelation of Zn^{2+} improves RGC survival and axonal regeneration. The signals linking RGC injury to Zn^{2+} accumulation in amacrine cells remain largely unknown. Here, we present evidence that the glutamate transporter GLT-1 expressed in retinal bipolar cells, Muller glia, and/or astrocytes responds to ONC by exporting glutamate, which activates NMDA receptors and culminates in Zn^{2+} elevation in synaptic terminals of amacrine cells and subsequent accumulation in RGCs. We previously showed that Zn^{2+} is liberated from intracellular reserves by nitric oxide (NO) that is generated by NO synthase-1 (NOS1) [Li et al. *SfN 2017. #742.09*]. NOS 1 is commonly activated by Ca^{2+} entry through activated NMDA receptors. To determine whether NMDA receptor activation is required for Zn^{2+} accumulation, we injected the NMDA receptor inhibitor MK801 prior to ONC, and found that this prevented Zn^{2+} elevation. Since NMDA receptor activation is mediated by glutamate, we next investigated the source of extracellular glutamate. Aside from vesicular release at synapses, glutamate can be exported by glutamate transporters operating in reverse. We found that both DL-threo-beta-benzyloxyaspartate, a general glutamate transport blocker, and dihydrokainate, a relatively specific blocker of GLT-1, prevented Zn^{2+} accumulation and enhanced RGC survival. The effect of each inhibitor on Zn^{2+} elevation was overridden by the addition of the NO donor DETA-NONOate, indicating that reversal of transport by GLT-1 is upstream of NMDA receptor activation. Immunohistochemistry using GLT-1 specific antibodies revealed that GLT-1 is expressed in bipolar cells, Muller glia, and astrocytes, but not the soma or dendrites of RGCs. Together, these results establish GLT-1 as a critical mediator of RGC degeneration and shed further light on the signaling events linking ONC to RGC degeneration.

Title: Fibrosis genes over-expression rat model for neurocysticercosis

Authors: *D. G. DÁVILA[1], R. P. CARMEN[1], R. H. GILMAN[2], R. CELIZ[1], E. BERNAL[1], A. D. DELGADO[1], C. QUISPE[1], B. J. CONDORI[1], F. ANCAJIMA[1], M. VERASTEGUI[1]

Abstract: Neurocysticercosis is a brain infectious disease with higher prevalence in developing countries. While neurocysticercosis pathology has been studied few data reports gene expression results which can explain changes seen in this pathology. Neurocysticercosis is characterized to form a fibrotic layer surrounding the parasite followed by an extensive area of gliosis. Fibrosis and gliosis varied depending on the viability of the cyst and its location. This study tried to characterize fibrotic gene response in viable cyst located in parenchymal tissue. In order to explain that, we used a rat model for neurocysticercosis, in which 13 rats of 12 days old were infected with *T. solium* oncospheres. After 6 months of infection, rats were euthanized and the tissue surrounding the cysticercus were dissected to study gene expression of fibronectin1, collagen1a1, collagen 3a1, Matrix metalloproteinase 2 and 9 (Mmp-2,9) by quantitative reverse transcription PCR. Twelve sections from six non-infected rats were used as a control and five housekeeping genes were tested. Lactate dehydrogenase A was the more stable housekeeping gene and was used for normalization. We found overexpression of all the aforementioned genes with exception of Mmp-9 in the tissue surrounding the cyst in compared to the non-infected tissue. The highest fold of change was found for col3a1 followed by Mmp-2, fibronectin, and col1a1 (values of a median of fold expression were 17.19, 8.25, 7.24 and 5.24, respectively. $P<0.01$). This data seems to be congruent with the pathology of neurocysticercosis where viable cysts are encapsulated by a fibrotic tissue. We highlight the importance of Mmp-2 which can be working as a regulatory molecule involved in the fibrotic response in neurocysticercosis.

Title: The role of interneuron death in traumatic brain injury

Authors: *A. M. ORTIZ RIVERA[1], J. KOENIG[1], M. ARMBRUSTER[3], D. KONG[2], C. G. DULLA[1]
[1]Neurosci., [2]Tufts Univ. Sch. of Med., Boston, MA; [3]Neurosci., Tufts Univ. Sackler Sch. of Biomed. Sci., Boston, MA

Abstract: Over 200,000 cases of traumatic brain injury (TBI) occur annually. Post-TBI pathologies include motor and cognitive dysfunction, as well as post-traumatic epilepsy (PTE). How TBI leads to these pathologies is largely unknown. Using the controlled cortical impact (CCI) model of TBI, we found that inhibitory GABAergic interneurons are lost. Similar losses in GABAergic interneurons are seen following human TBI. Parvalbumin (PV+) interneurons, which powerfully constrain cortical network function, are among those lost. However, it is unknown whether the loss of PV+ interneurons contributes directly to cortical network dysfunction after TBI. Studying interneuron loss post-TBI is challenging because it occurs alongside inflammation, vascular changes, and immune cell infiltration. Determining the role of interneuron loss in the pathophysiology of PTE could allow identification of novel drug targets. To elucidate the link between interneuron loss and PTE, we used viral (AAV5-taCasp3-TEVP) and genetic (cell type-specific Cre) tools to induce apoptosis in interneurons in the absence of traumatic injury. The virus expresses activated Caspase-3 in cells expressing Cre-recombinase to induce programmed cell death. We used both *PV-Cre* and *vGAT-Cre* to target PV+ and GABAergic interneurons, respectively. **We hypothesize that genetic elimination of GABAergic interneurons in the cortex will recapitulate phenotypes seen following TBI.** First, we established the viral approach to ablate GABAergic cells. Using immunohistochemical and genetic labeling strategies, we confirm that a viral approach can ablate interneurons with cell type specificity. Then, we assessed behavioral deficits using Rotarod and other assays. Preliminary findings suggest that there is a trend toward motor dysfunction in Cre+ animals following viral infection. These studies suggest viral ablation of cortical interneurons can lead to TBI-like phenotypes. Future studies will utilize these approaches to examine *in vitro* network

function and the development of seizures following cortical interneuron ablation. If virally-induced interneuron ablation mimics TBI-related phenotypes, we will know that interneuron loss is sufficient to lead to post-TBI deficits.

Title: Diffuse axonal injury in the rat - a study of post-traumatic axonal injury and oligodendrocyte activity in a rotation injury model

Authors: M. LOSURDO[1,2], *M. K. SKOLD[1,3]
[1]Karolinska Institutet, Stockholm, Sweden; [2]Dept. of Mol. Med., Univ. of Pavia, Pavia, Italy; [3]Dept. of Neurosurg., Uppsala Univ., Uppsala, Sweden

Abstract: Traumatic brain injury is a major medical problem with 2 million cases annually in Europe. Road traffic accidents is the main cause of TBI in adults[1]. The mechanics of impact is often of acceleration-deceleration where the head rotates in the sagittal plane with the neck acting as pivot. The brain is then accelerated within the rigid skull and it is subjected to shear stress with stretching and tearing of axons. In moderate to severe impacts, this result is diffuse axonal injury with oligodendrocyte and myelin degeneration.In this study we examine the extent and degree of diffuse axonal injury in rats that were exposed to rotational trauma. This new rotational injury model allows for precise quantification of trauma intensity delivered by adjusting the angular acceleration.Brain tissue was collected 24 and 72 hours after injury from animals subjected to acceleration ranging between 1.34 - 1.93 Mrad/s^2. Analyses were carried out by means of immunohistochemistry. Axonal injury was investigated through anti-APP antibody and anti-MBP antibody, while oligodendrocyte death and reactive proliferation through anti-Olig2 antibody, anti-NG2 antibody and anti-A2B5 antibody. Regions investigated were corpus callosum, external capsule, hippocampus, fimbriae and brainstem. Sham-operated and penetration-injury exposed subjects were used as controls. The results show that APP was upregulated predominantly at the borders between the corpus callosum and cortex. MBP downregulation was mainly observed at higher acceleration in the corpus callosum. Slight Olig2 downregulation was observed throughout the regions of interest. NG2 appeared to be upregulated in the hippocampus. We conclude that axonal injury is already present 24 hours after injury, that injury is more extensive in the frontal part of the brain subjected to greater rotational force and that APP is most clearly visible at the interface between white and gray matter where

the shear forces are more pronounced. Instead, in the investigated 24-72 hours post-injury time window, processes of degradation (myelin fragmentation and oligodendrocyte death) and of reactive regeneration (oligodendrocyte progenitors proliferation) may be just starting, thus making it a good time window for intervention.

Title: Intensity specific repetitive mild traumatic brain injury evokes an exacerbated burden of axonal injury in neocortical parvalbumin interneurons

Authors: *Y. OGINO, M. VASCAK, J. T. POVLISHOCK
Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: Mild traumatic brain injury (mTBI) is a major health care issue that can result in significant morbidity, particularly in those individuals who had sustained repetitive mTBI. While multiple factors may be at work in the genesis of this morbidity, recent work in both animals and humans suggest neocortical involvement in this process. Recent studies from our lab have demonstrated, in the case of uncomplicated mTBI, the occurrence of diffuse axonal injury (DAI) in the layer V neurons as well as its interneuronal subpopulation leading to an imbalance of excitation and inhibition, which most likely contributes to disordered brain function. In the current communication, we extend these studies to determine if repetitive mTBI of varying intensity can exacerbate the burden of DAI within the parvalbumin (PV) interneurons that are key regulators of cortical excitatory/inhibitory balance.
Mice were subjected to mild central fluid percussion at the injury magnitude of 1.4 or 1.6 atm, with or without a repetitive insult at a 3 h interval. All animals were physiologically monitored prior to injury and, after injury, their righting reflex time was assessed as a surrogate for the duration of any loss of consciousness. DAI in PV interneurons in the layer V was quantitatively assessed 24h post-injury via immunofluorescent double-labeling of p-c-Jun and PV, with electron-microscopic (EM) analysis.
Through these strategies, we confirmed that mTBI evoked PV interneuronal DAI. Importantly, with repetitive injuries, the number of PV interneurons sustaining DAI increased, with the caveat that this increase was linked to the intensity of the mTBI as these changes where the most conspicuous in the 1.4 vs the 1.6 atm injury group. Irrespective of the injury intensity, however,

the observed DAI and concomitant p-c-Jun expression occurred without any evidence of overt tissue damage or neuronal death. In fact, ultrastructural analysis revealed with the exception of the DAI, normal cortical detail with the preservation of the neuronal soma and their dendritic domains as well as the retention of intact glial and vascular elements.
These studies demonstrate that the PV interneurons are vulnerable to the forces of repetitive mTBI in terms of their axonal projections. These studies join with others ongoing in our lab that have confirmed a comparable exacerbation of DAI within the layer V neurons, mandating the need for future studies probing the subsequent excitatory/inhibitory imbalances and their overall functional consequences. (NIH grant NS077675).

Title: Time span of neurodegenerations after traumatic brain injury in the mouse, as detected with Neurosilver impregnation, Fluoro-Jade C and APP immunohistochemical staining

Authors: *G. XIONG[1], H. METHENY[1], A. S. COHEN[1,2]
[1]Dept. of Anesthesiol. and Critical Care Med., Children's Hosp Philadelphia, Philadelphia, PA; [2]Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neurodegeneration is a key pathological finding after traumatic brain injury (TBI), likely contributing to neuronal loss and neurological impairments. A major effort has been made over past decades to develop effective diagnostic techniques and specific sensitive markers to detect degenerations after TBI. However, previous investigations on TBI-induced degenerations usually adopted only one marker and/or focused at only one specific time point. In the present study, we used multiple markers to monitor neurodegenerations including Neurosilver impregnation (NS), Fluoro-Jade C (FJC) and amyloid precursor protein (APP) immunohistochemical staining. Multiple time points and different brain regions were tested after moderate to severe TBI induced by lateral fluid percussion injury (lFPI). Neuronal cell bodies positive for NS and FJC could be identified in the sensory and motor cortices, and hippocampus from beginning at 1 hr (after lFPI). Cell body staining in the hippocampus was dramatically decreased at 48 hr. At 7 d, cell body staining was mainly seen in the cortices and thalamus. Beaded dendritic staining could be detected starting at 6 hr and peaked at 10 hr in the hippocampus, extending from FJC-stained cell bodies. Clusters of spheroids and varicosities

could be detected in white matter tracts including the corpus callosum (cc) and alveus with APP but not FJC or NS. APP-positive spheroids could also be found in gray matter such as the cortex, caudate putamen (CPu) and thalamus. This APP staining appeared as early as 3 hr, reached peak staining at 10 hr and diminished 5 d. Axonal retraction bulbs and Wallerian degeneration could be clearly detected with NS. They appeared beginning at 4 d, peaked at 7 d and dramatically decreased at 1 mo. FJC demonstrated a small number of axonal degeneration among stained astrocytes in adjacent slices to those stained with NS. Diffuse axonal degenerations could be traced from the sensory and motor cortices to a variety of subcortical structures: that were seen passing through cc to enter CPu and globus pallidus, entering the thalamus via the internal capsule, following the cerebral peduncle and pyramidal tract to cross the midline at pyramidal decussation. Wallerian degeneration could also be detected in the hippocampus, spinal trigeminal nucleus and the cerebellum, or traveling the optical tract to enter the superior colliculus. The present study demonstrates that different markers for TBI-induced degenerations may be most effective at different time points. In addition to the well-studied pathology in white matter, there are also specific cortical regions and related subcortical nuclei that exhibit diffuse axonal pathology.

Abstract: Chronic traumatic encephalopathy (CTE) is a neurodegenerative disease associated with repeated head traumas. Using immunohistochemistry for Glial Fibrillary Acidic Protein (GFAP) as a marker, plus automated quantitative analysis, we examined the characteristics and extent of astrogliosis present in stage III CTE and stage IV CTE, along with Alzheimer's Disease (AD), and Frontotemporal dementia (FTD) cases. Surprisingly, overall astrogliosis in CTE patients was more diffuse compared to that of AD and FTD patients, which was concentrated in

the sulcal depths; this localization was the converse of the sulcal predisposition of tau pathology in CTE. Of 13 brains of patients with CTE, 9 exhibited signs of a degenerating astrocyte pathology, characterized by beaded, broken processes. This astrocytic degeneration was typically found to be diffuse throughout the white matter, although two cases demonstrated astrocytic degeneration in the gray matter. The degeneration was also observed in 2 of 3 AD and 2 of 3 FTD brains, with overall similar characteristics across diseases. We found that the extent of the white matter astrocytic degeneration was strongly correlated with the level of overall astrogliosis in both the white and gray mater. However, the astrocytic degeneration was not correlated with the overall extent of tau pathology. Specifically, there was no correlation between the levels of p-tau in the sulcal depths and astrocytic degeneration in the white matter adjacent to the sulcal depths. Thus, astrocytic degeneration and overall astrogliosis appear to represent distinct, though not unique, pathological features of CTE. Further investigation into these astroglial pathologies could provide new insights into the mechanisms underlying CTE and represent a potential target for *in vivo* assessment of CTE as well as other neurodegenerative disorders.

Title: Morphological changes in prefrontal cortex, dentate gyrus and hippocampus CA1 in the animal model of metabolic syndrome

Authors: *A. CASTRO-MENDEZ[1], J. C. PENAGOS-CORZO[1], R. A. VAZQUEZ, SR[2]
[1]Psychology, Univ. De Las Americas Puebla, San Andres Cholula, Mexico; [2]Inst. De Fisiología Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: Metabolic Syndrome (MS) is considered a global epidemic. Several studies show that this will have a greater incidence over the years. MS is a set of physiological, biochemical, clinical and metabolic factors associated with obesity, thus increasing the risk of suffering cardiovascular disease. It has been suggested that MS can cause complications in the brain, since chronic hyperglycemia and insulin resistance are risk factors for neuronal outburst, death when inducing a state of oxidative stress and an inflammatory response that affects cognitive processes. However, the neuronal mechanisms that are involved have not been studied deeply. The objective of the present study was to corroborate the presence of morphological changes in rats with a metabolic syndrome model.
Eight obese Zucker Diabetic Fatty rats (OZDF) were used, aged three months, these rats presented an increase in the weight, size, dyslipidemia and metabolic alterations that mimics the metabolic syndrome. In addition, seven Long Evans rats of three months of age were used, which formed the control group. Finally, eight Lean rats were used at three months of age. Ten neurons per animal from each group were analyzed in three regions: layer three of the prefrontal cortex, dentate gyrus and CA1 hippocampus, using Golgi-Cox Stain.
In this study, changes in dendritic morphology were found in the OZDF model, which reflects that this model of Metabolic Syndrome induces alterations at the level of the central nervous system in the brain.

Title: Spatiotemporal astroglial evolution following juvenile mild traumatic brain injury

Authors: *T. CLÉMENT[1], J. B. LEE[2], A. ICHKOVA[1], M.-L. FOURNIER[1], J. AUSSUDRE[1], M. O. OGIER[3], F. CANINI[3], M. KOEHL[4], N. D. ABROUS[4], A. OBENAUS[2,5], J. BADAUT[1,2]

Abstract: Traumatic brain injury (TBI) is a leading cause of disability and death among children worldwide. Mild TBI (mTBI) represents around 80% of all pediatric emergency visits and is associated with a higher probability to develop long-term affective and learning disorders. Astrocytes are involved in various physiological homeostatic brain functions including neuronal survival, myelination, regulation of neurotransmission, synaptogenesis and neurogenesis. Astrocytes become reactive after brain insults, a process termed astrogliosis. Thus, it is possible that post-traumatic astrogliosis may impact brain structure and contribute to the long-term affective and cognitive disorders emerging after juvenile mTBI. A Closed-Head Injury with Long-Term Disorder (CHILD) was induced over the left-parietal cortex using an electromagnetic impactor in juvenile C57BL6 wild-type mice and Nestin$xCre^{ert2}$ mice (100 mg/kg Tamoxifen injected 30min after CHILD) on postnatal day 17. Glial Fibrillary Acidic Protein immunolabeling was performed at 1, 7, and 30 days post-injury (dpi) and Nestin immunolabeling was carried out at 7dpi. Semi-automatic skeleton analysis was performed to depict astrocyte morphology in the somatosensory cortex (SSC), dentate gyrus (DG), amygdala and prefrontal cortex (PFC) in both brain hemispheres. Nestin and GFAP positive astrocytes were present in the SSC and PFC in sham mice. The number of double positive cells was not changed after injury for the WT. Nestin$xCre^{ert2}$ mice had increased number of nestin-positive cells in various brain regions, including the DG, but no Nestin-GFAP double labeling was observed after CHILD. There was no change in the total number of GFAP-positive astrocytes after CHILD. The morphology of GFAP-positive cells was altered over time after injury in the SSC, DG, amygdala

and PFC. Astrocytes were hypertrophic (60% size increase in SSC) and abnormally ramified (20% increase in DG) at 7 dpi in WT. However, GFAP-positive astrocytes exhibited similar morphology in sham and TBI mice in all brain regions at 30 dpi.Taken together, our results indicate that juvenile mTBI produces transient changes of astrocyte morphology in remote brain regions (ie. the PFC) in the acute phase post-injury. Thus, GFAP positive astrocytes may contribute to early neuronal network reorganization priming the long-term affective and cognitive disorders after juvenile mTBI.

Title: Olfactory bulb lesion induces acute cell death in olfactory cortical areas and commissural fibers in rats

Authors: *C.-F. F. CHEN[1], C.-H. LIN[2], H.-T. YANG[1]
[1]Grad. Inst. of Life Sci., [2]Grad. Inst. of Biol. and Anat., Natl. Def. Med. Ctr., Taipei City, Taiwan

Abstract: Bilateral olfactory bulbectomy (the surgical removal of both olfactory bulbs) is a common procedure to induce a rat model for major depression. The olfactory bulbectomy leads to abnormality in a wide range of behavioral tests and depression-like behaviors in the rats. However, how this brain injury eventually leads to the behavioral deficits remains unclear. In the present study, we focus on revealing acute effects of olfactory bulbectomy on the olfactory cortical circuits. We performed unilateral bulbectomy on 8-week-old Sprague-Dawley rats and examined the brain tissues 24/48/72 hours after this surgical treatment. We used terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay to detect apoptotic cells over brain sections in 30 μm thickness. Our results showed that unilateral bulbectomy led to apoptosis in several olfactory cortical regions, including endopiriform nucleus and piriform cortex, as soon as 24 hours after the surgical lesion. In contrast to previous data, we found that apoptosis in the piriform cortex peaks at 24 hours and gradually decreases until 72 hours after the bulbectomy. To our surprise, however, we observed heavy TUNEL labeling in corpus callosum, with the ipsilateral (lesion side) significantly heavier than the contralateral (unlesion side).

Interestingly, the number of apoptotic cells in corpus callosum increases every 24 hours following the lesion. These findings suggest that olfactory bulb trauma could lead to acute and pervasive cell death in the brain. Mechanisms underlying this lesion-induced cell death may be more complicated than sensory deprivation.

Title: Temporal analysis of biomarkers of brain damage in ovine survival models of hemorrhage and blast / hemorrhage polytrauma with perfluorocarbon treatment

Authors: *J. PARSONS[1], S. THUMMALA[2], J. MCCARTER[2], C. SWEENEY[2], P. MIDDLETON[2], J. ZHU[1], B. SPIESS[1]
[1]Anesthesiol., Univ. of Florida, Gainesville, FL; [2]Virginia Commonweatlh Univ., Richmond, VA

Abstract: Background: Secondary blast injury (due to airborne shrapnel) can result in severe hemorrhage in the far forward battlefield and can be life threatening with the absence of blood products and significant delay to forward surgical teams. Perfluorocarbon (PFC) oxygen therapeutics are capable of effectively oxygenating sensitive tissue in the absence of red blood cells. Alpha II spectrin breakdown products (markers of neuronal necrosis / apoptosis) and S100B (marker of blood brain barrier breakdown) can be measured in plasma and are associated with outcomes and efficacy of PFC therapy. PFC may improve the "golden hour" during en route care of far forward battlefield polytrauma soldiers.
Methods: Ovine (male, juvenile, 25-30 kg) were subjected to hemorrhagic shock or exposed to blast overpressure (~10-15psi) utilizing an Advanced Blast Simulator just prior to hemorrhagic shock. Mean arterial blood pressure (MAP) was maintained at ~30mmHg for 60 minutes. Sheep were resuscitated with Hespan until MAP was 65 mmHg for 10 minutes then randomized to receive intravenous PFC or saline (both 5 ml/kg). Venous plasma was collected 2 days before injury (baseline) and at 1, 4, and 7 days post injury. Plasma sample proteins were balanced by UV-Vis spectrophotometry, resolved by SDS-PAGE, and transferred to nitrocellulose. Western blots were probed for Alpha-II spectrin breakdown products or S100B using commercially available antibodies, visualized by chemiluminescence, and densitometerically analyzed. Experimental groups (all n=8): Hemorrhage+saline, Hemorrhage+PFC, polytrauma+saline, polytrauma+PFC, and controls.

Results: Total blood loss was 32.3-52.0% (Hemorrhage+saline), 29.6-48.0% (Hemorrhage+PFC), 7.4-45.7% (polytrauma+saline), and 15.2-51.6% (polytrauma+PFC). Lactate levels went from baseline to maximal mmol/L of 0.6-2.5 (Hemorrhage+saline), 0.8-2.4 (Hemorrhage+PFC), 1.5-2.2 (polytrauma+saline), and 0.5-1.4 (polytrauma+PFC). Both alpha II spectrin breakdown products and S100B biomarkers were not observed in any of the groups at any of the time points analyzed.
Conclusion: Neither alpha II spectrin nor S100B biomarkers were observed in the plasma of any of the groups at any time points. It is possible that alpha II spectrin breakdown products were generated, however, since the blood brain barrier remained intact, the breakdown products would only be found in brain tissue. It is also feasible that the level of hemorrhage and polytrauma for these studies was not severe enough, as lactate levels were not greatly increased. Efficacy of PFC as a treatment modality cannot be assessed from this study as changes in biomarkers were not observed.

Sch., Monash Univ., Melbourne, Australia

Abstract: Background: The project 2 of EpiBioS4Rx is a multicenter preclinical study that aims to identify targets and new therapies to prevent post-traumatic epilepsy (PTE) using the lateral fluid percussion injury (LFPI) model of severe traumatic brain injury (TBI). Hyperphosphorylated tau (p-tau) is implicated in neurodegenerative processes and has also been linked to TBI and PTE. **Objective:** To determine the temporal evolution of p-tau in the LFPI

model, specifically at 2-days and 1-week post-TBI. **Methods:** Male 11 week old Sprague-Dawley rats were randomized into naïve control (n=6), sham (craniotomy only; n=5/timepoint) or LFPI (n=5/timepoint) rats. Sham and LFPI rats were subjected to a 5 mm left parietal craniotomy; LFPI rats received a pulse of 3.2 (±0.1) atm at the craniotomy preserving the dura. Rats were euthanized at 2-days or 1-week post-craniotomy and perfused brains underwent immunohistochemistry for either p-tau at Ser202/Thr205 (AT8 antibody) or Thr231 (AT180 antibody). Signal densitometry of individual AT8 or AT180 cell somata was done with ImageJ. Results were referred as percentage of right cerebral cortex of the naïve control stained in the same assay. Background regions of interest devoid of cell somata were used to compare non-somatic background staining. Regions of interest were the primary motor (M1), somatosensory (S2a, S2b) and granular insular (GI) cortices. Densitometry and data analyses were done blinded to groups. Statistical analyses included linear mixed model and paired t-test; α was set at 0.05. **Results:** There was an overall trend for increased AT8 somatic immunoreactivity (AT8-ir) at the left (ipsilateral to injury) cortical regions, 2-days post-LFPI (LFPI-2d group). Statistical significances ($p<0.05$) were as follows: left > right LFPI-2d at M1, S2a, S2b, GI; LFPI-2d > controls at GI. Diffuse AT8-ir increase in the background was noted in the LFPI-2d compared to other groups at M1, S2a, S2b, and GI. Somatic AT180-ir was increased at the left M1 region of LFPI-2d ($p=0.01$) and Sham-2d ($p=0.04$) compared to controls; no other statistical differences were seen. However, there were trends for increased AT180-ir in the background of the left S2a and S2b ($p=0.06$) than the right homotypic regions. **Discussion**: Increased p-tau at Ser202/Thr205 (AT8-ir) expression is seen at the LFPI-2d group ipsilateral to the LFPI, but increase in Thr231 tau phosphorylation was limited to the left M1 region. Ongoing studies examine the p-tau expression at later timepoints. The data support the hypothesis that targeting p-tau might be a promising approach for the design of therapies with disease modifying and/or antiepileptogenic potential.

Title: CD8-expressing cell density is stage-specifically increased in chronic traumatic encephalopathy and comorbid Alzheimer's disease

Authors: *B. R. HUBER[1,2], I. MAHAR[2], D. KWASNIK[2], R. MATHIAS[1], V. ALVAREZ[1,2], C. JONATHAN[2], A. C. MCKEE[1,2]
[1]VA Boston Healthcare, Boston, MA; [2]Boston Univ. Sch. of Med., Boston, MA

Abstract: BACKGROUND: Chronic traumatic encephalopathy (CTE) is associated with increased microglial activation that increases with disease stage. The presence of activated microglia suggests activation of the innate immune system, however little is known about activation of the adaptive immune system in CTE. Cytotoxic T-cells are part of the adaptive immune system and can target cells for apoptosis via the MHC1 antigen presentation system. Cytotoxic T-cells expressing CD8 are observed acutely after traumatic brain injury and in other neurodegenerative conditions such as Alzheimer's disease. Cytotoxic T-cell can induce apoptosis in neurons *in vivo*. However, the relationship between CD8-related neurotoxicity and the progression neurodegenerative disease is poorly understood, particularly for CTE. In the current study we quantify CD8 expressing cells in CTE and AD to determine if these neurodegenerations activate the adaptive immune system and are associated with disease stage in CTE. METHODS: Fixed frontal cortex samples were obtained from the VA-BU-CLF Brain Bank (N=183): controls, early (stage 1-2) CTE, late (3-4) CTE, and CTE with Alzheimer's disease (CTE-AD). Sections were stained and scanned, cortical subregions traced, and staining quantified using a Leica Aperio system. ELISA values were from a Neuroinflammation Panel (Meso Scale Diagnostics). Corpus callosum thickness was measured cross-sectionally. RESULTS: Late CTE and CTE-AD cases had greater sulcal CD8-expressing cell density. AT8 staining correlated with CD8 cell density, and increased between controls, early CTE, late CTE, and CTE-AD cases. Late CTE and CTE-AD cases had increased expression of ICAM1 and MDC, whereas early CTE cases showed increased IL-13. CD8-expressing cell density inversely correlated with and anterior corpus callosum thickness.CONCLUSIONS: CD8 cell density is not increased in early CTE cases (despite elevated pTau), but is in later CTE stages. This may be related to increases in inflammatory cytokines in late CTE and transient IL-13 expression in early CTE. CD8 cell density is associated with white matter loss, and may contribute to clinical symptoms.

Title: White matter microstructural changes in the corpus callosum and external capsule following highly repetitive subconcussive impacts in the awake adolescent rat

Authors: *T. G. RUBIN[1], W. HOOGENBOOM[3], C. A. BRANCH[2], M. L. LIPTON[4]
[2]Mag. Reson. Res. Ctr., [1]Albert Einstein Col. of Med., Bronx, NY; [3]Dept. of Clin. Investigation, [4]Dept Radiology, Albert Einstein Col. Med., Bronx, NY

Abstract: In contact sports, such as a soccer and American football, players can accumulate thousands of subconcussive hits to the head over the course of a single season, and many more over a lifetime. Recent evidence has shown that these hits are associated with cognitive deficits and CNS symptoms independent of concussion, and may lead to long term behavioral and cognitive changes associated with chronic traumatic encephalopathy (CTE). While various animal models have been developed to reproduce the biomechanical, neurological, and pathological aspects observed in human concussive injury, subconcussive injury has been largely unexplored. Here we developed a new model of highly repetitive subconcussive injury to explore and characterize the changes in white matter and underlying mechanisms of injury. The protocol was approved by the IACUC at Albert Einstein College of Medicine. Young adult (~p35) male and female rats (n=6 experimental, n=6 sham) underwent subconcussive TBI induction without scalp incision or anesthesia using a Leica Impact One^{TM} Impactor, fit with a rubber impacting tip, 10 mm diameter impacting surface. Animals received 10 hits/day (1 minute apart), to the left parietal bone, midway between the ear and bregma, every day for 7 days, totaling 70 hits (impact velocity=2.5m/s, depth=5mm, dwell=100ms). Animals were mildly restrained in a cone-shaped plastic bag and placed in a foam cradle to ensure reproducible impact location while allowing the head to freely move following impact. Sham animals underwent the same procedures, but received no impacts. All animals underwent diffusion tensor imaging (DTI) prior to injury and 24 hours after the final injury. Animals were then sacrificed 24 hours after the final imaging or 3 months later for immunohistochemistry. All data were randomized and blinded before analysis. The corpus callosum, and bilateral external capsule were manually traced and quantified using MIPAV (v8.0.2). Animals showed no signs of gross pathology (e.g., skull fractures or hemorrhage) or overt behavioral abnormalities. In contrast to sham, impacted animals displayed numerically decreased mean FA (3-6%) for all regions of interest (ROIs) compared to preinjury levels. Also, axial and radial diffusivity (AD and RD) increased for all ROIs for both groups. Our data provide promising preliminary evidence that our model produces injury similar to that seen associated with human subconcussive injury and may be a viable tool for further exploring mechanisms of injury and recovery. Continuing studies will include characterization of behavioral changes as well as histopathology in the short- and long-term following subconcussive head impacts.

Title: MitoNEET (CISD1) knockout mice have increased susceptibility to intracranial hemorrhage

Authors: *S. A. BENKOVIC, JR[1], C. M. BROWN[2], W. J. GELDENHUYS[3]
[1]Basic Pharmaceut. Sci., West Virginia Univ. Res. Corp., Morgantown, WV; [2]Microbiology, Immunol. & Cell Biol., [3]Basic Pharmaceut. Sci., West Virginia Univ., Morgantown, WV

Abstract: MitoNEET is an iron-containing protein localized to the outer mitochondrial membrane that regulates mitochondrial respiration, iron transport into the mitochondrion, and lipid and carbohydrate homeostasis. We previously observed that deletion of mitoNEET resulted in a loss of tyrosine hydroxylase immunoreactivity, dopamine depletion in striatum, increased ROS production, iron accumulation, increased inflammatory protein expression, and behavioral deficits that caused a phenotype similar to Parkinson's disease. Here, we evaluated the histopathological consequences of a heterozygous mitoNEET deletion in six-month old male mice and observed brain-wide microhemorrhages and subsequent reactive gliosis of both astrocytes and microglia in comparison to wild-type control mice. Immunohistochemical analysis of mitoNEET reactivity revealed a near complete absence throughout the brain of mutant mice. Perls' Prussian Blue (PPB) staining revealed hemosiderin of microhemorrhages in most brain regions including: hippocampus, thalamus, cortex, cerebellum, olfactory bulb, and brain stem; and the white matter tracts connecting these regions: corpus callosum, stria terminalis, and fimbria of the fornix. Large microhemorrhages were on the order of $2000\mu^2$. Chromagen-enhancement of the PPB stain revealed ferritin-bound iron which accumulated in the striatum. Distinct populations of blue and brown cells were observed in several brain regions. Microhemorrhages caused activation of both astrocytes and microglia with a different pathological profile. Astrocytic reactivity was greater in proximity to the vascular disruption while microglial reactivity appeared homogeneously throughout the parenchyma. Microglia were observed filled with phagocytic debris from older hemorrhages or in the process of ingesting debris from newer hemorrhages. These data suggest that loss of mitoNEET causes a pathological elevation of ferritin-bound iron, microhemorrhage, reactive gliosis and reduced integrity of the neurovasculature.

Title: Hippocampal and entorhinal cortex Alzheimer's disease-like pathology in human chronic traumatic encephalopathy: A chronic effects of neurotrauma consortium study

Authors: *C. M. KELLEY, M. NADEEM[1], F. C. CRAWFORD[2], A. C. MCKEE[3], S. E. PEREZ[1], E. J. MUFSON[1]
[1]Barrow Neurolog. Inst., Phoenix, AZ; [2]Roskamp Inst., Sarasota, FL; [3]Boston Univ., Boston, MA

Abstract: Chronic traumatic encephalopathy (CTE) is a progressive neurodegenerative condition resulting from repetitive mild trauma to the head, a circumstance prevalent in contact-sport athletes and military personnel. Although the regional spread of tau pathology in the CTE brain marks disease stage and severity (McKee et al., 2013), very little is known about the distribution and morphology of tau positive profiles within the hippocampal complex. Eighteen male Caucasian and African-American former professional contact-sport athletes from Stage II (n = 6, age at symptom onset 20-65 y; age at death 25-70 y), Stage III (n = 6, age at symptom onset 24-40 y; age at death 45-67 y), and Stage IV (n = 6, age at symptom onset 30-68 y; age at death 62-80 y) were obtained from Boston University School of Medicine. Paraffin blocks containing the hippocampus and entorhinal cortex (EC) were sectioned at 8 µm and mounted on slides, treated with citric acid, and immunolabeled with AT8 (an early pathological tau marker). In addition, amyloid pathology was evaluated with antibodies against the amyloid precursor protein and Aβ (6E10), Aβ1-40, and Aβ1-42. AT8-positive profile number and size were analyzed using a 60X oil-immersion lens controlled by a MicorBrightField software suite; presence of various Aβ species was examined with a Nikon Eclipse 80 microscope. Quantitative analysis revealed significantly more AT8-positive neurons in the CA1 and CA3 hippocampal subfields and the EC in Stage IV compared with Stage II (CA1, 12.6-fold; CA3, 11.5-fold; EC, 11.0-fold; Mann-Whitney U, $p < 0.01$). The EC and hippocampal subfields also displayed significantly smaller AT8-positive neuronal area in Stage IV compared to Stage II by an average 37.8 % (EC, 26.5 %; CA1, 35.1 %; CA3, 51.7 %; Mann-Whitney U, $p < 0.01$). Stage III displayed intermediate values for both AT8-positive neuron count and size, suggesting a transitional pathological stage. In contrast, minimal Aβ profiles were seen in the hippocampal-EC complex, primarily in Stage IV cases, suggesting that amyloid and an altered Aß species

profile are not a requisite co-condition of tau pathology in CTE. Data suggest that phosphorylated tau (AT8) protein levels may provide a biomarker to track and a drug target to slow the progression of CTE.

Abstract: Repetitive traumatic brain injury (RTBI) may be a major risk factor for the neurodegeneration associated with chronic traumatic encephalopathy (CTE). Although TBI has been associated with acute dendritic and spine damage (Castejón et al., 2004), its potential enduring effects on cortical dendrites have not been investigated. Thus, the present study examined long-term changes in the dendritic systems of supragranular pyramidal neurons following RTBI, in cases with and without CTE diagnoses. Samples were obtained from the frontal and occipital poles of six males with a history of sports-related RTBI (M_{age} = 77 ± 13 years), five with CTE diagnoses and one without, and compared to tissue from 12 neurologically normal individuals (M_{age} = 72 ± 6 years; Jacobs et al., 1997). Tissue was prepared using a modified rapid Golgi technique, with 20 neurons sampled from each cortical region in post-RTBI tissue (n = 240), and 10 neurons sampled from each cortical region in control tissue (n = 240). Dendritic arbors were analyzed using computer-assisted morphometry. Compared to control tissue, quantitative dendritic and spine measures tended to be markedly decreased in all post-RTBI tissue regardless of CTE diagnosis. This decrease was observed in both cortical regions, with the prefrontal cortex being more severely affected than the visual cortex. Such dendritic declines following RTBI may have negative implications for cognitive functioning, with or without a specific neurodegenerative diagnosis.

Title: Role of head impact exposure in concussion for college and high school football athletes

Authors: *B. D. STEMPER[1,2], A. SHAH[3], R. CHIARIELLO[4], A. WILD[4], M. MCCREA[4]
[1]Med. Col. of Wisconsin Dept. of Neurosurg., Milwaukee, WI; [2]Biomed. Engin., Marquette Univ. and Med. Col. of Wisconsin, Milwaukee, WI; [3]Dept. of Neurosurg., [4]Neurosurg., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: The biomechanical mechanism of concussion has long been understood to be head impact resulting in high rate head rotational accelerations. However, recent evidence identified a possible role of repetitive head impact exposure (HIE) in concussion onset in contact sport athletes and cognitive/imaging changes in non-concussed athletes. This study outlined the profile of HIE in high school and college football athletes, and identified differences in HIE between concussed and non-concussed athletes. The study protocol was IRB approved and informed consent was obtained from all athletes or their legal guardian. Athletes were recruited from 4 local high school and 4 NCAA Division III football teams. Head impact accelerations were monitored for all contact activities during the 2015-17 football seasons using the Head Impact Telemetry (HIT) System (Riddell SRS). Only impacts with peak resultant linear acceleration greater than 10 g were included for analysis. All concussions in enrolled athletes were identified and diagnosed by team medical staff according to a standardized protocol. Following injury notification, the study team used HIT System and video data, as well as the concussion report, to identify a single concussive head impact. HIE was quantified using a Cumulative Metric (CM) that was calculated by summing the concussive injury risk according to peak head accelerations for each head impact over the period of interest. As such, CM magnitude increased for a greater number of head impacts and higher severity head impacts. Average daily CM and CM on the injury date were calculated for concussed athletes up to and including the injury date, and for all non-concussed athletes on all days of participation in contact activities. A total of 149 high school and 405 college football athletes were enrolled. Eight high school athletes sustained concussion during the study (rate: 5.4%) and 35 college athletes sustained concussion (rate: 8.6%). Approximately 88% of concussed high school and college athletes had average daily CM that was greater than the 50th percentile CM for non-concussed athletes. However, the percentage

of high school athletes that exceeded the 50th percentile CM on the injury date and for the 5- and 10-day periods leading up to the injury date (~88%) was considerably greater than the percentages (83%, 77%, 67%, respectively) for college athletes. These findings highlighted a higher rate of concussion in college football athletes, that concussed football athletes at both levels sustained more severe HIE than non-concussed athletes, and that the difference in HIE between concussed and non-concussed athletes was greater at the high school level.

Title: Prospective study of blood biomarkers in mild traumatic brain injury patients

Authors: *A. K. HABERG[1], G. CLARKE[1], C. EINARSEN[1], T. FOLLESTAD[1], H. ZETTERBERG[3], K. BLENNOW[3], A. VIK[2], T. SKANDSEN, 7030[1]
[1]NTNU, Trondheim, Norway; [2]NTNU, NTNU, Norway; [3]Salgrenska, Univ. of Gothenburg, Gothenburg, Sweden

Abstract: The aims of the study were to assess the level of glial fibrillary acidic protein (GFAP) and Neurofilament Light-1 (NFL) at five time points after mild traumatic brain injury (MTBI), and examine the relationship between GFAP and NFL levels and acute injury severity and post-concussive symptoms at 2 weeks. 379 consecutive patients with MTBI aged 16-60, were prospectively recruited from the emergency departments at a level 1 trauma center and a municipal outpatient clinic. Blood samples were drawn acutely (71 patients, 73 controls), at 72 hours (134 patients, 6 controls), at 2 weeks (177 patients, 9 controls), 3 (170 patients, 100 controls) and 12 months (158 patients, 55 controls) after injury. Plasma analysis was performed using the Quanterix Neurology 4-plex panel. Acute CT and brain MRI at 3T within 72 h were acquired. Posttraumatic amnesia (PTA) was recorded as short (≤1 hour) or long (>1 hour). Post concussive symptoms assessed at 2 weeks with the Rivermead Post concussion symptom questionnaire, high symptom burden was ≥3 items rated >2. Separate mixed model analyses were performed with logarithmically transformed values of NFL and GFAP values over time in

MTBI patients versus controls. Mann-Whitney U-tests were used for comparing MTBI patients stratified based on clinical characteristics versus blood brain biomarkers levels. In MTBI, GFAP peaked in the acute phase, while NFL peaked at 2 weeks. There was a 95% difference in GFAP levels in the acute phase between MTBI and controls (p<.0001), and a 80% difference in NFL levels between MTBI and controls at 2 weeks (p<.0001). By 12 months, both NFL and GFAP levels had returned to control levels in MTBI. The interaction effect of group and time was statistically significant for both NFL (p<.0001) and GFAP (p<.0001). Patients with traumatic axonal injury had near significantly higher NFL than patients with other intracranial lesions (p=0.051). Median NFL values were 119.6 versus 22.5 pg/ml. Patients with long and short PTA had higher GFAP and NFL than controls (p=0.001). NFL was higher in patients with long PTA (p=0.038) while no significant difference was found in GFAP between PTA groups. Patients with high symptom burden at 2 weeks had lower GFAP and NFL than patients with low symptom burden (p=0.050 and 0.024). In this longitudinal study of MTBI, we detect GFAP and NFL levels in peripheral blood that were different from those of controls from the acute phase, returning to control levels at 12 months. GFAP and NFL appear to be useful as biomarkers of acute injury severity in MTBI. Surprisingly, we found a negative association between high symptom burden at 2 weeks and blood biomarkers.

Title: Genetic basis of neurosurgically resected hemimegalencephaly and epilepsy

Authors: *C. GARCIA[1], H. MACHADO[1], W. JUNIOR[1], J. GLESSON[2]
[1]Univ. of São Paulo - USP, ribeirão preto, Brazil; [2]Howard Hughes Med. Inst., San Diego - CA, CA

Abstract: Hemimegalencephaly (HME) is a malformation of cortical development, characterized by enlargement of the convolutions and a cerebral hemisphere. It is considered the most common cause of refractory epilepsy in children. The clinical condition presents macrocephaly, delayed psychomotor development and hemiparesis. Studies demonstrated thatgenetic factors are involved in the HME. Essays on the molecular pathogenesis and cellular cortical malformations can reveal information about associated mechanisms and contribute to

new therapeutic approaches discovered for the treatment of symptoms. RCS patient, age 8, negative family history of genetic disorders, diagnosed with HME at two months of life, subjected to surgical treatment with a year of life. The microscopic exam show histological sections of the neocortex stained by H&E show áreas with Chaslin´s superficial cortical gliosis and extensive áreas of neuronal loss and neuronal bodies grouped, resulting in architectural distortion, mainly of the laminar distribution. Additionally, there are some rare foci of giant neurons, with large nuclei and wide cytoplasm. In some areas, the córtex presents reduction of the number of layers (four layers), with fusion of the gyri, some foci of rarefied neuropil in the córtex and White matter and some islets of cortical matter in the white matter. The patient was classified as dysplasia cortical focal Type IIA of the ILAE classification. He was taken to the medical genetics clinic for diagnostic investigation we performed the sequencing of the complete patient exoma in order to find mutations responsible for the clinical picture. Among the most relevant results, we found a mutation at position 1624 G>A in PI3KCA gene as a possible head of the HME and the results were valid for ddPCR and smMIPs. We conclude that patients with malformations of cortical development have genetic changes which may influence the individual's phenotype and this information can offer better pharmacological alternatives for treating these patients.

Abstract: Alterations in functional connectivity (fc) can be widespread in multiple brain networks following traumatic brain injury (TBI). We report data from a pilot study investigating network disruptions following TBI. T1 anatomical data and resting state functional magnetic resonance imaging were obtained from 10 TBI participants and 8 healthy controls (HC) using a 3T Siemens Prisma system. All subjects completed a battery of cognitive tests after each scan. Changes in fc and cognitive performance were evaluated at 2 different occasions. The second evaluation occurred an average of 60 days apart. Image data were pre-processed and warped to a template atlas in order to conduct pair-wise correlation analysis as an indicator of fc between regions within 35 sub networks and 170 specific brain regions of interest. The general linear model with correction (FDR $P<0.05$) and without ($P<0.005$) was used. Analysis revealed a significant effect of injury. Initial evaluation revealed that the TBI group had longer simple and complex reaction time and long delay recall deficits. The second evaluation indicated TBI associated deficits in reaction time were still present. We found group differences in fc at both time-points that were dominated by injury-associated hyperconnectivity (83% of significantly different connections $p<0.005$). These findings were observed in regions within the following networks: default mode, salience, dorsal attention, fronto-parietal and cerebellar ($P<0.005$). More robust findings that survived FDR correction were present within the dorsal-attention, language and front-parietal network. Moderate injury-related hypoconnectivity was also observed, and was confined mainly to circuits arising from seeds in sensory-motor, salience and default mode networks at both imaging sessions (4 of 24 connections and 5 of 30 connections at 1st and 2nd sessions, respectively). Overall changes across both imaging sessions showed greater changes in fc among the injured compared to the HC group ($P<0.005$). In particular, the TBI group showed temporal-associated decreases in fc in default mode and salience network and an increase in visual networks compared to HC ($P<0.05$ FDR). Deficits in reaction time were associated with

hyperconnectivity in the salience network and hypoconnectivity in the sensory-motor and default mode networks.

Title: In search of biomarkers for late recovery of patients with traumatic brain injury: A multimodal approach

Authors: *E. ROSARIO[1], J. DIVINE[2], M. JOHNSON[3], C. SCHNAKERS[4]
[1]Res. Inst., Casa Colina Hosp. and Centers For Healthcare, Pomona, CA; [2]Casa Colina Hosp. and Centers for Healthcare, Pomona, CA; [3]UCLA, Los Angeles, CA; [4]Casa Colina and Centers for Healthcare, Pomona, CA

Abstract: Research Objective: To provide a preliminary database of neural profiles that can be related to cognitive and functional outcome measures in chronic patients with moderate to severe traumatic brain injury (TBI). **Design:** Prospective longitudinal study. **Setting:** Casa Colina Hospital and Centers for Healthcare Research Institute (Pomona, CA). **Participants:** Six TBI patients (5 males; age range: 21-44 years old; 12-21months post-injury) were included in this study. **Main Outcome Measures.** The following data were collected at monthly intervals over 6 months: ***a) Blood sample*** to detect changes in molecular blood-based biomarkers such as neuron-specific enolase (NSE), glial fibrillary acid protein (GFAP), S-100β protein, myelin basic protein (MBP), cleaved tau protein (C-tau), spectrin breakdown products (SBDPs), ubiquitin C-terminal hydrolase-L1 (UCH-L1). Blood-based biomarkers are determined using ELISA. ***b) Magnetic Resonance Imaging (MRI)*** recordings were performed on a Siemens Magnetom Verio 3T to assess structural changes. MRI data are analyzed in collaboration with the UCLA Department of Psychology, using FMRIB Software Library (FSL). ***c) Electrophysiological recordings*** of 2 types were performed, using a B-Alert wireless system, to assess changes in electrical activity and processing: 5 minutes resting state and P300 auditory oddball (listening versus counting). EEG/ERPs analyses are performed using EEGLAB. ***D) Neuropsychological assessments*** were

performed by trained clinicians to assess cognition and functional recovery. **Results.** Significant correlations between functional abilities, neuroimaging and blood-based biomarkers were observed. Results also suggest both transient and enduring changes in neural activity over the 6-month study period of recovery. **Conclusion.** Our preliminary findings will help characterize the diverse range of brain activity patterns that occur as a result of chronic TBI and potentially lead to the development of adapted and tailored treatment plans for these patients.

Title: A distinct population of cholinergic neurons in the human parabrachial nucleus

Authors: *S. DE LACALLE
Biomed. Sci., Heritage Col. of Osteo. Med., Athens, OH

Abstract: Over the last 40 years, neurons of the Parabrachial Nucleus (PBN) were shown to play an important role in the processing and relaying of somato- and viscero-sensory information. A recent overview of clinical correlations (Benarroch, 2016) has presented additional evidence for the involvement of the human PBN in multiple modulatory functions. More recently, the question has been raised as to whether parts of the PBN belong to the ascending reticular arousal system. We investigated the distribution of cholinergic perikarya and putative cholinergic terminal fields in the human PBN, to provide a neurochemical background against which more accurately interpret the results obtained from human imaging and interventional studies of clinical relevance, such as the fMRI study on gustatory pathways, on brainstem respiratory control, on temperature, and on pain. Human brain tissue obtained at routine autopsy from neurologically intact individuals was sectioned on the coronal plane, and examined using light microscopy, following standard immunocytochemical techniques with polyclonal antibodies against Choline Acetyl Transferase (ChAT). Sketch overlay drawings were created to aid in visualizing immunoreactive elements and anatomical features of the region. Photographs were compared with current atlases of the human brainstem to define anatomical landmarks. ChAT-ir cells were medium-sized, oblong or triangular in shape, with 2-3 prominent dendrites. In double-stained sections they were found overlapping (but clearly distinct from) previously described CGRP-containing regions of the PBN. Most were scattered within the medial and lateral PBN, with two prominent clusters: one, at the level of the rostral tip of the superior cerebellar peduncle in the dorsolateral parabrachial area, and a second ventrocaudal cluster, in the external lateral nucleus of the PBN. Many, but not all, also contained CGRP-ir. These findings suggest a small,

widespread and distinct population of cholinergic neurons within the human PBN, lending morphological support to the possible involvement of this region in coma and sleep apnea, the pathophysiology of chronic pain, and other central autonomic regulation processes already described in other mammals. Additional refinements in neuroimaging and neuropathological analysis will help establish specific relationships in support of the clinical relevance of the PBN in neurologic disease.

Title: Cumulative effects of sport related concussions on functional brain oxygenation

Authors: *I. HELMICH, J. COENEN, S. SCHUPP, C. WAGNER, M. WERNKE, J. RUEHLING, S. EICH, E. PARDALIS, S. HENCKERT, H. LAUSBERG
German Sports Univ., Cologne, Germany

Abstract: Objectives: Sport related concussions (SRC) are a risk factor for cognitive impairment and its underlying brain functions. Previous studies reported hypometabolism in frontal brain regions during working memory tasks in athletes suffering from postconcussive symptoms. In addition, hypermetabolism in response to moderate working memory processing loads has also been described. We therefore investigated functional brain oxygenation during difficult and easy working memory tasks in athletes with the history of a SRC differentiating between high and low symptomatic individuals. Methods: 91 athletes with a SRC were investigated regarding their brain oxygenation in frontal cortices using functional NearInfraRed Spectroscopy (fNIRS) during a working memory (wm) task with a difficult and an easy task condition. The amount of concussions was included as a covariate in the analysis. Results: Individuals with a post-concussion symptom (PCS) score > 10 showed less correct answers and slower response times in the wm tasks and specifically, in the difficult wm task decreased brain oxygenation in frontal cortices. However, the same individuals showed increased brain oxygenation patterns during easy wm tasks. Furthermore, the amount of experienced concussions correlated negatively with the degree of brain oxygenation during wm tasks. Conclusion: Athletes with a history of concussion showed brain oxygenation patterns that were altered in relation to the present symptomatology. Whereas high wm processing loads lead to decreased brain oxygenation in symptomatic individuals, low processing loads lead to increased functional brain oxygenation.

Furthermore, the more concussions an athlete experienced, the lower the degree of functional brain oxygenation was observed. Thus, SRC present cumulative effects on functional brain oxygenation.

Title: Functional connectivity of the sensorimotor network is influenced by the corticospinal tract wiring pattern in unilateral cerebral palsy

Authors: *C. SIMON-MARTINEZ[1], E. JASPERS[2,1], K. ALAERTS[1], E. ORTIBUS[1], K. KLINGELS[1,3], N. WENDEROTH[2], H. FEYS[1]
[1]KU Leuven, Leuven, Belgium; [2]ETH Zurich, Zurich, Switzerland; [3]Hasselt Univ., Hasselt, Belgium

Abstract: Introduction. In unilateral cerebral palsy (uCP), the development of the corticospinal tract (CST) can be affected, resulting in different wiring patterns (contralateral, ipsilateral or bilateral). The CST wiring has been put forward as an important factor determining sensorimotor function and treatment response. Here, we explored differences in functional connectivity (FC) of the sensorimotor network between different CST wiring patterns, using resting state functional MRI (rs-fMRI). **Patients and methods.** Individuals with uCP due to periventricular white matter lesions underwent a rs-fMRI scan and a single-pulse Transcranial Magnetic Stimulation session (n=24, mean age (SD): 13y3m (±4y6m), 15 females; CST wiring: 9 contralateral, 8 ipsilateral, 7 bilateral). FC was determined for 8 bilateral sensorimotor regions of interest (ROIs) (primary motor (M1) and sensory (S1) cortex, secondary sensory cortex (S2), dorsal and ventral premotor cortex (dPMC, vPMC), supplementary motor area (SMA), thalamus, and putamen) and correlated to all other voxels in the brain (seed-based analysis). SPM one-way ANOVA models were used to contrast differences in interhemispheric and intrahemispheric FC between the CST wiring groups (height and cluster threshold p-uncorrected<0.01). **Results.** Within the non-lesioned hemisphere, FC between cortical seeds (M1, S2, dPMC, SMA) and primary sensorimotor and association sensory areas was increased in the bilateral CST group compared to

the other two groups. Similarly, within the lesioned hemisphere, those in the bilateral CST group showed increased FC between cortical seeds (M1, S2) and the primary and association sensory areas compared to the other groups. Interhemispheric FC between dPMC and the primary sensorimotor area was highest in the bilateral CST group, followed by the ipsilateral group, and lowest in those with contralateral CST wiring. Lastly, seeds placed in the thalamus and putamen resulted in higher FC with the cortical and subcortical structures within the lesioned hemisphere in the contralateral CST group, compared to the other two groups. **Discussion and conclusion.** Our results indicate that the CST wiring affects the long-range FC pattern of individuals with uCP, whereby bilaterally wired individuals have higher FC between cortical structures, whilst the contralaterally wired individuals have higher FC with subcortical structures. These results are a first step toward a better understanding of the underlying pathophysiology of white matter lesions by combining FC measures and CST wiring pattern in individuals with uCP.

Title: Delayed frontal responses discriminate malingered individuals from patients with brain injury

Authors: *S. STROTHKAMP[1,2], J. NEAL[2], E. BEDINGAR[2], B. WAGNER[2], V. VAGNINI[2], Y. JIANG[3]
[1]Lexington, KY; [2]Dept. of Behavioral Sci., Univ. of Kentucky Col. of Med., Lexington, KY; [3]Dept. of Behavioral Sci., Univ. of Kentucky Chandler Med. Ctr., Lexington, KY

Abstract: Traumatic brain injury (TBI) is a major public health concern in the United States. Neuropsychologists report that up to 40% of individuals undergoing evaluations for TBI may be malingering neurocognitive deficits. The current malingering tests can be manipulated via coaching. Thus, a malingering test involving measures of brain activity is needed for validating TBI while identifying malingerers. We hypothesize that, due to active mental manipulation, healthy malingers' frontal brain responses are delayed compared to those who have brain injury. The memory-related brain potentials were compared among three groups: individuals with moderate or severe TBI (n=14), individuals who are healthy but malingering neurocognitive deficit (age-matched, n=15) and individuals who are healthy and honest (age-matched, n=13).

The scalp electrophysiological signals and memory performance were recorded during an Old-New memory recognition task. The EEG signals were recorded with a 32-channel scalp EEG cap. The latency of frontal event related potentials indicative of cognitive processing, known as P3, were analyzed using EEGLAB by calculating fractional latencies of bilateral of frontal sites. Results show a significant delay in P3 fractional latencies in recognizing studied items (Old) in malingerers when compared to brain injured subjects in central (Fz) and left frontal electrodes (FP1, F3). A significant delay was also shown during old tasks in malingerers when compared to honest subjects in bilateral frontal electrodes F3 and F4. There were no significant differences in posterior sites. These findings, matching our previously reported reaction time performances, indicate the presence of additional processing time and effort in the brain activity of malingering individuals when compared to healthy honest and brain injured individuals.

Title: Cortical responses to 3D natural stimuli distinguishes between concussed and normal brains

Authors: *T. RUIZ[1], R. FARIVAR-MOHSENI[2]
[1]McGill MUHC, Montreal, QC, Canada; [2]Ophthalmology, McGill Univ., Montreal, QC, Canada

Abstract: Traumatic brain Injury (TBI) affects more than 2,000,000 people in North America yearly, and patients report visual complaints that can last for months. We have shown that visual performance is altered by TBI, as patients have higher visual noise, and an abnormal contrast sensitivity profile. Higher level visual dysfunctions that could explain TBI patients symptoms have yet to be discovered, although resting-state studies have hinted at a potential cortical synchronicity problem. Here, we explore the consequences of mTBI on cortical activity while patients watch a naturalistic movie, to investigate functional visual disturbances during scene and object representation. Seventeen mTBI patients were shown two 5 minutes clips of an underwater movie in a 3T Siemens MRI (TR=2000ms, Resolution=3mm3), once in 3D and once in 2D. Each control and mTBI cortical activity was fitted to an assigned normal template (obtained by averaging the time-series of the controls in a leave-one out procedure) and the betas and residual error distributions were compared across groups (t-test) to assess scaling differences as well as the variance explained by the template model. We found that mTBIs showed significantly lower betas than controls in the foveal area of the early visual cortex, and in the

sensory-motor cortices, especially for the 3D movie, which could suggest that mTBIs need less transformation to fit the normal template than the normal themselves. However, combined with the residual error differences, our results show that the traumatically injured brain does not fit the normal template adequately, except for the early visual areas. Our result suggest that tightly stimulus-driven cortical activity of the injured brain is constrained to a close-to-normal synchronicity in these regions, a synchronicity that does not propagate to the rest of the brain as it does in the control group. Interestingly, the low amount of scaling necessary to fit the model in the sensory-motor areas is accounted for by particularly high residual error, suggesting that the model simply does not explain these voxels' activity.

Abstract: The autonomic nervous system (ANS) plays a crucial role in maintaining homeostasis throughout the body. In a circulatory process called cerebral autoregulation, the ANS regulates the cardiovascular system and modulates cerebral blood flow in response to changes in metabolic demand within the central nervous system. Research has shown that cerebral autoregulation can be noninvasively assessed by measuring heart rate variability (HRV), the variation in time between heartbeats. In studies comparing athletes to sedentary people of comparable age and weight, athletes were found to have higher HRV, indicating a link between physical health and HRV. Similarly, decreased HRV has been associated with cardiac dysfunction, sepsis, and increased mortality.

Cerebral autoregulation has been shown to be particularly vulnerable to impairment by traumatic brain injury (TBI). This is due to an uncoupling of cerebral blood flow (CBF) with task-induced brain activity following TBI resulting in inducible headaches. This has been proposed as one of the mechanisms underlying some of the persistent symptoms of post-concussive syndrome (PCS). Physical exertion increases demand for CBF, though as a result of impaired autoregulation, the ANS may be unable to couple such demand with appropriate brain perfusion, leading to headaches and other symptoms of PCS. However, aerobic exercise below the threshold for PCS symptom onset has been shown to increase CBF and improve autoregulation, as measured by increased HRV (Clausen, M., *et al.*, 2015). Thus aerobic exercise shows therapeutic promise as a method to reduce PCS symptom severity, for which HRV may serve as a biomarker.

In this study, we enrolled 20 subjects > 14 years of age with mTBI and 20 healthy volunteers, all of whom underwent a graded-exercise test on a recumbent stationary bicycle, using a variation of the Buffalo Concussion Treadmill Test (Leddy, J.J., 2013). We collected measurements of heart rate and HRV with simultaneous ECG recordings and wrist-based beat-to-beat HR monitoring. Correlation analysis and power spectrum analysis of the HRV data found that participants with mTBI who became symptomatic during exercise had significantly reduced HRV compared to healthy control participants, consistent with prior research (Leddy, J. *et al.*, 2017).

These findings have informed our development of an ongoing longitudinal study investigating whether an at-home, remotely-monitored graded exercise regimen can reduce symptom severity in mTBI patients with ongoing persistent PCS symptoms.

Title: Longitudinal exRNA profiles in patients with aSAH

Authors: *A. COURTRIGHT[1], I. MALENICA[1], A. YERI[1], E. HUTCHINS[1], E. ALSOP[1], B. MEECHOOVET[1], T. BEECROFT[1], E. CARLSON[1], P. NAKAJI[2], M. S. KALANI[3], K. R. VAN KEUREN-JENSEN[1]
[1]Translational Genomics Res. Inst., Phoenix, AZ; [2]Barrows Neurolog. Inst., Phoenix, AZ; [3]Univ. of Virginia, Charlottesville, VA

Abstract: Subarachnoid haemorrhage (aSAH) is life threatening injury that carries significant societal and financial burdens. One of the leading causes of an SAH is an aneurysm, in which a weakness in the wall of a blood vessel ruptures. aSAH patients that survive are at risk of having delayed cerebral ischemia (DCI), vasospasm. This secondary injury results in restricted blood flow that can lead to significant neurological impact or mortality. Predicting this secondary injury cascade could help doctors treat and mitigate the damage. Despite extensive research and efforts to improve the outcomes of patients with SAH, there has been little change in patient outcomes and rates of morbidity or mortality.
A major obstacle to improving the care of this patient population has been the inability to sample affected tissues in patients, and the lack of validated animal models able to reproduce human conditions. Extracellular RNAs (exRNAs), contained within vesicles and RNA-binding proteins, are released from all tissues in the body, including the brain. ExRNAs are released into biofluids, such as cerebrospinal fluid and blood, and provide us with the opportunity to sample brain-related information from patient biofluid samples. They offer a promising means of identification of RNA elements that could predict outcomes and/or explain unclear pathological processes. The recognition of predictors of specific outcomes and early indicators of pathologic processes in patients with brain insults could lead to earlier and better treatments while improving the overall

understanding of the disease biology. Samples were collected from each patient over a ten day period, staring from day 1. CSF was collected from the ventriculostomy that patients have to relieve the pressure on the brain and blood was also collected and spun down to separate out the plasma. Both of these biofluids where sequenced for both microRNA and mRNA to evaluate the the exRNA. We have promising data that exRNAs can be used to stratify the risks for complications in patients with hemorrhagic events of the brain and that these candidate exRNAs can lend new insight into the disease process for the development of novel therapeutic targets.

Title: Prevalence of homelessness in veterans of operation enduring freedom (OEF) and operation Iraqi freedom (OIF) with traumatic brain injury from blast versus non-blast exposure

Authors: *K. L. PANIZZON[1], A. HARTOONIAN[2], N. CHOOTHAKAN[2], J. RAVAYI[2], B. ARYANFAR[2], R. A. WALLIS[2,3]
[2]Neurol., [1]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [3]Neurol., David Geffen UCLA Sch. of Med., Los Angeles, CA

Abstract: OBJECTIVE: To evaluate the prevalence of homelessness in veterans of Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF) who have had blast versus non-blast traumatic brain injury (TBI). BACKGROUND: Homelessness has been defined as not having a "fixed, regular or adequate night-time residence", which includes moving frequently between different types of accommodations and staying in homeless shelters and places not meant for human habitation such as vehicles or abandoned buildings. Among the general population, homelessness has been a social, economic, and public health issue in the United States for decades. Homelessness is also a concern because it is associated with a wide range of serious medical problems, such as mental health and substance abuse problems, premature mortality, and frequent hospitalizations. According to the Los Angeles Homeless Services Authority, in Los Angeles County there were a total of 57,794 homeless people, with 8% (4,828) of that being veterans. Within that group, there were 2,102 (4%) veterans that were chronically homeless. One of the signature injuries for veterans deployed in the OEF and OIF conflicts is

that of TBI, particularly blast TBI. In addition, homelessness is a relatively frequent issue particularly for patients with disabilities, such as TBI. We were interested in determining the prevalence of homelessness in veterans with TBI from blast versus non-blast exposure. METHODS: We conducted a pilot, retrospective chart review study of patients with TBI seen at the Poly-Trauma Clinic of the VA Greater Los Angeles Healthcare System. We collected data regarding blast versus non-blast TBI in OEF/OIF veterans. In addition, we collected data regarding homelessness in this patient population. RESULTS: A total of 737 charts were reviewed. Of these, 300 were identified as OEF/OIF subjects with a confirmed diagnosis of TBI. The racial/ethnic background of these subjects was 42.0 % Caucasian, 12.7% African-American, 27.0% Hispanic-American, 10.0% Asian-American, and 8.3% Other. We found that a mean 59.3% ± 4.3 (n = 178) of subjects had suffered blast-TBI and 40.7% ± 3.9 (n = 122) had non-blast TBI. The mean age of subjects with blast TBI was 24.5 ± 1.3 years, while those with non-blast TBI was 25.5 ± 1.4 years. The prevalence of homelessness following TBI in this patient group was 21.3% ± 3.4 (n=64). Homelessness was found in a mean of 19.7% ± 3.2 (n = 35) subjects with blast TBI, and 23.8% ± 3.7 (n = 29) in those with non-blast TBI. CONCLUSION: In this population of OEF/OIF veterans with TBI, homelessness was reported at a relatively high frequency following both blast and non-blast TBI.

Title: Altered brain functional connectivity after chemotherapy in men with gastric cancer

Authors: *J. AHN[1,2], Y.-C. JUNG[3,2]
[1]Dept. of Psychiatry, Yonsei University, Colle, Seoul, Korea, Republic of; [2]Inst. of Behavioral Sci. in Medicine, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [3]Dept. of Psychiatry, Yonsei University, Col. of Med., Seoul, Korea, Republic of

Abstract: Objective: In cancer patients, chemotherapy is essential for increasing survival rate of cancer. However, cognitive impairments such as executive functions, verbal memory, and motor function have been reported after chemotherapy. We investigated the effect of chemotherapy on gray matter and neural network features of gastric cancer patients.
Methods: 19 gastric cancer patients with adjuvant chemotherapy(C+), 14 gastric patients without adjuvant chemotherapy(C-), and 11 healthy controls(HC) were evaluated. We performed neuropsychological studies, voxel-based morphometric analysis, and resting-state functional

magnetic resonance imaging analysis twice at pre- and post-chemotherapy. Intrinsic resting state networks were examined with seed-based analysis method and correlation between brain connectivity patterns and results of neuropsychological studies were analyzed.
Results: Results of neuropsychological studies showed decrease in executive function after adjuvant chemotherapy in C+ group. The results of the analysis indicate decrease in functional connectivity in the default mode network at 3 months after chemotherapy. However, chemotherapy did not cause structural change.
Conclusion: Adjuvant chemotherapy did not cause structural changes in the brain, but the results showed decrease in default mode connectivity, which is associated with decrease in the executive function. Our results suggest that chemotherapy for gastric cancer patients has altered neural networks for executive control.

Title: Classifying concussion in university athletes using diffusion tensor imaging

Authors: *M. LY[1,2], S. SCARNEO[4], A. LEPLEY[3], K. COLEMAN[4], C.-M. CHEN[1], D. J. CASA[4]
[1]Dept. of Psychological Sci., [2]Brain Imaging Res. Ctr., [3]Kinesiology, Orthopaedic Surgery, Univ. of Connecticut, Storrs, CT; [4]Kinesiology, Korey Stringer Institute, Univ. of Connecticut, Storrs, CT

Abstract: Sports-related concussions, or mild traumatic brain injuries (mTBI), are extremely common and a major concern for athletes, athletic trainers, and coaches. Though quick concussion assessments can be conducted on the field to determine ability to return to play, there is a lack of consensus on the diagnostic criteria for mTBI. Due to its heterogeneous course, there is a need for objective diagnostic measures of concussion that are predictive of outcome so that individuals can receive appropriate care and treatment. While mTBI results in diffuse axonal injury, this is difficult to detect using conventional structural magnetic resonance imaging (MRI). However, the results may be able to be detected using diffusion tensor imaging (DTI), a measure of structural connectivity. The aim of this study is to generate a classifier using MRI and DTI to identify concussion. Thirty-four university athletes (15 diagnosed with concussion, 19 controls)

received structural MRI and DTI, the concussed athletes within 72 hours of injury. Diffusion weighted images were motion, eddy, and distortion corrected using TORTOISE. Anatomical images were reconstructed using Freesurfer. Eighteen major white-matter pathways were automatically reconstructed using global probabilistic tractography constrained by anatomical priors (TRACULA). Logistic regression identified nine contributive tracts for classifying concussion using fractional anisotropy (bilateral anterior thalamic radiations, bilateral cingulum - angular bundles, left cingulate gyrus, left corticospinal tract, right inferior longitudinal fasciculus, and bilateral superior longitudinal fasciculi) and eight contributive tracts using mean diffusivity (bilateral anterior thalamic radiations, bilateral cingulum - angular bundles, right cingulate gyrus, left corticospinal tract, right inferior longitudinal fasciculus, and left superior longitudinal fasciculus). Two types of classifiers (one linear, one nonlinear) were trained using 32 randomly sampled athletes and tested with the remaining 2, with 1000 iterations each. Logistic regression (22 degrees of freedom) achieved an overall accuracy of 72% for MD and 71% for FA. A nonlinear support vector machine classifier achieved an overall accuracy of 75% for MD and 74% for FA. These results indicate that DTI measures may be useful for identifying mTBI, though they may be most reliable in conjunction with other behavioral and MRI measures of injury. As concussion is a complex injury, clinicians will increasingly benefit from integrating biological, electrophysiological, and behavioral measures of injury in diagnosis.

Title: Abnormal cerebral hemodynamic responses to postural change during acute concussion

Authors: *J. LIU[1], M. FAVRE[1,2], A. KNOX[1,2], K. BREWER[1,2], M. FALVO[1,2], J. M. SERRADOR[1,2]
[1]Dept. of Pharmacology, Physiol. & Neurosci., New Jersey Med. School, Rutgers Univ., Newark, NJ; [2]War Related Illness & Injury Study Ctr., Veterans Admin. Hlth. Care Syst., East Orange, NJ

Abstract: Objectives: To determine the impact of concussion (i.e. mild traumatic brain injury, mTBI) on cerebral hemodynamic responses to postural change in its acute phase (<25 hrs). **Methods:** Sixteen rugby players (8 females) with acute (10~1482 min, median = 52 min) concussion and 37 non-concussed teammates (10 females) (as controls) participated in the study. The diameter and blood flow velocity were continuously recorded for 1 min at common (CCA) and/or internal carotid arteries (ICA) using duplex ultrasonography, along with a beat-by-beat blood pressure (BP) recording. The mean volumetric flow (Q_{Mean}) was calculated offline. Vascular resistance (VR) was derived as BP_{Mean}/Q_{Mean}; and the pulsatility of BP and flow velocity was assessed by the pulsatility index [PI = (Systolic - Diastolic)/Mean]. All data were collected on the field in both seated and supine positions. **Results:** The BP_{Mean} in concussed players was about 13 mmHg (6~20 mmHg for 95%CI) higher than controls, but no posture-related changes were observed in BP_{Mean} and BP pulsatility. At CCA, no significant change in VR was found from seated to supine postures, but a slightly increased Q_{Mean} and a decreased PI were observed in the absence of between-group differences regarding these responses. However at ICA, only controls showed responses similar to CCA; While in in concussed players, the Q_{Mean} was decreased (314±39 to 246±40 $mL \cdot min^{-1}$, P=0.006) and VR was increased (0.327±0.092 to 0.423±0.137 $mmHg \cdot min \cdot mL^{-1}$, P=0.038) with no significant change in PI from seated to supine postures. The repeated-measures ANOVA confirmed significant Position×Group interactions in these ICA hemodynamic responses. **Conclusions:** Following acute concussion, abnormal hemodynamic (Q_{Mean}, VR and PI) responses to postural change are likely found at the cerebral vessel (i.e. ICA), but not the peripheral vessel (considering the $Q_{ECA} \approx Q_{CCA} - Q_{ICA}$; ECA = external carotid artery), indicating an impaired postural CBF regulation. These metrics are related to the CBF regulation, and may provide a point-of-care assessment of important clinical relevance.

Title: Post-traumatic epilepsy in childhood increases the risk to develop attention deficit hyperactivity disorder: A 9-year follow-up study in Taiwan

Authors: *J. WANG[1], L.-Y. YANG[2], W.-C. LO[3], C.-C. HUANG[4]
[1]Grad. Inst. of Med. Sci. TMU, Taipei, Taiwan; [2]Taipei Med. Univ., Taipei City, Taiwan; [3]Inst. of Statistical Sci. Academia Sinica, Taipei City, Taiwan; [4]Dept. of Pediatrics, Col. of Medicine, Taipei Med. Univ., Taipei City, Taiwan

Abstract: Traumatic brain injury (TBI) in children (≤12 yr) may cause neurobehavioral developmental disorder. Our previous study has demonstrated that childhood TBI is associated with a greater likelihood of developing attention-deficit/hyperactivity disorder (ADHD). ADHD is also commonly observed in children with epilepsy. The aim of this study was to determine whether post-traumatic epilepsy (PTE) is an independent risk factor for the increased risk of ADHD during 9-year follow-up period. Using the National Health Insurance Research Database of Taiwan population, we included 488 newly diagnosed children with PTE (aged ≤12 y) from 2001 to 2002 . We randomly selected the TBI patients matched with sex, age, and registry year for each PTE patient (n=4,880). Cox proportional hazard regressions were performed to analyze the 9-year ADHD-free survival rate between these two cohorts. A total of 19 PTE patients (4.45%) developed ADHD during the 9-year follow-up period and 39 patients (1.83%) from the control cohort. TBI patients were found to be 2.03-fold ($p<0.001$) more likely to develop ADHD during the follow-up period than the control cohort. In conclusion, our data indicate an increased risk of ADHD in childhood PTE patients. This finding suggests that children who had suffered PTE were more susceptible to delayed ADHD. Clinicians and family members should be alert to ADHD in children with PTE history. Intensive monitoring or early treatment for delayed ADHD would be needed for TBI children with PTE.

Title: The morphology of the intraparietal sulcus of children prenatally exposed to alcohol and its role on number processing

Authors: *M. GREEFF[1,2], E. M. MEINTJES[2], S. W. JACOBSON[4,2,3], C. D. MOLTENO[3], J. L. JACOBSON[4,2,3], F. L. WARTON[2], C. M. R. WARTON[2]
[2]Human Biol., [3]Psychiatry and Mental Hlth., [1]Univ. of Cape Town, Cape Town, South Africa; [4]Psychiatry and Behavioral Neurosci., Wayne State Univ., Detroit, MI

Abstract: Introduction
The intraparietal sulcus (IPS) plays a critical role in number processing.(Dehaene *et al.*, 2003;

Ashkenazi *et al.*, 2008) a domain particularly sensitive to prenatal alcohol exposure (PAE).(Meintjes *et al.*, 2010; J. L. Jacobson *et al.*, 2011; Woods *et al.*, 2015) Although smaller parietal lobes have been reported in PAE(Archibald *et al.*, 2001) , the lateral and medial walls of the IPS have not been studied separately. Using "gold standard" manual tracing, we investigated whether PAE is related to morphological changes in IPS and whether these changes are related to number processing. This study was conducted in Cape Town, South Africa, where heavy prenatal alcohol use and fetal alcohol spectrum disorders (FASD)are prevalent in the Cape Coloured community.

Methods

52 right-handed children recruited from our cross-sectional (*n*=32)(Jacobson *et al.*, 2008; Meintjes *et al.*, 2010) and longitudinal (*n*=20)(S. W. Jacobson *et al.*, 2011) cohorts were scanned at 9-14 yr with a 3T Siemens Allegra MRI. The children were diagnosed by expert FASD dysmorphologists as fetal alcohol syndrome (FAS)/partial FAS (FAS/PFAS;*n*=15), non-syndromal heavily exposed (HE;*n*=13), or controls (*n*=24).

Manual tracing (coronal sections) involved tracing (1) all medial walls of the IPS (MIPS) and (2) the entire sulcus—medial and lateral (LIPS) walls. LIPS volume was calculated by subtracting MIPS from total sulcal volume. The occipital portion was excluded.

Results

Left LIPS volumes were smaller in children with FAS/PFAS compared to controls (F=4.854, p=0.012), effects that remained a trend after adjustment for TIV, sequence and sex (F=2.645, p=0.082). Larger left and right MIPS were related to better WISC Arithmetic Scaled scores (r=0.346, p=0.012; r=0.304, p=0.029, respectively), and larger left LIPS to poorer proximity judgment (PJ; r=-0.250; p=0.098). Relations to MIPS volumes survived adjustment for alcohol exposure, sex and age, while the association of LIPS with PJ became stronger (ß=-0.337, p=0.053).

Discussion

LIPS volume is smaller in FAS/PFAS than controls. While larger MIPS was associated with better WISC Arithmetic, smaller LIPS was associated with better PJ, which is surprising since PAE is related to lower levels of activation in regions of the IPS involved in number processing.(Woods *et al.*, 2015) Additional research is needed to clarify why a larger volume of the LIPS might be related to poorer number processing performance.

Title: Changes in functional connectivity are associated with one season of head-to-ball exposure in male collegiate soccer athletes

Authors: *D. C. MONROE[1], D. B. KEATOR[1], R. S. BLUMENFELD[2], J. W. HICKS[1], S. L. SMALL[1]
[1]Univ. of California Irvine, Irvine, CA; [2]California State Polytechnic University-Pomona, Pomona, CA

Abstract: Objectives: Recovery following mild traumatic brain injury (mTBI) depends on characteristics of both the injury and the injured, and the relationships between these characteristics are not well understood. Not all head impacts are immediately symptomatic or clinically recognized as mTBI. Studying the effects of these impacts may be informative. Autonomic dysregulation is thought to underlie many of the multi-dimensional symptoms following mTBI and may derive from altered connectivity in the brain central autonomic network (CAN). We sought to establish a relationship between non-symptomatic head-to-ball impacts (HBIs) and CAN connectivity in Male NCAA Division I soccer athletes.
Methods: 21 male NCAA Division I athletes (age: 20.2±1.5 years) served as participants.11 soccer athletes were monitored by athletic training staff throughout one season for HBIs. 3 cross-country athletes and 7 golfers served as controls. All participants underwent a resting-state fMRI pre- and post-season. 20 ROIs were selected based on regions previously implicated in control and modulation of basal autonomic function. Graph theoretical analysis was used to probe changes in network architecture among nodes (regions) with edge weights above threshold (|cost| >.3). Connectivity maps thresholded by seed and connection ($p < .05$ uncorrected) were examined to clarify changes in network connectivity. Contrasts were performed to test for changes across the season that were explained by individual differences in HBI exposure ($p < .05$ uncorrected).
Results: Within the 20 node network, HBIs accounted for reduced degree centrality of the left and right insular cortex and right putamen [$t(18)>2.36$, $p<.02$], increased degree and betweeness centrality in the left anterior and right posterior parahippocampal gyri [$t(18)<-2.22$, $p<.03$], and increased betweeness centrality in the anterior cingulate cortex [$t(18)=-3.11$, $p=.006$]. HBIs were associated with reduced functional connectivity among the anterior cingulate cortex [$F(5,14)=5.08$, $p=.0073$)], right hippocampus, left putamen, and left insular cortex [$t(18>2.23$, $p<.04$].
Conclusion: A contemporary hypothesis is that chronic exposure to repeated non-symptomatic head impacts has neurological effects. We demonstrate that soccer athletes sustaining the greatest number of HBIs also experienced the greatest altered connectivity among regions associated with autonomic function. Future work should consider the importance of impact magnitude and correlate network changes with peripheral measures of autonomic function at rest and in response to standardized stressors.

Title: Identifying electrophysiological components of covert awareness in patients with disorders of consciousness

Authors: *G. LAFORGE, A. M. OWEN, B. STOJANOSKI
Psychology, The Univ. of Western Ontario, London, ON, Canada

Abstract: A small but significant number of those who survive acute brain injury will transition into a state of unconscious wakefulness known as the vegetative state (VS). Patients in a VS remain behaviourally non-responsive during clinical examination and, despite exhibiting clear evidence of wakefulness, do not appear to possess conscious awareness. However, recent neuroimaging research has identified a subpopulation of these patients who reliably produce neural markers of "covert" awareness. Indeed, imagined motor-imagery paradigms have identified covert, rather than behavioural command-following ability in nearly 20% of patients tested and naturalistic movie-watching tasks in fMRI have been used to index higher-order "executive" processing, a proxy of awareness, in patients who appear to be entirely unconscious. Here, we demonstrate the utility of bedside EEG recorded during a naturalistic audio paradigm to detect higher-order stimulus processing in VS patients and others diagnosed with so-called disorders of consciousness (DoC). We used a correlated components analysis to calculate global and time-resolved inter-subject neural synchronization, an established measure of stimulus engagement, in healthy volunteers and patients with DoC while they listened to a suspenseful auditory narrative. At the group level, no significant differences were observed in global inter-subject correlations (ISC) between the intact narrative and a scrambled narrative condition in healthy controls, $t(14) = 1.22$, $p > .05$. However, we did find significantly more time points in the audio with significant ISC for the intact audio condition than the scrambled condition, $\chi^2(1, N = 152) = 4.52$, $p < .05$, that corresponded to suspenseful moments in the clip. As a group, patients with DoC had fewer time windows with significant ISC during the intact audio condition than either the intact, $\chi^2(1, N = 152) = 21.35$, $p < .0001$, or scrambled audio conditions $\chi^2(1, N = 152) = 7.35$, $p < .01$, in healthy controls. We then compared the neural response to the clip from individual DoC patients to healthy controls to quantify the similarity of their executive processing. We found that the correlated component topography and the degree of patient-to-group ISC could differentiate a demonstrably aware locked-in patient from those with DoC. Crucially, we found evidence of preserved narrative processing in one VS patient who has

previously demonstrated some residual awareness in fMRI. Together, these results suggest that EEG recorded during naturalistic auditory stimulation may provide a sensitive, low-cost, and portable means to assess the neural correlates of covert awareness in patients with DoC.

Abstract: Introduction: Combat-related mild traumatic brain injury (mTBI) is a leading cause of sustained cognitive impairment in military service members and Veterans. However, the mechanism of persistent cognitive deficits including working memory (WM) dysfunction is not fully understood in mTBI. Few studies of WM deficits in mTBI have taken advantage of the temporal and frequency resolution afforded by electromagnetic measurements. Using magnetoencephalography (MEG) and an N-back WM task, we investigated functional

abnormalities in combat-related mTBI. Method: Study participants included 25 symptomatic active-duty service members or Veterans with combat-related mTBI and 20 healthy controls with similar combat experiences. MEG source-magnitude images were obtained for alpha (8-12 Hz), beta (15-30 Hz), gamma (30-90 Hz), and low-frequency (1-7 Hz) bands. High resolution MEG source imaging technique, Fast-VESTAL, was used in creating MEG source magnitude images for the responses of N-back task. For each frequency band, a voxel-wise repeated measure ANOVA was performed to create F-value maps for examining the group differences (i.e., mTBI versus control groups), with 1-, 2-, and 3-back conditions treated as repeated measures. Family-wise error across voxels was corrected using cluster analysis for the F-value maps at a corrected $p<0.01$ level. Result: Compared with healthy combat controls, mTBI participants showed increased MEG signals (i.e., hyper-activations) across frequency bands in rostral prefrontal cortex (rPFC) including frontal pole (FP), ventromedial prefrontal cortex, orbitofrontal cortex (OFC), and anterior dorsolateral prefrontal cortex (dlPFC), but decreased MEG signals (i.e., hypo-activations) in posterior dlPFC and anterior cingulate cortex. Hyper-activations in FP, OFC, and anterior dlPFC were associated with slower reaction times. MEG hyper-activations from the lateral FP area were also associated with worse performance on neuropsychological tests that measure processing speed and executive functions (i.e., letter sequencing, verbal fluency, and digit symbol coding). These findings suggested that aberrant neuronal activity in combat-related mTBI, especially in PFC, was functionally significant, relating to individual differences in cognitive proficiency. Conclusion: Aberrant activations during WM were revealed for the first time in combat-related mTBI using MEG source magnitude imaging. Among all the abnormalities in the PFC, the profound hyper-activations in rPFC (mainly the FP, but also vmPFC, and OFC) revealed by the present study suggests that the aberrant rPFC is an important feature in combat-related mTBI.

Title: Influence of primary blast exposure on development of PTSD following deployment

Authors: *K. H. TABER[1,4,5], J. A. ROWLAND[2,6,5], E. EPSTEIN[2,5], S. L. MARTINDALE[2,6,5], H. M. MISKEY[3,6,5], R. D. SHURA[3,6,5]

Abstract: Service members are frequently exposed to blasts or explosions during deployment. These events may or may not be accompanied by acute symptoms of mild traumatic brain injury (mTBI). The long-term effects of primary blast exposure on veterans of the wars in Iraq and Afghanistan are currently unknown. As part of this study, we developed a structured interview that evaluates lifetime blast exposures and connects blast events to mTBI events. Posttraumatic stress disorder (PTSD) diagnosis was determined using the Clinician Administered PTSD Scale – 5 (CAPS-5). The Salisbury VAHCS IRB approved this study to ensure that the privacy of research subjects was maintained and their welfare protected. Participants included 165 combat-exposed post-deployment veterans who passed performance and symptom validity measures. Chi-Square analyses were conducted to analyze differences in categorical variables. ANOVA were used to analyze differences in continuous variables. Logistic regression was used to evaluate the contributions of variables to PTSD diagnosis or recovery. Most blast exposure events (71%) occurred during combat and relatively few (19%) were associated with acute symptoms indicative of mTBI. Primary blast exposure was associated with higher rates of both current ($p < .026$, Cramer's V=0.173) and lifetime ($p < .001$, Cramer's V=.296) PTSD. Deployment mTBI was associated with higher rates of lifetime PTSD ($p < .001$, Cramer's V=.276). When participants with deployment mTBI were removed from the analysis, blast exposure remained associated with increased rates of lifetime PTSD ($p < .001$, Cramer's V=0.378). In addition, higher severity of blast exposure remained associated with higher rates of both lifetime ($p < .032$, Cramer's V=.227) and current ($p < .017$, Cramer's V=.252) PTSD. Logistic regression was used to predict lifetime and current PTSD diagnosis from deployment mTBI and blast exposure. The model did not significantly predict current PTSD diagnosis, but significantly predicted lifetime PTSD diagnosis. An interaction was observed between blast exposure and deployment TBI ($p < .053$) such that experience of either or both increased the likelihood of a lifetime PTSD diagnosis. For the model including higher severity blast exposure, only blast exposure significantly predicted either current or lifetime PTSD. These results indicate that primary blast exposure increases risk for developing PTSD even when the blast exposure was not associated with acute TBI symptoms.

Title: Upregulation of lysosome by EGF-triggered endocytosis or trehalose attenuated zinc neurotoxicity via the increase of buffering capacity for intracellular free zinc

Authors: *J.-W. EOM, Y.-H. KIM
Sejong Univ., Seoul, Korea, Republic of

Abstract: Zinc is an essential metal ion for almost all of the organisms, and maintaining intracellular free zinc homeostasis is vitally required. To keep a balance of cytoplasmic free zinc, excess zinc is sequestrated into intracellular organelles, such as lysosome and mitochondria, as well as binds to metal-binding proteins, metallothionein. However, too much increase of intracellular free zinc provoked lysosome membrane permeabilization (LMP) and then cathepsin-mediated neuronal death.
Therefore, we tried to upregulate the number of lysosomes to reduce zinc neurotoxicity by augmentation the buffering capacity for intracellular free zinc through epidermal growth factor (EGF)-triggered endocytosis or pre-treatment of trehalose, known as a disaccharide, which increases lysosome biogenesis via mTOR-independent manner.
First, we examined whether EGF-induced endocytosis elevated the number of lysosome in mouse cortical cultures. Within 30 min after EGF treatment, LAMP-1/LAMP-2, as well as a mature form of cathepsin D, were increased in Western blot. Secondly, we observed that pre-exposure to EGF significantly attenuated zinc neurotoxicity, suggesting the possibility that increase of lysosomes by EGF-triggered endocytosis expand the handling capacity for intracellular free zinc. So, we next tried to see that chemical inhibitions of EGF-induced endocytosis and endosomal trafficking pathway affect zinc-induced cell death. Supporting the critical action of endocytosis and endosomal trafficking pathway in attenuation of zinc neurotoxicity by EGF, chlorpromazine, the chemical clathrin-dependent endocytosis blocker, or methyl-β-cyclodextrin, the chemical caveolin-dependent endocytosis blocker, almost completely reversed EGF-mediated neuroprotection against zinc toxicity. We also observed that the specific tyrosine kinase inhibitor of EGF, compound 56 or AG1478, blocked EGF-mediated neuroprotection against zinc toxicity as well as EGFR endocytosis after EGF treatment.
As another strategy for upregulation of lysosome, we treated Trehalose. As expected, Trehalose significantly reduced zinc neurotoxicity and noticeably increased LAMP-1 and TFEB in Western blot. Taken together, quantitative regulations of lysosome through EGFR endocytosis or

exposure of trehalose play a critical role in zinc homeostasis, and it ultimately could be a therapeutic target for acute brain injury.

Title: Neuroprotective strategies following experimental traumatic brain injury: Inhibition of mitochondrial permeability transition, lipid peroxidation-derived neurotoxic aldehyde scavenging and monoamine oxidase inhibition

Authors: *J. R. KULBE[1], I. N. SINGH[1], J. A. DUNKERSON[1], J. A. WANG[1], P. F. HUETTL[2], R. L. HILL[1], R. SMITH[1], E. D. HALL[1]
[1]Spinal Cord and Brain Injury Res. Ctr., [2]Ctr. for Microelectrode Technol., Univ. of Kentucky, Lexington, KY

Abstract: In the US, there are over 5 million people suffering from a traumatic brain injury (TBI)-related disability. Unfortunately, due to the complex pathophysiology that occurs following injury, there are no neuroprotective FDA-approved pharmacotherapies for TBI. Mitochondrial dysfunction and lipid peroxidation, including generation of lipid peroxidation-derived neurotoxic aldehydes, are central to the TBI secondary injury, and therefore, make promising therapeutic targets for prevention of neuronal death and dysfunction following TBI. The purpose of these studies was threefold. 1) Evaluate the neuroprotective effect of cyclosporine A (CsA), on synaptic and non-synaptic mitochondria. Mitochondria are heterogeneous, consisting of synaptic and non-synaptic mitochondria, which have distinct properties. Our results indicate that compared to non-synaptic mitochondria, synaptic mitochondria sustain greater damage 24h following severe controlled cortical impact injury in young male rats, and are protected to a greater degree by CsA, an FDA-approved immunosuppressant, capable of inhibiting mitochondrial permeability transition. 2) Evaluate the neuroprotective effects of a 72h subcutaneous continuous infusion of CsA combined with phenelzine (PZ), an FDA-approved monoamine oxidase inhibitor (MAOI) class anti-depressant capable of scavenging neurotoxic aldehydes compared to monotherapy. Our results indicate that 72h post-TBI (the peak of mitochondrial dysfunction and lipid peroxidation) that individually

CsA or PZ attenuate lipid peroxidation-derived neurotoxic aldehyde formation, PZ maintains mitochondrial respiratory control ratio and cytoskeletal integrity, but together, PZ + CsA, do not maintain neuroprotective effects. 3) Although neurotoxic aldehyde scavenging, a PZ mechanism of action, has proven neuroprotective properties, the effect MAO inhibition has on pathology following TBI is unknown. Therefore, the ability of PZ (aldehyde scavenger, MAOI), hydralazine (HZ, aldehyde scavenger, non-MAOI) and pargyline (PG, non-aldehyde scavenger, MAOI) to improve learning and memory 3 – 7 days post-injury was evaluated using Morris water maze (MWM). Although neither PZ, HZ, nor PG were able to improve retention memory, PZ animals did not learn during the acquisition phase and lost more weight compared to other groups, potentially due to high levels of norepinephrine or serotonin. In fact, when HPLC was utilized to evaluate monoamine and metabolite levels of our PZ, HZ, PG dosing paradigm in naïve rats, PZ showed a significant increase in norepinephrine and serotonin compared to other groups.

Title: Biophysical modeling reveals efficacious drug combinations for improved neuroprotection immediately after traumatic brain injury

Authors: *S. SUDHAKAR, T. CHOI, V. HETRICK, O. AHMED
Univ. of Michigan, Ann Arbor, MI

Abstract: Traumatic brain injury (TBI) is a long-standing public health concern in the United States with an estimated 5.3 million people currently living with a TBI-related injury. Depending on the severity of the injury, TBI can lead to a wide range of functional deficits. The altered ionic milieu, synaptic changes, and network dynamics following TBI create excitotoxicity resulting in cell death and changes in brain volume. Currently, there are no pharmacological drugs that offer complete neuroprotection immediately after TBI, and numerous clinical trials have failed to find a consistently efficacious drug. Antiepileptic drugs ($GABA_A$ agonists) that are often used to treat epilepsy are not effective in reversing the excitotoxicity following TBI. Using computational

modeling of a neocortical regular spiking neuron, we hypothesize that this could be due to the reversal of the chloride gradient caused by the upregulation of Na-K-Cl transporter (NKCC1) immediately following the injury. Our modeling results suggest that restoring the altered chloride gradient by blocking the NKCC1 transporter would release the neuron from depolarization block and therefore facilitate the neuroprotection provided by $GABA_A$ agonists. We subsequently tested the neuroprotective efficacy of a $GABA_A$ agonist in combination with a NKCC1 transporter blocker, using a controlled cortical impact (CCI) model of TBI in rats. This combination of drugs led to significantly reduced cortical damage compared to controls. Thus, biophysically-principled drug design might offer a rational way to identify ideal drug combinations for the treatment of TBI.

Title: Glycolytic inhibition with 2-deoxyglucose preserves inhibitory cortical network function following traumatic brain injury

Authors: *J. B. KOENIG[1], D. CANTU[1], C. S. LOW[2], D. KONG[1], C. G. DULLA[1]
[1]Neurosci., Tufts Univ. Sch. of Med., Boston, MA; [2]Tufts Univ., Boston, MA

Abstract: Following a traumatic brain injury (TBI), post-traumatic epilepsy (PTE) can occur. Chronic seizures can be a significant cause of disability for TBI patients, especially when the seizures are refractory to currently available anticonvulsant therapies. The latent period between a TBI and the onset of PTE provides a therapeutic opportunity to prevent the pathophysiological changes that result in a seizure-prone network. Post-traumatic epileptogenesis may be explained by a loss of network inhibition resulting in an excitatory/inhibitory imbalance of the network. By targeting the metabolic changes following TBI, namely acute increases in glycolysis, we may be able to prevent the downstream loss of inhibitory interneurons and resulting hyperexcitability. We hypothesize that 2-deoxyglucose (2DG), a glucose analog that competitively inhibits glycolysis, preserves cortical network function following TBI.
To study TBI, we have used a model known as controlled cortical impact (CCI) in mice. Using this approach we found cortical network hyperexcitability, increased glutamatergic signaling,

and a loss of parvalbumin and somatostatin inhibitory interneurons following injury. To examine the effects of glycolytic inhibition on post-TBI pathophysiology, we treated animals with vehicle or 2DG through systemic intraperitoneal injection daily for 7 days after CCI. We show that *in vivo* 2DG treatment after CCI prevented the development of epileptiform activity following injury and preserved the input-output relationship observed in healthy cortex. We also show that 2DG attenuated losses of parvalbumin expression in cortical inhibitory interneurons adjacent to the lesion site and rescued changes in excitatory and inhibitory postsynaptic currents. The protective effects of *in vivo* 2DG are independent of changes in CCI lesion volume or systemic metabolic effects (such as change in body temperature). Finally, we propose that glycolytic inhibition with 2DG may act through differential effects on the excitability of different neuronal subtypes, and are currently exploring potential metabolic differences between excitatory and inhibitory neurons.
Our research supports a role for glycolytic inhibition in the preservation of inhibitory network function and the prevention of epileptogenesis following TBI. Thus, 2DG has significant potential as a translational intervention for patients after TBI. Finally, our work reveals a possible mechanism of action for 2DG -- a novel cell type-specific coupling of metabolism to neuronal excitability.

Title: Effects of an orally active, highly selective, arginine vasopressin V1a receptor antagonist on cerebral edema after moderate traumatic brain injury

Authors: *T. R. MORRISON[1], N. G. SIMON[2,3], S.-F. LU[2], Z. CHENG[2], C. F. FERRIS[1,4], P. P. KULKARNI[1,4]
[1]Psychology, Northeastern Univ., Boston, MA; [2]Biol. Sci., Lehigh Univ., Bethlehem, PA; [3]Azevan Pharmaceuticals, Inc., Bethlehem, PA; [4]Ctr. for Translational Neuro-imaging, Boston, MA

Abstract: In the US, TBI is a contributing factor to a third of injury-related deaths, one of the leading causes of death and disability in persons under 35 and over 65, and carries an annual economic burden of ~$86 billion. Arginine vasopressin (AVP) is a chemical signal that influences brain water permeability and a major driver of the pathophysiology of brain edema after TBI. These cerebrovascular effects are mediated by interactions between AVP receptor signaling and aquaporin-4 channels. Previously, we showed that treatment with AVN576, a highly selective and orally active arginine AVP V1a receptor antagonist, for 5 days beginning 24 hrs after moderate head injury significantly reduced edematous enlargement of the lateral ventricles, and eliminated cognitive deficits following moderate TBI in rats.
In this experiment, we tested how shortening the time interval between injury and treatment altered the efficacy of AVN576 after a moderate TBI. We also examined whether AVN576 treatment affected biomarkers of injury severity, and if this change correlated with ventricular volume and/or hippocampal functional connectivity. A moderate TBI was produced using the momentum exchange model in male SD rats. Experimental animals were treated 6 hrs later with AVN576 and thereafter twice daily for 5 days. SHAM and concussed+vehicle treated rats served as controls. Prior to TBI, animals were pre-scanned for baseline functional connectivity and ventricular volume (T2 relaxivity), and then scanned again 5 hrs, 24 hrs, and 7 days after injury. Blood samples were taken in parallel with scans and evaluated for injury severity markers. All images were registered to a 3D MRI rat atlas to assess differences between groups across 171 brain areas. Scans showed that edema persisted 7 days after injury in untreated animals, and that AVN576 significantly reduced edema. Moreover, we also report changes in connectivity, and alterations in the relationship between biomarkers of injury severity and scanning parameters. These results, in accord with our previous findings, suggest that V1a antagonism may represent a novel approach for reducing or eliminating cerebral edema that significantly affects mortality and morbidity following moderate/severe TBI.

Abstract: Abstract
Traumatic Brain Injury (TBI) is a progressive and complex brain injury that results in many adverse and long-term neurological consequences. TBI triggers a cascade of molecular and cellular changes that can lead to development of post-traumatic co-morbidies, such as epilepsy and Alzheimer's disease. Mesenchymal stem cell (MSC)-based therapies have recently emerged as a promising, reliable and safe cell therapy approach for managing and treatment and of many neurodegenerative diseases, and may be effective in targeting the pathophysiology of TBI. MSCs have therapeutic effects possibly by their secretome at the site of brain injury results in regulate the damage and promoting the repair processes. The focus of this project is to investigate whether MSCs modified to secrete fibroblast growth factor 21 (FGF-21), a novel metabolic regulator that has emerged as potent neuroprotective agent, can further enhances the recovery in controlled cortical impact (CCI) TBI mice model.. Our preliminary results have shown MSCs-secreting FGF-21 enhance their migration ability using an in vitro assay. Moreover, mice that received an Intracerebroventricular (ICV) injection of MSC-FGF21 contralateral to the injury side after 24 hours of the CCI-TBI injury, showed significantly improved functional outcomes compared with mice treated with empty MSCs- Empty Vector (EV) or vehicle (PBS). The functional outcomes have been demonstrated improvements in cognitive functions (using Morris Water Maze test (MWM), and Novel Object Recognition test (NOR)), motor functions (Using Beam Walking test), emotional and behaviour functions (using Open Field test (OFT) and Forced Swim Test (FST)) in MSC-FGF21 treated mice compared with MSCs- Empty Vector (EV) or vehicle (PBS) treatment. The improved functional outcome might be explained by the enhanced neurogenesis and axonal remodelling following MSC-FGF21 transplantation. These data suggest that fgf-21 can enhances the potential of MSCs based therapy might be a useful approach to consider for treatment of TBI.

Title: Combined effects of suicidal gene-expressing mesenchymal stem cells and chemotherapy in experimental glioblastoma model

Authors: *J. HAN, D. JANG, H. SUH-KIM, S. KIM
Anat., Ajou Univ. Sch. of Med., SUWON, Korea, Republic of

Abstract: The intrinsic heterogeneous and infiltrative nature of glioblastoma cells to the adjacent normal brain parenchyma, as well as their resistance to most chemotherapeutic agents available currently, are the main obstacles to the treatment of GB. Human mesenchymal stem cells (MSCs) have emerged as attractive cellular vehicles to deliver therapeutic genes for ex-vivo therapy of diverse diseases; this is in part because they have the capability to migrate into tumors. Previously, we showed that MSC can deliver a bacterial suicide gene, cytosine deaminase (CD), and remove the glioblastoma multiform (GBM) via bystander effects. Here, we report that a potential application of MSC/CD in combination with temozolomide (TMZ), which is an oral alkylating agent used widely in the clinical treatment of high-grade gliomas. Glioblastoma LN229 cells were stably transduced to express a green fluorescence protein utilized for in vivo and in vitro experiments. Treatment with MSC/CD with 5-FC effectively suppressed the GBM and such effects were higher in the presence of TMZ. Therefore, we propose that combined treatment of MSC/CD with chemotherapy can be used to treat patients with GBM during the immediate postoperative period by sensitizing the GBM.

Title: Inhaled nitric oxide protects cerebral autoregulation through prevention of impairment of ATP and calcium sensitive K channel mediated cerebrovasodilation after traumatic brain injury

Authors: *W. M. ARMSTEAD[1], P. PASTOR[2], V. CURVELLO[2], H. HEKIERSKI[2]
[1]Univ. of PA, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Introduction: Hypotension and low cerebral perfusion pressure are associated with low cerebral blood flow, cerebral ischemia, and poor outcomes after traumatic brain injury (TBI). Cerebral autoregulation is impaired after TBI, contributing to poor outcome. Since ethical considerations constrain mechanistic studies in humans, we use an established porcine model of fluid percussion brain injury (FPI) to understand this pathology. In prior studies, ERK mitogen activated protein kinase (MAPK) and ET-1 had been observed to be upregulated and contribute to impairment of cerebral autoregulation and histopathology after FPI in the pig. Activation of ATP and Calcium sensitive (Katp and Kca) channels produce cerebrovasodilation and contribute to autoregulation, both impaired after TBI, contributory to poor outcome. Upregulation of ERK MAPK and ET-1 produces K channel function impairment after CNS injury. Inhaled nitric oxide (iNO) has recently been observed to prevent impairment of cerebral autoregulation and hippocampal CA1 and CA3 neuronal cell necrosis after FPI in pigs via block of upregulation of ERK MAPK and ET-1. We presently investigated whether iNO prevented impairment of Katp and Kca-mediated cerebrovasodilation after FPI. **Methods:** Lateral FPI was produced in anesthetized pigs. Pial artery reactivity was measured via a closed cranial window. Data (N=5) were analyzed by repeated measures ANOVA, with significance determined at $P < 0.05$. **Results:** Results show that pial artery dilation in response to the Katp agonist cromakalim, the Kca agonist NS1619, PGE2 and the NO releaser sodium nitroprusside (SNP) were blocked by FPI, but such impairment was prevented by iNO administered at 30 min or 2h post-injury. Protection lasted for at least 1h after iNO administration was stopped, indicating that protection was durable. **Discussion:** Using vasodilation as an index of function, these data indicate that iNO prevents impairment of cerebral autoregulation and limits histopathology after TBI through protection of K channel function via blockade of ERK MAPK and ET-1.

Title: Aging in mice with repeated concussive injuries: Implications of n-3 polyunsaturated fatty acid deficiency

Authors: *A. DESAI[1], H. CHEN[1], K. KEVALA[2], H.-Y. KIM[1]
[1]Natl. Inst. On Alcohol Abuse and Alcoholism, Bethesda, MD; [2]Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: Repeated head injuries can have protracted effects on neuropathology and behavior. Chronic traumatic encephalopathy has been observed in post-mortem brains of humans who had sustained multiple head injuries. The concentration of n-3 polyunsaturated fatty acids (n-3 PUFA) in diet and of docosahexaenoic acid (DHA) in the brain also impact the recovery in many models of acute brain injury. The present study was designed to explore if the effect of repeated head injuries during adulthood (4-5 months age) is sustained in aged mice (17-18 months age) and to investigate whether brain DHA concentration is relevant in this paradigm. Pregnant C57Bl/6N mice (E14) were fed with n-3 PUFA deficient diet. At weaning, the pups were either continued on the same diet (deficient group) or given n-3 PUFA adequate diet (adequate group). At 4-5 months age, the mice were given one head injury daily for three days using the closed head impact model of engineered rotational acceleration (CHIMERA). Behavioral studies including tests for anxiety- and depression-like behavior and learning/memory were performed after 2 months of injury (adult mice) or 17-18 months of age (aged mice). The mice were euthanized and their brains were collected for histology and biochemical studies. Mice fed with deficient diet had lower brain DHA concentration than the adequate group. The aged mice with repeated head injuries had a clear trend for increased activity compared to the sham. The deficient diet group of mice appeared to show anxiety-like behavior in the elevated plus maze test. Increased gliosis was also observed after injury, which was exacerbated by DHA deficiency. The results indicate that mice can show differences in behavior and brain pathology even after 13 months of having repeated head injuries and that the brain DHA status affects injury-related brain pathology.

Title: Lithium improves striatal dopamine neurotransmission and synaptic dopaminergic protein abundance following traumatic brain injury

Authors: *S. W. CARLSON, C. DIXON
Neurosurg., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Experimental models of traumatic brain injury (TBI) recapitulate neurobehavioral impairments and the development of secondary injury sequela observed in TBI patients. Previous work from our lab shows that TBI reduces formation of the soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex, protein machinery important for vesicular fusion, contributing to impaired neurotransmission in the weeks post-injury. In the hippocampus, lithium treatment increases SNARE monomeric protein abundance and SNARE complex formation, and promotes the recovery of cognitive function after controlled cortical impact (CCI). However, the effects of TBI on the SNARE complex formation have not been studied in the striatum, a region exhibiting deficits in evoked dopamine neurotransmission. The objective of this study was to evaluate the effect of lithium treatment on SNARE complex formation and dopamine neurotransmission in the striatum. To test this, anesthetized male Sprague-Dawley rats received CCI (2.7mm) or sham injury, and injected daily (i.p.) with vehicle or 1.0mmol/kg/ml lithium chloride for 7d, beginning 5 minutes post-injury. Daily treatment with lithium significantly improved high-potassium evoked striatal dopamine release at 7d post-injury (n=6-7/group). In a separate cohort, animals received CCI or sham surgery as described and the brains were dissected at 7d post-injury and processed to produce synaptosomal lysates for immunoblotting (n=6/group). CCI significantly reduced cysteine string protein alpha, VAMP2 and SNARE complex formation in striatal synapses. Treatment with lithium did not increase SNARE protein abundance or SNARE complex formation. However, lithium increased the abundance of alpha synuclein, D2 receptor and phosphorylation of tyrosine hydroxylase. These findings demonstrate treatment with lithium improves striatal neurotransmission, and suggests that lithium may increase the abundance of multiple dopaminergic proteins after TBI.

Title: Purinergic agonists reduce cerebral damage in a preclinical mouse model of Blast-induced traumatic brain injury

Authors: *E. BOZDEMIR KURBANOV[1], F. A. VIGIL[1], V. BUGAY[1], S. H. CHUN[1], S. KHOURY[1], L. ESPINOZA[1], D. M. HOLSTEIN[1], H. AKAL[2], I. SANCHEZ[1], M. HOBBS[1], R. ELLIOT[3], C. SPRAGUE[3], G. RULE[3], J. CAVAZOS[1], B. LUND[3], M. SHAPIRO[1], R. BRENNER[1], J. D. LECHLEITER[1]
[1]Univ. of Texas Hlth. Sci. Ctr. at San A, San Antonio, TX; [2]Berkshire Med. Ctr., Pittsfield, MA; [3]U.S. Army Inst. of Surgical Res., San Antonio, TX

Abstract: Rationale- Blast concussions are a too common occurrence for many soldiers. Although blast trauma is correlated with epilepsy development, it is unknown if blast injury causes early seizures that contribute to epilepsy. As a first step towards treatment, we developed a mouse model of post blast seizures and investigated purinergic receptor agonists as potential therapeutics.
Method- We used the shock tube apparatus located at the Sensory Trauma Division, US Army Institute for Surgical Research (USAISR) to produce pressure waves having the characteristic "Friedlander" waveform of a free-field blast wave. 10-week-old C57BL/6J mice were subjected to repeated blasts (3X in 3 days, 14 kPa) directed head-on. 30 minutes following trauma, mice were treated with either vehicle or purinergic agonist (AST-004 0.2 mg/kg or MRS2365 0.85 mg/kg). The day after the last blast exposure, one group of mice was implanted with screw-type EEG electrodes and allowed 24 hours to recover. They were then recorded continuously over the following 48 hours. The rest of the mice were not implanted with EEG electrodes. All mice were sacrificed 7 days after the initial blast exposure and brains harvested for brain slice electrophysiology, biochemistry or histology. GFAP and Iba1, established markers for astrocytes and microglia, were used as biomarkers for injury. We also used Sholl Analysis to investigated astrocyte morphology.
Results- Blast injured mice demonstrated a significant increase in GFAP and Iba1 levels as well as morphology changes indicating astrogliosis. Purinergic treatments significantly reduced all injury markers, primarily in the hippocampal region. EEG recordings showed that 5/10 mice exhibited generalized seizures ranging in frequency from 1/day to 9/day, with durations of 5-36 sec per seizure (average 22 sec). Seizures correlated with behavioral arrest in some, but not all animals. Patch clamp recording from hippocampus dentate gyrus granule neurons indicated blast injury increased intrinsic excitability. Biochemical studies indicated a significant increase in phospho- tau (S202), with no change in total Tau, which was reduced by purinergic treatment.
Conclusions- Repetitive moderate blast injuries cause early seizures and neuronal hyper-excitability. Reactive astrogliosis, microglial activation and phospho-tau are elevated after blast injury. Pharmacological activation of purinergic receptors substantially protected against blast injury as indicated by reversal of GFAP and phospho-tau levels.

Title: A novel self-guided rehabilitation task activates limbic memory circuitry and preserves cognitive performance after diffuse traumatic brain injury in the rat

Authors: *L. LAW[1], D. R. GRIFFITHS[2], J. LIFSHITZ[2]
[1]Child Hlth., [2]Translational Neurotrauma, Barrow Neurolog. Inst. at PCH, Phoenix, AZ

Abstract: Traumatic brain injury (TBI) is not a transient event from which all people recover; the resulting damage can evolve into neurological disease. As with patients, experimental TBI disrupts rodent memory circuits, evident as impaired cognitive performance. Experimental rehabilitation strategies, such as enriched environment and exercise, have partial success in alleviating symptoms. New rehabilitation strategies are necessary to demonstrate therapeutic efficacy and explore cellular mechanisms that promote recovery. Diffuse brain injury by midline fluid percussion leads to cognitive impairments by 1 month post-injury, permitting a timeframe to implement and investigate delayed interventions. We hypothesize that rehabilitation targeting the spatial and contextual memory circuit will prevent the onset of injury-induced memory impairments by specifically activating rodent limbic circuitry. Rehabilitation occurs in a box with a peg-board floor that allows for 10cm plastic pegs to be inserted at 2.5cm intervals in designated layouts; termed Peg Forest Rehabilitation (PFR). Uninjured and brain-injured rats were exposed to PFR (15 min/day), allowing free navigation through random layouts of the peg-filled arena for 10 days over 2 weeks or for 5 days starting one or two weeks post-injury. Controls were exposed to an open-field arena (15 min/day) or served as caged-controls. One-month post-injury, cognitive performance was tested for short-term, long-term, and working memory. Brain-injured animals exposed to PFR performed no different than uninjured rats on all three cognitive assessments. Brain-injured control rats performed significantly worse than shams on all three cognitive assessments, demonstrating injury-induced cognitive impairment in the absence of rehabilitation. In naïve rats exposed to PFR, neurons in the limbic memory circuit exhibited increased cFos expression compared to caged controls, confirming specific circuit activation. Results following a single week of rehabilitation preliminarily indicate that 2 weeks of PFR are necessary for spared cognitive performance. Thus, passive, intermittent rehabilitation targeting specific circuitry can prevent cognitive symptomatology. The Peg Forest is a viable

rehabilitation strategy to explore cellular and molecular mechanisms to preserve neurological function.

Title: Minocycline plus N-acetylcysteine improves structure and function of distal brain regions even when dosed days after closed head injury

Authors: *K. WHITNEY[1], M. A. SANGOBOWALE[2], A. ALEXIS[1], E. NIKULINA[1], D. L. DICKSTEIN[3], T. C. SACKTOR[1], P. J. BERGOLD[1]

Abstract: Patients with moderate to severe traumatic brain injury (TBI) receive treatment within hours. Patients with mild TBI are more likely to delay seeking treatment and therefore will need drugs with a longer therapeutic time window. Drugs to treat experimental TBI lose potency as the therapeutic time window increases. Previous studies have shown that the drug combination of minocycline (MINO) plus N-acetylcysteine (NAC) loses little potency when first dosed at 1 or 12 hours. The therapeutic time window in mice was further examined after a first dose of MINO plus NAC at 12 hours (MN12) or 72 hours (MN72) after closed head injury (CHI). Behavioral recovery was assessed with an active place avoidance task, which requires two functioning hippocampi and the connections between them; and Barnes maze which only requires one functioning hippocampus. Both gray and white matter injury was assessed histologically. MN12 improved both Barnes maze and active place avoidance as well as preventing white and gray matter injury in the hippocampi ipsilateral to the impact site. MN72-treated mice acquired and retained Barnes maze, despite histological damage to ipsilateral brain regions. The ability to acquire Barnes maze suggests that MN72 restored synaptic plasticity in the contralateral hippocampus. This hypothesis was tested by examining hippocampal synaptic plasticity in MN72-treated mice. The atypical protein kinase C, PKMζ, is needed for long-term potentiation (LTP) of Schaffer collateral-CA1 synapses. CHI damaged cellular ultrastructure, impaired LTP and decreased PKMζ levels in both hippocampi; MN72 treatment restored LTP and PKMζ levels only in the contralateral hippocampus. MN72 treatment also maintained neuronal structure and synaptic density in the contralateral, but not the ipsilateral hippocampus. These data show that MN12 treatment prevents both white and grey matter damage proximal to the injury. There is a

loss of potency when MINO plus NAC is dosed at 72 hours, yet it still prevents gray matter damage and restores synaptic function distal to the impact site. When dosed soon after injury, MINO plus NAC may have sufficient potency to treat moderate and severe TBI. The long therapeutic time window of MINO plus NAC suggests it may be effective to treat mild TBI.

Title: Towards developing methods for non-invasive and online suppression of cortical spreading depolarization simulated on a mesoscale model

Authors: *A. CHAMANZAR, S. GEORGE, A. MENON, S. KELLY, M. CHAMANZAR, P. GROVER
ECE, CMU, Pittsburgh, PA

Abstract: Rationale: Cortical spreading depolarizations (CSDs) are waves of silencing of normal brain activity which propagate across the cortical surface [Zandt, et al., 2015]. Evidence shows that a near-complete neuronal energy depletion during CSD propagation can cause secondary brain damages after a wide range of neurological diseases, e.g. TBI, stroke, and hemorrhages [Dreier, et al., 2018][Lauritzen, et al., 2011]. This motivates us to examine possible solutions to stop this devastating wave.Commonly used techniques for CSD suppression involve invasive and/or pharmacological methods. These include (i) lesion extraction or decompression after TBI and hemorrhages to remove clotted blood and stop CSDs [Hartings, et al., 2014], and (ii) Injecting vasodilating drugs such as L-arginine to maintain enough oxygen and energy supply to the neurons [Scheckenbach et al, 2006].
Due to the side effects of surgery and chemical injections in brain, and the time it takes to stop CSDs using these methods, we are motivated to explore physiological mechanisms of CSD propagation and suppression, which is the first step towards a broader goal of designing non-invasive techniques, e.g. through transcranial current stimulation, to suppress CSDs.
Methods: We use a CSD model [Tuckwell, 2008] that is based on reaction and diffusion of components that are involved in CSD propagation, i.e. ions (K+, Ca++, Na+, Cl-) and neurotransmitters (GABA and glutamate) in intra and extracellular space. Using this model and inspired by a recent theoretical work on seizure suppression [Zhang, et al., 2017], we vary

parameters of neurons, e.g. calcium conductance, glutamate pump strength, and membrane cut-off potential, across space and time, to examine their effect individually on CSD propagation.Results: Our simulation results suggest that changing these neural parameters can indeed suppress CSD waves completely and in real time. We attempt three different types of changes in the region which contains the entire CSD wave at the initial stage of propagation: (i) constant change (increase or decrease) in the parameter values, (ii) spatially randomized Gaussian parameters, and (iii) 2D sinusoidal perturbations. We observe that changing glutamate pump strength using method (i) and (ii), calcium conductance using all three methods, and membrane cut-off potential using only method (i), can suppress CSDs.Conclusions: Our simulation results suggest that perturbing neural parameters can be used to suppress CSD waves. It remains to be fully understood if these spatial patterns of perturbations can be implemented and used for CSD suppression using available non-invasive stimulation techniques.

Title: Brain repair after traumatic injury through NeuroD1-mediated astrocyte-to-neuron conversion

Authors: *Z. LEI, F. ZHANG, G. CHEN
Pennsylvania State Univ., University Park, PA

Abstract: Background
Traumatic brain injury (TBI) is one of the leading causes of death in the US, especially among young people. So far there is no effective treatment to repair the damaged brain after TBI.

Our recent studies on in vivo reprogramming have shown that internal glial cells can be directly converted into functional neurons in the central nerves system in situ, which may shed lights on potential treatment for TBI.
Method
A closed head injury (CHI) model is set up to mimic brain concussion injury such as that suffered by football players. The impact can be controlled precisely to cause a focal blunt injury over the intact skull of a mouse, which will trigger further damages to its brain tissue and neural network. Then NeuroD1 or control viruses will be applied through intracranial injection into the injury site to investigate the effect of in situ astrocyte-to-neuron conversion.
Results
There is no evident internal neurogenesis in the control adult mouse cortex after TBI. However, NeuroD1 treatment can regenerate a large number of newborn neurons from astrocytes throughout the injured mouse cortex. These newborn neurons showed a transitional stage in-between an astrocyte and a neuron in early time points, and later became fully functional mature neurons with integration into the internal neural networks. Furthermore, with the regeneration of new neurons and reconstruction of damaged neural networks, the astrocyte-to-neuron (AtN) conversion induced by NeuroD1 also has substantial beneficial effects in ameliorating the local environment.
Conclusion
NeuroD1-mediated neuroregeneration and neuroprotection can be a novel therapeutic treatment for TBI.

Abstract: Background: EpiBioS4Rx aims to identify new therapies to prevent post-traumatic epilepsy (PTE) following traumatic brain injury (TBI). The EpiBioS4Rx project 2 has created a multicenter preclinical therapy screening platform to enhance reproducibility and implemented pharmacokinetic (PK) and pharmacodynamic (PD) studies early in the preclinical screening process to optimize treatment delivery. PK and PD modeling can accelerate drug discovery and development by helping to identify lead compounds, optimizing drug delivery, scaling doses across species, and guiding the design of human studies. In EpiBioS4Rx a multi-disciplinary team is screening compounds for antiepileptogenic effects using the lateral fluid percussion injury (LFPI) rat model of TBI in which PTE is well documented. **Objective**: To utilize PK and ultimately PK-PD modeling and simulation to select the best treatment protocols in the rat LFPI model. Here we tested levetiracetam and sodium selenate. **Methods:** Male 11-week old Sprague Dawley rats were used as either naïve controls or following LFPI. induction at the left parietal region, using a 5mm craniotomy and injury parameters optimized to induce moderate/severe TBI with a mortality of ~30%. Rats received either a bolus injection (intraperitoneal or subcutaneous (SC)) given in controls or immediately after LFPI or a bolus followed by SC minipump placement (ALZET 2ML1) 1hr later. The minipump was removed after 7 days. Blood was collected from the lateral tail vein at specified timepoints bracketing 0 and 24 hours after the bolus, or between minipump placement and 2hr after pump removal to study drug exposure and washout. Parietal cortical samples were collected at similar timepoints. Levetiracetam concentrations in plasma and brain were measured using validated HPLC-MS/MS methods and sodium selenate and selenium were measured using ICP-MS systems. A population-based PK and PD modeling approach was utilized. **Results:** Brain-to-plasma ratios ranged from 0.8-1 for levetiracetam, ~1 for sodium selenate and <0.1 for selenium. Levetiracetam and sodium selenate concentrations were well fit by one-compartment, first-order absorption PK models with and apparent clearances of ~130 and 16.5mL/hr/kg and volumes of distribution of ~400 and 10 mL/kg, respectively. **Conclusions:** Obtaining PK information early in the screening allows us to develop PK/PD models and simulate the effect of drugs on efficacy and safety measurements, guiding optimal treatment protocols in EpiBioS4Rx. These models will be validated in future antiepileptogenic studies and ultimately used to inform design of human clinical studies.

Br., Galveston, TX

Abstract: Poly (ADP-polymerase) 1 (PARP1) is activated in response to DNA damage induced by reactive oxygen species and excitatory amino acids, all of which are important effectors in the pathophysiology of TBI, and has been shown to occur in the pericontusional neurons after brain trauma. Activation of PARP1 promotes the depletion of NAD and ATP, inducing mitochondrial dysfunction and cell death; and is implicated in pro-inflammatory signaling. On the other hand, PARP1 deficient mice exhibit a neuroprotective phenotype, and PARP1 polymorphisms in humans correlate with differential neurological outcomes after TBI. Recently, two potent PARP1 inhibitors have been approved as chemotherapeutics in ovarian cancer, allowing the possibility of repurposing for non-oncological diseases. Here, we examined the effect of olaparib (Lynparza), a clinically approved PARP inhibitor, in both in vitro and in vivo models of TBI. Our *in vitro* studies showed that olaparib effectively reverses oxidant-induced cell death in a differentiated B35 neuroblastoma cell line, and significantly reduces apoptosis of neurons and astrocytes that were derived from human fetal brain neural stem cells in a stretch injury model. In an *in vivo* study using a closed-skull weight drop TBI model, treatment with olaparib reduced TBI-induced hippocampal reactive astrogliosis and improved cognitive function in mice (as assessed by novel object recognition test). In conclusion, PARP may be a potential target for intervention to protect against neuronal injury in the acute phase of TBI. Further studies are needed to determine whether olaparib is also effective to prevent the later-stage neurological deterioration secondary to acute or repetitive TBI.

Title: Lateral cerebellar nucleus stimulation promotes motor recovery and suppresses neuroinflammation in a fluid percussion injury rodent model

Authors: *H. H. CHAN[1,2], C. A. WATHEN[3], N. D. MATHEWS[2], O. HOGUE[4], J. P. MODIC[2], R. KUNDALIA[2], C. WYANT[2], H.-J. PARK[3], I. M. NAJM[5], B. D. TRAPP[2], A. G. MACHADO[3], K. B. BAKER[6]

Abstract: Many traumatic brain injury (TBI) survivors live with persistent disability from chronic motor deficits despite contemporary rehabilitation services, underscoring the need for novel treatment. We have previously shown that deep brain stimulation (DBS) of the lateral cerebellar nucleus (LCN) can enhance post-stroke motor recovery and increase the expression of markers of long-term potentiation in perilesional cerebral cortex. We hypothesize that a similar beneficial effect will be for motor deficits induced by unilateral fluid percussion injury (FPI) in rodents through long-term potentiation- and anti-inflammatory based mechanisms. Male Long Evans rats with a DBS macroelectrode in the LCN underwent FPI over contralateral primary motor cortex. After 4 weeks of spontaneous recovery, DBS treatment was applied for 4 weeks, with the pasta matrix, cylinder, and horizontal ladder tests used to evaluate motor performance. All animals were euthanized and tissue harvested for further analysis by histology, immunohistochemistry, RNA microarray assay and Western Blot. LCN DBS-treated animals experienced a significantly greater rate of motor recovery than untreated surgical controls, with treated animals showing enhanced expression of RNA and protein for excitability related genes, suppressed expression of pro-inflammatory genes, suppressed microglial and astrocytic activation, but proliferation of c-fos positive cells. Finally, our data suggest a possible role for anti-apoptotic effects with LCN DBS. LCN DBS enhanced the motor recovery following TBI, possibly by elevating the neuronal excitability at the perilesional area and mediating anti-apoptotic and anti-inflammatory effects.

Title: Insulin-like growth factor-1 overexpression promotes survival of adult-born neurons and improved cognition following traumatic brain injury

Authors: *E. LITTLEJOHN[1], D. SCOTT[1], K. E. SAATMAN[2]
[1]Univ. of Kentucky, Lexington, KY; [2]Spinal Cord & Brain Injury Res. Cntr, Univ. Kentucky, Lexington, KY

Abstract: The pathology associated with traumatic brain injury (TBI) manifests in motor and cognitive dysfunction following injury. Immature neurons residing in the neurogenic niche of the dentate gyrus (DG) in the hippocampus, a brain structure required for learning and memory, are particularly vulnerable to TBI. The inability to restore this population of hippocampal immature neurons following TBI has been causally linked to cognitive impairment. Insulin-like growth factor-1 (IGF-1) is a potent neurotrophic factor capable of mediating neuroprotective and neuroreparative processes. We have shown that elevating brain levels of IGF1 stimulates hippocampal neurogenesis, enhancing the recovery of immature neuron numbers after severe TBI in mice. However, little is known about the effectiveness of IGF1 to promote long-term survival of neurons born after injury. To this end, astrocyte-specific IGF1 conditionally overexpressing mice (IGF1-TG) and wild-type (WT) mice received controlled cortical impact (n=9/genotype) or sham (n= 2/genotype) injury and 50 mg/kg BrdU (i.p.) twice daily for 7 days following TBI. At six weeks following injury, total numbers of proliferated cells ($BrdU^+$) and the subset expressing a mature neuronal marker ($NeuN^+/BrdU^+$) were counted at the injury epicenter (3 sections/animal). IGF1 significantly increased $NeuN^+/BrdU^+$ cell density at 6 weeks post-injury ($p<0.05$, compared to WT injured mice. IGF1 overexpressing mice had improved cognitive flexibility during radial arm water maze reversal learning. These data suggest that IGF1 stimulates end-stage survival of posttrauma-born neurons and improves long-term cognition.

Title: Therapeutic tms reduces tbi-induced cognitive, anxiety, spasticity, and balance disabilities

Authors: *F. J. THOMPSON[1,2,3], J. HOU[1,2], R. NELSON[1], S. TSUDA[1,2], G. MUSTAFA[1,2], J. WATTS[1,2], N. MOHAMMAD[1], A. LERNER[1], J. PEDRAZA[1], P. BOSE[1,2,4]

Abstract: TBI can initiate enduring cognitive, anxiety, and sensory/motor disabilities that significantly impact the quality of life. Therapies are urgently needed that can provide safe and effective reduction in these long-term disabilities without negatively impacting cognitive recovery. During the course of CNS function evaluations in rats following TBI, we observed potentially significant therapeutic benefits induced by a recruitment ladder evaluation protocol using TMS. The objective of the current studies was to systematically evaluate potential therapeutic benefits induced by this TMS protocol on measures of cognitive performance, anxiety, spasticity, and balance functions following TBI in adult rats. Closed head (impact acceleration) TBIs were produced by a modification of the Marmarou procedure (450g x 1.25m drop height). The TMS treatments consisted of single pulse cranial surface TMS (Mgstim, 25mm figure 8 coil). An intensity ladder from 30% through 70% maximal intensity was delivered three times/week for one month. At the completion of treatment, cognitive performance was assessed using a serial learning paradigm in a Morris water maze (MWM). Spasticity was quantitated using velocity dependent ankle torque and triceps surae EMGs. Anxiety was assessed using time spent and entry patterns in open and closed areas of an elevated plus maze (EPM). Balance was tested using a rotorod balance beam protocol. Compared with intact animals, the TBI animals revealed significant increases in: a) escape latency during serial learning in a MWM, b) time spent in closed portions of the EPM, c) velocity dependent ankle torque and stretch evoked triceps surae EMGs, and d) significant decreases in time spent on the rotating beam of the rotorod. Compared with the untreated TBI animals, the TMS treated TBI animals revealed significant reduction in MWM escape latency, time spent in the closed portions of the EPM, spasticity, and balance deficits. Immunohistochemistry of neural tissues associated with these functions (hippocampus, amygdala, motor cortex, lateral vestibular nucleus, showed significant

increases in trophic and neuromodulatory factors (BDNF, DβH, $GABA_b$), in treated, compared with untreated TBI animals. The locus coeruleus (which plays a vital role in regulation of excitability, immune responses, blood brain barrier integrity) showed significant inflammation (NFkB, MMP-9, GFAP, OX-42), and cell loss in TBI animals. Inflammatory marker expressions were significantly less in the TBI-TMS treated animals. These preliminary studies indicate a significant therapeutic reduction in long-term TBI disability measures.

Title: Effects of the iron chelator on the blood-brain barrier (BBB) disruption and inflammatory responses following traumatic brain injury (TBI) in rats

Authors: *S. TSUDA[1,2], J. HOU[1,2], R. NELSON[1], G. MUSTAFA[1,2], K. BUCKLEY[1], K. RICHARDSON[1], P. BERNAVIL[1], J. PEDRAZA[1], J. WEISER[1], R. J. BERGERON, Jr.[3], F. J. THOMPSON[1,2,4], P. BOSE[1,2,5]
[1]Brain Rehabil. Res. Ctr. of Excellence (151), North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Physiological Sci., [3]Medicinal Chem., [4]Neurosci., [5]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Each year, over 10 million people in the world suffer mortality or hospitalization due to traumatic brain injuries (TBIs). The majority of these injuries are closed-head TBIs (cTBIs) of mild/moderate severity. There is a growing concern that in addition to specific TBI-disabilities, even mild TBI may significantly elevate risk factors for long-term chronic inflammation-induced progressive diseases. Acceleration/deceleration TBIs induce damage of micro-vessels which results in endothelial shear injury, BBB dysfunction, and micro-bleeding. Microbleeds-derived iron can provide an enduring promotion of inflammation, further breakdown of the BBB tight junctions, and cell death through multiple inflammatory pathways. Thus, removal of toxic iron is potentially an important therapeutic design for TBI treatment and rehabilitation. The current studies were initiated to examine the BBB disruption, neuronal viability, and inflammatory

responses as well as test the safety and efficacy of a novel iron chelator (Hexadentate monosodium salt, NaHBED) on these pathological complications following a moderate cTBI (450g/1.25m) in rats. BBB disruption following cTBI was detected using Evans blue dye (1 ml; 4%) injection into the left ventricle. In a separate cohort of animals, immunofluorescence studies were performed on coronal brain sections of intact and cTBI animals that were labelled with antibodies against dopamine beta-hydroxylase, neuronal nuclei, inflammatory markers (e.g. IL5, TNFα) , and key molecules involved in the BBB disruption (NF-kB, MMP-9 etc.). To detect the neuronal cell deaths, the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assays were also performed. Our data to date, indicate that following TBI, the number of viable neurons in certain brain regions (e.g., locus coeruleus, mesencephalic nucleus of trigeminal nerve, etc.) was significantly reduced. In addition, the contents of the Evans blue dye, the expressions of molecules involved in the BBB disruption (NF-kB, MMP-9, etc.), and inflammatory responses (e.g. IL5, TNFα) were significantly elevated following cTBI. These detrimental pathological complications were significantly attenuated by iron chelator (NaHBED) treatment. These results suggest that: 1) iron deposit via cTBI-induced BBB disruption accelerates neuroinflammation and inflammation-mediated neuronal cell death (i.e., pyroptosis), and 2) these can be attenuated by an iron chelator treatment. The present study provides new information regarding the understanding of cTBI-induced neuropathology that can contribute to the development of a novel therapy.

Title: Remote ischemic conditioning attenuates the peripheral component of neuroinflammation and improves chronic behavioral outcomes in diffuse brain injured female mice

Authors: *M. SABER[1,2], Y. HUR[1,2], K. R. GIORDANO[1,2], I. CHRISTIE[1], R. K. ROWE[1,2,3], J. LIFSHITZ[1,2,3]
[1]Neurotrauma, Uofa Col. of Med. - Phoenix, Phoenix, AZ; [2]Barrow Neurolog. institute at Phoenix Children's Hosp., Phoenix, AZ; [3]Phoenix VA Healthcare Syst., Phoenix, AZ

Abstract: Introduction: Remote ischemic conditioning (RIC) is intermittent restriction of blood flow to a limb or non-vital organ. This therapeutic strategy protects major organs from ischemia-reperfusion injury, reduces cognitive impairments in vascular dementia models, and halts the increase of acute biomarkers after severe traumatic brain injury (TBI). Though the mechanism of RIC is unknown, RIC may modulate the inflammatory response, which shows sex differences after experimental TBI. We hypothesize that post-injury RIC reduces the population of peripheral macrophages in the diffuse-injured brain acutely, with sustained therapeutic effect on cognitive performance and anxiety, and protects against secondary inflammatory challenge more effectively in males than females.
Methods: Diffuse brain injury by midline fluid percussion or sham injury was performed on adult mixed sex C57BL/6 mice. After 1-hour, mice received 4x5 minute sessions of RIC (tourniquet on thigh) with 5-minute reperfusion between each session or anesthesia control. Blood, spleen, and brain were collected at 3 and 7 days post-injury (DPI), and processed for flow cytometry to quantify inflammatory monocytes in the spleen and blood ($Ly6c^{high}Cd115+$) and peripheral macrophages in the brain ($Cd11b+CD45^{high}$). Ongoing studies will complete the analysis of therapeutic efficacy on cognitive performance and anxiety over 90DPI. Protection against secondary inflammatory challenge (10 mg/kg LPS, i.p.) at 100DPI and will be measured using open-field and neuroinflammation using immunohistochemistry.
Results: After TBI, female mice had significant decreases in peripheral monocyte populations in the blood and spleen after RIC treatment compared to non-RIC treated TBI controls at 3DPI. These findings extended to the brain; RIC reduced peripheral macrophage populations in RIC-treated mice compared to non-RIC treated controls ($F(1,11) = 8.046$, $p<0.05$). Data from male mice showed a similar trend without significant differences in the peripheral macrophage response after TBI or RIC treatment. These population changes resolved by 7DPI for both sexes.
Conclusions: RIC modulated the peripheral macrophage and monocyte response to TBI in a sex-dependent, time-dependent manner. Behavioral outcomes and secondary immune challenge will determine whether therapeutic efficacy extends to recovery of neurological deficits. RIC remains a practical, personalized therapy for TBI, in part by reducing neuroinflammation.

Title: RNA aptamers for FGFR3 to modulate glia function after brain injury

Authors: *N. KAMATKAR[1], M. LEVY[2], J. HÉBERT[1]
[1]Dept. of Neurosci., [2]Dept. of Biochem., Albert Einstein Col. of Med., Bronx, NY

Abstract: Glial cells include astrocytes and oligodendrocytes, both of which are critical for normal brain function and in response to brain injury. Recently, our lab has implicated FGF signaling in astrogliosis and oligodendrogenesis, both in the injured and uninjured cortex. Specifically, for astrocytes, we have shown that activation of FGF signaling keeps astrocytes quiescent both in the normal and injured cortex. For oligodendrocytes, we observed an increase in oligodendrogenesis after activation of FGF signaling in the subventricular zone and in the cortex after a demyelination injury. Both these processes were observed with a constitutively active form of FGFR3. To confirm these genetic findings and in order to modulate these processes pharmacologically, we sought to develop novel ligands specific for FGFR3 since there are no specific agonists or antagonists for the FGFRs. Because aptamers are molecules that tend to bind targets that have heparin binding domains, we systematically evolved nuclease stabilized RNA aptamers that specifically bind FGFR3. In our functional screen of these aptamers, we found that one aptamer specifically, NK01, demonstrates high affinity for FGFR3 and inhibits FGF2 from binding FGFR3. Interestingly, upon dimerizing NK01, the aptamer reverses its role and behaves as an agonist, mimicking FGF2 in its function. I have further characterized these molecules in a primary culture model to 1) test for specificity and 2) test how these ligands effect downstream signaling factors of FGFR3, particularly phospho-ERK. I have locally delivered the drugs to the injured cortex to modulate both astrocyte activation and oligodendrogenesis. My preliminary results suggest that we see an increase in oligodendrocyte precursor cells at the site of injury. I am currently working on analyzing the astrocytic response upon delivery of the drug and after injury.

Title: Prolonged dexamethasone release from gelatin/PLGA hydrogel for suppression of neuroinflammation after traumatic brain injury

Authors: T. ZHAO[1], N. GONZALEZ[2], J. JOHNSON[1], *R. SAIGAL[3]
[1]Univ. of Washington, Seattle, WA; [2]UCLA, Los Angeles, CA; [3]Neurolog. Surgery, UW Neurolog. Surgery, Seattle, WA

Abstract: Traumatic brain injury (TBI) is a significant public health concern that affects individuals in all demographics. Neuroinflammation can cause secondary injury after TBI. Dexamethasone, an FDA-approved corticosteroid, has been shown to produce neuroprotective effects by inhibiting inflammation. However, delivery of large systemic doses of steroids is limited by side effects, such as sepsis and pneumonia. Therefore, a localized delivery system may be favored to allow for a therapeutic dose at the injury site. Gelatin-based films without added drug delivery are already in use as an absorbable implant after decompressive craniectomy to avoid tissue adhesion. Our work focuses on developing a gelatin-based hydrogel system that can be implanted for both tissue isolation and a prolonged local drug release of dexamethasone. Zero length cross-linker was used to fabricate a fully absorbable gelatin gel. Cross-linker concentration was carefully optimized to form a stable low-swelling/shrinking hydrogel. For prolonged drug release, PLGA, a biodegradable polymer was first blended with dexamethasone to form microparticles, which were then encapsulated in the gelatin gel (Figure 1a). The gelatin/PLGA hydrogel system provides a sustained release profile for over 72 hour and showed slower, controlled release compared to the gelatin alone (Figure 1b). After incubating the gelatin/PLGA hydrogel with activated BV2 microglial cells in vitro, nitric oxide (NO), an inflammatory cytokine up-regulated at the injury site, was measured using the Griess assay. Significant reduction of NO production was observed from the gelatin/PLGA group, especially after 3 day's incubation compared to the no treatment control and the other faster releasing systems (Figure 1c). This indicates the gelatin/PLGA system provides a prolonged anti-inflammation function. CyQUANT cell proliferation assay showed no toxic effects on the microglia. This gelatin/PLGA system thus shows great promise as a local, sustained drug release system for treatment of neuroinflammation after TBI.

Title: Telemetric monitoring of penile pressure during mating in rats with different spinal cord contusion injury severities

Authors: *C. J. STEADMAN, C. H. HUBSCHER
Univ. of Louisville, Louisville, KY

Abstract: Sexual dysfunction is rated a top priority quality of life issue amongst the spinal cord injury (SCI) population. In SCI males, erectile function, ejaculation, and fertility are severely impaired. Currently, limited research is exploring the mechanisms underlying sexual dysfunction after SCI. The present study utilized a telemetric pressure transducer implanted into the corpus cavernosum of the penis to examine the differences in erectile function and pre-determined mating parameters during awake mating behavior for various injury severities using a rat contusion model. After pre-injury mating experience, animals received either a sham laminectomy or a mild (150 kD) or moderate (175 kD) or moderate-severe (210 kD) contusion injury. Animal groups were given two weeks of recovery post contusion, then underwent a weekly mating behavior paradigm for six weeks. The set mating behavior paradigm examined the counts, average pressure, and average duration of mating parameters including mounts, intromissions, ejaculations, partial erectile events (30 mmHg < baseline pressure < 130 mmHg), and full erectile events (>130 mmHg above baseline pressure). Animals in the mild and moderate contusion groups showed partial deficits in the mating parameters examined compared to intact animals, but less deficits than moderate-severely injured animals. Such deficits in examined mating behaviors and erectile function is likely due to disruption of the descending bilateral reticulospinal projections within the spinal cord. Pressure deficits of injured animals as compared to intact animals suggests alterations to the sensory circuitry at the level of the erectile center at the L6-S1 spinal cord. Differences in the duration of the mating parameters suggests a disruption of the descending and/or local input to the penile musculature, including the bulbospongiosus and the ischiocavernosus muscles that are responsible for maintenance of erection. Utilizing telemetric pressure transducers to record erectile event in an awake, behaving animal model may further elucidate the mechanism by which sexual function deficits occur after SCI.

Title: Longitudinal profiling of peripheral myeloid cells in a person with traumatic spinal cord injury

Authors: *O. BLOOM[1], M. A. BANK[2], M. D. GALLO[3], D. GRIFFIN[4], A. B. STEIN[5]
[1]The Feinstein Inst. for Med. Res., Manhasset, NY; [2]North Shore Univ. Hosp., Manhasset, NY; [3]Feinstein Inst. for Med. Res., Manhasset, NY; [4]STARS, Northwell Hlth., East Meadow, NY; [5]Zucker Sch. of Med. at Hofstra Northwell, Manhasset, NY

Abstract: Life expectancy for persons with traumatic spinal cord injury (SCI) has not improved in decades and is lower than for able-bodied persons. Infections are the leading cause of death after SCI. Inflammation is also common in persons with SCI, where it may promote common medical consequences of SCI. Infections and inflammation may oppose neurological recovery, particularly in the first year after SCI. The cellular mechanisms contributing to infection susceptibility and inflammation after SCI remain unknown. Dendritic cells (DCs) are the most potent antigen presenting cells, linking innate to adaptive immune responses. Here, we profiled functional recovery and circulating DCs from a person at day 4 and then at 3, 6 and 12 months after SCI. The standard of care physical exam, the International Standards for Neurological Classification of SCI, classifies motor and sensory function throughout the body. The SCI was classified as American Spinal Injury Association Impairment Scale (AIS) grade D, indicating a neurologically incomplete injury. Due to changes in sensory scores, the neurological level of injury changed over time and was C8, C1, C7 and T5 at day 4 and at 3, 6 and 12 months after SCI. The Neuromuscular Recovery Scale measured the person's ability to perform tasks related to mobility, standing and walking. The person's phase improved over time and was 3B, 3C and 4A, indicating good recovery of function, at 3, 6 and 12 months after SCI. The Spinal Cord Independence Measure (SCIM) evaluates activities of daily living on a 100-point scale. The SCIM scores were 87, 89, and 89 at 3, 6 and 12 months. By flow cytometry, the percentage of activated CD11c+HLADR++ myeloid DCs increased over time and was 1.7, 6.7, 5.5, and 8.5% of CD11c+ CD16- CD3-CD56- cells at day 4 and at 3, 6 and 12 months after SCI. The percentage of CD123+ HLADR+ plasmacytoid DCs increased over time and was 0.25, 0.74, 0.65, and 0.69% of CD56-CD3- cells at day 4 and at 3, 6 and 12 months after SCI. In the future, we will profile gene expression of peripheral blood leukocytes in this and other individuals to determine if markers of immunity and inflammation are changed over time.

Title: Spinal electromagnetic stimulation induces modulation of M-wave and H-reflex responses and recovery of frequency-dependent depression of H-reflex in chronic spinal cord injured rats

Authors: *H. A. PETROSYAN[1,3], L. LIANG[1], A. TESFA[3], C. ZOU[2], S. SISTO[2], V. L. ARVANIAN[1,3]
[1]Neurobio. and Behavior, [2]Physical Therapy, Stony Brook Univ., Stony Brook, NY; [3]Northport VA Med. Ctr., Northport, NY

Abstract: The main reason for functional loss after SCI is the lack of propagation of signals through not only damaged/cut axons, but through survived fibers as well. Using animal models and intracellular recordings from individual motoneurons, we have previously demonstrated that administration of several treatments that have been designed to improve transmission in damaged spinal cord usually associated with recovery of function after SCI. In clinics, however, evaluation of neurophysiological parameters is limited to measuring EMG, H-reflex and M-wave responses evoked by peripheral electric stimulation. Our recent results of animal studies demonstrate that spinal electromagnetic stimulation (SEMS) is capable of enhancing synaptic transmission in damaged spinal cord by increasing the function of NMDA receptors at the neuronal networks. Additionally, our recent human studies revealed that administration of repetitive SEMS induced long-lasting modulation of M-wave and H-reflex responses in SCI participants. However, the mechanisms underlying these effects of SEMS in humans remain understudied and require investigation using animal models. In this study, we have examined effects of SEMS on M-wave and H-reflex responses using an animal model. Non-injured adult rats and rats that received chronic mid-thoracic contusion injury were used to investigate effects of SEMS. Effects of SEMS on M-wave and H-reflex responses and on frequency-dependent depression of H-reflex (FDD), as well as possible mechanisms underlying these effects have been examined. Our results demonstrate that SEMS induces significant changes in excitability at spino-muscular circuitry in both non-injured and SCI rats. A single train of SEMS (25 minutes, 0.2Hz, total 400 pulses) induces long lasting facilitation of both of M-wave and H-reflex responses and leftward shift of threshold intensities, i.e. lower threshold intensities required to evoke these responses. These changes are long-lasting and are sustained for approximately 3 hours post SEMS administration. Consistent with literature, the FDD rate was decreased (i.e. it was less depression) in SCI animals. Importantly, our results revealed that SEMS was able to recover frequency-dependent depression (FDD) of H-reflex in chronic SCI rats. Using intraspinal injections of the NMDA receptor blocker MK-801, we have identified NMDA receptors as an important contributor in the induction of SEMS induced changes in the properties of H-reflex. These results identify SEMS as a novel non-invasive tool for long-lasting modulation of neuro-muscular circuits, and importantly, modulation of spinal networks after chronic spinal cord injuries

Title: 'Implant-host tissue matching' using ultrasound elastography for olfactory ensheathing cell transplantation in spinal cord injury: Measuring the stiffness of injured spinal cord using intraoperative ultrasound elastography in a natural canine model provides a target to create matched stiffness collagen hydrogels encapsulating olfactory ensheathing cells, which can increase cell survival after transplantation into sites of chronic spinal cord injury

Authors: *J. PRAGER[1], D. ITO[2,1], C. ADAMS[3], A. DELANEY[3], D. CARWARDINE[1], G. CHANOIT[1], J. TARLTON[1], L.-F. WONG[1], D. CHARI[3], N. GRANGER[1,4]

Abstract: Spinal cord injury (SCI) can cause irreversible paralysis and incontinence. Intraspinal transplantation of olfactory ensheathing cells (OECs) improves walking in dogs and is promising in humans, but inconsistent return of function implies that refinements are necessary. Experimentally, increased cell transplant number is associated with improved functional outcomes and hydrogel biomaterials improve cell survival. However, to be safely delivered in patients, hydrogel stiffness must be compatible with host tissue to avoid iatrogenic damage or increased inflammatory responses. This is of particular concern in the central nervous system given its soft structure and intricate cellular architecture that is easily disrupted by mechanical stress. However, there is no data on *in vivo* stiffness after SCI.
We aimed to determine spinal cord stiffness in a spontaneous canine model of SCI and create a cell-hydrogel construct of the same stiffness. Further, we tested if a hydrogel of matched SCI stiffness could improve cell survival.
We recruited 15 dogs with SCI undergoing decompressive surgery after acute intervertebral disc herniation at the University of Bristol Veterinary School (ethical approval VIN/15/036). We measured spinal cord stiffness at the lesion epicentre and lesion periphery non-invasively using ultrasound elastography. We determined a target stiffness for injured cord of 18.3kPa (IQR 11.6-31.1kPa) and found surrounding spinal cord to be significantly stiffer (median 47.9kPa, IQR 32.6-81.7kPa).
We measured the stiffness of varying concentrations of collagen hydrogels (1.5-8.5mg/mL). Encapsulating OECs consistently increased hydrogel stiffness by 80±1%; for example, the

stiffness of 7.5mg/mL hydrogels increased from 10.2±1.4kPa to 19.2±1.0kPa (n=4), a stiffness that is comparable to injured canine spinal cord.
As a proof of principle, we injected OECs expressing green fluorescent protein (GFP) into chronic dorsal column crush lesions in rats within either matched stiffness collagen hydrogel (n=8) or media (n=6). The percentage of surviving GFP-positive OECs at 2 weeks after transplantation was significantly higher in hydrogel transplanted animals (4.3±2.6%) compared to media controls (0.72±0.35%).
We therefore provide evidence that: (i) spinal cord stiffness can be non-invasively determined intraoperatively; (ii) hydrogels encapsulating OECs can match this stiffness; (iii) matched stiffness hydrogel constructs increase OEC survival. This could address a safety concern of hydrogel implant and suggests that OEC transplantation in hydrogel may improve neurological outcome after SCI by increasing cell survival.

Title: Activity-based training effects on upper urinary tract function following spinal cord injury

Authors: *J. GUMBEL[1], L. R. MONTGOMERY[2], C. H. HUBSCHER[3]
[1]Anatom. Sci. and Neurobio., [2]Dept. of Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [3]Anatom. Sci. and Neurobio., Univ. of Louisville, Louisvile, KY

Abstract: Common urinary dysfunction deficits that arise after spinal cord injury (SCI) include polyuria, urinary tract/bladder infections, detrusor-sphincter dyssynergia, incontinence, and urinary retention. For this reason, bladder dysfunction is ranked as a top priority. Using a contusion male rat model for SCI, we have previously demonstrated that activity-based training (ABT) can lead to improvements in both upper and lower urinary tract function, although the mechanisms are currently unknown. In the current study, using one of the kidneys from each rat for Western blot, we demonstrate that vasopressin (AVP) V2 receptor density significantly decreases following chronic SCI while natriuretic peptide receptor density (NPR-A) significantly increases. Furthermore, these levels are normalized (relative to sham surgical controls) in groups of rats receiving either of two different forms of ABT, fore-limb only stepping or quadrupedal

stepping on a treadmill for 1 hour daily. Using immunohistochemical analyses of the other kidney from each rat, support is obtained for elevated atrial natriuretic peptide levels. Further, a significant amount of glomerular loss is observed in the kidneys of non-trained animals, suggesting an exercise-induced effect that maintains glomerular integrity. Thus changes in the upper urinary tract following activity based training offer a potential mechanism through which exercise can have a positive effect on urinary complications experienced following SCI.

Abstract: Spinal cord injury (SCI) involves changes to the cellular, molecular, and tissue integrity of the spinal cord. SCI results in deficits in of motor control and mobility, and sensory and autonomic dysfunction. The complexity of SCI limits reproducibility of findings across laboratories and translation of new treatments from bench-to-bedside. The SCI research field has a ‘big-data’ problem; there are too many variables, metrics, and symptoms associated with SCI

to identify a single mechanistic target that generalizes across the full heterogeneity of the SCI syndrome. Data analytics, machine learning, and contemporary data science tools have the potential to enable researchers to query and extract patterns from complex data to form hypotheses and make new discoveries. To use these tools large volumes of data are needed, requiring sample sizes exceeding those typically collected within a single laboratory. Cultural skepticism to data sharing has provided a major barrier to pooling data, limiting the potential of data science. Yet in the past 8 years the SCI research community has demonstrated a growing willingness to share data and work collaboratively, pooling data across 13 laboratories to form the VISION-SCI repository, now housing subject-level data from over 3000 rodents with SCI. A collective of SCI researchers are now focused on building a scalable, structured data sharing platform that enables users to upload, query, and download data: the Open Data Commons for Spinal Cord Injury (http://ODC-SCI.org), a partnership with the Neuroscience Information Framework (part of the NIH Neuroscience Blueprint Initiative). The ODC-SCI platform is compatible with NIH-endorsed data stewardship principles that biomedical data be made FAIR (Findable, Accessible, Interoperable, and Reusable) and the NINDS Common Data Elements (CDE) project for neurotrauma. The ODC-SCI (beta) accommodates raw data underlying published figures as well as unpublished data and metadata. The portal helps to harmonize and democratize data, and grant users access to large volumes of data that are otherwise inaccessible. ODC-SCI has the potential to improve reproducibility across laboratories, and hasten new discoveries within SCI research with a data-driven approach.

Title: Loss of perfusion measured by ultrafast contrast enhanced ultrasound (CEUS) predicts injury severity following acute spinal cord injury

Authors: *Z. Z. KHAING[1], L. CATES[1], J. HYDE[1], R. HAMMOND[2], M. F. BRUCE[2], C. P. HOFSTETTER[3]
[1]Neurolog. Surgery, [2]Univ. of Washington, Seattle, WA; [3]Dept of Neurolog. Surgery, Univ. of Washington, Seattle, WA

Abstract: Traumatic spinal cord injury (tSCI) often leads to debilitating loss of sensory and motor function at and below the site of injury. Acutely, tSCI causes an almost complete loss of blood flow at the site of injury (primary injury), followed by significant ischemia in the penumbra of the injury, which may contribute to progressive cell death over time (secondary injury). Neuroprotective treatment strategies seek to limit secondary injury. However, techniques to simultaneously monitor temporal and spatial patterns of blood flow in the contused spinal cord are lacking. Here, we utilized a pre-clinical tool enabling visualization of local perfusion changes in real time in a rat tSCI model. Contrast-enhanced ultrasound imaging (CEUS) using Definity® microbubbles provides high resolution and real-time information of local blood perfusion changes in and around regions of tSCI. Using a research ultrasound device (Verasonics Vantage, USA) combined with a 15MHz linear array transducer (Vermon, France), plane-wave nonlinear Doppler acquisitions enabled the visualization of blood flow in the rat spinal cord using 10KHz pulse repetition frequencies. Serial US imaging of the spinal cords was performed at pre-injury, ~15 minutes post, and 8 weeks post contusion injury (Infinite Horizon at T7/T8; 150 or 200 kDyne). Images were acquired over 300 milliseconds at an effective 400 frames per second. Acutely, moderate contusion resulted in a significantly smaller area of perfusion deficit (1.79 ± 0.14 mm^2) compared to animals that sustained a severe contusion injury (2.88 ± 0.38 mm^2)($p<0.03$). In addition, ultrafast CEUS imaging of bolus kinetics found a delay (~ 1 second) in arrival time of microbubbles to tissue adjacent to the hypoperfused area wihtin the injury site, in both moderate and severe injuries. Correlation analysis between area of hypoperfusion and locomotor behavioral scores (BBB test) at 5 days post injury revealed a significant correlation between the extent of perfusion deficit and functional recovery ($r^2 = -0.82$; $p<0.005$). At 8 weeks post injury, there was still a difference in areas of hypoperfusion between mild (1.04 ± 0.42 mm^2) and moderate (1.77 ± 0.27 mm^2), although the difference was no longer significant ($p = 0.18$). Interestingly, there was a significant correlation between area of acute perfusion deficit and chronic (8 week post injury) BBB scores ($r2 = -0.14$; $p<0.001$). These data suggest that local blood perfusion data obtained using ultrafast CEUS imaging can be used to predict lesion severity and functional deficits. Development of intra-operative ultrafast CEUS imaging may be useful in the clinic to determine injury extent and severity in patients.

Title: Relationship of gender and inflammation to depression in a rodent model of spinal cord injury

Authors: *K. BRAKEL, M. TERMINEL, S. KAPLER, K. NOVAK, M. HOOK
Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Major depressive disorder (MDD) is a significant, but understudied, consequence of spinal cord injury (SCI). Approximately 11-24% of SCI patients experience MDD, compared to 8% in the general population. However, in the general population, females are twice as likely to develop depression as males. While this trend would be expected to persist in the SCI population, epidemiological data has so far proved inconclusive. As the importance of gender specific treatments becomes more apparent throughout medicine, it also becomes critical to consider gender differences in research. Previously, we have shown that approximately one-third of male spinally injured rats exhibit behavioral, physiological, and immunological correlates of depression. This incidence is commensurate with the clinical population. Here, we compare depression in age-matched male and female Sprague Dawley rats. An array of depression-like behaviors (social activity, sucrose preference, forced swim, open field activity, burrowing) were examined prior to injury and for twenty-four days post-injury. Females had higher sucrose preference at the end of the study, indicating lower depression, but males and females also exhibited behavioral differences before injury. Males had higher center time activity in an open field, while females displayed higher social activity. Additionally, females expressed lower levels of serum pro-inflammatory cytokines TNFα, IL-17, and IL-18 than did the males before injury, and 10 days post-injury, female cytokine levels increased to levels commensurate with the males. However, by 24 days post-injury, anti-inflammatory cytokines IL-2 and IL-4 had also increased to levels higher than those of the males. These results indicate that there is a gender-specific response on a molecular level after SCI. They also reiterate the importance of considering gender-specific treatments after SCI, as pre-existing differences in biology and behavior may exist and persist throughout recovery.

Title: Effects of a transection to the dorsolateral funiculus on ulnar nerve excitability in the rat

Authors: *B. WILD, R. ARNOLD, R. MORRIS
Sch. of Med. Sci., Univ. of New South Wales (UNSW Sydney), Sydney, Australia

Abstract: Assessment of nerve excitability with the use of electrophysiological techniques is an essential tool for investigating the function of peripheral nerves following spinal cord injury (SCI). One significant outcome of a SCI is the abolishment of the supraspinal input to the motor neurons below the level of the transection, therefore, resulting in paralysis. Clinical studies investigating the underlying mechanisms of these deleterious effects have been impeded by the heterogeneity of patients and limitations of conventional electrophysiological procedures. Nerve excitability testing (NET) is a sophisticated electrophysiological method that enables the indirect assessment of peripheral nerve function. More specifically, NET provides information regarding pathophysiological and biophysical changes that precede irreversible degenerative events after SCI. This study aimed to examine whether transections to the dorsolateral funiculus (DLF) induce abnormalities in ulnar nerve function that could be detectable by NET. NET was performed on 13 adult Long Evans rats one week prior and after DLF transections. Comparing the nerve excitability results between pre- and post- SCI demonstrated significant differences in multiple parameters. Post-SCI axons required significantly greater stimulus intensity (mV) to elicit a 50% compound muscle action potential (CMAP) response ($p<0.05$*).Post-SCI axons also showed a significantly greater threshold change to long hyperpolarising currents (hyperpolarising threshold electrotonus (-119.17 ± 7.41) when compared with the control values (-161.62 ± 4.86, $p<0.01$**). The resting current-threshold parameter was significantly reduced on the post-SCI recording compared to the baseline ($p<0.05$**). Both the resting current-threshold and threshold electrotonus parameters are sensitive measures of membrane potential. Taken together, these results suggest increased threshold for activation and with evidence of hyperpolarisation following a transection to the DLF. In conclusion, this study demonstrates that a DLF transection has a significant effect on ulnar nerve excitability properties, specifically nerve hyperpolarisation, following the loss of input to the ulnar nerve resulting from the DLF transection at the cervical level.

Title: A translationally relevant model of inducible pneumonia after spinal cord injury

Authors: *A. R. FILOUS[1], B. BROMMER[2], J. M. SCHWAB[1]
[1]The Ohio State Univ., Columbus, OH; [2]F.M.Kirby Neurobio. Ctr., Childrens Hosp. Boston, Boston, MA

Abstract: After spinal cord injury (SCI), patients become immunocompromised, making them highly susceptible to infections. Not only is pneumonia the leading cause of death after SCI, but even patients that survive the infection have a reduced potential to regain function, compared to SCI patients that have not suffered an infection. The mechanism is unclear as to how infections during an early stage after injury can lead to chronic changes in recovery potential. We have developed a mouse model of inducing pneumonia in a controlled fashion after SCI, as well as a scale to assess and track their sickness severity after infection. This model is translationally relevant, as it mimics many aspects of human SCI, and it can be used to explore the underlying mechanisms of this impaired recovery after infection.

Affiliated Hosp., Hangzhou, China

Abstract: Spinal Cord Injury (SCI) is often a result of compression to the spinal cord leading to neurological changes in both anterograde and retrograde direction from site of injury. Neuroimaging studies in SCI have mostly examined the functional organization of the cortex with limited attention to the sub-cortical substrates of the injury. Further, recovery rate of SCI population is relatively poor, often with secondary complications such as chronic pain, phantom limb and spasticity etc. Prevailing theories of chronic pain in the central nervous system indicates a dysfunction in the spinothalamo-cortical pathway. Besides, the modern view of the thalamus as both a driver and modulator demands the investigation of individual thalamic sub-nuclei to gain insight into thalamic neuroplasticity following deafferentation. To accomplish this, we used resting-state functional magnetic resonance imaging to perform both data driven and model driven connectivity analysis of the different thalamic sub-nuclei. A non-parametric two-sample t-test with permutations was performed for each of thalamic nuclei to compute functionality connectivity (FC) differences between 19 healthy controls (10 females) and 17 complete SCI (3 females) subjects with paraplegia. Results using data driven technique showed thalamic nulcei corresponding to anterior default mode network to exhibit decreased network strength with prefrontal cortex in SCI group. Results using model driven technique showed bilateral mediodorsal nucleus in SCI group to exhibit reduced functional connectivity with right middle temporal gyrus, dorsal anterior cingulate cortex, and insula. Additionally, left pulvinar nucleus of SCI group demonstrated a significant increase in connectivity with left inferior frontal gyrus and at a lower threshold with regions of the frontoparietal network. This is the first study to explore thalamic functional connectivity following SCI in humans. Our study establishes the use of resting-state fMRI to examine the functional alterations of the different thalamic sub-nuclei following SCI.

Title: Preliminary results of long term stability epidural ECoG recordings in Human with two wireless WIMAGINE implants

Authors: *T. COSTECALDE[1], S. COKGUNGOR[2], T. AKSENOVA[2], A. YELISYEYEV[2], F. SAUTER-STARACE[2], G. CHARVET[2], A.-L. BENABID[2]
[1]CEA, Grenoble, France; [2]Univ. Grenoble Alpes, CEA, LETI, CLINATEC, MINATEC Campus, Grenoble, France

Abstract: Since several years, several Brain Computer Interface (BCI) approaches were used from EEG to single unit recordings, or ECoG (ElectroCorticoGram) recordings [1]. The WIMAGINE® implant was developed to record ECoG signals for long term clinical applications. This implantable medical device [2] is composed of an array of 64 electrodes, on hermetic titanium housing including the electronic boards, and an antennae for wireless transmission of data and remote power supply.
Bilateral implants were inserted epidurally in a patient using two 50mm craniotomies (https://clinicaltrials.gov/show/NCT02550522). Control ECoG recordings throughout the surgery were obtained. ECoG recordings were also performed up to three times a week during several months.
Results: WIMAGINE® allowed us to perform chronic ECoG recordings for a period of several months after implantation. No change in signal quality has been observed, analysis of evolution in time of ECoG showed a stable signal in frequency and amplitude along time, which is an important criterion for signal processing and treatment with sophisticated algorithms like those developed at Clinatec [3].
Conclusion: Long term signal recordings were obtained for the first time using two novel wireless WIMAGINE® implants, providing further support for BCI trials.

Title: Paralyzed and non-paralyzed muscle: A comparative analysis in an acute rat spinal cord injury model

Authors: *M. E. HARRIGAN, A. R. FILOUS, T. WARNER, J. M. SCHWAB
Neurol., The Ohio State Univ., Columbus, OH

Abstract: Spinal cord injury (SCI) is a devastating condition that engenders severe disability and affects 250,000-500,000 people annually worldwide. Recent findings suggest that maintenance of muscle mass, the 'substrate' for proprioceptive input back into the spinal cord, plays a substantial role in functional recovery (1) and avoidance of secondary SCI consequences (2,3). To date, explanations for muscle wasting post-SCI have been confined to direct consequences of chronic paralysis, primarily disuse, which offer nominal therapeutic potential. Utilizing thoracic (T3) transection (Txn), to ensure complete paralysis of the lower extremity, in adult male Sprague Dawley rats we systematically investigated for: 1) acute muscle wasting - an optimal time point for intervention, and 2) wasting in non-paralyzed muscle, suggesting targetable systemic mechanisms of atrophy. Harvested Triceps brachii (upper extremity, non-paralyzed) and Gastrocnemius (lower extremity, paralyzed) wet muscle weights established significant early systemic muscle wasting (sarcopenia) also affecting non-paralyzed muscles. We hypothesize that atrophy of paralyzed muscle is likely driven by a combination of upper motor neuron (UMN) injury and systemic consequences of SCI. In contrast, wasting of non-paralyzed muscle, which retains UMN innervation, provides an avenue to pinpoint uniquely systemic consequences. Here we provide a characterization between paralyzed and non-paralyzed muscle, which will inform future mechanistic studies of this early and systemic phenomenon. Differential analysis includes Hematoxylin & Eosin (H&E) and Succinic Dehydrogenase (SDH) enzymatic histology to investigate morphological changes and metabolic fiber type shifting/rearrangement. Motor unit number estimation (MUNE) electromyography was used to determine whether UMN injury and/or systemic SCI effects affect function of lower motor neuron units. Lastly, we measured *in vivo* and *in situ* muscle contractility to quantify the functional impact of atrophy on muscle function.

Title: Spinal cord injury differentially modifies peripheral and central BDNF and TrkB expression

Authors: *S. PARVIN[1], S. M. GARRAWAY[2]
[1]Physiol., Emory Univ., Atlanta, GA; [2]Physiol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Although chronic neuropathic pain is a clinically challenging outcome of spinal cord injury (SCI), the underlying neurobiological mechanisms are not fully elucidated. The neurotrophin BDNF and its receptor TrkB have been implicated in central sensitization and nociceptive plasticity, particularly associated with inflammatory pain. However, whether BDNF or TrkB plays a role in neuropathic pain after SCI is less understood. In prior studies, we showed noxious stimulation that increased the expression of mechanical allodynia after SCI reduced spinal expressions of BDNF and TrkB, suggesting that pain after SCI may even be independent of central BDNF-TrkB signaling [Garraway et al. *Neuroscience 199: 86-102; 2011* and reviewed by Garraway & Huie JR; *Neural Plast. 2016*]. It was recently shown that low threshold mechanoreceptors (LTMRs) include a population known as Aδ-LTMRs. Aδ-LTMRs innervate hairy skin and signal directional touch. They express TrkB and require BDNF-TrkB signaling for normal function. The genetic identification of Aδ-LTMRs provides a prospective mechanism by which BDNF-TrkB signaling can contribute to pain after SCI, one involving Aδ-LTMR dysfunction. In this study, we assess central and peripheral changes in BDNF and TrkB expression after SCI in adult $TrkB^{CreER}$ mice, which allow for selective targeting of Aδ-LTMRs. The mice received a contusion SCI at T10 or a sham surgery. At 21 days after surgery, they were assessed for mechanical sensitivity with von Frey hairs, following which cellular assays were undertaken to measure BDNF and TrkB expression in the injured spinal cord and adjacent trunk

skin. SCI mice showed significant hind-paw sensitivity compared to pre-surgery baselines ($p<.0001$; *paired t test*) and sham controls ($p<.001$; *t test*). qRT-PCR showed that TrkB and BDNF mRNA were significantly reduced in the lesioned spinal cord, but significantly increased in most trunk skin sites examined ($p<.05$; *t test*), Similarly, western blot analyses showed that compared to sham subjects, TrkB protein was increased in the skin ($p<.05$; *t test*), although BDNF protein expression was unchanged. Preliminary histological studies in TrkB::tdtomato mice also showed a redistribution of TrkB expression after SCI, with a trend towards an increase in expression in the trunk skin. Current studies are assessing changes in BDNF and TrkB expression at an earlier time-point after SCI. Overall, these data suggest that peripheral BDNF-TrkB mechanisms which may involve Aδ-LTMRs' dysregulation, is likely contribute to pain hypersensitivity after SCI.

Title: Behavioral conditioning approaches to investigate and reverse effects of peripheral afferent stimulation in a mouse model of neuropathic pain after spinal cord injury

Authors: *D. J. NOBLE, R. DONGMO, S. M. GARRAWAY
Physiol., Emory Univ., Atlanta, GA

Abstract: Recently, our lab has been investigating cutaneous afferents known as C-LTMRs that innervate hairy skin and normally encode for pleasant, affiliative touch. These afferents may be converted to transduce mechanical allodynia following spinal cord injury (SCI). We recently found that mechanical stimulation delivered at the level of injury and tuned to selectively recruit C-LTMRs evoked acute increases in respiratory rate (RR) in adult mice 1 week after SCI ($p < .05$). We have now shown that mice with a contusion SCI also avoid a context associated with this stimulation in a conditioned place aversion (CPA) setup. This increase in preference for the light "escape" chamber progressively developed over the course of 5 weeks, reaching significance at 21, 28, and 35 days post injury ($p < .05$ in each case). Given the different timelines of RR and behavioral changes, early RR increases could predict the emergence of affective pain. Here, we performed a series of pilot studies to assess the efficacy of a novel feedback-based strategy to reverse RR increases after SCI. Adult C57BL/6 or Th::ChR transgenic (for optogenetic targeting of C-LTMRs) mice received a T10 contusion SCI (70

kdynes, IH impactor) or sham surgery and were assessed starting 1 week after surgery. At weekly time points, repeated truncal stimulation (once/min for 10 mins) was administered in a modified CPA paradigm, either with a small brush or blue laser to mechanically or optically activate C-LTMRs. We then tested the feasibility of slow respiratory rate (SRR) training using a paradigm developed in uninjured rats to lower RRs over time and potentially reduce reactivity to stressful and nociceptive stimuli. Mice underwent 10-15 daily 2-hour SRR training sessions, during which RR was continuously recording via remote electric field sensors. Recorded data was processed by a customized interface in LabVIEW to monitor breathing and provide real-time LED feedback (aversive strobe light) that turned off whenever RR $\leq$ 240 breaths/min. SCI mice significantly decreased their RR from baseline by the second SRR training session ($p < .05$) and spent ~80% of each session below the target RR. Control animals trained using reversal conditioning procedures (rewarded for RR $\geq$ 220 breaths/min) did not experience a similar decrease. Furthermore, post-training RRs in SCI mice were statistically indistinguishable from resting RRs in a cohort of age-matched, experimentally naïve mice. These results demonstrate adaptability of SRR conditioning procedures to mice for studies into neuropathic pain following SCI. Ongoing studies are examining the impact of SRR training on C-LTMR-mediated pain aversion and stress-associated behaviors.

Title: Assessment of bowel function after human spinal cord injury

Authors: *A. N. HERRITY[1,2], K. JOHNSON[1,2], T. ABELL[3], S. J. HARKEMA[1,2], C. HUBSCHER[1,4]
[1]Kentucky Spinal Cord Injury Res. Ctr., [2]Neurolog. Surgery, [3]Gastroenterology, [4]Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: Spinal cord injury (SCI) results in profound changes to sensorimotor function and autonomic systems, including bowel dysfunction, which is ranked as a top problematic issue affecting quality of life. The prevalence of bowel dysfunction includes dysmotility, chronic constipation and difficulty with evacuation, unexpected episodes of fecal incontinence, as well as autonomic dysreflexia associated with a distended rectum. Many individuals living with SCI are also dependent on a caregiver to assist with toileting procedures and previous studies have

indicated that time dedicated to one's bowel program may take up to 2-3 hours in SCI populations. Based off questionnaires with participants using the International Spinal Cord Injury Data Set for bowel function, we previously reported a significant improvement in participants' time required to complete their bowel program following activity-based, task-specific locomotor training. To begin understanding mechanisms underlying this and other subjective improvements reported in questionnaires, physiological measurements of bowel function were obtained in this feasibility study via anorectal manometry testing. Individuals (n=15) having either complete or incomplete (AIS A and B) SCI participated. Measurements of internal and external anal sphincter pressure, squeeze increase pressure, presence of the recto-anal inhibitory reflex, anorectal sensations, and balloon expulsion time were obtained. Mean squeeze pressure and squeeze increase pressure values were found to be below recommended guidelines in both AIS A and B participants. Sensations of rectal fullness and urge were noted to occur at lower thresholds in AIS B participants as compared to AIS A participants. These data provide quantifiable evidence for the occurrence of anorectal dysfunction following chronic SCI, including a deficit in the ability to generate sufficient squeeze pressure necessary for preventing fecal incontinence as well as for expulsion of contents, necessitating the use suppositories and/or digital evacuation. Delays in sensation underscores the importance of maintaining regularly scheduled bowel programs to prevent constipation.

Title: Development of a comprehensive protocol for detecting bowel dysfunction after spinal cord contusion in wistar rats

Authors: *R. F. HOEY[1], C. HUBSCHER[2]
[1]Anatom. Sci. and Neurobio., Univ. of Louisville Sch. of Med., Louisville, KY; [2]Dept Anatom. Sci. & Neuro, Univ. Louisville Sch. Med., Louisville, KY

Abstract: Bowel dysfunction is highly prevalent after spinal cord injury (SCI) with 95% of patients requiring some method to induce defecation. Symptoms of bowel disruption are typically: reduced motility, constipation, fecal impaction, anal sphincter dysfunction, incontinence, and autonomic dysreflexia. These complications can lead to significant impairment

in quality of life (QOL) as well as numerous hospitalizations. Anorectal manometry (ARM) is a technique to measure function in the distal colon, rectum, and anal sphincter in humans. Initial data collected in human patients shows that locomotor training improves bowel function as shown by reduced amount of time to complete their bowel program. ARM techniques have not seen widespread use in animal models of SCI. Therefore, the goal of this preliminary study was to develop an animal model that included ARM and motility measurements for a comprehensive picture of bowel function after SCI in Wistar rats. This model can then be used to elucidate the underlying mechanisms of dysfunction after SCI and test possible therapeutic interventions. The current study has utilized weekly motility measures (24 hour collections from metabolic and home cages) and terminal procedures (rectal and bowel ARM, anal sphincter electromyography (EMG), EMG response to balloon distension of the sphincter, and responses to balloon inflation at many levels of the rectum/distal colon) to investigate bowel function after a T9 contusion (210 kDyne) injury in male Wistar rats (n=36). Food and water intake, urine volume, and animal weight were also recorded. Initial analysis (repeated measures ANOVA) found that there is a significant increase in fecal pellet production in the first week after contusion. After the first week there is a decline in pellet production that becomes significantly reduced from baseline after 35 days postinjury and continues up to 12 weeks post-injury. This decrease is not due to reduced food intake or weight loss. ARM recordings show feasibility of the procedure to detect ongoing bowel activity and responses to stimulation in a chronic SCI model. These data are in line with bowel symptoms in humans and support the development of this animal model for use in mechanistic and translational studies.

Abstract: Introduction: High-thoracic spinal cord injury (SCI) is a devastating condition characterized by a loss of descending sympathetic input to the heart and vasculature. Chronically, high-thoracic SCI leads to cardiac unloading, myocardial dysfunction and atrophy; however, the immediate or acute cardiac consequences of SCI are not understood. Therefore, this study therefore examined the impact of acute T2 SCI on left ventricular (LV) function using a pig model of SCI. **Method:** Seven Yucatan mini-pigs (24.2±2.5 kg) were instrumented with a LV pressure-volume admittance catheter to assess LV load-dependent function (i.e. stroke volume, SV; maximal rate of pressure generation, dp/dt_{max}), load-independent contractile function (i.e. slope of end-systolic pressure-volume relationship, $ESPVR_{slope}$) and arterial elastance (E_a), and a Swan-Ganz catheter advanced to the pulmonary artery for thermodilution measurements of cardiac output ($\dot{Q}$). Animals received a T2 contusion SCI with compression that was removed 2hrs post-SCI. Measurements were taken at baseline (pre-SCI) and hourly up to 4hrs post-SCI. Data are presented as mean±SD, pre-SCI versus 4hrs post-SCI. **Results:** Mean arterial pressure (87±15 vs. 77±12mmHg, p=0.047) and E_a (3.71±1.20 vs. 2.85±1.08mmHg·ml^{-1}, p=0.001) were lower post-SCI. SV was increased (28±7 vs. 36±11ml, p=0.04) while $\dot{Q}$ was not significantly altered post-SCI (2.73±0.62 vs. 2.98±0.36L·min^{-1}). Although load-dependent dp/dt_{max} was unchanged following SCI (1628±218 vs. 1698±238mmHg·s^{-1}), the $ESPVR_{slope}$ was reduced by 24% post-SCI (2.52±0.80 vs. 1.90±0.66mmHg·ml^{-1}, p=0.03). **Conclusion:** These data are the first to demonstrate impaired LV contractility immediately following high-thoracic SCI, providing novel evidence that sympathetic decentralization is a key contributor to LV systolic dysfunction after SCI.

Hosp., Dept. of Anatom. Pathology, Vancouver, BC, Canada

Abstract: Introduction: While animal studies have populated much of our knowledge about the histopathologic sequelae of spinal cord injury (SCI), empirical studies of human spinal cords after traumatic injury are comparatively rare. Furthermore, past human studies have largely described histopathologic findings without correlation to detailed clinical information regarding the nature and severity of neurologic impairment or to advanced imaging findings. Magnetic resonance imaging (MRI) has been playing an increasingly important role in spinal trauma patients due to high sensitivity for detection of acute soft tissue damage and cord injuries. In order to provide more quantitative and specific information about spinal cord tissue structure and health, new advanced MRI techniques are being developed. To-date, no study has examined the correlation between clinical findings, advanced MRI metrics and histology using human post-mortem spinal cord injury tissue after traumatic SCI. **Objective:** Our goal is to perform a detailed analysis of the relationships between severity of neurologic impairment, mechanisms of injury, in vivo MRI, ex vivo MRI, and histopathology in human spinal cord tissue obtained post-mortem after traumatic SCI. Such spinal cord tissue has been acquired within our locally established SCI Biobank from individuals who have died after suffering an acute SCI. **Hypothesis:** Severity of neurologic impairment, the mechanism of injury, and quantitative MRI markers for specific aspects of tissue will correlate with histological staining for those same tissue markers. **Methods:** Archived formalin-fixed spinal cord tissue will be used. Neurologic assessments and in vivo spinal cord MRIs acquired prior to death will be reviewed. Spinal cord samples will undergo quantitative MRI at 7 Tesla (T_1, T_2, diffusion, phase, myelin water, inhomogeneous magnetization transfer). Spinal cord tissue will then undergo histological analysis for comparison with the quantitative MRI metrics. The degree and extent of MRI and histology abnormalities will be compared to neurologic scores and injury mechanisms. **Significance:** Our research will shed novel insights into the relationships between neurologic impairment, MRI characteristics, and underlying histopathology in human SCI. We will validate how accurate new MRI methods are at measuring different kinds of damage to the spinal cord. Validating new MRI techniques, and understanding their limitations, is an important next step in moving these more sophisticated and quantitative MR methods towards every-day use in the clinic, and for testing new treatments.

Univ., Daegu, Korea, Republic of; [6]Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Introduction: One of the most disabling, impactful, and overlooked consequences of spinal cord injury (SCI) is bladder dysfunction. Aside from the enormous impact it has on the day-to-day function of SCI individuals and their overall quality of life, the costs associated with managing related secondary complications (e.g. urinary tract infections, renal stones, renal failure, and even exacerbation of pressure ulcers) are massive. While the rodent model of SCI has been traditionally used for the development of pharmacologic agents aimed at improving bladder function, such small animal models of SCI are not suitable for the development and translation of novel human-sized devices. As such, larger animal species such as dogs, pigs, and goats have been utilized for the evaluation of bladder devices, albeit not in the context of SCI with a neurogenic bladder. Hence, in this study we investigated the features of morphological and functional changes occurring in the urinary bladder of spinal cord injured pigs. **Method:** SCI was induced by weight-drop contusion at T10 in female Yucatan pigs. Urodynamics and external urethral sphincter (EUS)-electromyography (EMG) assessments were performed simultaneously in awake, slightly restrained (using a sling) pigs on various days post-SCI. In addition, volume and flow rate during voiding and bladder histology was assessed. Voiding efficiency was also calculated as the ratio between voided and infused volume. **Results:** During voiding bladder contractions, pre-SCI pigs exhibited voiding with simultaneous increases in Pdet (detrusor pressure) and Pves (bladder pressure), which occurred during periods of reduced EUS-EMG activity. While fluid elimination from the urethra in SCI pigs coincided with a similar increase in Pdet and Pves, EUS-EMG bursting activity was sustained during these changes. SCI pigs also showed reduced voiding efficiency by almost 10-fold compared to pre-SCI pigs. Hematoxylin

and eosin staining of bladder tissue showed detrusor muscle hypertrophy. Moreover, the urinary bladder of SCI animals showed a 1.5-fold increase in wet weight. **Conclusion:** Spinal cord contused pigs demonstrated detrusor over-activity; which, may have obstructed micturition resulting in incomplete bladder emptying and high residual urine volumes. Our pig model of SCI allows for repetitive measurements of both bladder and EUS function at different time points in the same animal under fully awake conditions and opens promising avenues to investigate lower urinary tract dysfunction in a translational approach.

Inst., Phoenix, AZ

Abstract: Introduction: Spinal cord injury (SCI) is a devastating condition with high variability in injury mechanisms and neurologic recovery. Neurologic impairment following SCI is measured and classified by functional examination, and is extremely challenging in the acute setting, lacking sensitivity and having poor prognostic capacity. The lack of objective tools to

classify injury severity and predict outcome impedes the success of clinical trials and therapeutic development for spinal cord injury. Biological markers (biomarkers) that accurately classify injury severity and predict neurologic outcome would represent a paradigm shift in the diagnosis of patients, and in the way clinical trials are conducted. MicroRNA have emerged as attractive biomarker candidates in neurological disorders due to their stability in biological fluids, their phylogenetic similarities, and their tissue specificity.
Method: We have used next-generation sequencing and machine-learning algorithms to identify microRNA associated with injury severity within the CSF and serum of human patients with acute traumatic SCI. Human CSF and serum samples were obtained at five time points (~24, 48, 72, 96 and 120 hours post-injury) from 42 individuals with an acute SCI (22 AIS A, 10 AIS B, 10 AIS C) and 6 non-SCI control patients. Next-generation sequencing data was validated using TaqMan real-time PCR.
Results: We analysed sequencing data from plasma- and CSF derived microRNA from 42 SCI patients and identified over a hundred human extracellular microRNA that are dramatically elevated after SCI. We identified a set of microRNA whose profiles and dynamics can discriminate injury severity between SCI patients.
Conclusion: CSF and serum microRNA have the potential to serve as novel biomarkers for the evaluation of injury severity of SCI or other forms of traumatic, acute, neurologic injury.

Abstract: Introduction: Current clinical practice guidelines for acute SCI patients recommend that the mean arterial pressure (MAP) be augmented to 85-90 mmHg to increase spinal cord (SC) perfusion and potentially improve neurologic function. However, clinicians who hemodynamically manage acute SCI patients with MAP augmentation must do so without any real-time physiologic information about what the MAP augmentation is actually doing within the injured cord. A non-invasive method for measuring these parameters inside the injured SC would greatly enhance the ability of clinicians to wisely optimize the hemodynamic management of acute SCI. The purpose of this study was therefore to develop an implantable optical sensor, based on Near Infra-Red Spectroscopy (NIRS), for non-invasive real-time monitoring of regional SC tissue oxygenation and hemodynamics after SCI. **Methods:** Nine Yorkshire pigs weighing between 25-30 kg underwent a dorsal laminectomy at T10 and received a contusion/compression weight-drop injury. A multi-wavelength NIRS system with a custom-made miniaturized optical sensor was applied directly onto the dura at T9 to non-invasively measure tissue oxygenation and hemodynamics within the SC. To validate the NIRS measures, an invasive Intraparenchymal (IP) combined O_2/blood flow sensor was inserted directly into the SC adjacent to the NIRS probe at T11. Using NIRS, the SC tissue oxygenation percentage (TOI%) as well as concentrations of oxygenated, deoxygenated and total hemoglobin were monitored after SCI and during episodes of MAP alterations. Using norepinephrine and nitroprusside, MAP was increased and decreased by 20mmHg for 30 min periods, simulating the types of hemodynamic changes that SCI patients experience post-injury. **Results:** Changes in SC hemodynamics and oxygenation levels were detected in all subjects as measured by both the invasive IP and the non-invasive NIRS sensors. Significant changes of TOI% during MAP increase (1.64 ± 1%, $p<0.005$) and decrease (-3.97 ± 2.17%, $p<0.005$) were indicative of a significant effect of MAP alterations on tissue oxygenation within the injured cord. A consistent decrease in TOI (-15.94 ± 12.14%, $p<0.005$) was observed following SCI, indicating SC tissue hypoxia at the injury site. **Conclusions:** We have demonstrated that our novel NIRS sensor has the potential to monitor real-time post-SCI changes in SC oxygenation and hemodynamics. This pre-clinical demonstration of the ability of NIRS to achieve this is the first step in developing a clinically applicable device that spine surgeons could potentially place on the dura at the time of surgical decompression to monitor SC tissue hemodynamics post-injury.

Abstract: Introduction: One of the challenges associated with conducting experiments in animal models of traumatic SCI is inducing a consistent injury with minimal variability in the degree of tissue damage and resultant outcomes. In this study we evaluated how the variability in morphometry of the spinal cord and surrounding cerebrospinal fluid (CSF) contributes to the variability in behavioral and histologic outcomes in our porcine model of SCI. **Methods:** Using intra-operative ultrasound imaging, the morphometry of the spinal cord and surrounding CSF compartment at the impact site were assessed in 7 Yucatan mini-pigs undergoing a weight-drop T10 contusion-compression injury. Bivariate and multivariate *analysis and modeling* were used to identify native morphometric determinants of the inter-animal variability in histological and behavioral outcomes. **Results:** The measured biomechanical impact parameters (force, impulse, velocity, displacement) did not correlate with the histologic measures or hindlimb walking behavior (Porcine Thoracic Injury Behavior Scale, PTIBS). In contrast, clear associations were revealed between pre-SCI cord morphometry and the amount of white matter and tissue sparing. Specifically, the dorso-ventral diameter of the dural sac and ventral CSF space were strong predictors of behavioral and histologic outcome and together explained ≥95.0% of the variance. Additionally, a dorso-ventral diameter of the spinal cord less than 5.331 mm was a strong contributing factor to poor behavioral recovery over 12 weeks. **Conclusion:** These results indicate that inter-animal variability in cord morphometry provides a potential biologic explanation for the observed heterogeneity in histological and behavioral *outcomes*. Such knowledge is helpful for appropriately balancing experimental groups for future studies.

Abstract: Introduction: Currently there are few treatment options for patients with acute SCI, and clinical trials of novel therapies for acute SCI are exceedingly difficult to conduct. A major obstacle for translational research in acute SCI is the lack of biomarkers that can be utilized to objectively stratify injury severity and predict outcome. Research in neurochemical biomarkers for acute SCI is facilitated by the availability of both blood and cerebrospinal fluid (CSF) samples. Many biomarkers that have been shown to be associated with neurological conditions, however, are not present in high enough concentrations in the blood to be detected with today's standard assay technology. Here, we will evaluate CSF and serum samples obtained from patients with acute SCI for the protein Ubiquitin C-Terminal Hydrolase L1 (UCH-L1) using the ultra-sensitive Quanterix Simoa assay platform. **Method:** CSF and serum samples were collected as part of an ongoing clinical initiative in which acute SCI patients have had lumbar intrathecal catheters inserted for the collection of CSF over the first 5 days post-injury. This multicenter clinical initiative has amassed CSF and blood from acute SCI patients with prospectively collected neurologic outcomes at 6 months post-injury (ClinicalTrials.gov NCT01279811). UCH-L1 concentrations and time-course was measured using the Quanterix Simoa platform, and correlated to injury severity and neurologic recovery. **Results:** Our data suggest that UCH-L1 levels in CSF are increased in SCI patients compared with non-SCI controls, with levels being significantly different between AIS grades and over the course of the 5 days examined. Conversely, there was no significantly difference in serum UCHL-1 between control and SCI subjects. While initial levels of CSF UCH-L1 were not significantly different between those SCI patients who improved an AIS grade over 6 months versus those who did not improve,

categorizing subjects based on the trajectory of CSF UCHL-1 over the first 5 days post injury was 80% accurate in predicting AIS conversion in AIS A subjects. Further, 24-h post-injury CSF UCH-L1 concentrations were negative correlated with motor score change over 6 months. **Conclusion:** Our first evaluation of UCH-L1 in acute SCI shows promise as a biomarker to reflect injury severity and predict outcome in acute SCI. *Further* studies are *currently underway* to evaluate UCH-L1 in serum samples of individuals with SCI and add more CSF samples to our current data set.

Abstract: Acute spinal cord injury (SCI) leads to unloading, immobilization and induces rapid muscle atrophy and accelerated bone loss in the paralyzed limbs, limiting the ability to stand or walk. Some improvements in muscle and bone have been reported with electrical stimulation (ES) or neuromuscular electrical stimulation (NMES) in SCI, but improvements in standing and walking for given changes in shank muscle volume have not been studied. In this study our aim is to present results for bilateral shank volume, for anterior and posterior compartments and for different stimulation parameters, before and after training. In addition, we will incorporate the effects of ES of multiple leg muscles, especially anterior and posterior shank muscles and weight bearing, on the neural control during standing and stepping in individuals with clinically motor complete SCI. For motor complete SCI, the ES alone group does not improve motor pool activation in the flexors and extensors of the lower limbs during standing or stepping. Motor pool activation during standing does not improve after stand training alone and is lower during stepping (without ES) following all training paradigms. Motor pool activation during stepping (without stimulation) increases only after ES and stand training combined. Data suggests that

gains in neural activation and alterations in neural circuitry after severe human spinal cord injury may require both, repetitive task specific training and sufficient muscle activation.

Title: Neuromuscular responses to electrical stimulation ramping profiles

Authors: *R. PILKAR, K. MOMENI, A. RAMANUJAM, E. GARBARINI, G. F. FORREST
Human Performance and Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: During neuromuscular electrical stimulation (NMES), electrical current is applied to a nerve to elicit action potentials in denervated, peripheral muscles. NMES has been used to assist or restore neuromuscular function to paralyzed muscle after spinal cord injury (SCI). Further, chronic application of electrical stimulation (ES) has been shown to have a therapeutic effect on tissue health and voluntary function. Surface electromyography (EMG) provides an effective way to analyze underlying muscle activity. However, the presence of overpowering electrical stimulus artifact limits the assessment of the direct effect of ES on a muscle or nerve. Recent advances in biomedical signal processing have yielded algorithms that show significant success in removing ES artifacts from EMG signals recorded from the electrically stimulated muscle. Previously, we showed the effectiveness of a custom-developed computational algorithm, utilizing empirical mode decomposition (EMD) and notch filtering, to remove the ES artifact from EMG recordings of the electrically stimulated (35 Hz, 300μs) rectus femoris muscle (RF). We showed distinguishable, artifact-free muscle activations during two conditions of "ES-alone" and "ES+VOL," which is ES combined with volitional effort to contract the muscle, in SCI (n=5) and able-bodied (n=5) participants. In this investigation, we extend our analysis to examine the neuromuscular responses to linear increases in ES intensity by studying the artifact-free EMG activities in SCI (n=5) and able-bodied (n=5) participants. We confirm our findings by assessing concurrent torque profiles, measured using an isokinetic dynamometer. The results of this investigation can help to establish a relationship between ES intensity and its resultant neuromuscular response of a targeted muscle group. This could be significant as such relationships have only been established using mechanical outputs such as torque which could be the result of contributions from multiple muscle groups.

Title: Mechanical measurement of muscle contraction for individuals with spinal cord injury

Authors: *K. MOMENI, A. RAMANUJAM, E. L. GARBARINI, G. F. FORREST
Kessler Fndn., West Orange, NJ

Abstract: Prolonged immobilization after complete spinal cord injury (SCI) produces a rapid denervation of muscles below the level of injury. To minimize muscle deterioration, mechanical loading interventions have previously examined weight bearing and muscle contractions elicited by neuromuscular electrical stimulation (NMES).
In this work, we employed a novel, non-invasive, tensiomyographic measuring technique (i.e., MC sensor), shown to be accurate and reproducible in measuring muscle tension, to mechanically quantify muscle contraction in able-bodied individuals and those individuals with an SCI. Ramping protocol experiments involving volitional and NMES-induced contractions of the lower limbs established a series of recruitment curves for a given set of stimulation parameters. Muscle tension indices (MC sensor values) were compared to joint torque (Biodex values).
Results indicate a strong correlation for normalized muscle tension indices and joint torque values at each contraction and stimulation intensity. The findings of this preliminary study establishes the reliability of using MC sensors during volitional and NMES-induced isometric contractions.

Med. at Arkansas S, State University, AR; [7]Dept Pharmacol., Univ. of Arizona Col. of Pharm., Tucson, AZ

Abstract: Previous work uncovered broad changes in rat DRG (Dorsal Root Ganglion) neurons in receptor and ion channel expression following spinal nerve ligation, notably a massive up-regulation of Bradykinin and ATP receptor expression and a down-regulation of cholinergic and TrpV1 expression 14 days post injury (Raghuraman et. al., manuscript in preparation). We have extended this work by identifying the individual DRG cell types that are undergoing these receptor changes and tracking the progression of their transformation. The dorsal root ganglion (DRG) contains a diversity of somatosensory neurons, which can be clustered into broad cell classes based on a number of morphological and functional characteristics. To differentiate between these cell classes, we dissociate the neurons in culture, and assay between 800-1500 neurons in a single experiment. Using CGRP-GFP antibody staining to identify peptidergic neurons and isolectin B4 for nonpeptidergic nocioceptors, we then apply a host of TRP channel agonists, ATP, ACh, and bradykinin while measuring calcium influx to establish consistent "constellations" allowing further cell type classification. The changes in receptor expression observed after spinal nerve ligation have distinct time courses in the different DRG neuronal subclasses.

Title: A translational assessment of adult human and rat spinal cord neural stem/progenitor cell behaviour

Authors: *A. GALUTA[1,2], C. D. GHINDA[4], M. BEDAIWY[4], M. S. TACCONE[4], M. ALSHARDAN[4], C. LAI[4], J. RABSKI[4], S. CHEN[3], E. C. TSAI[4,1,3]
[1]Univ. of Ottawa, Ottawa, ON, Canada; [2]Neurosci., [3]Ottawa Hosp. Res. Inst., Ottawa, ON, Canada; [4]The Ottawa Hosp., Ottawa, ON, Canada

Abstract: Rationale: The mammalian spinal cord harbors neural stem and progenitor cells (NSPCs) that are recruited following traumatic injury. NSPCs can be utilized to promote regeneration in animal models through the regulation of their proliferation and differentiation behaviour. However, it is unclear how efficiently adult human SC NSPCs can be modulated towards similarly beneficial fates.
Objectives: To compare the *in vitro* proliferation and differentiation tendencies of adult human and rat spinal cord NSPCs under identical conditions and to direct their fate using signaling factors.
Methods: Thoracic spinal cord was obtained from adult humans (n=15) and rats (n=10) and cultured using the neurosphere assay to expand NSPCs. Primary derived NSPCs (pdNSPCs) were assessed for spontaneous differentiation with serum supplementation (1%) and for proliferation with mitogen treatment (epidermal growth factor, basic fibroblast growth factor2). To direct cell fate, pdNSPCs were treated with retinoic acid (RA), platelet derived growth factor (PDGFα), and bone morphogenic protein-(BMP4) to direct differentiation into neurons, oligodendrocytes and astrocytes, respectively. pdNSPCs were treated for 7 or 14 days, fixed, and characterized by immunocytochemistry (β-III tubulin, GFAP, O4, Sox2, BrdU). BrdU was added 24 hours prior to fixation to track proliferation.
Results: Upon spontaneous differentiation, rat pdNSPCs favored a glial phenotype (74.6±6.7%) consisting mostly of astrocytes (71.0±4.2%) while human pdNSPCs formed mostly neurons (68.5±16.9% for pdNSPCs) with little gliogenesis (<2%). Mitogen stimulation increased proliferation of rat pdNSPCs more than in humans (3.7±0.7 fold and 5.5±0.4 fold, respectively, after a 14 day treatment). Neuronal differentiation of human and rat NSPCs could be enhanced with RA treatment, PDGFα only increased oligodenrocyte differentiation of rat pdNSPCs, and BMP4 only increased astrocyte differentiation of human pdNSPCs.
Conclusion: When cultured identically, adult human and rat spinal cord NSPCs possess distinct differentiation profiles and respond differently to external cues relevant to regeneration. This

information is important for the translation of regenerative strategies targeting endogenous human spinal cord NSPCs.

Title: Effect of patient-safety oriented enhanced recovery after surgery (pso-eras) on hospital stays of patients undergoing anterior cervical discectomy

Authors: *J. C.-C. WU[1], Y.-H. CHIANG[2], W.-C. LO[3], J.-H. LIN[4], Y.-S. YANG[5], Y.-S. TSOU[3], K.-Y. CHEN[2]
[1]Dept. of Surgery, Col. of Med., [2]Taipei Med. Univ., Taipei, Taiwan; [3]Taipei Med. Univ. Hosp., TAIPEI, Taiwan; [4]Dept. of Neurosurg., Taipei Med. Univ. Hosp., Taipei, Taiwan; [5]Dept. of Neurosurg., Taipei Med. Univ. Hosp., TAIPEI, Taiwan

Abstract: Introduction: Anterior cervical discectomy is an effective method of treating cervical spondylolisthesis and cervical spine degenerative changes, and patients have excellent outcomes with minimal side effects after surgery. The implementation of ERAS had been beneficial in other fields of surgery, and its benefits in anterior cervical discectomy had not been reported. While the benefits of ERAS are desired, patient safety is paramount. In this study, we implement PSO-ERAS in anterior cervical discectomy, and investigate the effects on post-operative recovery, complications and hospital stays.
Materials and Methods: From July 2016 to June 2017, 214 cases were enrolled into our study. 119 cases from July to December of 2016 received anterior cervical discectomy without PSO-ERAS, 95 cases from January to July of 2017 received the same surgery with implementation of PSO-ERAS. PSO-ERAS included explicit implementation of bed rest 4 hours after surgery, and post-operative surgical radiography of cervical spine. Factors of Age, Gender, underlying diseases, levels of surgery, blood loss, surgery time, length of hospital stay, recovery and complications were recorded. Pre-operative pain scores and Japanese Orthopedic Association (JOA) scores were compared to post-operative pain scores and Japanese Orthopedic Association (JOA) scores.
Results: The age for the patients receiving anterior cervical discectomy ranged from 26 to 80 years old, and 108 males versus 107 females. There are a total of 118 patients with diabetes mellitus, coronary artery disease, and hypertension, 58 in the group without PSO-ERAS, and 60 in the groups with PSO-ERAS. Also, average operating time between the 2 groups was

indifferent, averaging at 173.5 minutes and 184.0 min (p=0.142). The length of hospital stays were significantly different (p=0.027), the group receiving PSO-ERAS was 0.42 days shorter than the group without PSO-ERAS.
Conclusion: We observed shortening of hospital stays with implementation of patient-safety oriented enhanced recovery after surgery (PSO-ERAS). While the shortening of hospital stay requires a larger clinical trial to confirm, the concept of patient safety is important and should be paramount in post-operative patient recovery.

Title: Endothelin B receptor agonist, IRL-1620, significantly improves motor functions in an adult rat model of spinal cord injury

Authors: *M. FORNARO[1], H. SHARTHIYA[2], K. RINEHART[3], J. RIDGEWAY[4], M. HORNICK[5], S. BRIYAL[5], A. GULATI[5]
[1]Dept of Anat., [2]Anat., Midwestern Univ., Downers Grove, IL; [3]Anat., Midwestern University, Chicago Col. of Osteo. Med., Downers Grove, IL; [4]Anat., Midwestern University, Arizona Col. of Osteo. Med., Glendale, AZ; [5]Pharmaceut. Sci., Midwestern University, Chicago Col. of Pharm., Downers Grove, IL

Abstract: Spinal cord injury (SCI) is a major health issue worldwide which impacts those involved both economically and physiologically. Sci is often mentioned among the first conditions for which stem cells may provide a new therapeutic approach. In fact, the recent discovery of niches of endogenous multipotent stem cells within the adult spinal cord has shed light on stem cell therapies to promote a self-healing mechanism within damaged spinal cord. Endothelin B receptor (ET_B) agonist, IRL-1620 has demonstrated neurogenesis by stimulating neuronal stem cells in several models of CNS disease and injury. Endogenous neuronal stem cells have been shown to be present in the spinal cord. However, the effect of utilizing IRL-1620 in a traumatic SCI model has not been previously investigated. The present study was conducted to determine the therapeutic effects of IRL-1620 on functional motor recovery following experimental SCI in rats. Male Sprague-Dawley rats were randomly divided into 5 groups (n=7-10/group): 1 - Sham surgery, 2 - SCI + vehicle (saline), 3 - SCI + IRL-1620 (1 µg/kg, low dose),

4 - SCI + IRL-1620 (3 µg/kg, mid dose), and 5 - SCI + IRL-1620 (5 µg/kg, high dose). Following a T10 bilateral laminectomy, the Infinite Horizons impactor device was used to create a reproducible, moderate concussive injury of 150kdyn. Treatments of vehicle or IRL-1620 were administered intravenously at 2, 4, and 6 hours on days 1, 3, and 6 post-surgery. Function of each hind limb was evaluated using the Basso, Beattie, Bresnahan (BBB) scale preoperatively and on days 3, 5, 7, 10, 14, 21, 30, 60 post-surgery.
To verify that the extent of the injury was consistent, only animals with significant motor impairment (BBB score 0-7) on day 3 post-surgery were included. For the right hind limb, while not statistically significant, locomotor scores for the low dose IRL-1620 group indicated improved recovery as compared to vehicle at days 14 (+50.2%, p=0.2497), 21 (+34.9%, p=0.4349), 30 (+27.2%, p=0.5099), and 60 (+26.8%, p=0.4882). Motor function in the left hind limb of rats treated with the low dose of IRL-1620, however, was significantly improved as compared to that of vehicle-treated animals at post-surgery day 14 (+63.2%, p=0.023), day 21 (+62.5%, p=0.0171), day 30 (+55.2%, p=0.0284), and day 60 (+45.8%, p=0.0652). Mid and high doses of IRL-1620 improved motor function following SCI but did not reach statistical significance. These results for the first time indicate that IRL-1620 significantly improves hind limb locomotor function following SCI. Further study to determine the mechanism of action of IRL-1620 in SCI repair and the morphological changes at the site of the lesion is in progress.

Title: The role of fast inhibition in facilitation of phrenic nerve and diaphragm activity during epidural stimulation following complete cervical spinal cord injury in rats

Authors: *V. MARCHENKO, T. BEZDUDNAYA, M. A. LANE
Dept Neurobiology/Anatomy, Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spinal cord injury (SCI) at mid- to high-cervical spinal levels often results in life-threatening respiratory complications and requires long-term mechanical ventilator assistance. Thus, restoring diaphragm activity and regaining voluntary control of breathing are the primary clinical goals for patients with respiratory dysfunction following cervical SCI. Epidural stimulation (EDS) is a promising strategy that has been explored extensively for non-respiratory

functions, and to a limited extent within the respiratory system. The goal of the present study was to test the efficacy for EDS applied to the center of phrenic nucleus location (C4 cervical segment, C4-EDS) in combination with intrathecal GABAa and glycine inhibitory receptors antagonists (GABAzine and strychnine) administration on paced breathing following complete C1 cervical transection (C1Tx). To avoid the suppressive effect of anesthesia all experiments were performed in decerebrate, unanesthetized, non-paralyzed or paralyzed animals. High-frequency C4-EDS (100-400 Hz) (240-350 μA, 0.2 ms of biphasic pulse duration, stimulation during 0.3 s, one train per sec) was able to maintain breathing with stable diaphragm EMG (DiEMG), normal end-tidal CO_2 level and raise blood pressure. In addition, 100-300 Hz of C4-EDS showed time- and -frequency dependent changes (short-term facilitation) of evoked phrenic nerve (PN) and DiEMG responses during of each stimulus train that may serve as a target mechanism for pacing of phrenic motor circuits. C4-EDS applied with frequencies 350-400 Hz causes depression of PN and DiEMG responses. Ten minutes after intrathecal application of GABAzine and strychnine, (GABAz+STR, 25 μMol - 30 μl) over C3-C5 segments and C4-EDS (200-300Hz), respiratory flow was increased by 26±7.3% ($p<0.05$), DiEMG - by 19±5.6%, and PN responses by 354±42.9%. Based on these results, we conclude that respiratory circuits at the level of phrenic nucleus are tonically inhibited after C1Tx and their pharmacological modulation has the potential to enhance efficacy of EDS in people with SCI.

Title: Exploration of mechanisms of electrical stimulation of spinal cord microcircuits

Authors: *M. K. CHARDON, M. D. JOHNSON, J. F. MILLER, C. J. HECKMAN
Physiol., Northwestern Univ., Chicago, IL

Abstract: Reflex circuits are well defined and repeated segmentally throughout the spinal cord. For example the canonical motor microcircuit (CMM), comprised of Ia sensory axons that connect monosynaptically to homonymous motoneurons (MN) and to the inhibitory interneurons (IN) of their antagonists, forms the basis of reciprocal inhibition throughout the limb and is critical for inter-joint coordination. Because these circuits are repeated throughout the spinal cord, they are an attractive target for electrical stimulation in the context of spinal cord injury (SCI) as CMMs far from the injury site should remain intact and findings on one CMM should

be generalizable. Practically, these circuits are also easily accessible via the Ia afferents found in the dorsal roots and should have the lowest threshold to electrical stimulation. A clear relationship between electrical stimulation and CMM behavior is still misunderstood. For instance, proper CMM functioning is dependent on descending neuromodulation (PICs) which alters the excitability of its neuronal elements and can be disrupted by SCI. This interplay between electrical stimulation and neuron excitability is not known. In addition, the interplay between agonist/antagonist CMM pairs with respect to electrical stimulation is also unknown. Here we tested in the decerebrate cat (n=2), the effects of surface electrical stimulation on sensory inflow to CMMs of an ankle joint agonist/antagonist motor pair, the soleus (Sol) and tibialis anterior (TA). We varied the location of an electrode along the rostral-caudal axis at the dorsal root entry zones favoring the Sol and TA motor pools (L6-S1). We delivered a 5 s pulse train of varying intensities and frequencies. To mimic sensory inflow we superimposed a 3 s Sol TVR. Excitation and inhibition was effectively controlled in a progressive and location dependent manner by electrical stimulation as measured by force production in Sol in response to tendon vibration. Stimulation modulated the tendon vibratory reflex response over regions where sensory input activated the antagonist . This effect was changed as the stimulating electrode was moved away from the antagonist muscle region. Additionally as stimulus intensity and frequency was increased, a post-inhibitory rebound emerged resulting in activation of the agonist muscle. These results suggest that the excitatory/inhibitory balance between motor pools can be effectively modulated by electrical stimulation of the CMM via dorsal spinal stimulation. Activating these circuits to restore proper balance after SCI may aid in post injury therapies aimed at regaining simple motor behaviors such as standing and weight bearing.

Title: Intravenous delivery of miR133b along with Argonaute-2 24hrs post-injury enhances spinal cord recovery following cervical contusion in mice

Authors: *C. A. DANILOV[1], Y. GU[5], V. PUNJ[2], Z. WU[6], S. TAHARA[3], F. M. HOFMAN[4], T. C. CHEN[1]
[1]Dept. of Neurolog. Surgery, [2]Dept. of Med., [3]Dept. of Mol. Microbiology and Immunol., [4]Dept.

of Pathology, USC, Los Angeles, CA; [5]Dept. of Spine Surgery, Second Military Med. Univ., Shanghai, China; [6]Dept. of Orthopedics, Tongji Univ., Shanghai, China

Abstract: Axon regeneration of the corticospinal tract (CST) and functional motor recovery are both limited following spinal cord injury (SCI). As a result, spinal cord trauma leads to paralysis or other related conditions that involve axon disconnections. Previous studies in zebrafish, a model of spontaneous nerve regeneration, show elevated levels of microRNA133b (miR133b) in regenerating neurons following a spinal cord injury. Similarly, lentiviral delivery of miR133b at the time of injury after a controlled compression at the thoracic level shows improved functional recovery in mice. In this study, we investigated whether intravenous delivery of miR133b is reliable and efficient at enhancing spinal cord recovery when administered 24hrs after a unilateral cervical contusion in C57Bl/6 mice. Here, we used a system that targets fibrous scar formation at the lesion site by intravenous co-injection of miR133b with Argonaute 2 (Ago2), a protein that participates in miRNA processing and has been found to protect miRNA degradation. The treated group received miR133b/Ago2 and the control group miR-Negative control/Ago2 via tail-vein injection for 3consecutive days starting1day postinjury.We found that intravenous delivery of miR133b/Ago2 strongly inhibited key extracellular matrix (ECM) genes and reduced microglia/macrophage mobilization to the lesion scar. Forelimb function was assessed for 8 weeks post-injury using a grip strength meter task. While a poor recovery of forelimb gripping function was observed in control group, mice receiving miR133b/Ago2 treatment showed the first sign of recovery at about two weeks post-injury and that was improved over time. Our findings show that corticospinal tract (CST) axon re-growth was enhanced in miR133b group as more BDA (biotinylated dextran amine) labeled axons could be found at the injury site and caudal to the lesion, when compared to control group mice. In summary, our results provide an insight regarding a potential miR133b/Ago2 therapy targeting the microenvironment of the contused spinal cord, that can be used within 24hrs of injury.

Title: Controlled-releasing of epothilone B from functional self-assembling peptide nanohydrogel to improve neural regeneration after spinal cord injury

Authors: *C. LI, S. RAMAKRISHNA, L. HE
Guangdong-Hong Kong-Macau Inst. of CNS Regener, Guangdong, China

Abstract: Fibrous scar is a major obstacle for neural regeneration after spinal cord injury. Microtubule dynamics regulate the scarring. Moderate microtubule stabilization can reduce scarring and promote axon regeneration. Epothilone B, a microtubule stabilizing drug, can promote axon regeneration. Here, we have examined the effects of different concentrations of Epothilone B on differentiation of neural stem cells and show that Epothilone B has double-sided role on neural stem cell. It is show that high concentrations of Epothilone B harm to the cells. Low concentrations of Epothilone B favor the differentiation of neural stem cells into neurons and low concentrations of Epothilone B are more conducive to axon extension. Together, nanohydrogel, releasing Epothilone B, was transplanted to the rats after spinal cord injury. Nerve regeneration can be observed by immunofluorescence staining. The behavior recovery was studied by BBB locomotion assessment. Axon regeneration can be observed after two weeks. Therefore, Epothilone B has application prospects in spinal cord injury repairing.

Title: Reactive astrocytes inhibit neuronal regeneration after spinal cord injury

Authors: *H. LEE[1,2], H.-L. LEE[3], M. NAM[4], J. LEE[4], K. KIM[2], K. PARK[4], J. C. LEE[4], Y. HA[2]
[1]Seodaemun-Gu, Seoul, Korea, Republic of; [2]Yonsei Univ., Seoul, Korea, Republic of; [3]Yonsei Univ., Seodaemun-Gu, Seoul, Korea, Republic of; [4]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: The spinal cord is a central nervous system that functions primarily in the transmission of neural signals between the brain and the rest of the body by both integrating and transmitting signals. Therefore damage to the spinal cord brings about degeneration of motor capacity, sensory defect, and disability of autonomic nervous system depending on the level of seriousness of the damage done. Histologically, inflammatory damage to the spinal cord can occur in the result of the damage due to decrease in the blood flow and hypoxia following the primary injury. Secondary damages such as nerve apoptosis, neuropathic pain, and formation of

glia scar only exacerbates the symptoms. Despite the countless numbers of breakthroughs and innovation in medical technologies, there has been no absolute cure for spinal cord injuries, and development of drugs to control neuropathic pain accompanied by spinal cord injury has not yet been showing great results throughout the world. Various drugs are currently being used to treat these spinal cord injury related diseases. Among those drugs, gavapentin and pregabaline are widely used. They primarily functions as glutamate inhibitor, designed as agonist of GABA, blocking the voltage gated calcium channel. However, these drugs are only effective in limited period of time, and it only shows significant enough effectiveness in 50 percent of the treated patients. Due to such drawbacks of these drugs, it is critically essential that researchers come up with an alternative drug.
MaoB participates as an enzyme in the metabolism of a dopamine, and it is know to impact numerous neurological disorders such as Parkinson's disease, Alzheimer disease, and multiple sclerosis. There also has been increasing numbers of research findings asserting a prominent correlation between this enzyme and astrocytes. Our reseach focuses on the increased glial scar, which is known to be the aftermath of spinal cord injury. Here, we strive to induce nerve regeneration and rescue neuropathic pain through control of active oxygen and GABA, by specifically inhibiting the metabolism of MaoB in the mitochondria of reactive astrocyte.

Title: Development of advanced-*in vivo* reprogramming system for spinal cord injury therapy

Authors: *H.-L. LEE[1], H. LEE[3], K. KIM[2], Y. HA[4]
[1]Yonsei Univ., Seodaemun-Gu, Seoul, Korea, Republic of; [2]Yonsei Univ., Seoul, Korea, Republic of; [3]Brain Korea 21 Plus Project For Med. Science, Y, Seodaemun-Gu, Seoul, Korea, Republic of; [4]Yonsei Unuversity, Seoul, Korea, Republic of

Abstract: Spinal cord injury is induced by trauma or compression that often leads to blocking the stimulus, and disorder to function of motor system, sensory and autonomic nervous system. The fundamental treatment of spinal cord injury is not yet developed. Generally, it has been applied that decompression therapy, drug treatment and rehabilitation for spinal cord injury. However, the treatments have shown that limited effects. Because of that reason, new treatments

are in the studying including gene therapy and stem cell therapy. Among them, in vivo reprogramming is regarded as promising futuristic technology. In this study, we develop the in vivo reprogramming system for treatment of spinal cord injury by reprogramming the astrocytes to neurons.
In this study, we used two kinds of astrocytes that human astrocytes and primary astrocytes from mouse. These cells were direct reprogramming by specific vectors for 6 weeks. After then reprogramming cells verify by immunocytochemistry. At the In vivo study, male C57BL/6 mice (n=10, postnatal 7 weeks) were randomized into three groups: Group 1= EMEM group and Group 2= reprogrammed group. Genetic transduction was conducted 2 weeks after spinal cord injury and subjects were observed for 6 weeks. To evaluate functional behavior, each group was examined with basso mouse scale (open field test). Also, immunohistochemistry proceed for reveal in vivo direct reprogramming and neuronal regeneration.
At the in vitro study, the both kinds of astrocytes were reprogrammed from astrocyte to neurons by reprogramming. Also, we verified the behavior was improved and astrocytes were reprogrammed to neurons, when we applied in vivo reprogramming technology to spinal cord injury animal models.
In this research, we developed the new type of In vivo reprogramming system for progress of in vivo reprogramming technic. For check the system working, new system was transduced to astrocytes in vitro. The astrocytes were induced to neurons and GFP was positively expressed. As well as, new system induced neurons from astrocytes in spinal cord injured animals. The reprogrammed neurons improved the animal behavior. From these results, we can confirm the new system works as new in vivo reprogramming system. Also they have the potential to new treatment for spinal cord injury.

Title: Biomaterials-based drug delivery systems for promoting recovery after spinal cord injury

Authors: *B. SHULTZ, J. NONG, Z. WANG, Z. ZHANG, Y. ZHONG
Biomed. Engin., Drexel Univ., Philadelphia, PA

Abstract: Spinal cord injury (SCI) results in partial to complete loss of motor and sensory function below the level of injury. Generally, efforts to improve functional recovery aim to

attenuate secondary injury progression and/or promote tissue regeneration. While stem cell transplantation has yielded mixed to beneficial outcomes following SCI, ethical and safety concerns may hinder rapid translation of stem cell therapies from the lab to the clinic. To date, a large and growing number of drugs have been shown to promote functional recovery in animal models of SCI, including small molecules, proteins and proteoglycans. Administration of these drugs, however, remains a major limitation, as many pharmaceuticals exhibit poor blood-brain barrier permeability. To achieve sufficient doses within the central nervous system, researchers must administer high systemic doses of drugs or implant osmotic pump-driven intrathecal catheters. Because high systemic doses often induce deleterious off-target effects, and indwelling catheterization greatly increases risks of further injury and infection, neither of these approaches are clinically viable. In this study, we describe several drug delivery systems capable of providing sustained, localized drug release to the injured spinal cord. First, we developed and characterized a hydrogel-based system for delivery of triiodothyronine (T3), a poorly soluble small molecule and potent inducer of oligodendrocyte differentiation/myelin production. This system was found to induce modest improvements in oligodendrogenesis and myelination following injury in rats. Because post-SCI chronic inflammatory signaling including tumor necrosis factor-alpha (TNF) have been shown to hinder oligodendrocyte maturation and remyelination, we next sought to deliver an anti-TNF synthetic peptide, XPro1595. To this end, we developed a novel, injectable microparticle-embedded hydrogel system capable of delivering proteins and peptides. All delivery systems were fabricated from naturally occurring polymeric biomaterials, without the use of harsh, environmentally taxing organic solvents or processing methods. Collectively, these systems can serve to bridge the gap between benchtop innovation and clinical utility for therapeutic interventions following SCI.

Title: Sodium butyrate exerts neuroprotective effects in spinal cord injury

Authors: *M. CAMPOLO, M. LANZA, G. CASILI, A. FILIPPONE, S. CUZZOCREA, E. ESPOSITO
Dept. of Biological, Chemical, Pharmaceut. and Envrn. Sci., Univ. of Messina, Messina, Italy

Abstract: Sodium butyrate (SB) is a dietary microbial fermentation product of dietary fiber and serves as an important neuromodulator in the central nervous system. Recent experimental

evidence has suggested potential therapeutic applications for butyrate, including its utility in treating metabolic and inflammatory diseases. The aim of the present study was to evaluate the potential beneficial effects of SB in a mouse model of spinal cord injury (SCI) and its possible mechanism of action. SCI was produced by extradural compression for 1 min of the spinal cord at the T6-7 level using an aneurysm clip, and SB (10-30-100mg/kg) were administered by oral gavage 1 and 6 h after SCI. For locomotor activity, study mice were treated with SB once daily for 10 days. Morphological examination was performed by light microscopy through hematoxylin-eosin (H&E) staining. In addition, NF-kB, IkB-alfa, COX2 and iNOS expression were assayed by western blot analysis and IL-1beta and TNF-alfa levels by immunohistochemistry analysis. The results showed that SB treatment significantly ameliorated histopathology changes and improved recovery of motor function changes in spinal cord injury in dose-dependet manner. Moreover, from the results obtained, SB modulated NF-kB pathway showing a reduction in cytokines expression. This study showed that SB exerts neuroprotective effects on spinal cord injury and anti-inflammatory properties. The observed neuroprotective action suggests that SB may serve as a potential candidate for future treatment of spinal cord injury.

Title: Combinatorial treatment of rolipram and rhoa sirna delivered by pgp nanoparticle increases functional recovery in a rat contusion spinal cord injury model

Authors: *J. LEE[1], S.-J. GWAK[1], J. YU[2], C. MACKS[1], H. ZHU[2], M. LYNN[3], K. WEBB[1], K. MARK[2]

Abstract: Spontaneous recovery of sensory and motor function following spinal cord injury (SCI) is inhibited by multiple pathophysiological mechanisms including progressive secondary injury, extrinsic growth inhibitors, and intrinsic deficiencies in neuronal biochemistry. Combination therapies using treatment modalities targeting two or more of these barriers have

achieved promising preclinical results, but their application is complex and often requires multiple interventions. We have developed a cationic, amphiphilic copolymer, poly (lactide-co-glycolide)-graft-polyethylenimine (PgP) as a carrier for combinatorial therapy. Previously, we demonstrated that PgP/siRhoA nanoparticles injected in the SCI lesion can achieve RhoA knockdown for up to 4 weeks accompanied by a reduction in apoptosis, cavity size, and astrogliosis [1] and an increase in axonal regrowth/sparing and Rm-PgP nanoparticles injected at the SCI lesion can restore cAMP levels to sham level and reduce inflammation and apoptosis in rat compression SCI model [2]. In this study, we evaluated the effect of Rm-PgP and PgP/siRhoA co-administration on motor functional recovery in rat contusion SCI model. Moderate contusion injury model was created at T9-T10 spinal cord of female SD rats (200-250 g) using the impactor (IH-0400, PSI) with a force of 150 kdyn. Rm-PgP (10 µg Rm) and PgP/siRhoA (20 µg siRhoA) were co-administered immediately after injury by intraspinal injection**.** Rm-PgP (10 µg Rm) only and PgP/siRhoA (20 µg siRhoA) only were used for comparison and untreated SCI and sham (laminectomy only) were used as controls. Motor functional recovery of the hindlimb was evaluated using BBB locomotor rating scale once per week until 4 weeks after SCI. We observed that BBB score of rats treated with co-administration was significantly higher than that of Rm-PgP only, PgP/siRhoA, and untreated SCI rats, at all time points. At 4 weeks, rats were perfused with 4% paraformaldehyde, spinal cords embedded in OCT, sectioned, and stained for histological analysis. We observed that lesion volume was significantly smaller in rats treated with co-administration than that in Rm-PgP only, PgP/siRhoA only, and untreated SCI. In conclusion, these results demonstrate that combinatorial treatment of Rm-PgP and PgP/siRhoA can synergistically improve motor funcitonal recovery and reduce necrotic cavity formation.

Title: Repeated activation of adult dorsal root ganglion neurons using designer receptors exclusively activated by designer drugs (DREADDs) enhances functional sensory axon regeneration after dorsal root crush injury

Authors: *D. WU, T. SALTOS, V. J. TOM
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Short-term neuronal activity activates growth programs and synaptogenesis programs. However, whether repeated bouts of activation of adult neurons with injured axons enhance axon outgrowth or their integration back into a circuit is not known. We took advantage of DREADDs to remotely alter neuron activity in a spatially and temporally-specific manner. We hypothesized that activating adult DRG neurons expressing the excitatory DREADD hM3Dq with CNO combined with modulation of inhibitory chondroitin sulfate proteoglycans (CSPGs) at the dorsal root entry zone (DREZ) with chondroitinase ABC (ChABC) will promote functional regeneration of primary afferents after a dorsal root crush. We first tested our hypothesis in vitro using adult DRGs transduced with AAV-hM3Dq or -mCherry plated on a spot of CSPG, an established model of the inhibitory environment after injury. With ChABC digestion of CSPG, CNO-activated, $hM3Dq^+$ DRGs grew more axons across the inhibitory substrate than CNO-treated, $mCherry^+$ DRGs. We then assessed if this strategy enhanced regeneration through the DREZ after a dorsal root crush in adult rats. Three weeks after injecting AAV-hM3Dq or -mCherry into C6-C8 DRGs unilaterally, we crushed the ipsilateral C5-T1 dorsal roots. After the crushes, ChABC was injected into the C5-C8 dorsal horn. In all animals, CNO was injected subcutaneously daily starting the day of the root crush for the duration of the experiment (3 months). Sensory and sensorimotor function was assessed weekly. Histological analysis revealed that AAV-DREADD or -mCherry primarily transduced large caliber DRGs. There was no difference between groups in the von Frey or Hargreaves' tests. However, while $hM3Dq^+$ and $mCherry^+$ animals had comparable numbers of foot slips while walking on the grid early on, $hM3Dq^+$ animals had more correct paw placements than $mCherry^+$ animals starting 6 weeks post-crush, suggestive of better proprioceptive, sensorimotor function. This behavioral improvement was associated with increased axon regeneration in $hM3Dq^+$ animals. We saw no difference in the total number of axons that penetrated the DREZ between groups, but $hM3Dq^+$ animals had more axon regrowth into the gray matter. To determine if axons that regenerated established synapse with spinal neurons, we stimulated the ipsilateral median and ulnar nerves to transsynaptically induce c-Fos expression in deafferented dorsal horn. More c-Fos+ neurons were observed in $hM3Dq^+$ animals than in $mCherry^+$ animals. Thus, modulating neuronal activity intermittently for a prolonged period of time is a strategy to promote functional axonal regeneration beyond a ChABC-treated DREZ after dorsal root crush.

Abstract: Traumatic spinal cord injury (tSCI) often leads to a debilitating loss of sensory, motor, and autonomic function and chronic pain. Immediately following the initial trauma, microvessels in the spinal cord rupture leading to hemorrhaging. Bleeding is a major contributor to a cascade of subsequent changes defined as the secondary injury, which includes swelling, inflammation and oxidative stress. Hemorrhage enlarges progressively over time after the primary injury, and the extent of bleeding has been shown to correlate with injury severity and functional deficits. We hypothesize that limiting bleeding would limit secondary injury, and subsequently lead to better functional outcomes. Here we employed newly developed hemostatic nanoparticles (hNPs), which have been shown to localize to the injury site and reduce bleeding after liver resection injury, in a contusion type tSCI in a rodent model. The hNPs (9.0 mg/mL in saline; 0.5 mL injection) or control particles were introduced intravenously within 3 minutes of the tSCI (Infinite Horizon device). Using our unique ultrafast contrast enhanced ultrasound imaging (CEUS), we visualized local spinal blood perfusion, including blood flow in the microcirculation, in real-time before injury, then at one hour and at 4 hours following injury. Preliminary data show that at one hour after injury, area of perfusion deficits seen using CEUS appeared smaller in hNP treated animals to controls (~15% smaller area of perfusion deficit). Interestingly, there was a 15% reduction in swelling of the spinal cord associated with injury in the presence of hNPs compared to control animals. At the end of the study, animals were injected intravenously with tomato lectin (0.2 mg injection) to label all patent blood vessels. Clusters of

hNPs were found within areas of hemorrhage and blood clot within the injury epicenter. Interestingly, hNPs were never seen co-labeled with tomato lectin, suggesting that hNPs were only within spinal parenchyma in areas of active bleeding. Our results suggest that hNPs are localized to the areas of active bleeding exclusively, presumably involved in blood clotting acutely after a contusion type tSCI. Current studies are underway to 1) analyze real-time hemodynamic data obtained from ultrafast CEUS imaging and 2) evaluate the chronic 3D blood flow imaging, functional and histological outcomes from hNP treatment after tSCI.

Title: Testing robustness of promising FDA approved neuro-protective drug candidates in a cervical hemi-contusion model of rats

Authors: *W. T. PLUNET, N. JANZEN, J. LIU, E. RAFFAELE, S. KAMAKARI, O. SEIRA, K. KOLE, Y. JIANG, L. MCPHAIL, W. TETZLAFF
ICORD, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: A significant number of FDA approved drugs have demonstrated efficacy in preclinical spinal cord injury (SCI). These studies predominantly used a moderate thoracic contusion model yet less than 5% of human SCI are incomplete thoracic injuries. Most human injuries occur at the cervical levels (>65%), half of these are incomplete, and this group should benefit the most from neuroprotective treatments. Moreover, the acute time-period of intervention used in animal studies (often immediate or less than one hour after injury) are difficult to translate in human trials. In addition, many preclinical studies are underpowered, subject to experimenter biases or conflict of interest, which significantly reduces their value as predictors of success in a human trial. We therefore created a team of research staff to assess the effects on functional recovery of the most promising FDA approved drugs when these are administered 3 hours after a cervical spinal cord hemi-contusion injury using group sizes of n = 16-21. Previously, we tested 9 different FDA approved drugs (riluzole, valproic acid, fluoxetine, metformin, inosine, rosuvastatin, acetyl-l-carnitine, glibenclamide, tamoxifen) that had been

reported to improve functional recovery in SCI models. In our experiments none of the 9 treatments improved recovery compared to control groups, and only glidenclamide improved the amount of spared spinal cord tissue. RT-PCR measurements of mRNA expression changes of injured spinal cord tissue in the five drugs we have done short-term studies for indicate appropriate changes in gene expression for all treatments indicating the drugs are biologically active at the injury site. This year we tested 4-Aminopyridine (started 3 hours after injury) both in a cervical hemi-contusion model and the more widely used T9/10 thoracic contusion injury model. In neither of these two injury models did we see better recovery in the treated animals compared to the control groups, and there were no differences in amount of spared tissue area between groups in either injury model. Having poor success with these 10 individual treatments we decided to test combination treatments. We compared a control group against a group treated with glibenclamide plus taxmoxifen, or a group treated with glibenclamide, tamoxifen plus inosine. We are still analysing this study and will report the behavioral and histology results on the poster. As in previous replication studies, establishing robustness in preclinical models is challenging and possible reasons will be discussed. Supported by the Rick Hansen Foundation through the ICORD-Rick Hansen Institute - Blusson Integrated Cure Partnership.

Title: Regeneration of dorsal horn spinal cord neurons after injury via *in situ* NeuroD1-mediated astrocyte-to-neuron conversion

Authors: *B. PULS, H. LI, M. METZGER, T. RANA, Y. DING, M. PAN, G. CHEN
Pennsylvania State Univ., State College, PA

Abstract: Spinal cord injury (SCI) is an acute trauma to the central nervous system that can leave patients with deficits in sensation, movement, and bodily function, including paralysis of the limbs. These deficits result not only from the initial tissue damage, but also from secondary damage caused by the release of toxins, inflammation, oxygen and nutrient restriction, and reactive oxygen species. To protect healthy tissue from this toxic environment, local astrocytes proliferate and form a glial scar which, while limiting the short-term effects of the injury,

prevents the tissue from recovering into functional neural tissue in the long-term. Our lab has pioneered a new technology to convert glial cells into neurons after injury or diseases (Guo et al., 2014). In this study, we use both retroviral and adeno-associated viral (serotype 9) vectors carrying the neurogenic transcription factor NeuroD1 to directly convert injury-induced reactive astrocytes into mature neurons in the dorsal horn of the mouse spinal cord in vivo at high efficiency. We show that these neurons obtain neuronal subtypes specific to the dorsal horn of the spinal cord, consistent with other experiments in the brain where NeuroD1-converted neurons obtain subtypes relevant to their local environment. We also show that these neurons are functional and can re-integrate into local networks. Our future work includes targeting other proliferative cell types including oligodendrocyte precursor cells (OPCs) to generate other subtypes of neurons, and further investigating the mechanisms of NeuroD1-mediated conversion in the spinal cord. This work is supported by the Charles H. Skip Smith Endowment Fund to Gong Chen (Principal Investigator).

Abstract: Motor neurons of mammalian spinal cord hardly regenerate from damage or lost that are caused by injury or disease. Pharmacologic approach is popular treatment for neuron regeneration. In this study, we propose to combine the pharmacological method with electrical stimulation to enhance the axonal regrowth of motor neurons. From previous study, we confirmed that the axons of motor neurons grow directionally through the micro-grooves in the microfluidic platform and the cell body and axon can be distinguished. The microfluidic platform is attached on the planar-type microelectrode array (MEA) in order to monitor and/or modulate the activity in the growing axons. The micro-grooves of the microfluidic platform were aligned with the electrodes of the MEA. Based on this platform, it is available to apply electric

stimulation to a desired target position of growing axons. Therefore, it is possible to study axonal regeneration by monitoring the morphological change of motor neurons.

Authors: *L. ZHOLUDEVA, M. L. RANDELMAN, R. DILBAROVA, L. QIANG, I. FISCHER, M. A. LANE
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: There is a growing interest in the use of neural progenitor cells (NPCs) to treat spinal cord injury (SCI). Despite extensive preclinical research, it remains unclear as to how donor cells develop, differentiate and integrate with host injured circuitry, and if integration can be enhanced and/or guided using noninvasive means such as activity based therapy. With a focus on the phrenic circuit and respiratory dysfunction after cervical SCI, the present work tests the hypothesis that pairing cellular transplantation with a rehabilitation strategy (daily acute intermittent hypoxia, dAIH) will enhance neuroplasticity and promote donor-host connectivity. Cultured NPCs (neuronal and glial restricted progenitor cells) isolated from GFP rats were transplanted into a cervical (C3/4) contusion injury in adult Sprague Dawley rats, one week after injury. Animals received 4 weeks of dAIH (10-5minute exposures to 10% oxygen intermittent with normoxia, 5 days a week), beginning one week post-transplantation. Donor cells survive, differentiate, and integrate with the host spinal cord as assessed with transynaptic pseudorabies virus tracing (PRV) and immunohistochemistry. Respiratory training resulted in significantly enhanced donor-host connectivity, compared to untrained transplant recipients. Preliminary data suggests the underlying mechanism for directing donor-cell outgrowth towards phrenic inter- and motoneurons is in part mediated via BDNF expression within the cervical spinal cord. Transplant recipients, with and without dAIH training, showed greater muscle (diaphragm) recovery than vehicle-controls, as measured by terminal electromyography. Transplant and dAIH training recipients demonstrated greater ability to respond to hypoxic but not hypercapnic respiratory

challenge. These ongoing experiments suggest that rehabilitative strategies such as dAIH may be an effective way for enhancing donor cell outgrowth and connectivity.

Title: Moderate hypoxia produces voiding in rats with spinal cord injury-induced severe urinary dysfunction

Authors: *W. F. COLLINS, III[1], M. E. TORPIE[2], C. WANG[2], I. C. SOLOMON[2]
[1]Neurobio. and Behavior, [2]Physiol. & Biophysics, Stony Brook Univ., Stony Brook, NY

Abstract: In humans, spinal cord injury (SCI) results in sustained lower urinary tract (LUT) dysfunction with reduced voiding efficiency and urine retention that are associated with a high degree of morbidity and mortality. Therefore, interventions that improve voiding in individuals with SCI are needed. To this end, we investigated the potential therapeutic benefit of acute exposure to moderate hypoxia (10-12% O_2) to improve LUT function in a rat model of SCI. Adult female Sprague Dawley rats (225-250g) received thoracic (T8 vertebra) SCI consisting of either a moderate contusion (200 kilodynes) or a complete spinal cord transection. Four weeks following SCI, bladder intravesical pressure and external urethral sphincter (EUS) EMG activity were recorded in spontaneously breathing, vagus nerves intact rats under urethane anesthesia (1.4 g/kg) during continuous infusion of saline (0.04-0.07 ml/min) into the bladder. The four-week survival time was chosen because initial recovery from SCI has stabilized (e.g., rats are able to spontaneously void) but functional motor deficits remain. Under these conditions, the degree of LUT dysfunction varied between rats, and the present report focuses on a subset of rats (in both moderate contusion (n=7) and transection SCI (n=7) subjects) that exhibited a severe LUT dysfunction phenotype characterized by rhythmic non-voiding contractions leading to bladder distension and sustained elevated bladder pressure >20 mmHg. Baseline LUT activity was continuously recorded for >60 min, after which the rats were exposed to an acute episode of moderate hypoxia (5 minute duration; 10-12% O_2, balance N_2). In each case, exposure to moderate hypoxia produced an immediate void and an associated transient decrease in bladder pressure. The hypoxia-induced voids occurred in the absence of well-defined bladder

contractions although bladder contractions during hypoxia were observed in some cases. These observations suggest that a single acute exposure to moderate hypoxia is effective in producing voiding in subjects with severe LUT dysfunction.

Title: Chronic hypoxia induced by pericytes contributes to hypersensitivity and allodynia after spinal cord injury

Authors: A. M. LUCAS-OSMA[1], Y. LI[1], K. HOLYK[1], S. LIN[1], L. SANELLI[1], K. FOUAD[2], *D. J. BENNETT[3]
[1]Neurosci. and Mental Hlth. Inst., [2]Physical Therapy, [3]Univ. of Alberta, Edmonton, AB, Canada

Abstract: The spinal cord is one of the most metabolically active systems, and thus it is critical that blood flow adapts to the demands for oxygen and glucose. Recently, we have shown that pericytes play a key role in regulating blood flow in the spinal cord, by constricting in response to monoamines (Li et al. 2017). Furthermore, we found that after chronic spinal cord injury (SCI) pericytes excessively constrict capillaries, leading to chronic hypoxia in the entire spinal cord below the injury. This hypoxia is produced by a paradoxical excess activity in monoamine receptors (5-HT1), despite the absence of monoamines. These receptors activate pericytes that locally constrict capillaries, reducing blood flow to ischemic levels. The paradoxical receptor activity results from trace amines (tryptamine) produced by pericytes that ectopically express the enzyme aromatic-L-amino-acid-decarboxylase (AADC). Importantly, improving blood flow by blocking AADC, or briefly inhaling pure oxygen, produces substantial relief from hypoxia and improves locomotor function. While these studies focused on motor function, dysfunctions in the sensory systems, including allodynia and pain, are hallmarks of SCI. Thus, we examined here whether improving blood flow normalizes sensory transmission after SCI. Adult rats with a chronic sacral spinal cord transection (2 months prior) were evaluated for the sensitivity to light touch (von Frey hair threshold for tail flick) and noxious heat (tail flick latency on hot plate). We found that initially rats were hypersensitive to light cutaneous stimuli, like allodynia seen in humans with SCI. However, we found that restoring blood flow below the SCI with an AADC blocker reduced the cutaneous hypersensitivity, increasing the von Frey threshold to a level near

that in uninjured rats. Likewise, increasing spinal cord oxygenation by inhalation of 95% oxygen also reduced the hypersensitivity to light touch. Interestingly, the same treatments increased the sensitivity to heat, consistent with a low threshold afferent gating of pain fibers. Our results suggest that a lack of adequate blood flow contributes to hypersensitivity and allodynia after chronic SCI and improving spinal cord blood flow offers a promising new strategy to treat sensorimotor dysfunction.

Title: Overcoming anddegrading inhibitory proteoglycans globally to promote axonal regeneration andfunctional recovery after a chronic thoracic spinal cord injury

Authors: *A. MILTON[1], M. A. DEPAUL[2], J. VERHAAGEN[4], E. J. BRADBURY[5], J. SILVER[3]
[1]Cleveland, OH; [2]Dept. of Neurosciences, [3]Dept Neurosci, Case Western Reserve Univ., Cleveland, OH; [4]Neth Inst. Neurosc, Amsterdam, Netherlands; [5]King's Col. London, London, United Kingdom

Abstract: The potently inhibitory environment that surrounds axons three months after a thoracic-level eight (T8) contusive spinal cord injury (SCI) significantly contributes to failured axon regeneration, leading to impaired functional recovery of the lower body. In this chronic model of SCI, the glial scar and perineuronal net (PNN) around as well as far distal the injury site each display a profound upregulation of growth restricting chondroitin sulfate proteoglycans (CSPGs). CSPGs can be stripped of their inhibitory glycosaminoglycan (GAG) chains locally, by enzymatic removal through direct administration of Chondroitinase ABC (ChABC). However,

focal administration of ChABC in the vicinity of the lesion has not been especially effective after a contusive SCI. Impaired fiber regeneration and sprouting is also mediated by GAG binding to the leukocyte common antigen-related family receptor protein tyrosine phosphatase sigma (RPTPσ). This interaction entraps axon terminal in both the scar and at synapses throughout the central nervous system. Systemic administration of synthetic PTPσ receptor blocker, Intracellular Sigma Peptide (ISP), acutely after SCI promotes robust recovery of axon sprouting via the inhibitory PNN. However, ISP alone has shown only minimal therapeutic effects chronically. Thus, our goal was to more expansively degrade and broadly overcome CSPG mediated inhibition to foster both regeneration and sprouting of regenerating axons over long distances. We accomplished this via the use of a far ranging CSPG digestion strategy using lentiviral delivery of ChABC (Lenti-ChABC) combined with ISP treatment. We now show that this combination treatment (but not when either strategy is used alone) significantly improves locomotion after chronic T8 contusive SCI in adult rats. Furthermore, chronically injured animals treated with either ISP, Lenti-ChABC or both (but not saline) had increases in serotonergic fiber sprouting caudal to the injury. However, an obvious correlation between highest 5-HT^{+} fiber density in animals with the most robust functional recovery was not found, suggesting improved behaviors may be attributed only in part to increased serotonergic innervation onto motor targets. These findings demonstrate that manipulating the glial scar and PNN using a minimally invasive enzyme and peptide therapy three months after contusive SCI facilitates nerve growth and recovery of some critical functions. This injury model is clinically relevant and supports a path for a translatable treatment paradigm for individuals suffering from paralysis long after spinal cord trauma.

Abstract: Injured axons fail to regenerate in the adult mammalian central nervous system (CNS) leading to permanent deficits in sensorimotor function. Recent work in our lab has shown that increasing the activity of proprioceptive dorsal root ganglion (DRG) neurons using an enriched environment induces a long-lasting increase in their regenerative potential that is dependent on CREB Binding Protein (CBP) mediated histone acetylation (Hutson *et al.* under revision). Pharmacological activation of the acetyltransferase CBP/p300 using a small-molecule activator (CSP-TTK21) which can pass the blood brain barrier, enhanced histone acetylation and neurite outgrowth of DRG neurons. Delivery of CSP-TTK21 within a clinically relevant time frame after a dorsal column injury promoted regeneration of sensory axons, enhanced conduction through the lesion and significantly increased sensorimotor recovery. CSP-TTK21 treatment also promoted sprouting of afferents below the level of the lesion, facilitating spinal circuitry re-organisation that may contribute to behavioural recovery. These findings demonstrate the importance of the chromatin environment to the regenerative capacity of DRG neurons. Identifying and manipulating key histone modifiers that can orchestrate broad changes in gene transcription may lead to significant improvements in axon regeneration and functional recovery.

Title: *In vivo* cellular reprogramming to restore respiratory function after SCI

Authors: S. FERNANDES[1], L. V. ZHOLUDEVA[1], Y. LI[2], P. W. BAAS[2], M. A. LANE[1], *L. QIANG[1]
[1]Drexel Univ., Philadelphia, PA; [2]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The injured adult mammalian spinal cord is incapable of significant repair. This limitation is due in part to two major neuropathological consequences of spinal cord injury (SCI): i) *the formation of growth-inhibitory glial scars*, of which activated astrocytes are a key component, and ii) *the destruction of intraspinal neuronal connectivity*, contributed to by the loss of the interneurons in the spinal circuitry. Previous cell-based strategies have traditionally been focused on transplantation of various neural stem cells into the injury site to replace lost neurons, improve the inhibitory environment and modulate inflammation; however, there are significant hurdles to their applications. For example, obtaining sufficient amounts of purified cells for transplantation may be difficult; the procedure often requires the use of immuno-suppression, which has detrimental effects on the host; and successful implementation of such a strategy needs to address the challenges of cell survival and appropriate cell differentiation without formation of tumors. Our *in vitro* data validated that Ascl1 and mir124+mir9/9*+NeuroD1 are both potent reprogramming factors that were able to convert the activated astrocytes into functional glutamatergic neurons. However, the mir124+mir9/9*+NeuroD1 group had a higher conversion efficiency than Ascl1 group. The converted neuronal cells not only were stained positive for pan-neuronal markers, but also were mature enough to bear typical neuronal electrophysiological properties. Therefore, using SD rats with cervical contusive injuries as our in vivo models, we applied both strategies to reprogram resident reactive astrocytes to potential functional interneurons. The *in vivo* conversions were also achieved using both strategies injured in cervical spinal cord contu, yet with a much more diminished yield. The reprogrammed interneurons were able to integrate into the phrenic circuit validated by PRV tracing studies. As we expected, functional behavior examinations such as plethysmography showed no significant improvement. However, terminal diaphragm electromyography (tEMG) studies indicated that the animals treated with mir124+mir9/9*+NeuroD1 show a modest recovery. In all, our pilot study serves as a proof-of-concept for its potential translational applications in SCI repair.

Title: A “stealth” gene switch for GDNF to define the therapeutic time window for motor neuron regeneration following ventral root avulsion/reimplantation

Authors: F. DE WINTER[1], R. EGGERS[1], E. R. BURNSIDE[2], B. HOBO[1], S. HOYNG[1], M. R. TANNEMAAT[3], M. J. A. MALESSY[4], E. MUIR[5], E. BRADBURY[2], *J. VERHAAGEN[1]
[1]Neth Inst. Neurosc, Amsterdam, Netherlands; [2]King's Col. London, London, United Kingdom; [3]Dept. of Neurol., [4]Dept. of Neurosurg., Leiden Univ. Med. Ctr., Leiden, Netherlands; [5]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Gene therapy is a powerful strategy to promote spinal cord regeneration. It is essential to restrict transgene expression to the appropriate therapeutic time window. The doxycycline (dox)-inducible system is the most used regulatable gene expression platform, but this system depends on a foreign, immunogenic transactivator (TA). This precludes reliable regulation of the therapeutic gene and limits clinical translation. The glycine-alanine repeat (GAr) of Epstein-Barr virus nuclear antigen-1 inhibits its presentation to cytotoxic T cells, allowing virus-infected cells to evade the host immune system. We generated a chimeric transactivator (GArTA) and show that GArTA has an immune-evading advantage over TA in a bioassay for human antigen presentation. A comparative study of lentiviral vectors expressing the TA and GArTA in the spinal cord shows that the GArTA system is inducible for 6 dox-cycles over a 47 week period, whereas with the TA-based system luciferase expression declines during the 3rd cycle and is not reinducible, indicating that GArTA provides an immune-advantage over TA. Timed expression of GDNF with the “stealth” gene switch significantly increased spinal motor neuron survival and prevented axon trapping in a ventral root avulsion/reimplantion model. Compound muscle action potentials (CMAP) revealed that 4 week GDNF expression led to an earlier recovery of CMAP responses compared to animals with 24 weeks GDNF expression. Although time-restricted GDNF expression in a long distance regeneration model is beneficial, axon growth into the chronically denervated distal nerve stump is still only 10% of the original number of motor axons present in the intact nerve. This may be due to remodeling of the extracellular matrix in

the chronically injured nerve rendering the cellular environment less permissive for axon growth. To overcome this we have applied a lentiviral vector for the enzyme Chondroitinase ABC (ChABC) to render the matrix of the denervated nerve more permissive for axon regeneration. Currently we are investigating whether combinatorial gene therapy for GDNF and ChABC will promote more distal axon regeneration and functional recovery.

Title: Descending motor tracts synapse formation with spinally-grafted porcine iPSC-NPCs: A systematic study using a novel subpial vector-labeling technique in the rat

Authors: *Y. KOBAYASHI, M. SHIGYO, T. TADOKORO, S. MARSALA, M. MARSALA
Neuroregeneration Laboratory, Anesthesiol., Univ. of California San Diego, La Jolla, CA

Abstract: (Purpose) In our recent study, we have generated and extensively characterized porcine iPSC-derived neural precursors both in vitro and after in vivo brain and spinal grafting. We have demonstrated that such iPSC-NPCs acquire a differentiation profile, which is consistent with a mature porcine CNS tissue including excitatory and inhibitory neurons at 7 -10 months after grafting. The development of synaptic contacts with the host neurons, however, is not defined at present. The goal of our current study was two fold: i) to define the development of regional spinal inter-neuronal synaptic contacts between grafted porcine iPSC-NPCs and neurons of the host, and ii) to study descending motor tracts sprouting and synapse formation with spinally grafted iPSC-NPCs.**(Methods)** Previously established and characterized porcine iPSC-NPC expressing GFP under ubiquitin or synapsin promoter were used for in vivo grafting in immunodeficient or immunocompetent-FK-506 immunosuppressed (3mg/kg/day) naïve rats. Two weeks prior lumbar spinal cord cell grafting, animals received a cervical subpial injection of AAV9-UBI-RFP (10ul) to label descending motor tracts. After cell grafting, animals survived between 2- 6 months and the presence of grafted GFP+ cells and formation of synaptic contacts with labeled RFP+ motor axons studied using immunofluorescence and confocal microscopy.**(Results)** i) In vitro differentiated iPSC-NPCs showed presence of neurons (Tuj1) astrocytes (GFAP) and oligodendrocytes (Olig2). ii) At 2-6 months after in vivo spinal grafting**,**

an extensive GFP+ graftswith a high density of GFP+ neurons (NeuN+) and terminals co-expressing synaptophysin+ puncta on the host neurons was seen. iii) RFP+ descending motor axon terminals were seen throughout GFP+ grafted regions. Some terminals appeared to develop a putative synaptic contacts with grafted GFP+ neurons. **(Discussion)** i) These data demonstrate that iPSC-derived neurons can effectively establish synaptic contact with the regional spinal host interneurons as well as with a long descending motor tracts. ii) The properties of iPSC-derived neurons appear to be similar as seen for fetal tissue or embryonic stem cell-derived neural precursors. iii) Accordingly**,** the use of iPSC-NPCs can represent an alternative cell source to be used in cell-replacement therapies aimed at restoring local synaptic circuitry.

Title: Three dimensional quantitative evaluation of descending tracts after spinal cord injury

Authors: *M. SHINOZAKI[1], N. NAGOSHI[2], K. NAKANISHI[1], O. TSUJI[2], F. M. RENAULT[1], M. NAKAMURA[2], H. OKANO[1]
[1]Dept. of Physiology, Keio Univ. Sch. of Med., Shinjuku-Ku, Tokyo, Japan; [2]Dept. of Orthopedics, Keio Univ. Sch. of Med., Shinjuku-Ku, Tokyo, Japan

Abstract: For many researches of spinal cord injury (SCI), evaluations of motor neural circuits are performed. Corticospinal tract is one of the main descending tracts of the motor circuits, and it predominantly works for upper extremities, especially in digit dexterity. In lower extremities of rodents, other descending tracts such as reticulospinal tract, rubrospinal tract, vestibulospinal tract, and monoamine-dependent tracts takes large part of its motor function. Therefore, it is indispensable to evaluate multiple descending axons for SCI researches with thoracic injury model animals which have impairments in lower extremities. Three dimensional evaluation of spinal cord tissue using transparent technique has developed in recent years. When tracer-injected central nervous tissue are transparently cleared and observed with microscopies with long working distance, it is possible to visualize three dimensional neural circuits. There are several reports which utilize the transparent spinal cords, but few of them address the precise

construction of neural circuits like fiber angle or number of branches. We made thoracic SCI model of mice, and injected fluorescent tracers into multiple descending tracts. We had transparent spinal cords with techniques of passive CLARITY technique and ScaleS, and observed them with lightsheet microscopy and multiphoton microscopy. We made an original algorism and used it to evaluate neural fibers, and quantified the outcome. Our findings demonstrate that transparent techniques can be more quantitative evaluation, which are necessary for scientific studies.

Title: Suppression of PTEN expression in neural stem cells enhances neurite growth from grafts-derived neurons in the injured spinal cord

Authors: *H.-H. PARK[1], D. HWANG[2], H. KIM[2], Y. OH[2], B. KIM[3]
[1]Ajou Univ. of Med., Suwon, Korea, Republic of; [2]Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [3]Ajou Univ. of Sch. of Med., Suwon, Korea, Republic of

Abstract: Spinal cord injury causes a permanent loss of neurological functions by disrupting neural network connecting above and below the injury site. Transplantation of neural stem cells (NSCs) into the injured spinal cord holds promise to repair the disrupted neural connections by providing new neurons. However, poor capacity of axon growth from NSC-derived neurons would diminish the ability of NSCs to rebuild neural circuits. It has been reported that deletion of phosphatase and tensin homolog (PTEN), a well-known tumor suppressor gene, promotes robust axonal regeneration after CNS injury. We hypothesized that PTEN suppression in NSCs could promote axonal growth from NSC-derived neurons and that transplantation of NSCs with suppressed PTEN would lead to an improved functional recovery by allowing more frequent formation of neural connections with host neurons. NSCs obtained from fetal rat spinal cord at the 14th embryonic day were transduced with AAV2-shPTEN. NSCs with AAV2-shPTEN considerably increased the extent of neurite outgrowth *in vitro* either on permissive or inhibitory substrate. Transplantation of NSCs with AAV2-shPTEN into injured spinal cord resulted in a

significant increase in graft survival. Grafted NSCs with PTEN suppressed exhibited highly elongated morphology compared to those transduced with control AAV2-GFP. Most of the elongated neurites were positive with neurofilament immunoreactivity. Furthermore, we observed frequent synaptic contacts between grafts-derived neurons and host axons, indicating formation of new neural circuits. We are now evaluating functional recovery of injured rats with transplantation of NSCs with AAV2-shPTEN. Our results suggest that suppression of PTEN expression could improve therapeutic value of NSCs in future regenerative strategy for regaining lost neural functions following spinal cord injury.

Abstract: Restoration of function after a lesion of the central nervous system, such as spinal cord injury (SCI), is one of the biggest challenges modern medicine is currently facing. The complex pathophysiology of SCI, and especially the accumulation of axon-growth inhibitors, presents a major obstacle to structural and functional repair. To promote regeneration in the CNS, we focused on a group of prenylflavonoids derived from hops. Recently, we identified a flavonoid called “Enhancement of Neuronal Differentiation Factor 1” (ENDF1) presenting great neuroregenerative potential. We showed that ENDF1 acts neuroprotective, promotes neuronal differentiation and enhances regrowth and branching of neurites in sensory neurons. The neuroregenerative activity of ENDF1 was further investigated on rat dorsal root ganglion (DRG)

neurons and compared to NGF, factor known to stimulate neurite outgrowth. DRG neurons were either seeded on pro-regenerative laminin or one of the following extracellular matrix (ECM) derived inhibitors: Semaphorine3A, EphrinA4 or a mix of chondroitin sulphate proteoglycans. Our assays showed that ENDF1 was as efficient as NGF to enhance regrowth and branching of neurites in rat (P2) DRG neurons. Furthermore, ENDF1 neutralised the growth inhibitory effects of the ECM inhibitors tested. To enable *in vivo* applications, we developed a method to encapsulated ENDF1 in beta-cyclodextrin complexes retaining the biological activities and providing solubility and stability under physiological conditions. Mass-spectrometry demonstrated the bioavailability of ENDF1 complexes following intravenous and intraperitoneal applications in rats, thus opening the door for investigation of the regenerative activity of ENDF1 treatments following injury of the nervous system.

Title: Clinical use of optical density ratio in determining the prognosis of central serous chorioretinopathy

Authors: *J. WON[1], Y. PARK[2]
[1]St. Paul's Hosp., Seoul, Korea, Republic of; [2]St.Seoul Hosp., Seoul, Korea, Republic of

Abstract: Central serous chorioretinopathy (CSCR) is the fourth most common retinopathy after age-related macular degeneration, diabetic retinopathy and branch retinal vein occlusion. Foveal attenuation, chronic macular oedema, and damage of the foveal photoreceptor layer have been reported as causes of visual loss in CSC. Photoreceptor degeneration in the fovea, despite successful retinal reattachment, typically occurs after a duration of symptoms of approximately 4 months. Acute CSCR is a self-limited condition with resolution of neurosensory retinal detachment and generally good recovery of visual acuity within three months. However, recurrences of CSCR have been documented in up to 50% of patients within one year. Treatment should therefore be considered after 3 months if there is angiographic evidence of ongoing foveal leakage in recurrent chronic CSC or in a single CSC episode accompanied by signs of chronic CSC alterations. The prognosis of patients with chronic CSCR is poor partially because of late treatments. If we could predict the chronic nature of CSCR, we could treat the CSCR earlier and get the good prognosis of CSCR. Thus the purpose of our study is to evaluate prognostic factors

of CSCR by using initial Optical Density Ratio (ODR). A total of 87 paticipants with new onset central serous chorioretinopathy was included in the study. The optical density ratio of these eyes was evaluated by Spectralis Domain OCT (Heidelberg Spectralis OCT) at initial and 3months follow-up. The visual outcomes were measured at initial and final visit. The ODR of acute CSC was 2.09±1.36 and the ODR of chronic CSC was 7.07±3.39. It's is showed statistically significant difference (*P*= 0.0001). In ROC Curve, if the ODR of CSC is more than 3.687, CSC tends to be chronic. In conclusion, by using initial OCT findings, we could predict the prognosis (chronification) of CSC, but further evaluation is needed.

Title: System x_C^- expression during diabetic retinopathy development: Modulation by Nrf2

Authors: *R. C. SANTOS[1], K. D. CALAZA[2]
[1]Univ. Federal Do Rio De Janeiro, Rio de Janeiro, Brazil; [2]Fluminense Federal Univ., Niteroi, Brazil

Abstract: Introduction: Diabetic retinopathy is one of the main causes of blindness in young adults, and increased oxidative stress is related with its development. System xc-, a glutamate/cystine exchanger, facilitates cystine uptake. In the intracellular medium, cystine is converted to cysteine, which is used for glutathione (GSH) synthesis, an important antioxidant molecule. System xc- is composed by 4FC and xCT proteins, and xCT, the functional subunit of this system, is under regulation of Nrf-2 due to binding at the antioxidant responsive element (ARE) region and its activity is decreased in the retina in diabetic condition. Objective: to investigate the temporal relationship between xCT levels and Nrf2 activity during the progression of diabetic retinopathy. Methods: Diabetes was induced in male Wistar rats weighting 200 g by a streptozotocin injection, and their retinas were collected after 15 days, 1, 2 and 6 months of diabetes induction. Expression of xCT was analyzed by qPCR and by western blot. Reactive oxygen species (ROS) were quantified using DCFH-DA and GSH levels were measured by a commercial kit. Nrf-2 activity was determined by a commercial kit. Nrf2 binding to ARE region was measured by ChIP protocol. Results: xCT expression (mRNA and protein) in the retina were significantly decreased in PCR (46 ± 15%, N=4) and western blot (38 ± 25%, N=5) analyses after 1 month of diabetes. At 2 months, xCT expression return to normal levels, however, at 6 months of diabetes xCT was again reduced (PCR: 46 ± 15%, N=6 / Western blot: 39 ± 11%, N=6). Activity of Nrf-2, an inducer of xCT, was impaired within 15 days of diabetes (39 ± 15%, N=4) and 1 month (30 ± 15%, N=4). At 2 months, Nrf2 activity came back to normal levels whereas after 6 months, Nrf-2 activity was decreased (37 ± 14%, N=6). Confirming the causal relation between Nrf-2 activity and xCT expression, Nrf-2 binding to xCT ARE region was reduced after 1 month (63 ± 12%, N=4) and 6 months (73 ± 7%, N=4). Consistent with the role of xc- in protection against oxidative stress due to GSH production, after 1 month, GSH levels were reduced (33 ± 12%, N=5) and continued to be subnormal until 6 months of diabetes. Also, ROS is increased after 15 days (205 ± 94%, N=4) and remained altered until later stages. Conclusion: These data show a temporal relationship between xc-, Nrf2, and other parameters implicated in the maintenance of oxidative stress, and suggest that reduced Nrf-2 activity could play a role in impairing proper function of the system xc- during the progression of diabetic retinopathy.

Title: The medial geniculate body as a target for deep brain stimulation to treat tinnitus: A rodent study

Authors: *G. VAN ZWIETEN[1], M. L. F. JANSSEN[4], J. V. SMIT[5], A. M. L. JANSSEN[2], M. ROET[6], A. JAHANSHAHI[3], R. J. STOKROOS[7], Y. TEMEL[8]
[2]Methodology and Statistics, [3]Neurosurg. and Neurosci., [1]Maastricht Univ., Maastricht, Netherlands; [4]Neurol. and Neurophysiol., [5]Ear Nose and Throat/Head and Neck Surgery, [6]Neurosci., [8]Neurosurg. and Neurosci., [7]Maastricht Univ. Med. Ctr., Maastricht, Netherlands

Abstract: Tinnitus is a debilitating phenomenon and remains a therapeutic challenge. Neuromodulation is a promising treatment modality for tinnitus. The medial geniculate body (MGB) of the thalamus plays a key role in the pathophysiology of tinnitus, as it integrates and processes auditory and limbic information. We already showed that deep brain stimulation of the inferior colliculus and dorsal cochlear nucleus, both nuclei of the central auditory pathway, suppressed tinnitus-like behavior in rats. Compared to these candidate targets for deep brain stimulation (DBS), the MGB is more easily accessible using stereotaxy in human. This experiment assessed the effect of high frequency stimulation and low frequency stimulation of the medial geniculate bodies on tinnitus in a noise-induced tinnitus rat model. Anxiety-related side-effects were evaluated in the elevated zero maze and open field. Eleven subjects were included and a repeated measures design was used. Presence of tinnitus was verified using the gap induced pre-pulse inhibition of the acoustic startle response paradigm. Hearing thresholds were determined before and after noise trauma with auditory brainstem responses. Results show tinnitus development after noise-trauma and preserved hearing thresholds of the ear that was protected from noise trauma. We found that high frequency stimulation of the medial geniculate bodies suppressed tinnitus-like behavior. This effect maintained directly after stimulation when the stimulation was turned off. Low frequency stimulation did not have any effects on the gap:no-gap ratio of the acoustic startle response. No anxiety or locomotion related side-effects were found in the elevated zero maze and open field. Thus, high frequency DBS of the MGB might be a promising treatment option for patients with severe, refractory tinnitus.

Title: Analysis of ketamine-induced gamma burst pattern in rats using k-means clustering of continuous wavelet transform power-frequency estimates

Authors: *J. A. GUIDERA[1], N. E. TAYLOR[2], J. T. LEE[4], K. VLASOV[5], J. PEI[5], E. N. BROWN[6], K. SOLT[3]
[1]Med., Univ. of California, San Francisco, San Francisco, CA; [2]Anaesthesia, [3]Anesthesia and Critical Care, Massachusetts Gen. Hosp., Boston, MA; [4]Brain and Cognitive Sci., MIT, Westwood, MA; [5]Brain and Cognitive Sci., [6]MIT, Cambridge, MA

Abstract: INTRODUCTION: Ketamine is a general anesthetic that induces distinct frontal electroencephalogram (EEG) oscillations in humans, including a "gamma burst" pattern characterized by periods of elevated delta (1 - 4 Hz) power alternating with periods of elevated gamma (25 - 80 Hz) power (Akeju et al. 2016). Whether the ketamine-induced gamma burst pattern extends beyond the prefrontal cortex (PFC) to subcortical or other cortical structures is not known. In addition, an objective method for identifying the distinct delta dominant and gamma dominant states to enable their separate analysis is lacking. In this study, we conducted simultaneous cortical and subcortical local field potential (LFP) recordings in rats under ketamine anesthesia. We used k-means clustering, which has been used to identify sevoflurane-induced LFP states (Hudson et al. 2014), and the continuous wavelet transform (CWT) to objectively identify the gamma and delta dominant states of the ketamine-induced gamma burst pattern.
METHODS: Five anesthetized male Sprague-Dawley rats were implanted with intracranial electrodes in the PFC, parietal cortex (PC), and central thalamus (CT). In a separate surgery, a femoral central venous catheter was placed. After full recovery from surgery, the rats underwent an infusion of ketamine (2 $mg{\cdot}kg^{-1}min^{-1}$ iv). LFP power and coherence were estimated using wavelet methods. K-means clustering of PFC LFP power-frequency estimates was used to identify delta dominant and gamma dominant states.
RESULTS: Ketamine induced a gamma burst pattern in PFC, PC, and CT LFPs that was most prominent in the PFC LFP. K-means clustering of CWT PFC LFP power-frequency estimates effectively identified delta dominant and gamma dominant states. At the group level, the gamma and delta dominant states were characterized by peak increases in gamma and delta PFC, PC,

and CT LFP power, respectively. During the delta dominant state, cortical (PFC-PFC and PFC-PC) and thalamo-cortical (PFC-CT and PC-CT) LFP delta coherence were increased. During the delta dominant and gamma dominant states, prefrontal (PFC-PFC) and thalamo-parietal (PC-CT) LFP gamma coherence were increased.
CONCLUSIONS: These results suggest that the ketamine-induced gamma burst pattern extends beyond PFC to subcortical and other cortical structures. The delta dominant state of the gamma burst pattern is accompanied by increased low-frequency connectivity between distant regions. K-means clustering of CWT power-frequency estimates enables characterization of anesthetic-induced oscillatory dynamics that consist of more than one state.

Title: Detecting tinnitus in nonhuman primates by using a non-acoustic startle paradigm

Authors: *L. ROGENMOSER, P. KUSMIEREK, D. ARCHAKOV, J. RAUSCHECKER
Georgetown Univ., Washington, DC

Abstract: Tinnitus impairs the quality of life of millions of Americans, making it a current concern for Public Health in an aging population. Animal models are indispensable for the development of evidence-based therapy. Existing rodent models of tinnitus have been criticized because their results failed to translate to human patients. The reason for this may be that rodents lack a brain area in medial prefrontal cortex (vmPFC) that human imaging studies have shown to be causally related to the gating of tinnitus. Since vmPFC is highly developed in nonhuman primates, we aimed to establish a tinnitus model in rhesus monkeys.Tinnitus was determined by using a non-acoustic startle paradigm. In contrast to most animal studies in which the startle response is recorded by an accelerometer, we measured the eye blink, as commonly done in human startle experiments. Eye blinks were monitored by recording electromyographic (EMG) activity in response to air-puffs as startle stimuli, preceded by short auditory stimuli varying in frequency and intensity. The tones were adjusted according to the hearing thresholds, which were determined by frequency-specific Auditory Brainstem Response recordings. The threshold-

adjusted intensity levels were: +30dB SL,+6dB SL and -6dB SL. Since tinnitus loudness is known to range between 6-30 dB SL, we expected tinnitus to mask the mimicking frequency at the +6dB SL level, revealing the tinnitus frequency by an altered startle response. In this pilot study, one monkey was tested at its baseline, at a reversible tinnitus level (after administration of salicylate, 200mg/kg), and at a follow-up level. In order to ensure translation of the results to humans, a sample of human tinnitus patients and of matched control subjects without tinnitus underwent the same testing paradigm.The peaks of the EMG activity were extracted and subjected to inferential statistics. Unlike previous studies on tinnitus that make use of the Prepulse Inhibition phenomenon for tinnitus detection, our preliminary data strongly suggest the opposite, namely a Prepulse Facilitation. Our preliminary results suggest that the preceding tone facilitates the eye blink response as long as it is reliably perceived. In both species, the +6dB adjustment revealed the tinnitus frequency by a lack of facilitation.
The use of a non-acoustic startle stimulus is advantageous since it is free from acoustic interference and less aversive (especially for patients with hearing issues like tinnitus and hyperacusis). Since startle paradigms do not require instrumental conditioning or training, this set-up could easily be applied to a larger population, such as geriatric monkeys in a primate center.

Title: Retinal albinism and abnormal electroretinograms in VAMP7 null

Authors: *N. ORTIZ VEGA[1,2], I. D. SANTIAGO[1], B. MELENDEZ[1], J. SEVILLA[1], R. A. JORQUERA[1,3]
[1]Neurosci., Univ. Central Del Caribe, Bayamon, PR; [2]Biol., Univ. de Puerto Rico, Bayamon, PR; [3]Ctr. for Integrative Biology, Fac. of Sci., Univ. Mayor, Santiago, Chile

Abstract: Throughout evolution, the visual systems have preserved photoreceptor cells for phototransduction and chemical synapses for downstream neuronal connectivity. The composed signal of an electroretinogram (ERG) records the electrical activity of phototransduction and

synaptic transmission evoked by light stimulation. In *Drosophila* ERGs, light stimulation induces a sustained depolarization associated with phototransduction with characteristic On and Off responses associated with synaptic transmission at the afferent and efferent visual inputs. Nevertheless, the molecular mechanisms that underlie these components and their relevance in image acquisition are not completely elucidated. Light-evoked responses are transient when the TRPC channels are reduced, and severely diminished when the phototransduction pathway is impaired. In turn, a reduction in the endocytic capacity for activated photoreceptors extends the prolonged depolarization after light (PDA), while both alterations can modify the On/Off components. Proteins required for membrane fusion and recycling like non-canonical SNAREs can potentially modify the On/Off and/or the phototransduction components. However, the role of non-canonical SNAREs in the visual system is not clear. VAMP7 is a non-canonical SNARE involved in membrane recycling and fusion with lysosomes. Here we scrutinize the role of VAMP7 in the visual system of *Drosophila* by using a VAMP7 null model. VAMP7 null ERGs display overall biphasic characteristics like WHITE null animals. A detailed ERG analysis indicates that VAMP7 null displays abnormal Off components. Additionally, VAMP7 null presented diminished and slower phototransduction kinetics with an extended PDA. A slower recovery of the fast ERG component was also observed. Consistent with the role of lysosomes in the accumulation of visual pigments in the retina, *Drosophila* VAMP7 null adults display retinal albinism. The same TRPC mediated phototransduction pathway has been observed in vertebrate photosensitive pigment cells of the iris. Our data, suggest that similar visual pathophysiology may be present in patients with abnormal lysosomal function, as in Hermansky-Pudlak Syndrome, a condition with retinal albinism and visual impairment.

Title: Effect of Vestibular Galvanic Stimulation on eye movements and orientation of the head and body

Authors: O. GONZÁLEZ[1], *R. VEGA[3], E. SOTO[2]
[1]Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [2]Benemérita Univ. Autónoma de Puebla, Puebla Pue, Mexico; [3]Benemerita Univ. Autonoma De Puebla, Puebla, Mexico

Abstract: Vestibular alterations have a high prevalence in the population in Mexico that varies from 1.8% in adults to more than 30% in old age. This work provides data for the design of a prosthetic device based on galvanic vestibular stimulation (GVS). We used three arrays of peri auricular electrodes for the bilateral bipolar GVS, arranged parallel to the semicircular canals (CSS, anterior, posterior and horizontal) with the polarity inverted on each side of the head. Twenty voluntary subjects, 7 women and 13 men (age 20 to 30 years) were recruited. For the experiments subjects were informed of the GVS character and consent informed was signed according to the Helsinki declaration of Ethical Principles for Medical Research Involving Human Subjects. The direct current injection had a mean of 1.7 ± 0.2 mA and duration of 10 s. The inclination of the head was measured by means of a triaxial accelerometer system (3DM-GX3-15, MicroStrain), the distribution of body weight (CBP-center of pressure) was measured using a stabilometric platform, and eye movements were studied by means of a video nystagmograph (Micromedical Technologies). The distance traveled (sum of the trajectories of displacements), magnitude and direction of the displacement vector was analyzed. The GVS in parallel to the anterior SCC, modulated gaze control by modifying the magnitude of the horizontal travel path and its direction and decreased the magnitude of the CBP tilt vector as the path traveled by the inclination of the head in the roll plane increased. The GVS in the direction of the posterior SCC, produced head tilt in the roll plane, decreased the path traveled from the antero-posterior CBP, and changed the direction of inclination of the CBP. The GVS in the direction of the horizontal SCC, decreased the path of the eyes vertically. The path traveled by the inclination of the head increased in the planes of the roll and pitch and the direction of inclination of the head changed from left and front to the left and back. Results showed that GVS had an effect on the parameters studied with periauricular electrode arrays aimed to specifically stimulating the three SCC. Title: Involvement of pedunculopontine tegmental nuclei in sensorimotor gating: Chemogenetic-induced inhibition of general, cholinergic and glutamatergic PPTg neurons

Authors: *N. FULCHER[1], E. AZZOPARDI[2], C. DE OLIVEIRA[2], S. SCHMID[1,2]
[1]Program in Neuroscience, Schulich Sch. of Med. & Dent., [2]Anat. & Cell Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: The human brain persistently receives sensory inputs from the environment. An innate process that filters out redundant stimuli is called sensorimotor gating, which can be quantified through prepulse inhibition (PPI) of the acoustic startle response (ASR). Deficits of PPI are seen in a host of psychiatric illnesses, such as schizophrenia, autism spectrum disorder, Tourette's syndrome, etc. Chronic lesions of the midbrain pedunculopontine tegmental nucleus (PPTg) have shown to disrupt PPI. Albeit underlying mechanisms of PPI remain unclear, cholinergic PPTg projections to the startle-mediating giant neurons in the brainstem have been suggested as an integral part of the PPI pathway. Importantly, the PPTg is comprised of three distinct neuron types: cholinergic, glutamatergic and GABAergic neurons. Our work revisits the hypothesis that PPTg projections in general, and PPTg cholinergic projections specifically, mediate PPI. We intracranially delivered bilaterally a general-, a cholinergic- or a glutamatergic cell-specific inhibiting DREADD (designer receptors exclusively activated by designer drugs), or a control vector, into the rat PPTg. Three weeks later, animals were tested for startle, PPI of ASR, open-field and morphine-induced conditioned place preference (CPP) deficits after receiving an i.p. injection of the DREADD ligand clozapine-n-oxide (CNO) in Dimethyl Sulfoxide (DMSO) to activate the virus, or vehicle. In order to enhance area specificity, general DREADD expression was combined with local CNO micro-infusions into the PPTg through chronically implanted bilateral cannula After behavioural testing, animals were perfused and immunohistochemistry or FISH (fluorescence *in situ* hybridization) was performed to ensure successful expression and location of the respective DREADDs. Results suggest that transient DREADD inhibition of all PPTg neurons disrupts PPI, while cholinergic inhibition does not significantly alter PPI. Moreover, data suggests that glutamatergic silencing disrupts PPI. These data highlight the important role of the PPTg in sensorimotor gating and its deficits, but suggest that glutamatergic and not cholinergic PPTg neurons mediate PPI.

Title: Blast-induced structural and transcriptome changes in the ear lead to hearing impairments in rats

Authors: *Y. WANG, R. URIOSTE, Y. WEI, D. WILDER, Y. CHENG, S. SAJJA, I. GIST, P. ARUN, J. LONG
Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: Auditory dysfunction is one of the most common disabilities in military personnel and civilian exposed to blast shockwaves. To better understand the pathological processes underlying this injury, we have evaluated damages to ear structures and carried out global gene expression profiling of the cochlea at acute and chronic stages after blast shockwave exposure of rats in an advanced blast simulator using RNA-Seq. Auditory dysfunction was verified by DPOAE and ABR assessments which revealed significant changes in the ABR waveforms and elevations of threshold after blast exposure. These changes were observed over the entire acoustic frequency spectrum and persisted over several months. Compared to high frequency (40 kHz) hearing loss after blast exposure, low frequency (8 kHz) hearing recovered relatively early after insult. Cochlear RNA-seq identified (according to an FDR-corrected p-value 0.05) 1158 differentially expressed genes (DEGs) which represent 3.98% of the total, at 1 day post-injury, of which 462 were up-regulated and 696 were down-regulated. At 28 days post-injury, the data showed 48 DEGs (0.16% of the total), of which 28 were up-regulated and 20 were down-regulated. The DEGs were categorized according to gene ontology (GO) annotation. The top categories in biological processes which include localization, regulation of cation channel activity, transport, nervous system development, neurotransmitter levels and cell-cell signaling were significantly altered at 1 day post-injury, while a category in antigen processing and presentation was significantly changed at 28 days post-injury. Seven DEGs were found in the acute and chronic phases that associate with inner ear mechanotransduction, cytoskeletal reorganization, myelin development and axon survival. Further studies on altered gene expression may provide insights into new therapeutic targets and methods for treating or preventing blast-induced auditory deficits.

Title: Salicylate enhanced the neural synchrony at the auditory cortex in behaving rats

Authors: *T.-W. CHIU[1], S.-T. HSU[2], D. SUTA[3]
[1]Dept of Biol. Sci. and Technology, NCTU, Hsinchu, Taiwan; [2]Inst. of Mol. Med. and Bioengineering, Natl. Chiao Tung Univ., Hsinchu, Taiwan; [3]Dept. of Cognitive Systems and Neurosciences, CIIRC Czech Tech. Univ., Prague, Czech Republic

Abstract: High dose salicylate (SS) is well known to induce temporal tinnitus in human and animals and the SS-treated animal model has widely used for exploring how the temporal tinnitus can be generated. Here we tried to determine the neural mechanisms of SS-induced tinnitus by assessing the changes in auditory evoked potentials (AEPs) recorded from the auditory cortex in awake rats after systemic injection of SS. AEPs were recorded from awake rats (n=6) with electrodes surgically implanted at the auditory cortex a. A week after surgery, we recorded cortical AEPs to clicks and tone pips with frequencies at 1, 10 and16 kHz at random intensity steps from 0 to 75 dB SPL. Control data were first collected. Animals were then given daily injection of SS (250 mg/kg, i.p.) for 5 consecutive days. Sound evoked responses were collected every day within 2-6 hrs post- injection. Average EPI (EP integral) was first extracted and amplitude-intensity-functions were obtained to evaluate the SS effects. Then, the single trial AEPs were analyzed by level-response probability function, inter-trial correlation and inter-trial coherence (with EEG lab) to evaluate the SS-effects on neural synchrony of cortical activities. Comparing to the control, SS significantly increased the average EPI, response probability, inter-trial correlation coefficients and inter-trial trial coherence to the middle to high intensity sounds. Results suggested that SS enhanced AEPs may relate to an elevation of the central gain manifested by enhanced neural synchrony.

Abstract: The neovascular aged-related macular degeneration (AMD) causes severe vision loss due to neuronal death in retina consecutive to inflammation, breakdown of blood retinal barrier and choroidal neovascularization. In seeking of efficient treatments to prevent retinal damage, the kallikrein-kinin system (KKS), a key player in inflammation, has been tested in the present study. Particularly, the role of kinin B1 receptor (B1R) has been examined since this receptor plays a crucial role in retina inflammation in diabetic retinopathy. Moreover, the interaction of B1R with the vascular endothelial growth factor VEGF is investigated in relation to the central role of this factor in AMD. The choroidal neovascularization (CNV) was induced in the left eye of Long-Evans rat. Treatments were initiated immediately with a single intravitreal injection of B1R siRNA (10 nmol/5µL) or anti-VEGF (125µg/5µL), or after one week with an eye-drop application of the B1R antagonist R-954 (≈100 µg/10µL bid) or their respective controls. The impact of those treatments was measured on vascular permeability, leukostasis and on gene expression of retinal inflammatory mediators (qRT-PCR). The distribution of B1R on retinal cell types was investigated by immunocytochemistry. The B1R was found overexpressed on endothelial and glial cells in retinas with CNV. Anti-VEGF and B1R blockade/deletion significantly reduced CNV lesions and the inflammatory response (adherent leukocytes and enhanced vascular permeability). Whereas anti-VEGF blunted the overexpression of most markers (B1R, B2R, VEGF, VEGF-R2, HIF-1α, TNF-α, MCP-1, ICAM-1 and VCAM), R-954 had no significant impact on the VEGF system, HIF-1α, MCP-1, VCAM-1. However, the overexpression of both kinin receptors, IL-1β, TNF-α and ICAM-1 was prevented by R-954. Our data suggest that VEGF and B1R pathways have different effects on retina damage in a model of AMD and that blockade of B1R by eye-drops application of R-954 may represent a less invasive therapy in the treatment of AMD than anti-VEGF therapy.

Title: Photomodulation of spontaneous electrical activity in guinea pig corneal cold nerve terminals by means of a p2x channel -permeant photoswitch

Authors: *V. MESEGUER, D. ARES, E. VELASCO, S. QUIRCE, M. ACOSTA, C. BELMONTE, J. GALLAR
Inst. de Neurociencias UMH-CSIC, Sant Joan D´Alacant, Spain

Abstract: Photo-isomerizable small molecules (photoswitches) allow modulation of neural activity by acting on native ion channels without requiring exogenous gene expression. DENAQ, a synthetic photoswitch, confers light-induced firing to retinal ganglion cells (RGCs) in a mouse model of retinitis pigmentosa; DENAQ entry into RGCs depends on functional upregulation of P2X receptors. We explored here: first , whether photoswitches modulate the electrical activity of peripheral sensory nerve terminals of the cornea. Secondly, whether this modulation depends on functional expression of P2X and/or TRPV1 channels at corneal nerve terminals. We recorded nerve terminal impulse (NTI) activity in cold terminals of excised guinea-pig corneas pre-incubated with 2 mM DENAQ for 40 min at 34ºC. In a separate set of experiments, DENAQ was co-applied with either the P2 receptor antagonist suramine at 1mM or the TRPV1 channel antagonist capsazepine at 10 µM performed 15 minutes before DENAQ. Afterwards, extracellular electrophysiological recording of NTI activity was initiated in the dark. Cold-thermoreceptor terminals fired spontaneous NTIs at 34ºC; this frequency increased markedly in response to a cooling ramp down to 15°C. A Light-Emitting Diode was used to deliver 125 mW/cm^2 of blue (460 nm) light in 5 cycles of alternating 15-sec light/dark intervals. In DENAQ-treated corneas, ongoing activity at 34ºC in the dark was higher (5.16 ± 0.66 $imp*s^{-1}$) than in the light (3.28± 0.62 $imp*s^{-1}$, $p=2.96 \times 10^{-14}$, Bonferroni post-hoc pair test, n=25). Contrarily, in non-treated corneas, ongoing activity was not affected by exposure to the light (7.37 ± 0.81 vs 7.55 ± 0.83 $imp*s^{-1}$, p=0.318, n=24). Prior application of the P2 receptor antagonist suramine significantly reduced the photo-modulation mediated by DENAQ (9.01 ± 1.04 in dark vs 8.69 ± 0.97 $imp*s^{-1}$ in light, p=0.331, n=8). The possibility of TRPV1 mediated DENAQ entry was excluded by application of the TRPV1 antagonist capsazepine, which did not modify NTI ongoing activity (4.08 ± 0.96 in dark vs 3.33 ± 0.89 $imp*s^{-1}$ in light, p=0.015, n=7). Taken together, these results suggest that DENAQ enter to corneal cold sensory nerve endings primarily through P2X channels and produces a robust decrease of the cold thermoreceptors spontaneous electrical activity in the presence of blue light.

Title: Spiperone produces nociception in rats by activation of calcium-activated chloride channels

Authors: *A. PLUMA[1], I. VELAZQUEZ-LAGUNAS[2], J. MURBARTIAN[3], V. GRANADOS-SOTO[4]
[1]Cinvestav, Unidad Coapa, Ciudad DE Mexico, Mexico; [2]Dept. de Farmacobiologia, Cinvestav, Coapa, Ciudad de Mexico, Mexico; [3]Cinvestav, Sede Sur, Mexico, DF, Mexico; [4]Dept. De Farmacobiologia, Cinvestav, Coapa, Ciudad de Mexico, Mexico

Abstract: Previous studies have suggested that spiperone activates Ca^{2+}-activated Cl^- channels (CaCCs) in cell culture. Since stimulation of CaCCs in vivo leads to nociception, it is likely that spiperone would produce nociception in naïve rats and would increase formalin-induced nociception. The aim of this investigation was to assess the participation of CaCCs in the pronociceptive effect of spiperone in rats. In addition, we compared the effects of spiperone with that of the CaCCs activator Eact. Local peripheral injection of spiperone (1-10 μg) or Eact (1-30 μg) induced nociception in naïve rats in a dose-dependent manner. Furthermore, local peripheral injection of spiperone (3-10 μg) or Eact (10-30 μg) enhanced 0.5% formalin-induced nociception. Local peripheral administration of selective CaCCs inhibitors ($T16A_{inh}$-A01 and $CaCC_{inh}$-A01, 0.1-1 μg) diminished spiperone (10 μg)- and Eact (30 μg)-induced nociception. Moreover, CaCCs inhibitors (0.1-1 μg) dose-dependently reduced the pronociceptive effect of spiperone (10 μg) or Eact (30 μg) and 0.5% formalin. Finally, the TRPV1 channel blocker capsazepine (3-30 μg) reduced in a dose-dependent fashion nociception induced by Eact but not by spiperone. Our results suggest that spiperone and Eact activate CaCCs in vivo to induce nociception and to enhance formalin-induced nociception. The nociceptive effect of Eact, but not spiperone, also depends on activation of TRPV1 channels. Thus, spiperone induces nociception by activation of CaCCs but not TRPV1 channels.

Abstract: Thalidomide is considered an anti-inflammatory and analgesic drug, that can modulate the production of proinflammatory cytokines such as: TNF-α, interferon ɤ, interleukin 10, interleukin 12 and prostaglandins. However, due to its teratogenic effects, thalidomide has been classified as a restricted drug. Thalidomide is a chiral molecule formed by a phthaloyl and glutarimide moiety: *S*-isomer has been suggested to be responsible of the teratogenic side effect. Recent studies have found that the pharmacological effects such as analgesic and antiinflammatory, induced by thalidomide are consequence to the presence of pthaloyl group. Based on the previous (*o*-phenyl)-isoindolin-1,3-dione (OFI) and (*p*-phenyl)-isoindolin-1,3-dione (PFI), symmetric thalidomide analogues, were synthesized to preserve or improve the analgesic and anti-inflammatory effect of lead compound.
The antinociceptive and anti-inflammatory effects were evaluated by two tests: 1) the formalin test, in which 1% formalin was injected subcutaneously into the plantar surface of the right hindpaw and the number of flinching of the injected paw was measured; 2) the tail-flick test using radiant heat (I=14), in which "tail flick" latency was measured. For each test, 5 groups of male Sprague Dawley rats (n= 8) were employed: 1) indomethacin (5 mg/kg), 2) 0.5% carboxymethylcellulose in phosphate buffer as the control group, three PFI doses 3) 100, 4) 316 and 5) 421.7 mg/kg.
The results have shown that OFI 100 mg/kg and 421.7 mg/kg doses decreased the number of flinches in the formalin, but the effect was not significant. Nevertheless, the same OFI doses caused a significant increase in the withdrawal latency of the tail whereby OFI could be considered as an analgesic drug. On the other hand, PFI presented a significant decrease in the number of flinching with the three tested doses and a significant increase in the withdrawal latency of the tail suggesting that PFI has an analgesic and further anti-inflammatory effect.

Title: A novel lysophosphatidic acid receptor 5 antagonist, AS2717638, exerts analgesic effects in rodents

Authors: *N. MURAI, H. HIYAMA, T. KISO, T. SEKIZAWA, T. WATABIKI, H. OKA, T. AOKI
Drug Discovery Res., Astellas Pharma Inc., Tsukuba, Japan

Abstract: Lysophosphatidic acid (LPA) is a bioactive lipid that acts via at least six G protein-coupled receptors, LPA receptors 1-6 (LPA1-6), for various physiological functions. We examined 1) whether LPA5 is involved in pain signaling in the spinal cord; and 2) the pharmacological effects of a novel LPA5 antagonist on synaptic transmission in spinal cord slices, intrathecal prostaglandin (PG)- and (*S*)-α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-induced allodynia, and neuropathic and inflammatory pain in rodents. Intrathecal injection of a selective LPA5 agonist, geranylgeranyl diphosphate, and a non-selective agonist, LPA, induced allodynia in wild type, but not in LPA5 knockout mice. These results suggest that LPA5 is important for pain signal transmission in the spinal cord. AS2717638 (6,7-dimethoxy-2-(5-methyl-1,2-benzoxazol-3-yl)-4-(piperidin-1-ylcarbonyl)isoquinolin-1(2*H*)-one) bound to the LPA-binding site on LPA5 and selectively inhibited LPA-induced cAMP accumulation in human LPA5- but not LPA1-, 2-, or 3-expressing cells. Further, oral administration of AS2717638 inhibited LPA5 agonist-induced allodynia in mice. AS2717638 also significantly improved PGE_2-, $PGF_{2\alpha}$-, and AMPA-induced allodynia, while both pregabalin and duloxetine alleviated only PGE_2-induced allodynia in mice. Similarly, AS2717638 significantly ameliorated static mechanical allodynia and thermal hyperalgesia in a rat model of chronic constriction injury (CCI)-induced neuropathic pain. In addition, AS2717638 reduced miniature EPSC frequency in dorsal horn neurons from CCI rats. AS2717638 also showed analgesic effects in a rat model of inflammatory pain. These findings suggest that LPA5 is involved in broad pain signaling in the spinal cord such as neuropathic and inflammatory pain and that pharmacological antagonism of LPA5 is an attractive novel pain therapy.

Title: Fingolimod does not reduce pain behavior in the spinal nerve ligation model of pain or prevent the development of morphine tolerance in rat

Authors: *V. JOKINEN[1], T. LILIUS[1], P. RAUHALA[1], E. KALSO[1,2]
[1]Pharmacol., [2]Div. of Pain Medicine, Dept. of Anesthesiology, Intensive Care and Pain Medicine,, Univ. of Helsinki, Helsinki, Finland

Abstract: AIMS OF INVESTIGATION: Neuropathic pain and opioid tolerance remain major clinical challenges. Microglia activation and related neuroinflammation are known to play a significant role in the pathophysiology of both conditions. Interestingly, fingolimod (FTY720), sphingosine-1-phosphate (S1P) receptor agonist, used to treat multiple sclerosis has been recently recognized as a potent microglia modulator. Indeed, fingolimod has been shown to decrease chemotherapy-induced neuropathic pain behavior via microglial S1P receptor, and to reduce pain behavior in a model of central neuropathic pain and a spared nerve injury model for neuropathic pain. The aims of this investigation were to evaluate the efficacy of fingolimod on peripheral nerve injury in the spinal nerve ligation model of pain, but also on the development of morphine tolerance. The research was confirmatory.
METHODS: Effects of fingolimod (0.01 or 1 mg/kg, i.p.) on mechanical and thermal withdrawal thresholds were studied after ligation of lumbar spinal nerve (SNL) on male Wistar-Han rats (120-150 g). Fingolimod was administered daily beginning on the second day after the surgery. Mechanical allodynia was assessed using a force gauge with blunt tip on postoperative days 4, 7, 11, 13, and 27. Cold allodynia was assessed using acetone on days 7, 8, 11, and 13.
Morphine tolerance was induced in male Sprague-Dawley rats (170-250 g) using two different schemes: progressively increasing morphine doses delivered through injections, or constant-releasing morphine pumps. Fingolimod (0.1 or 1 mg/kg, i.p.) was administered daily. The development of morphine tolerance was assessed using thermal antinociceptive tests, tail-flick and hot plate, on days 4, 7, and 8.
N=6-12 per study group. The treatments applied were compared to the relevant drug vehicle controls treated otherwise identically. All behavioral measurements were performed in a blinded fashion.
RESULTS: The SNL caused a robust decrease in withdrawal thresholds for mechanical and thermal stimulus. Fingolimod (0.01 or 1 mg/kg) did not, however, have an effect on either the mechanical or thermal allodynia tested on any of the experiment days. Fingolimod administration with morphine did not prevent the development of morphine tolerance.
CONCLUSION: The results suggest that fingolimod holds no beneficial effects on neuropathic pain related to peripheral nerve injury, but also that concomitant fingolimod treatment does not have an effect on the development of morphine tolerance. The inconsistent results regarding the efficacy of fingolimod in different models of neuropathic pain warrants further research.

Title: Antinociceptive and antipruritic effects of kappa opioid receptor agonists on pain and itch models

Authors: A. ZANON, Jr[1], Y. DARBAKY[1], *L. DIOP[2]
[1]ANS Biotech, Riom, France; [2]ANS Biotech, Riom Cedex, France

Abstract: Itch and pain are unpleasant sensations mediated by nociceptive neurons. These noxious stimuli are perceived as distinct, however, and induce different behavioral responses in rats such as itching or biting. Nalfurafine, a selective κ-opioid receptor (KOR) agonist, has been approved in Japan for the treatment of itch in patients with chronic kidney disease. (-)U-50,488H, another KOR agonist, is frequently used as a pharmacological tool in preclinical and clinical models of pain, notably in neuropathic, visceral and inflammatory pain. The aim of these studies was to compare the effects of Nalfurafine and (-)U-50,488H in pain and itch models.
Methods Nalfurafine and (-)U-50,488H were first evaluated in the ALGOGram™, an *in vivo* High Throughput Screening tool based on a battery of 11 validated animal models/tests covering 5 pain areas. In follow-up studies of inflammatory pain, Nalfurafine (3, 10, 30 µg/kg, s.c.) or NaCl 0.9% (n=10/group) was given 15 min before an intraplantar injection of Capsaicin (0.1%), and mechanical threshold was determined using the electronic Von Frey test. In a model of pruritus, Nalfurafine (3, 10, 30 µg/kg, s.c.), (-)U-50,488H (0.1, 0.3, 1 mg/kg, s.c.) or NaCl 0.9% (n=10/group) was given 30 min before the intradermal injection of Serotonin (5-HT) 2% used here as a pruritic stimulus. The cumulative scratching time was measured during a 45-minute period of observation post dose.
Results: In the screening model (ALGOGram™), Nalfurafine and (-)U-50,488H exhibited potent activity in various pain models. In the inflammatory pain model, Nalfurafine decreased tactile allodynia induced by intraplantar administration of Capsaicin. Within the same dose-range, Nalfurafine was effective in reducing itching behavior induced by intradermal injection of 5-HT. Likewise, (-)U-50,488H was also effective in the 5-HT model of pruritus.
Conclusions: This study demonstrates that both κ-opioid receptor agonists were effective in models of pain and pruritus. In particular, Nalfurafine exhibited equipotent antinociceptive and antipruritic activities in both pain and non-histaminergic pruritus models.

Title: Anxiety-like behaviors are attenuated by a NTS2-selective analgesic in rats experiencing chronic inflammatory pain

Authors: *M. VIVANCOS[1], R. FANELLI[2], M. ORLIAGUET[1], J.-M. LONGPRÉ[1], J. MARTINEZ[2], F. CAVELIER[2], P. SARRET[1]
[1]Pharmacol. and Physiol., Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]IBMM, UMR-CNRS-5247, Montpellier, France

Abstract: Chronic pain is commonly associated with affective disorders, such as anxiety and depression and the under-management of pain can have significant impact on the development of comorbidities. In recent years, the tridecapeptide neurotensin (NT) has emerged as an important modulator of nociceptive transmission, exerting its analgesic activity by interacting with class A G protein-coupled receptors, namely NTS1 and NTS2. In addition, the neurotensinergic system is also thought to play a major role in the physiological expression of stress and anxiety. In the present study, our goal was thus to evaluate if a NTS2-selective compound can produce sustained analgesic responses and reduce the anxiety-like behaviors that are associated with chronic pain.
We previously synthesized a series of NT(8-13) analogs harboring site-specifically modified natural or unnatural amino acids. Binding studies demonstrated that incorporation of a reduced amide bond between Lys^8-Lys^9, substitution of the Tyr^{11} by a positively charged amino acid (Lys) and replacement of the Leu^{13} residue with the more hydrophobic (trimethylsilyl)alanine (TMSAla) non-natural amino acid (JMV-5966) improved the selectivity by more than 100-fold toward NTS2 (1.38 nM and 166 nM for NTS2 and NTS1, respectively). Furthermore, the presence of these modifications greatly increased the plasma stability (half-life > 2 hours). Then, JMV-5966 was tested in acute (tail-flick test), tonic (formalin test) and chronic pain models (Chronic Constriction Injury (CCI) and Complete Freund's Adjuvant (CFA)). We found that intrathecal (i.t.) injection of JMV-5966 at 23 nmol/kg produced potent analgesic responses in different pain conditions, compared to saline-treated rats. We next evaluated the anxiolytic potential of JMV-5966 in a rodent model of persistent inflammatory pain (CFA model), in which rats develop hypersensitivity to mechanical stimuli and display anxiety-like behaviors in light/dark and elevated plus maze paradigms. We found that intracerebroventricular injection of

JMV-5966 at 11.4 nmol/rat significantly reduces the anxiety-like behaviors in the light/dark and elevated plus maze tests. Diazepam (1.5 mg/kg, i.p.) was used as a reference anxiolytic drug. Altogether, these results prove that activation of the NTS2 receptor subtype represents a promising avenue to both improve pain control and treat the anxiety-like behaviors associated with chronic pain.

Title: Trk inhibitor ameliorates spontaneous pain behaviors in rats treated with complete freund's adjuvant (CFA)

Authors: *S. KOYAMA, Y. OHTSUKA, M. WAKABAYASHI, Y. ENDO, H. ARAI, S. MIHARA, T. KOMATSU, M. MICHISHITA, N. SHINOTSUKA, T. TABATA, K. FUKANO, M. TANAKA, A. KAGEYAMA, T. SHIRAI, K. YAMAMOTO, K. KAWASAKI, S. YOSHIKAWA
Lab. for Pharmacol., Asahi Kasei Pharma Corp., Izunokunishi, Japan

Abstract: Spontaneous behaviors such as rearing and horizontal movements in rodents could be valuable readouts for better understanding painful symptoms, considering that preclinical studies focusing only on evoked pain have resulted in low success rate of clinical trials in pain research area. We have previously validated that rats treated with complete freund’s adjuvant (CFA) into hind paw showed significant decrease in both rearing and horizontal movements. Tropomyosin receptor kinase (Trk) inhibitor has been an attracting analgesic candidate for inflammatory pain including osteoarthritis related pain because of the involvement of nerve growth factor (NGF) in the pathogenesis. However, its efficacy on spontaneous pain in animal models as well as patients has not been investigated yet. Here, we evaluated peripherally selective pan-Trk inhibitor (compound A) on both rearing and horizontal movements in rats treated with CFA. We also investigated the efficacy of compound A in combination with current analgesics (NSAIDs or pregabalin) in this animal model. Our results show that both compound A and NSAIDs treatment significantly ameliorated the deficit in rearing and horizontal movements in rats treated with CFA compared to vehicle treatment. Pregabalin treatment showed the tendency to improve the decreased spontaneous behaviors, however, with no significant difference from vehicle treatment. Interestingly, compound A showed more potent efficacy in some combination therapies. This study strongly supports a therapeutic potential of trk inhibitor in the treatment of

inflammatory pain and also suggests the usefulness of some combination therapies of compound A and other analgesics in inflammatory pain.

Title: Combined treatment with low doses of ibprofen and dexamethasone attenuate trigeminal neuropathic pain

Authors: ***D. K. AHN**[1], S.-H. KANG[1], M.-K. PARK[2], J.-Y. SON[1], J.-S. JU[1], M.-K. LEE[3]
[1]Dentistry, Kyungpook Univ., Daegu, Korea, Republic of; [2]Kyung-Woon Univ., Gumi, Korea, Republic of; [3]Dong-Eui Univ., Busan, Korea, Republic of

Abstract: The present study investigated anti-nociceptive effects of combined therapy of dexamethasone and ibuprofen on neuropathic mechanical allodynia in rats with inferior alveolar nerve injury. Sprague-Dawley male rats were anesthetized with ketamine (40 mg/kg) and xylazine (4 mg/kg). Under anesthesia, the left lower second molar was extracted, followed by the

placement of a mini-dental implant to intentionally injure the inferior alveolar nerve. Inferior alveolar nerve injury, induced by the mal-positioning of dental implants, produced a significant mechanical allodynia on postoperative day (POD) 1 and persisted until POD 30. Intraperitoneal injection of high doses of ibuprofen (30 mg/kg) or dexamethasone (25, 50 mg/kg) inhibited mechanical allodynia, but low doses of ibuprofen (1, 5, 10 mg/kg) or dexamethasone (2.5 mg/kg) did not attenuate neuropathic mechanical allodynia in rats with inferior alveolar nerve injury. We examined effects of combined treatment with low doses of ibuprofen (5 mg/kg) and dexamethasone (0.01, 0.1, 1 mg/kg) on neuropathic mechanical allodynia on POD 1, 2, 3 (early treatment) respectively. Early combined treatment with ibuprofen (5 mg/kg) and dexamethasone (0.1, 1 mg/kg) significantly inhibited mechanical allodynia. This anti-allodynic effect was recovered within 24 hours after injection. We also examined combined treatment with ibuprofen and dexamethasone on mechanical allodynia on POD 7, 8, 9 (late treatment). Similar to early and late treatment with ibuprofen (5 mg/kg) and dexamethasone (0.1, 1 mg/kg) also significantly inhibited mechanical allodynia. Anti-nociceptive effect of combined treatment of low doses ibuprofen and dexamethasone is compatible to effects of gabapentin treatment. We confirmed anti-nociceptive effects of combined therapy on neuropathic mechanical allodynia by analysis of *c-fos* expression. Inferior alveolar nerve injury produced significantly increases in *c-fos* immuno-positive cells in the medullary dorsal horn on POD 3 and 9. Combined treatment with ibuprofen (5 mg/kg) and dexamethasone (1 mg/kg) significantly inhibited the number of *c-fos* immuno-positive cells on POD 3 and 9, respectively. These results suggest that combined treatment with low dose of ibuprofen and dexamethasone, which inhibited the trigeminal neuropathic pain, is a new potential therapeutic target for neuropathic pain control including the orofacial area pain (supported by NRF-2017R1A5A2015391).

Title: The antinociceptive effects of low dose morphine but not pregabalin are enhanced by the selective Cav2.2 blocker CNV2197944 in the rat

Authors: N. UPTON[1], *A. S. FISHER[1], C. TAYLOR[1], K. GIBSON[2], Z. ALI[2]
[1]Transpharmation, London, United Kingdom; [2]Calchan, London, United Kingdom

Abstract: Introduction: Cav2.2 remains a compelling analgesic target but despite 2 decades of intensive research, a selective small molecule blocker efficacious at safe doses in humans remains elusive.
At the spinal level, there is the opportunity to modulate presynaptic release from primary terminals of primary afferents by targeting μ-opioid, $\alpha_2\delta$ pathways as well as Cav2.2.
This study aimed to determine if low doses of the Cav2.2 blocker CNV2197944 could potentiate the effects of low doses of morphine and/ or pregabalin (PGB) preclinically- given the convergent nature of modulation between all three mechanisms.
Results: *Inflammatory pain;* Intraplantar injection of Complete Freund's Adjuvant (CFA) induced hypersensitivity was detected by a shift in weight-bearing between injured and non-injured hind paws at 24 hrs post dose. Both Celebrex (10mg/kg p.o.) and CNV2197944 (30mg/kg p.o.) at all test times significantly reversed the hypersensitivity. Morphine alone, produced a dose-related reversal of the hypersensitivity over the dose-range of 0.3-10mg/kg i.p. From this and previous studies, minimally effective doses of CVN2197944 (3 & 10mg/kg p.o.) and Morphine (0.3mg/kg i.p.) were selected for combined administration to evaluate potential additive/synergistic effects. Overall, the effects of CVN2197944 appeared to be largely additive to those of morphine (0.3mg/kg i.p.) at the time points evaluated.
Neuropathic pain; The chronic constriction injury (CCI) model of neuropathic pain was used to determine the effects of CNV2197944 (1 & 10mg/kg p.o.) alone and in combination with PGB (3mg/kg p.o.) following a sub chronic dosing regimen.
The control dose of PGB (30mg/kg p.o.) produced a clear reversal of the mechanical allodynia that occurs following CCI surgery, equivalent to shams at the 1 hr time point, indicating efficacy. CNV2197944 dose-dependently attenuated CCI-induced mechanical allodynia, with a significant increase in PWT observed at the 1 hr time-point in the 10mg/kg p.o. group.
CNV2197944 (10mg/kg p.o.) in combination with PGB (3mg/kg p.o.) increased PWT at both the 1 hr and 3 hr time-point but, the effect was not greater than that observed with CNV2197944 alone at 10mg/kg p.o. As such, there was no indication of a synergistic effect of these two compounds on PWT.
Conclusion: Using the current repeat-dose protocol PGB and CNV2197944 caused no overt sedative effects on the day of testing either alone or, in combination, compared to vehicle treated CCI animals
CNV2197944 could enhance the effect of morphine in the CFA model but not PGB in the CCI model. Suggestive of a different modulation of opioid versus $\alpha_2\delta$ mechanism and/or inflammatory versus neuropathic pain.

Title: Drug induced pain responses in human iPSC derived sensory neurons using MEA system

Authors: *A. ODAWARA[1,2,4,5], N. SHUHEI[2], M. NAOKI[2], I. SUZUKI[3]
[1]Sendai-Shi, Japan; [2]Tohoku Inst. of Technol., Sendai, Japan; [3]Tohoku Inst. of Technol., Sendai, Miyagi, Japan; [4]Tohoku Univ., Sendai, Japan; [5]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Functional evaluation assays using human induced pluripotent stem cell (hiPSC)-derived sensory neurons are expected to predict the pain-related toxicity of drugs and the pharmacological effects. However, evaluation assays in hiPSC-derived sensory neurons has not been established, and electrophysiological response to pain-related molecules are not known. In this study, we aimed to evaluate the physiological responses aginst pain-related molecules including anti-cancer drugs in cultured hiPSC-derived sensory neurons using high-throughput multi-electrode array (MEA) system. Human iPSC-derived sensory neurons were cultured on MEA chips (Presto), and the electrophysiological responses against capsaicin, menthol, allyl isothiocyanate (AITC), anti-cancer drug vincristine and oxaliplatin were measured by the MEA system. We firstly confirmed the expression of typical sensory marker Nav1.7, TRPV1, TRPM8, and TRPA1 using immunostaining in culture hiPSC-derived sensory neurons at 8 weeks culture. Evoked responses against capsaicin, menthol, and AITC administration were detected using MEA system. To confirm the responses depending on each receptor, we examined the responses in presence of each receptor antagonist. As the responses almost disappeared in presence of each channle bloker, these responses were confirmed to be channel specific responses. The evoked responses against anticancer drug vincristine and oxaliplatin administration were also detected. Next, we examined whether the increase of cold sensitivities occur in presence of anticancer drug oxaliplatin in vitro hiPSC-derived sensory neurons. The responses against AITC were increased in presence oxaliplatin and in a concentration-dependent manner. In summary, we have succeeded in detecting the electrophysiological pain reponses against capsaicin, menthol, allyl isothiocyanate (AITC), anti-cancer drug vincristine and oxaliplatin in hiPSC-derived sensory neurons using MEA system. We found that the increase of cold sensitivities in vivo phenomenon was also detected in vitro hiPSC-derived sensory neurons. MEA measurements using hiPSC-derived sensory neurons are useful to pain evaluation assay in human peripheral nervous system.

Title: Effect of midazolam on morphine-mediated analgesia, tolerance, and respiration in a rat model

Authors: *B. CHEPPUDIRA, H. KLEMCKE, A. TREVINO, R. CHRISTY, S. CRIMMINS
Pain Res., US Army Inst. of Surgical Res., San Antonio, TX

Abstract: Introduction: Midazolam and morphine are often used clinically to achieve sedation and analgesia. Development of analgesic tolerance and respiratory depression are some undesirable effects produced by morphine when used repeatedly. In the present study, we examined the role of midazolam on morphine-mediated analgesic tolerance and respiratory parameters in a rat model of opioid tolerance. Methods: Adult male Sprague-Dawley rats received subcutaneous midazolam (**MI**; 2.5 mg/kg, n = 6) or morphine (**MO**; 10 mg/kg, n = 6) or midazolam (2.5 mg/kg) + morphine (10 mg/kg, n = 6; **MM**) or saline (**S**; 0.5 ml, n = 5), twice per day for four days and once on the fifth day. Analgesia was tested by paw withdrawal from a heat stimulus. Respiratory parameters by whole body plethysmography were recorded as well. Results: Co-administration of morphine and midazolam (MM) produced prolonged analgesia compared to morphine alone ($P < 0.001$), and reduced development of analgesic tolerance ().05). Acute and chronic treatment of midazolam had no effect on the nociceptive threshold ($P > 0.05$). When compared with S rats, tidal volume was unaffected by any treatment on days 1-4 ($P > 0.05$). On the contrary compared with S, respiration rate decreased on post-treatment days 2-4 by MM ($P < 0.05$), and on days 2 ($P < 0.05$) and 3 ($P < 0.05$) by MI. MO alone did not affect respiration rate on any day ($P > 0.05$). Conclusions: Our preliminary data indicate that midazolam reduces morphine-mediated tolerance but contributes to respiratory depression. Experiments are underway to further examine midazolam-morphine interactions in opioid tolerance.

Title: Mechanism of the analgesic effect of duloxetine in oxaliplatin-induced neuropathic pain

Authors: *W. KIM[1], J. LEE[2], S. WOO[2], S. KIM[3]
[1]Col. of Korean Med., Seoul, Korea, Republic of; [2]Dept. of Sci. in Korean Med., Grad. School, Kyung Hee Univ., Seoul, Korea, Republic of; [3]Dept. of Physiol., Kyung Hee Univ. Col. of Korean Med., Seoul, Korea, Republic of

Abstract: Oxaliplatin is a widely used chemotherapy agent, which also induces serious peripheral neuropathy. Duloxetine is a dual reuptake inhibitor of serotonin and norepinephrine, and is shown to be effective against pain. However, its effect as well as its mechanism of action in oxaliplatin-induced allodynia are not fully understood. A single injection of oxaliplatin (6 mg/kg, intraperitoneal; i.p.) induced cold and mechanical allodynia in rodents. Cold and mechanical allodynia were assessed by acetone and von Frey filament tests, respectively. When significant allodynic signs were observed, three different doses of duloxetine (10, 30, and 60 mg/kg, i.p.) were injected. Administration of 30 and 60 mg/kg of duloxetine significantly reduced both the cold and mechanical allodynia, whereas 10 mg/kg did not. By using an *in vivo* extracellular recording method, we further confirmed that 30 mg/kg of duloxetine could significantly inhibit the hyperexcitability of spinal wide dynamic range (WDR) cells. Furthermore, we conducted experiments to clarify the site of action of duloxetine in the spinal cord. The anti-allodynic effect of duloxetine was completely blocked by an intrathecal injection of phentolamine (non-selective adrenergic receptor antagonist, 20 g), or prazosin (α_1-adrenergic receptor antagonists, 10 g); however, idazoxan (α_2-adrenergic receptor antagonist, 10 g) could not block the anti-allodynic effect of duloxetine. These results suggest that 30 mg/kg of duloxetine treatment alleviates oxaliplatin-induced cold and mechanical allodynia in rodents through the activation of the α_2-adrenegic receptors.

Title: Synergistic effect of treatment with NMDA antagonists and muscarinic M1 positive allosteric modulator in the rat neuropathic pain model

Authors: A. VUYYURU, V. GOURA, R. KALLEPALLI, *P. JAYARAJAN, R. ABRAHAM, R. NIROGI
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Neuropathic pain is a major therapeutic challenge in the clinical research. Current analgesics are not completely effective and cause serious adverse effects. Literature review suggests that increase in N-methyl-D-aspartate receptor (NMDAR) contributes to central sensitization in neuropathic pain. Recent research showed that NMDA antagonist can reduce hyperalgesia and allodynia condition in animal models of neuropathic pain. However, clinical studies using NMDA antagonists on neuropathic pain suggests minimal therapeutic effects. Muscarinic M1 receptors are involve in the modulation of pain. Therefore we attempted for combination therapy of NMDA antagonist with muscarinic M1 positive allosteric modulator. In the current study we tested BQCA (1-(4-methoxybenzyl)-4-oxo-1,4-dihydroquinoline-3-carboxylic acid) (M1 PAM) in combination with NMDA antagonists (Memantine, MK-801 and SDZ-220581) in chronic constricted injury model of neuropathic pain in rats. Paw withdrawal thresholds were evaluated using Von Frey monofilaments. Motor side effects were assessed using open field and rotarod test. Combination therapy showed significant synergistic analgesic effects in all the tested combinations. Moreover no adverse motor side effects was observed in all the tested combinations. These observations recommend further studies in finding out a promising therapy for treating neuropathic pain.

Title: Exploring the effects of neurotensin receptor 1 gene (NTSR1) polymorphisms on receptor function

Authors: *E. EISELT, S. GRASTILLEUR, S. BEAULIEU, J.-M. LONGPRÉ, L. GENDRON, P. SARRET
Pharmacol. and Physiol., Sherbrooke Univ., Sherbrooke, QC, Canada

Abstract: Neurotensin (NT) is a tridecapeptide widely distributed throughout the brain, acting as a neuromodulator of dopaminergic and serotonergic transmission. Among the three NT receptors identified, the high-affinity NT receptor NTS1 which belongs to the G-protein coupled receptor class mediates several of the central and peripheral effects of NT. In Human, the *NTSR1* gene is located on chromosome 20q3 and contains three introns and four exons spanning more than 10 kb. Over the last decades, mapping and sequencing of the human genome have provided detailed information on the function of any gene or protein of interest and have given us important insights into the genetic variations among individuals. Genetic variations in the *NTSR1* gene have previously been associated with disease vulnerability and variation in drug responses. Indeed, single-nucleotide polymorphisms (SNPs) have been reported to be associated with schizophrenia, alcohol dependence and performances of processing speed and working memory in healthy Chinese-Han subjects. Likewise, *NTSR1* gene variants were found to be associated with opiate dependence in population of European ancestry. Importantly, all these SNPs are located in intronic non-coding DNA or untranslated 5'UTR and 3'UTR regions. Polymorphisms in the coding sequence of the *NTSR1* gene have, however, been identified in people from different ethnic origins. These three SNPs result in amino acid substitutions in the gene encoding hNTS1, leading to the replacement of Alanine by Valine at position 72 (A72V), Glutamine to Histidine at position 275 (Q275H) and Valine by Isoleucine at position 304 (V304I). A72V and V304I are respectively located in the first and sixth transmembrane domains whereas Q275H is present in the third intracellular loop. The mutation A72V is found in 1% of the Caucasian population, Q275H at 5% in the African population and V304I at 2% in combined populations. To our knowledge, these mutations discovered by genomic screening have not been associated with genetic susceptibility or phenotypes. The present study was therefore designed to determine whether these SNPs located in the hNTS1 coding sequence result in gain or loss of function. We investigated whether these single mutations affect the NT binding to hNTS1, induce changes in receptor trafficking (i.e. internalization, cell surface expression), modify the G protein-dependent and G protein-independent signaling pathways associated to NTS1 activation, or regulate the

formation of hNTS1 homo-or heteromers. Altogether, these results will provide a better understanding of the impact of these SNPs on NTS1 function and may help to link them to potential phenotypes.

Title: MMG22 efficacy and target receptor expression in the dorsal root ganglia after peripheral nerve injury

Authors: *R. SPELTZ-PAIZ[1], M. M. LUNZER[2], E. AKGÜN[2], R. REED[3], A. E. KALYUZHNY[3], P. S. PORTOGHESE[2], D. A. SIMONE[4]
[1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Medicinal Chem., Univ. Of Minnesota, Minneapolis, MN; [3]Bio-Techne, Minneapolis, MN; [4]Dept.Diagnostic & Biol. Sci., Univ. Minnesota, Minneapolis, MN

Abstract: The Mu opioid receptor (MOR) and the metabotropic glutamate receptor 5 ($mGluR_5$) are G-protein coupled receptors involved in pain and analgesia. $mGluR_5$ antagonists have been shown to decrease opioid induced analgesic tolerance and self-administration, while increasing opioid analgesic potency. Previous studies have shown that the expression of both MOR/OPRM1 and $mGluR_5$/GRM5 (protein/mRNA respectively) can be differentially regulated in various rodent models of pain. However, how expression levels change during the development and maintenance of neuropathic pain has not been investigated. MMG22 is a novel bivalent ligand made of an $mGluR_5$ antagonist and a MOR agonist. The first objective of these studies was to determine the effectiveness and potency of MMG22 in decreasing mechanical hyperalgesia caused by nerve injury. These studies also examined the co-localization and temporal dynamics of $mGluR_5$/GRM5 and MOR/OPRM1 expression in the lumbar dorsal root ganglia and lumbar dorsal horn after nerve injury. Studies comparing receptor expression patterns to the analgesic efficacy of MMG22 are ongoing. Adult C57BL/6J male and female mice were used for these studies. Mice were subjected to the spared nerve injury (SNI) model of nerve injury induced neuropathic pain. Behavioral testing on mice included von Frey, and conditioned place preference assays. Cumulative dose response curves for subcutaneous morphine and MMG22

were obtained on days 10, 20 and 30 after nerve injury. Mice were sacrificed at 1, 3, 10, 20 and 30 days after surgery. The dorsal root ganglia of L4 - L6 spinal nerves and the corresponding L4 - L6 segments of spinal cord were removed and used for 2 color in situ hybridization using RNAScope® (ACD/Biotechne®) technology, immunohistochemistry, and western blot analysis. The antinociceptive efficacy and potency of MMG22 in reducing mechanical hyperalgesia were greatest 10 days after spared nerve injury. MMG22 (10mg/kg but not a lower dose) was able to induce analgesic conditioned place preference in SNI mice 10 days after, but not 4 weeks after nerve injury. The same dose of MMG22 was unable to induce conditioned place preference in naïve mice or sham mice at any time point. We observed co-localization of OPRM1 and GRM5 mRNAs in some dorsal root ganglia neurons and dorsal horn neurons. We are presently comparing changes in MOR/mGluR$_5$ protein and OMPR1/GRM5 mRNA levels in lumbar dorsal root ganglia as a function of time after peripheral nerve injury.

Title: Novel neuroactive steroid with hypnotic properties exerts analgesia in post-surgical pain model

Authors: *S. JOKSIMOVIC[1], K. KRISHNAN[2], D. F. COVEY[2], V. JEVTOVIC-TODOROVIC[1], S. M. TODOROVIC[1]
[1]Univ. of Colorado, Anschutz Med. Campus, Aurora, CO; [2]Dept Developmental Biol., Washington Univ. Sch. Med., Saint Louis, MO

Abstract: Introduction: We have recently shown that novel neuroactive steroid (3β,5β,17β)-3-hydroxyandrostane-17-carbonitrile (3ß-OH) induces hypnosis in neonatal rats and provides analgesia in chronic pain, likely by blocking T-type calcium channels (T-channels). Several studies implicate T-channels in chronic pain; however, their role in acute pain resulting from surgical tissue injury is yet to be determined. Therefore, the aim of our study was to investigate if novel neurosteroid analogue, 3ß-OH, can also be used as analgesic in an acute post-operative pain model.
Methods: An incisional pain model was developed by performing deep tissue incision of the plantar surface of the hind paw in Sprague-Dawley rats. In order to establish the anesthetic dose

in young adult rats, animals were injected intra-peritoneally (i.p.) with different doses of 3ß-OH and loss of righting reflex (LORR) was monitored. To test spinal, local and systemic analgesic effects of 3ß-OH, the drug was injected intrathecally (i.t.) between L4 and L5 vertebrae, intraplantarly into the plantar surface of the incised paw (i.pl). or i.p.. In vivo assessment of antihyperlagesic effect was measured in tests of paw threshold responses to mechanical or radiant heat stimulus.
Results: After testing the range of doses of 3ß-OH injected i.p., we identified that 60 mg/kg i.p. dose induced LORR in more than 90% of injected rats. The same dose reduced the amount of isoflurane necessary to achieve anesthesia for surgical incision from 2.5 to 1%. Furthermore, animals that underwent surgery under 3ß-OH with 1% isoflurane, exhibited reduction in the response to thermal stimulus as compared to the group anesthetized with 2.5% isoflurane only. After i.t. injection of three different doses in healthy animals, 3ß-OH exerted a significant analgesic effect to mechanical stimulus during 120 minutes post-injection, as compared to the vehicle (VEH) group. Furthermore, when 16 µg dose was injected repeatedly 2 h and 24 h post-surgery, mechanical hypersensitivity was significantly reduced post-injection. Also, single acute i.t. injection of the same dose given either 24 h or 48 h post-injection, exerted significant antihyperagesic effect. After applying repeated i.pl. injections during three consecutive days (2, 24 and 48 h post-surgery), we noticed a significant increase in mechanical hypersensitivity threshold of incised paws vs. VEH, during 7 days of post-operative recovery.
Conclusion: Our study strongly suggests that 3ß-OH, a novel T-channel blocking neuroactive steroid analog, may be a promising general anesthetic with unique analgesic properties following systemic, intrathecal and peripheral delivery.

Title: Glial glutamate transporter activator attenuates nociception and rescues hippocampal memory deficit in mice

Authors: *G. ALOTAIBI, S. RAHMAN
South Dakota State Univ., Brookings, SD

Abstract: Previous studies have shown that glial glutamate transporter-1 (GLT-1) in the hippocampus and anterior cingulate cortex (ACC) is critically involved in pain processing and modulation. However, the role of glial GLT-1 in nociceptive pain involving the hippocampus and ACC, important brain regions associated with cognitive and affective modulation of pain remains unknown. The objective of the present study was to investigate the role of LDN-212320, a GLT-1 activator, in nociceptive pain and associated hippocampal cognitive impairments. We evaluated the effects of LDN-212320 in formalin-induced nociceptive pain model. In addition, formalin-induced impaired hippocampal cognitive behaviors were measured using Y-maze, elevated-plus maze (EPM) and object-recognition test. Furthermore, GLT-1 expression was measured in the hippocampus and ACC using Western blot analysis. The LDN-212320 (10 or 20 mg/kg, i.p.) significantly attenuated formalin-evoked nociceptive behavior. The anti-nociceptive effects of LDN-212320 were reversed by systemic administration of DHK (10 mg/kg, i.p.), a GLT-1 antagonist. Moreover, intraperitoneal (i.p) administration of LDN-212320 (20 mg/kg,) significantly increased time spent in novel arm of the Y-maze compared to formalin-injected mice. In addition, treatment with LDN-212320 (20 mg/kg, i.p) significantly reversed the formalin-induced deficits in spontaneous alternation in the Y-maze test. Formalin-injected mice exhibited a reduced preference for the displaced object. However, mice treated with LDN-212320 (10 mg /kg or 20 mg/kg, i.p) significantly increased preference for the displaced object. Administration of LDN-212320 (20 mg/kg) significantly reversed formalin-induced less number of open arm entries of the EPM. Additionally, LDN-212320 (10 or 20 mg/kg, i.p.) increased GLT-1 expressions in the hippocampus and ACC. Taken together, these results suggest that the GLT-1 activator, LDN-212320, prevents nociceptive pain associated with hippocampal memory deficit by upregulating astroglial GLT-1 expression in the hippocampus and ACC. Therefore, GLT-1 activator could be a novel a drug candidate for nociceptive pain.

Abstract: The prototype butyrophenone, haloperidol, has been widely used as antipsychotic agent. Recently, some authors have described the anti-nociceptive effects of haloperidol mediated by sigma-1 receptors antagonism. Besides, morphine is a prototype analgesic opioid drug currently used in the clinical practice. **Objective.** To determine the type of interaction generated by the combined therapy of haloperidol with morphine in neuropathic pain, induced by chronic constriction injury (CCI). **Methods**. The anti-hyperalgesic effects of haloperidol (0.0178, 0.0316, 0.0562 and 0.1000 mg/kg, s.c.) and morphine (1.0 mg/kg, s.c.) were determined after single-doses, both in monotherapy and combined, using the von Frey test in the CCI model. Evaluations were done until 10 days post-surgery at 30, 60, 90, 120 and 180 minutes after drugs administration. **Results.** Haloperidol showed a dose-dependent anti-hyperalgesic effect on CCI rats, while the assayed dose of morphine achieved a moderate anti-hyperalgesic effect. The analysis of pharmacological potency of tested treatments demonstrated that haloperidol ED_{50} (0.0785) was twice higher than combined therapy ED_{50} (0.0382), being the combination the most potent. Moreover, it was found that among four combinations evaluated two (haloperidol 0.0178 and 0.0316 mg/kg + morphine 0.1 mg/kg) resulted in additive effects and two combinations produced anti-hyperalgesic effect of type potentiation (haloperidol 0.0562 and 0.1000 mg/kg + morphine 0.1 mg/kg). **Conclusions**. These results demonstrate that low doses of morphine significantly enhance anti-hyperalgesic efficacy and potency of haloperidol, suggesting a potential use of this pharmacological combination in neuropathic pain therapy.

Abstract: While nonsteroidal inflammatory drugs (NSAIDs) are the first line of therapeutics for the treatment of mild to moderate somatic pain, they are not generally considered to be effective for neuropathic pain. In the current study, direct activation of spinal Toll-like 4 receptors (TLR4) by the intrathecal (IT) administration of KDO_2 lipid A (KLA), the active component of lipopolysaccharide (LPS), elicits a robust tactile allodynia that is unresponsive to cyclooxygenase (COX) inhibition, despite elevated expression of COX metabolites in the spinal cord. IT KLA increases 12-lipoxygenase-mediated hepoxilin production in the lumbar spinal cord, concurrent with expression of the tactile allodynia. The TLR4-induced hepoxilin production also was observed in primary spinal microglia, but not in astrocytes, and was accompanied by increased microglial expression of the 12/15-lipoxygenase enzyme 15-LOX-1. Finally, the inhibitors ML127 and ML351 both reduced activity of the rat homolog of 15-LOX-1 heterologously expressed in HEK-293T cells and completely abrogated NSAID-unresponsive allodynia *in vivo* following IT KLA. Taken together, these findings suggest that the spinal TLR4-mediated hyperpathic state is mediated at least in part through activation of microglial 15-LOX-1.

Title: Analysis of frontal electroencephalogram after fentanyl administration

Authors: *A. C. MULLEN[1], J. A. DONOGHUE[1], E. N. BROWN[2], P. L. PURDON[3]
[1]Brain and Cognitive Sci., [2]MIT, Cambridge, MA; [3]Anesthesia, Critical Care, and Pain Mgmt., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Fentanyl is frequently used during cardiovascular surgery to induce hemodynamic stability, beneficial for creating a clear operating plane. We retrospectively analyzed the frontal electroencephalogram (EEG) data from patients (n=6) at the Massachusetts General Hospital (MGH) who received fentanyl during induction of general anesthesia for cardiac surgery. After

fentanyl-induced loss of consciousness, but before intubation, an increase in the delta oscillation (1-4 Hz) and profound decrease in their beta and gamma band activity (15-40 Hz) developed. This pattern of EEG activity is distinct from other common forms of anesthetics such as propofol or sevoflurane which develop high power oscillations in the 0.5-1.5Hz and 8-12 Hz bands during sedation. We observed that during fentanyl administration, the patient's EEG changes above some threshold concentration, and thereafter, power within the delta band (1-4Hz) tracks the trajectory of the predicted effect site concentration. This suggests a potential dose-dependent electroencephalogram signature for opioid effect. Additionally, there appears to be a ceiling effect on the EEG power in the delta band suggesting that the maximum effective dose of fentanyl may be achieved with less drug being administered. We hypothesize that, beyond this ceiling, administration of additional fentanyl might not convey significant additional benefit of sedation, analgesia, or hemodynamic stability. Further study will be required to explore these possibilities. These studies also suggest that the EEG could be used to titrate opioid effect, which could help optimize the quantity of opioids delivered during surgery, and reduce potential post-operative complications associated with opiate administration.

Title: Loss of GluN2B impacts nociceptive processing of intrathecal NMDA

Authors: *C. PETERSON[1,2], K. F. KITTO[2], K. R. PFLEPSEN[1], O. NGUYEN[1], E. DELPIRE[3], G. L. WILCOX[4], C. A. FAIRBANKS[5]

Abstract: Glutamatergic signaling within the spinal cord is implicated in the development and maintenance of chronic pain and opioid tolerance. Intrathecally delivered excitatory amino acids (EAAs), including N-methyl-D-aspartate (NMDA), are well characterized as eliciting distinct

behavior profiles: an early-onset behavioral expression of caudally directed grooming and scratching behaviors and a transient thermal hyperalgesia. These behaviors can be inhibited by pre- or co-treatment with NMDA antagonists or opioid agonists, allowing us to interrogate the spinal circuitry underlying the initiation and modification of distinct aspects of nociceptive signaling. We therefore sought to characterize the effect of intrathecally delivered NMDA and the ability of well-characterized NMDA receptor antagonists, including MK-801, ifenprodil, and agmatine, to inhibit these NMDA-elicited behaviors in both wildtype (WT) and GluN2B-knockdown (KD) mice. The GluN2B-knockdown mice were generated by intrathecal injection of AAV9-hSyn-Cre into Grin2B-floxed mice at p21. We observed that an equivalent dose of NMDA elicited significantly fewer nociceptive behaviors in KD mice as compared to WT, and that this decrease in potency could be overcome by increasing the dose of intrathecal NMDA. However, thermal hyperalgesia was unchanged from the WT to KD conditions, suggesting that an alternative NR2 subunit or nitric oxide synthase accounts for that effect. MK-801 was able to inhibit both nociceptive behaviors and thermal hyperalgesia in both WT and KD animals, but neither agmatine nor ifenprodil was effective at inhibiting nociceptive behaviors or thermal hyperalgesia in KD animals. These data suggest that GluN2B receptors contribute to NMDA-evoked nociceptive behaviors but not NMDA-evoked thermal hyperalgesia and that agmatine targets NR2B subunits.

Title: Antinociceptive effect of a modified protonectin isolated from parachartergus fraternus wasp

Authors: *P. GALANTE[1], M. MORTARI[2]
[1]Inst. de Ciências Biológicas - Dept. de Ciências Fisiológicas- Bl. G, Univ. of Brasilia, Brasilia, Brazil; [2]Dept. de Ciências Fisiológicas, Univ. of Brasília, Brasilia, Brazil

Abstract: According to International Association for the Study of Pain (IASP), pain is an unpleasant sensory or emotional experience associated with actual or potential tissue damage. It is a public health problem that affects about a third of the world population. Therefore,

neuroactive compounds are of great interest for their relevant potential to design novel drugs, important to prevent and/or treat diseases as well as to develop other pharmacological tools to minimize side effects and increase the effectiveness of the treatment. In this context, the arthropods venom presents as a rich and effective platform for the design of new neuroactive compounds. Succeeding this premise, an antinociceptive compound was bioinspired from a peptide isolated from the social wasp Parachartergus fraternus, denominated protonectin-F. Previous study showed that in the hot plate test when administered intracerebroventricular (i.c.v), protonectin-F revealed an antinociceptive activity comparable to morphine sulfate 1µM, presenting a lower motor deficit. The evaluation of the mechanism of action by pharmacological antagonism performed with naloxone hydrochloride (4 mg / kg), presenting the same inhibitory effect of antinociceptive activity during 240min of the test. These data suggest that protonectin-F may act on the opioid pathway directly in the recognition of opioid receptors or indirectly by activation in the release of endogenous opioids.

Title: Comparative analysis of the antinociceptive effect of naproxen-arginine and sodium naproxen

Authors: *N. VEGA CABRERA[1], A. ALEJO-MARTÍNEZ[2]
[1]IMSS , Medicina Familiar, UNAM, Mexico, Mexico; [2]CInvestav-Unidad Coapa, Mexico, Mexico

Abstract: The main function of pain is to warn about potentially harmful situations or stimuli; however, it becomes a pathological condition when it provokes dysfunction to the sufferer; so it looks like one of the major reasons for medical consultation worldwide. **Objective**: The aim of this study was to compare the antinociceptive effect of the naproxen-arginine versus sodium naproxen administered either separately in male Wistar rats on the “Pain-induced functional impairment model in the rat” (PIFIR model). **Method:** Nociception was induced by the intra-articular injection of uric acid (30%) in the right hind limb producing its dysfunction. Antinociception was determined by evaluating temporal curves and the dose-response curves of each analgesic. **Results:** Naproxen-arginine and sodium naproxen (0.316-177.8 mg/kg p.o.) demonstrated a dose-dependent antinociceptive response with similar efficacy (AUC= 275.1±13.3 au and 240.0±18.0 au, respectively). In the time course, when the maximum doses of both compounds were compared (177.8 mg/kg) it was observed that the administration of

naproxen-arginine obtained a maximum effect of 86.6±8.4% at 1.5 h versus naproxen-sodium (64.2±4.3%). To analyze the pharmacological potency, the ED_{50} were compared, naproxen-arginine was more potent than sodium naproxen. **Conclusions**: The results suggest that naproxen-arginine and sodium naproxen have adequate antinociceptive effects on the PIFIR model, and support the use of these analgesic compounds for the treatment of arthritic pain.

Title: Peripherally-restricted opioids and cannabinoids attenuates neuropathic pain in mice

Authors: *S. GRENALD[1], Z. CHEN[2], Q. HUANG[2], S. HE[2], Y. GUAN[2], S. RAJA[2]
[1]Anesthesiol. & Critical Care Medicine/ Psychiatry & Behavioral Sci., [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Damage to somatosensory nervous tissue produces pronounced chronic neuropathic pain that is refractory to current therapeutic options due to off-target CNS effects. Moreover, neuropathic pain affects approximately 20 million adults, representing 7-8% of the US population. Previous work has demonstrated the inhibition of tactile and thermal hypersensitivity in rodent models of neuropathic pain with the use of the peripherally acting mu opioid receptor (MOR) agonists, loperamide and DALDA. The potential advantages of the use of peripheral opioids on the inhibition of neuropathic pain is further supported by their lack of CNS penetration, which is thought to prevent some of the deleterious adverse effects. Additionally, cannabinoids have demonstrated efficacy in producing analgesia in rodent and human models of inflammatory and neuropathic pain. We aimed to determine if co-treatment with peripherally restricted opioids and cannabinoids would result in a synergistic antinociceptive effect in the management of neuropathic pain. We utilized various behavioral paradigms as an opportunity to determine potential therapeutic synergy following the co-administration of the peripherally-restricted opioid, DALDA, and a peripherally acting cannabinoid, CB13, in rodent neuropathic pain models. A significant reduction in mechanical hypersensitivity was observed in mice treated with CB13 and DALDA compared to vehicle-treated controls. The mixture of the two agents potentiated this reduction in mechanical allodynia in a synergistic manner. Furthermore, co-treatment with these peripherally acting agents enhanced spontaneous activity in the animals without inducing motor deficits, and resulted in significant preference using the Conditioned Place Preference (CPP) behavioral paradigm. *In vivo* imaging of animals genetically encoded with the calcium indicator GCaMP6, suggests a peripheral site of action. Studies are ongoing in conditional knockout mice to shed mechanistic insight and determine the contribution of each of these receptor systems in the reduction of neuropathic pain-related behavior. Thus, dual targeting

the peripheral opioid and the cannabinoid systems may present a novel avenue to explore for the management of chronic neuropathic pain.

Title: Analysis of 3'UTR isoform diversity in human dorsal root gangla (DRG) neurons using PacBio IsoSeq and CSI-UTR

Authors: *M. MICHAEL[1], E. GRLICKOVA-DUZEVIK[1], J. C. PETRUSKA[2,3], E. C. ROUCHKA[4], B. J. HARRISON[1]
[1]Dept. of Biomed. Sciences, Col. of Osteo. Med., Univ. of New England, Biddeford, ME; [2]Dept. of Anatom. Sci. & Neurobio., [3]Kentucky Spinal Cord Injury Res. Ctr., [4]Dept. of Computer Engin. and Computer Sci., Univ. of Louisville, Louisville, KY

Abstract: 3’ Untranslated Regions (3’UTRs) influence gene function by controlling transcript stability, translational efficiency and mRNA transport. These functions are coordinated by 3’UTR interaction with specific cis-interacting molecules, including microRNAs and RNA-Binding Proteins (RBPs). The recent surge of high-throughput transcriptome sequencing has revealed a surprising diversity of 3’UTR isoforms. 3’UTR isoforms are regulated in a tissue-type and cell-type specific manner, and the longest 3’UTRs transcripts are expressed in the nervous system. To profile 3’UTR isoform diversity in Human DRG neurons, we performed Pacific Biosciences (PacBio) IsoSeq whole-transcript sequencing of RNA pooled from seven Human DRG samples. Limitations of the IsoSeq methodology are 1) it is cost-prohibitive for use with larger comparative experiments and 2) the resulting data is not quantitative across conditions. Therefore, we developed a pipeline employing an in-house developed algorithm - CSI-UTR - to analyze 3’UTR isoform expression in DRG neurons using standard mRNA libraries sequenced with Illumina technology.

Title: Analysis of 3'UTR-RNA Binding Protein (RBP) interactions in dorsal root ganglia (DRG) neurons

Authors: *E. GRLICKOVA-DUZEVIK, M. MICHAEL, B. J. HARRISON
Dept. of Biomed. Sciences, Col. of Osteo. Med., Univ. of New England, Biddeford, ME

Abstract: RNA binding proteins (RBPs) are required for post-transcriptional control of gene function. RBPs have multiple roles in neurons, and contribute to neuron-type specificity and neuroplasticity. 3' untranslated regions (3'UTRs) of transcripts contain binding sites for RBPs. The majority of protein coding genes have multiple 3'UTR isoforms that interact with specific subsets RBPs thereby conferring transcript-specific functions. Publicly available high-throughput sequencing databases provide the opportunity to reanalyze data using updated/novel algorithms. We developed and employed a novel analysis algorithm called CSI-UTR to characterize 3'UTR isoforms and RBP binding sites in RNA-Seq profiles generated from dorsal root ganglia (DRG) neurons. Using this approach, we assessed strain, sex, age and cell-type specific variation in RBP-3'UTRs interactions in rat, mouse and Human DRG. This approach, applied to the study of somatosensory neurons, is uncovering exciting new insights about the multimodality of touch sensation and is providing novel targets to develop therapeutics for neuropathic pain.

Title: The differential roles of collateral sprouting and regeneration in the development of neuropathic pain following nerve injury

Authors: *S. DINSDALE[1], E. GRLICKOVA-DUZEVIK[2], M. MICHAEL[2], J. C. PETRUSKA[3,4], B. J. HARRISON[2]
[1]Col. of Arts and Sci., [2]Dept. of Biomed. Sciences, Col. of Osteo. Med., Univ. of New England, Biddeford, ME; [3]Dept. of Anatom. Sci. & Neurobio., [4]Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Rodent models of nerve injury-induced neuropathic pain (NP) typically employ injury to the sciatic nerve and/or its branches. Studies using these models have provided pioneering mechanistic data about the drivers of peripheral nerve regeneration and the causes of NP. It however remains largely unclear what contribution collateral sprouting of afferents plays to the development of NP. To address this, we have been using an adapted version of the spared dermatome model of collateral sprouting. This model was developed by Jack Diamond and colleagues in the 1980s to induce collateral sprouting of sensory neurons anatomically isolated from the injured neurons (sprouting neurons are in separate ganglia to the injured ones) - an approach that is not feasible using standard sciatic nerve models. Using this model, they discovered that collateral sprouting is neurotrophically distinct to axon regeneration: Collateral sprouting is dependent on NGF, whereas regeneration of injured axons could proceed even in the presence of NGF blockade. We have been assessing the utility of Jack Diamond's spared dermatome model in the study of neuropathic pain. We present data comparing the relative contribution of collateral sprouting and regeneration to hot, cold and mechanical hypersensitivity, hyperalgesia and allodynia.

Title: Development of a high-throughput aptamer screen to target the Nerve Growth Factor (NGF) pathway

Authors: *E. D. MCCORMAC[1], E. GRLICKOVA-DUZEVIK[2], M. MICHAEL[2], B. J. HARRISON[2]

[1]Col. of Arts and Sci., [2]Dept. of Biomed. Sciences, Col. of Osteo. Med., Univ. of New England, Biddeford, ME

Abstract: Nerve Growth Factor (NGF)-responsive neuron populations contribute to the etiology of diverse human diseases including neuropathic pain. Therapeutic trials involving NGF have demonstrated that targeting this trophic pathway could be a powerful approach. However, the use of NGF as a pharmacological agent may be unfeasible due to an unacceptable side-effect profile. A long-term goal is to develop therapeutics that regulate the actions of NGF, while minimizing potential side-effects. Towards this end, we are developing a cell culture based assay to quantify the effects of novel NGF modifying peptides conjugated to cell-penetrating peptides (CPPs). To optimize this assay, we have assessed a panel of candidate CPPs for toxicity profiles, cell penetration efficiency and effects on cell morphology and excitability. We now plan to employ this assay in a high-throughput format to screen candidate NGF pathway modifying aptamers for drug development.

Title: An *in vitro* approach to investigate excitability differences in DRG neurons from neuropathic and inflammatory pain disease models

Authors: *A. BERSELLINI FARINOTTI[1], D. NASCIMENTO[1], R. RUDJITO[1], K. SANDOR[1], S. LARDELL[2], P. KARILA[2], C. SVENSSON[1]
[1]Karolinska Institutet, Stockholm, Sweden; [2]Cellectricon AB, Göteborg, Sweden

Abstract: In dorsal root ganglion (DRG) neurons, differential expression of e.g. ion channels and markers of nerve stress indicate mechanistic differences in the pain pathophysiology. However, after prolonged peripheral inflammation, changes in DRG neurons resemble changes observed after nerve injury. This suggests that pain of inflammatory origin may evolve into a condition that resembles neuropathic pain. In our previous work we have characterized the

neurochemical profile of DRG neurons in mice from an arthritis model that show this “shift” in pain mechanism over time. The aim of the current study was to explore if changes in neuronal excitability induced by nerve injury or long-term inflammation is still present after establishment of primary cell cultures using a combined electric field stimulation and imaging approach.
BALB/c female mice were subjected to a spared nerve injury (SNI, model of neuropathic pain) or collagen antibody-induced arthritis (CAIA, model of long-lasting joint inflammation with a neuropathic component). Lumbar DRG neurons were collected 6 days after SNI and up to 50 days after induction of CAIA. Primary DRG neuronal cell cultures were prepared in 384 well plates and two days after plating the cells were loaded with a calcium indicator and transient calcium elevations were recorded as the change in the ratio of the fluorescence intensity before and during electric field stimulation. The excitability responses in DRG neurons from the animal models were compared to DRGs from untreated or sham operated control animals.
Results: Mechanical hypersensitivity was observed from day 1-6 in the SNI model and day 3-50 in the CAIA model. A robust joint inflammation was noted from day 7-30 in the CAIA model and even though the inflammation resolved, pain-like behavior persisted for at least an additional 20 days. In vitro, there was a clear difference in the excitability response (approximately 100% as measured as the ratio of the fluorescence intensity; N=6 animals and 18 wells/condition) in DRG neurons from the ipsilateral side compared to the contralateral side in the SNI model. A similar pattern was seen comparing data from experiments in which the neuronal cultures were established from DRGs collected after induction of CAIA compared to saline.
Conclusions: Using a high capacity system, we demonstrate that, in primary cultures from mice subjected to nerve injury, neurons retain differences in excitability in vitro. This opens up opportunities to explore underlying conditions in the excitatory properties of sensory neurons and may open new avenues for utilizing in vitro models to advance our understanding of pain pathophysiology.

Title: Amelioration of neurogenic and inflammatory hyperalgesia through modulation of iNOS, COX-2 and inflammatory cytokines by bergapten and mixture design in mice

Authors: *G. SINGH, JR[1], R. BHATTI, Jr[1], P. SINGH[2]
[1]Dept. of Pharmaceut. Sci., [2]Dept. of Chemitry, Guru Nanak Dev Univ., Amritsar I, India

Abstract: Background Bergapten is the major bioactive component of medicinal plants such as *Aegle marmelos* documented for analgesic activity. **Aim** To explore the toxicity, median effective dose (ED_{50}) and underlying mechanisms of analgesic effect of bergapten alone and in mixture. **Methods:** The mice were assessed for general behaviour and mortality in varying doses (50, 300, 2000 $mgKg^{-1}$) of bergapten for acute toxicity over 14 days. The analgesic effect was investigated using acetic acid and formalin induced hyperalgesia and anti-inflammatory activity was explored in carrageen induced paw edema. ED_{50} of bergapten was calculated using Design Expert software. Involvement of nitric oxide and cyclooxygenase pathways was investigated by agonist challenges with L-arginine and substance P respectively. The expression of inducible nitric oxide synthase and Cycloxygenase 2 was determined in spinal sections by immunohistochemical analysis. Lipopolysaccharide (LPS) challenge was used to assess in-vivo effect on inflammatory cytokines (TNFα and IL-6). Formation of mixture design of different concentration of different drugs (Bergapten, paracetamol and indomethacin) by using Design Expert software and characterization of mixture design by XRD, LCM and SEM. **Results:** Acute toxicity studies revealed no behavioural abnormality or mortality with bergapten treatment and unremarkable histological findings. Bergapten was found to significantly decrease acetic acid and formalin induced hyperalgesia (ED50=3.102 mg $kg-^{1}$) and carageenan induced paw edema with no toxicity symptoms. Bergapten produced a marked decrease in iNOS and COX-2 expression as well as TNFα and IL-6. The findings corroborate to modulation of iNOS and COX-2 and inflammatory cytokines by bergapten. This study provides promising insights and prospects for application of bergapten in pain management. In mixture design study markedly enhanced the analgesic study on both
neurogenic and inflammatory phase. XRD and SEM data mixture of drugs are crystalline in nature and non-interacting with one another in solid state mixture.

Title: Inflammation-induced hyper-excitability and spontaneous activity of trigeminal afferent neurons that innervate subcutaneous orofacial regions: Implications in orofacial pain

Authors: *V. VIATCHENKO-KARPINSKI, F. EROL, J. LING, J. GU
Anesthesiol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Tissue inflammation results in hyperalgesia and spontaneous pain. It has been proposed that the inflammatory pain is due to the enhanced excitability and spontaneous activity of afferent neurons that innervate the affected tissues. This hypothesis has been tested in isolated dorsal root ganglion neurons of rats following hind paw inflammation. In the present study, we seek to determine whether inflammation in orofacial regions may induce hyper-excitability and spontaneous activity of trigeminal afferent neurons that innervate subcutaneous orofacial regions. Different from previous studies, the present work applied patch-clamp recordings from neurons situated in whole-mount trigeminal ganglions. Orofacial tissue inflammation was induced by subcutaneous injection of Complete Freund's Adjuvant (CFA) and neurons innervate this region was retrogradely labeled by DiI. All patch-clamp recordings were performed from DiI-labeled small-sized (soma diameter from 19 to 28 μm) trigeminal neurons. At room temperatures of 24ºC and under current-clamp configuration, rheobase for evoking action potentials became significantly reduced from 533.3±52.48 pA (n =15) in neurons of control group to 400±34.18 pA (n=18, $p<0.05$) in neurons of CFA-injected group. Spontaneous action potentials were never seen in both control (n=9) and CFA groups (n=18) at 24 ºC However, a small population of neurons (6 out of 18 cells) in CFA group but none in control group showed spontaneous action potentials at the temperature of 34ºC. Under voltage-clamp recordings, we examined currents evoked by voltage steps and we also examined passive membrane properties. We found that input resistance of cells was significantly increased from 368.3±35.7 mΩ (n = 15) in control group to 668.3±62.4 mΩ (n =18) in CFA group. We also observed significant reduction of outward potassium currents following CFA injections. Taken together, orofacial inflammation results in hyper-excitability and spontaneous activity in trigeminal ganglion neurons, which may be due to the changes of potassium channels in trigeminal ganglion neurons following tissue inflammation.

Title: Anaplerosis in the transition of acute pain to chronic

Authors: *O. K. MELEMEDJIAN, T. LUDMAN
Dept. of Neural & Pain Sci., Univ. of Maryland Dent. Sch., Baltimore, MD

Abstract: Acute pain is an essential physiological response to injury, allowing for a quicker recovery by promoting the protection of damaged tissue. In some cases, this acute, protective pain becomes chronic, a debilitating condition which persists after the initial injury has healed. Furthermore, the molecular bases for how chronic pain is initiated and maintained are not well understood. Since metabolism is inextricably linked to every aspect of cellular function and the shift from acute to chronic pain would require metabolic changes that can maintain the chronic pain state, we hypothesized that metabolic reprogramming leads to the transition of acute pain to chronic. Utilizing the nerve growth factor (NGF)-induced hyperalgesic priming model, we tested this hypothesis. Intraplantar injection of NGF evokes tactile hypersensitivity that resolves within 72 hours. However, the animals that received NGF become primed for developing prolonged hypersensitivity following the intraplantar administration of prostaglandin E2. We determined that pain is associated with a distinct metabolic phenotype where sensory neurons display increased glycolysis and reduced pyruvate oxidation. Moreover, during the primed phase the animals do not display tactile hypersensitivity and the sensory neurons exhibit enhanced anaplerotic flux. Crucially, normalizing pyruvate oxidation alleviated pain while inhibiting anaplerosis prevented the resolution of pain following NGF injection. Hence, these findings provide novel insights into the role of anaplerosis in the development and maintenance of chronic pain.

Col. of Physicians and Surg, New York City, NY; [7]Bluestone Ctr. for Clin. Res., New York Univ. Col. of Dent., New York, NY

Abstract: Oral squamous cell carcinoma (SCC) patients experience severe, mechanically-induced pain. Oral SCC pain is mediated by the action of proteases in the cancer microenvironment, which cleave protease activated receptor 2 (PAR_2), in turn activating downstream signaling in nociceptor neurons. Our research with oral cancer patients show that the poorly characterized protease legumain is increased in oral cancer patient samples. We therefore investigated whether legumain could induce nociception in a mouse using reflexive and operant nociceptive assays. Mice with conditional knock out of PAR_2 in neurons expressing $Na_v1.8$ (PAR_2-$Na_v1.8$) were used to confirm the role of PAR_2 activation by legumain. Legumain 300 ng induced nociception, as measured by paw withdrawal (percent reduction in nociceptive threshold), in wild-type mice but not PAR_2-$Na_v1.8$ mice at day 0 (93.55 ± 11.36 vs 56.8 ± 23.05, n=5), day 1 (88.8 ± 9.07 vs 58.6 ± 25.88, n=5) and day 4 (85.2 ± 10.83 vs 48 ± 17.89, n=5) ($p<0.01$, $p<0.05$, and $p<0.01$, two-way ANOVA multiple comparisons analysis, respectively). To measure nociception in the trigeminal region legumain 300 ng was injected into the facial region and facial withdrawal was measured. Facial withdrawal following legumain injection was increased in wild-type compared to PAR_2-$Na_v1.8$ mice at day 0 (2.8 ± 0.24 vs 1.4 ± 0.11, n=5), day 1 (2.90 ± 0.15 vs 1.87 ± 0.16 n=5) and day 4 (2.78 ± 0.08 vs 1.8 ± 0.43 n=5) following the injections ($p<0.01$, $p<0.01$, and $p<0.01$, two-way ANOVA multiple comparisons analysis, respectively). We measured the effect of legumain on operant nociceptive behavior with the dolognawmeter, an assay and device that measures gnaw time as a proxy for nociception. Injection of legumain 100 ng into the tongue significantly increased gnaw time in wild-type mice compared to PAR_2-$Na_v1.8$ mice (percent change from baseline, 143.70 ± 169.54 vs 2.57 ± 25.35, n=7, $p<0.05$ two-way ANOVA). A similar nociceptive effect was observed after 300 ng legumain injection (150.9 ± 123.5 vs 4.89 ± 53.15, n=7, $p<0.05$, two-way ANOVA). We measured the effect of legumain on dissociated trigeminal neurons from wild-type mice using whole cell patch clamp recording. Legumain 4.4 ng increased half-width of action potentials (vehicle 1.66 ± 0.32 ms, n=3; legumain 5.45 ± 0.07 ms, n=2), and decreased rheobase (vehicle 60 ± 0 pA, n=3; legumain 35 ± 7.07 pA, n=2) in wild-type mice, indicating that legumain induces neuronal hyperexcitability. Our results suggest that legumain causes nociception through inhibition of potassium channels, which leads to increased neuronal excitability. Legumain-induced nociceptive behavior is dependent on cleavage of PAR_2.

Title: Cellular and molecular mechanism of HIV-gp120 induced sensory neuropathy

Authors: *S. YUAN, J. DU, Y. SHI, W. RU, M. CABO JAUME, X. LIU, S.-J. TANG
Neurosci. and Cell Biol., Univ. of Texas Med. Br. at Galveston, Galveston, TX

Abstract: Painful sensory neuropathy in HIV patients is often described pathologically as 'dying-back' degeneration of the peripheral free-endings. However, in an HIV pain mouse model, we observed not only the typical 'dying-back' degeneration of $PGP9.5^+$ nociceptors but also the re-innervations of $GAP43^+$ nerve fibers in the hindpaw glabrous skins. The $GAP43^+$ fibers were largely $CGRP^+$, indicating that they were peptidergic nociceptors. Single fiber recording of the skin-nerve preparations revealed that gp120 induced a decrease of c-fibers and an increase of δ fibers. Blockage of axon growth by local application of Sem3a abolished the gp120-induced innervation of $GAP43^+$ fibers and alleviated mechanical allodynia. We further showed that Wnt5a signaling played a critical role in the gp120-induced innervation and allodynia. In particular, the Wnt-planar cell polarity (PCP) pathway mediated both the innervation and allodynia. Our findings reveals novel cellular and molecular mechanisms of HIV-associated sensory neuropathy.

Title: Epigenetic changes in DRG neurons under hyperglycemia

Authors: *M. CHATTOPADHYAY, V. S. THAKUR
Ctr. of Excellence in Diabetes and Obesity, Texas Tech. Univ. Hlth. Sci. Ctr. - El Paso Campus, El Paso, TX

Abstract: Abstract
The purpose of this study was to explore how histone deacetylases (HDACs) and histone acetyltransferases (HATs) could influence the expression of voltage gated sodium channel 1.7

($Na_v1.7$), epithelial sodium channels (ENaCs) and high mobility group box 1 protein (HMGB1) under hyperglycemic environment. $Na_v1.7$ is a voltage gated sodium channel that is expressed at high levels in the dorsal root ganglion (DRG). Studies have shown that this channel is an important component in nociception. The mammalian epithelial Na^+ channel (ENaC) family are shown to be the components of a mechano-sensory receptor for touch and are expressed in cervical and lumbar DRG. High mobility group box 1 protein (HMGB1) is a cytokine mediator of inflammation and is known to play a key role in pain. Epigenetic mechanisms such as DNA methylation, histone modifications, or non-coding RNA-mediated pathways, could influence chromatin structure and DNA accessibility, leading to turning 'on' or 'off' our genes. The precise epigenetic mechanisms in hyperglycemic neurons are not fully understood. Our preliminary studies suggest that increase in histone deacetylases (HDAC) levels/activity is associated with diabetic neuropathy. The current studies were conducted in immortalized F11 neuronal cell line, a hybrid cell line of rat embryonic dorsal root ganglion neurons and mouse neuroblastoma cells under normoglycemic and hyperglycemic conditions for 24 hours. Our study demonstrates increases in HDAC3, HMGB1, ENaC and $Na_v1.7$ in hyperglycemic F11 cells after 24 hours as compared to cells propagated in normoglycemic conditions. PCAF (P300/CBP-associated factor), a transcriptional coactivator, was down regulated after 24 hours of high glucose insult compared to normal glucose condition. The results from this study demonstrate that epigenetic regulatory changes affected by HDAC3 and PCAF could play an important role in the upregulation of $Na_v1.7$ and ENaC channels under hyperglycemic conditions in F11 neuronal cell lines.

Title: How the activation of macrophages by a novel neuropeptide leads to hypersensitivity of peripheral sensory neurons?

Authors: N. DEMCHENKO, B. ABDELKADER, *K. OKUSE
Imperial Col. London, London, United Kingdom

Abstract: Recent microarray analysis of rat DRG mRNA in different models of neuropathic pain has revealed up-regulation of a common gene, vgf. VGF is 617-amino acid protein, a precursor

for neuropeptides. We have previously found that a VGF-derived peptide, TLQP-21 activates rat bone marrow-derived macrophages, and inoculation of TLQP-21-stimulated macrophages into rat hind paw caused mechanical hypersensitivity. We then successfully identified gC1qR as a receptor for TLQP-21 using affinity chromatography and LC-MS/MS techniques. Application of a neutralizing antibody against gC1qR reduced the number of cells responding to TLQP-21 significantly. Furthermore, application of the gC1qR-neutralizing antibody to rats with partial sciatic nerve ligation resulted in a delayed onset of nerve injury-associated mechanical hypersensitivity. These results indicate that TLQP-21 stimulates macrophages via gC1qR, and the activated macrophages somehow sensitizes sensory neurons. Furthermore, conditioned medium from TLQP-21 activated macrophage culture induced hypersensitivity of DRG neurons. This suggests the potential mechanism of bi-directional crosstalk between sensory neurons and macrophages in eliciting neuropathic pain.

Title: Endometriosis (ENDO) induced vaginal hyperalgesia in the rat: Influence of the endocannabinoid system on sensory and sympathetic cyst innervation

Authors: *S. L. MCALLISTER[1], N. DMITRIEVA[2]
[1]Dept. of Anesthesia, Perioperative and Pain Med., Stanford Univ. Sch. of Med., Stanford, CA; [2]Florida State Univ., Tallahassee, FL

Abstract: Endometriosis is a painful disorder defined by extrauteral endometrial growths (ectopic growths/cysts). How the growths contribute to painful symptoms such as dyspareunia (vaginal hyperalgesia) is poorly understood. A rat model of endometriosis (ENDO) is created by autotransplanting pieces of uterus onto abdominal arteries (Vernon & Wilson, 85). These ectopic growths form vascularized cysts and are associated with painful symptoms including vaginal hyperalgesia similar to women with endometriosis. In both rats and women, the cysts recruit

their own sensory and sympathetic nerve supply (Berkley et al., 04; 05). Previous studies suggest that the cyst sensory and sympathetic innervation contribute to the development and maintenance of endometriosis-associated vaginal hyperalgesia (McAllister et al, 09; 12; Zhang et al., 08). Further, the cyst sensory and sympathetic innervation express cannabinoid receptors (CB1) and CB1 receptor agonists decrease, whereas CB1 receptor antagonist increase, endometriosis-associated hyperalgesia (Dmitrieva et al, 10; McAllister & Sinharoy, 18). These findings, with the knowledge that the endocannabinoid system (ECS) is involved in uterine function and dysfunction and that exogenous cannabinoids have been used for centuries to alleviate dysmenorrhea, suggest that the ECS is involved in both endometriosis and its associated pain (Dmitrieva & Berkley, 02; Bradshaw & Walker, 04; Russo, 02). To test this hypothesis further, ENDO rats were treated with either (1) URB597, a fatty acid amide hydrolase (FAAH) inhibitor to prevent the degradation of the endocannabinoid AEA, a CB1 receptor agonist or (2) Rimonabant (RIM), a CB1 receptor antagonist, or (3) DMSO (vehicle). Treatment was delivered for 4 weeks (i.p.) during the time period that cyst innervation and vaginal hyperalgesia are known to develop in the rat model of endometriosis (McAllister et al., 2012). Then, cyst sensory and sympathetic innervation were analyzed and quantified in the stage of proestrus. Results show that relative to vehicle, URB597 significantly increased cyst sensory and sympathetic innervation whereas, RIM significantly reduced cyst sensory innervation. No significant differences were found between groups relative to cyst number, size, or burden. Together, these findings provide further support for the involvement of the ECS in mechanisms underlying endometriosis and its associated pain, potentially through ECS effects on cyst innervation, thereby providing a novel approach for the development of badly-needed new treatments.

Title: Dorsal root ganglionic field stimulation selectively blocks nociceptive sensory afferents

Authors: *B. PAN[1], D. CHAO[1], Q. H. HOGAN[2]
[1]Anesthesiol., [2]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Dorsal root ganglion field stimulation (GFS) has been shown to be effective in relieving clinical pain associated with nerve injury and neuropathic pain in nerve injury animal models. However, its mechanism has not been explored. We employed *in vivo* single unit

recording from fibers teased from the 4th lumbar dorsal root. Fiber types (Aβ, Aδ, C) were defined by conduction velocity. Action potentials (APs) generated by GFS (20Hz) in C-type units progressively vanished within 20 seconds, whereas block of GFS-induced Aβ activity persisted, while Aδ showed intermediate stability. Activity generated peripherally by electrical stimulation of the sciatic nerve and punctate mechanical stimulation of the receptive field (glabrous skin) was likewise promptly blocked (within 20 s) by GFS, with a preferential blockade of AP trains in C-type units, whereas Aβ and Aδ units were minimally affected. After tibial nerve injury, punctate mechanical stimulus (von Frey) threshold was reduced from 29.4±5.48 gram (n=10) to 2.71±0.45 gram (n=7), which was reversed to 14.29±2.98 gram (n=7) during GFS. These results suggest that GFS produces use-dependent blocking of afferent AP trains, possibly by inducing enhanced filtering of APs at the sensory neuron T-junction.

Title: Linking toll like receptor activation to Fcγ receptor mediated pain

Authors: *M. A. HUNT[1], A. B. FARINOTTI[2], D. S. M. NASCIMENTO[2], K. SANDOR[2], T. L. YAKSH[1], C. I. SVENSSON[2]
[1]Anesthesiol., UC San Diego, LA Jolla, CA; [2]Dept. of Physiol. and Pharmacol., Karolinska Institutet, Stockholm, Sweden

Abstract: Fcγ receptors (FcγRs) expressed on dorsal root ganglia (DRG) sensory neurons have recently been implicated as drivers of pain, in the absence of inflammation, in autoimmune disorders such as rheumatoid arthritis (RA). Neuronal FcγRs, activated by antibodies in immune complex (IC), have been shown to directly induce pain like behaviors in mice. The work presented here aimed to explore whether FcγR expression, in DRGs, changes in response to inflammatory stimuli.
Using qPCR, we found that Fcgr1 and Fcgr2b mRNA levels in L3-L5 DRGs increase in response to both intrathecal (IT) injection of endogenous (disulfide HMGB1) and exogenous (LPS) toll like receptor 4 (TLR4) ligands. In order to determine if this occurs also in the absence of immune cells, and thus, is a general feature of TLR ligands, we used neuronal enriched primary DRG cultures. We observed that stimulation with LPS increased Fcgr mRNA levels, but not TLR2

(LTA), TLR5(FLA-ST), or TLR7 (ssRNA40) agonists. Following IT injection of the TLR agonists, we observed similar results with TLR4 acting as the strongest inducer of Fcgr mRNA (assayed with NanoString's nCounter® PanCancer Immune Profiling Panel). The largest increase in Fcgr mRNA in DRGs was observed between 6 and 24 hours following IT LPS, and peak protein expression was observed around 24 hours. While FcγRI was only detected in macrophages in the DRG, FcγRIIb was observed exclusively in neuronal soma. FcγRIIb was primarily present in small and medium sized DRGs (soma area <700μm2). Following IT LPS, both the number of neurons expressing FcγRIIb and intensity of FcγRIIb immunoreactivity increased. Network analysis on the NanoString data indicated interferon regulatory factor (IRF) and Jak/STAT signaling may act as key intermediates/regulators of TLR4 activation induced Fcgr expression changes. Indeed, we observed that IRF7 is present in small/medium sized DRG neurons, and IRF7 expression significantly increases in response to LPS both in vitro and in vivo.
These studies indicate that transient TLR4 activation increases FcγRIIb expression in neurons. It's currently unknown whether neuronal FcγRIIb is associated with excitatory or inhibitory properties in sensory neurons, thus the change in FcγRIIb expression could either potentiate or reduce the pronociceptive actions of antibodies in IC. It is important to further explore the role of FcγRIIb in nociception as this could be clinically relevant to pain in autoimmune disorders such as RA, where patients are often non-responsive to analgesic therapies.

Title: Sigma-1 receptor chaperones substance P in the mouse dorsal root ganglions

Authors: *H.-E. WU, T.-P. SU
IRP/NIDA/NIH, Baltimore, MD

Abstract: Synthesized at the somata of sensory neurons in the dorsal root ganglion (DRG), the excitatory neurotransmitter substance P (SP) is transported to central and peripheral sensory nerve terminals, where SP is released upon noxious stimulus to elicit pain signaling/response. The ER chaperone protein sigma-1 receptor (Sig-1R) has been known to play a role in modulating the neuropathic pain and also known to enriched at the DRGs. The study examined the relation between SP and Sig-1R at the DRG within the context of the neuropathic pain. It has been shown that the knockout of the SP encoded tac1 gene potentiates the morphine

antinociception. This in turn is in alignment with the notion that Sig-1R antagonism can increase opioid analgesia. Therefore, we test the hypothesis that the Sig-1R may chaperone the SP, leading to the maintenance of stable SP level that provides excitatory signaling in the DRGs. The SP's tissue expression level, its protein amount, and the mRNA level were compared in DRGs obtained from wild type and Sig-1R knockout mice. The DRG neurons were stratified into different neuronal subpopulations by their function and size in the immunohistochemical experiments. Immunohistochemical staining in Sig-1R knockout DRGs, when compared to those seen from wild type samples, showed a decreased SP expression. Concomitantly, immunoblotting of SP also demonstrates a trend of decreased expression in the Sig-1R knockout mouse DRGs. Intriguingly, the SP mRNA level was increased in the Sig-1R knockout mouse DRG, when compared to those seen in wild type mouse DRGs. Taken together, our results suggest that the endogenous Sig-1R chaperones SP and leads to an increased level of SP. In contrast, in Sig-1R knockout DRGs, the decreased level of SP may call for a transcriptional increase of SP, thus leading to an increase of its mRNA. Our results suggest a key role of Sig-1R on the stability of SP in the DRG and implicate thus the Sig-1R as a target for treating neuropathic pain through the regulation of SP.

Abstract: Chronic pain affects more than 100 million US adults according to the IOM report (2011) on Chronic Pain in America. Our understanding of the development of persistent pain and the specific environmental and genetic factors thought to impact susceptibility to chronic pain is lacking. Acatalytic carbonic anhydrase-8 (CA8, protein sign) is an allosteric inhibitor of inositol trisphosphate receptor-1 (ITPR1), which regulates neuronal intracellular calcium release. In our

previous investigation, we demonstrated that murine *Car8* (murine gene symbol) is involved in persistent pain regulation via the ITPR1-intracellular calcium signaling pathway. We showed that murine Car8 overexpression in the dorsal root ganglion (DRG) by injection of the sciatic nerve downregulated pITPR1, inhibited ATP-stimulated intracellular free calcium release, and abolished mechanical allodynia and thermal hyperalgesia. In this study, we assess the human CA8 signaling pathway to show evidence that overexpression of the human wild-type carbonic anhydrase 8 ($CA8^{WT}$) in NBL and HEK293 cultures, but not the reported *CA8* S100P loss-of-function mutation ($CA8^{MT}$), inhibits nerve growth factor (NGF)-induced phosphorylation of ITPR1, TrkA (NGF high-affinity receptor), and ITPR1-mediated cytoplasmic free calcium release *in vitro*. In addition, we show that gene transfer using AAV8-V5-$CA8^{WT}$ viral particles via sciatic nerve injection demonstrates retrograde transport to dorsal root ganglia (DRG) producing prolonged $CA8^{WT}$ expression, inhibition of ITPR1 and TrkA activation by phosphorylation and profound analgesia and anti-hyperalgesia in male C57BL/6J mice. AAV8-V5-$CA8^{WT}$-mediated overexpression prevented and treated allodynia and hyperalgesia associated with chronic neuropathic pain produced by the spinal nerve ligation (SNL) model. These AAV8-V5-CA8 data provide a proof-of-concept for precision medicine through targeted gene therapy of NGF-responsive somatosensory neurons as a long-acting local analgesic able to prevent and treat chronic neuropathic pain through regulating TrkA signaling, ITPR1 activation, and intracellular free calcium release by ITPR1.

Title: Triadic forebrain structures that directly control the auditory midbrain of echolocating bats

Authors: *T. ITO[1], R. YAMAMOTO[2], T. FURUYAMA[3], K. HASE[3], K. I. KOBAYASHI[3], S. HIRYU[3]

Abstract: Echolocation bats change spectrotemporal parameters of sonar pulses during navigation. Furthermore, echoes may convey emotional values which interfere or modify the plan of pathways. Since the echoes arrive several milliseconds after the emission of pulses, the inferior colliculus (IC), the midbrain auditory nucleus that analyzes the echoes, must be quickly adjusted for each pulse. Here, we demonstrate that three forebrain structures, namely infralimbic cortex (IL), magnocellular part of the basal nucleus of the amygdala (Bmg), and auditory cortex (AC), send direct descending projection to the IC by using a retrograde tract tracing method. All three structures projected to bilateral IC although the ipsilateral projection was dominant. Comparisons of pattern of retrogradely labeled cells across animals suggested that ipsilateral AC projection to the IC is tonotopically organized. Projections from other forebrain structures did not show clear tonotopicity. Together with evidence of previous studies, these results demonstrated the triadic descending projections to the IC which make loops between forebrain and IC. As IL, Bmg, and AC relate to navigation, emotional value, and spatial coding, respectively, the loops may quickly optimize active sensation during navigation.

Title: Elevated cochlear adenosine-mediated metabolic disruption causes hearing loss

Authors: *J. M. MANALO[1], H. LIU[2], M. ADEBIYI[2], D. DING[3], T. NEMKOV[4], A. D'ALESSANDRO[4], R. SALVI[3], F. PEREIRA[5], Y. XIA[2]

Genet., Univ. of Colorado Denver–Anschutz Med. Campus, Aurora, CO; [5]Huffington Ctr. on Aging, Baylor Col. of Med., Houston, TX

Abstract: Over 360 million people in the world have been diagnosed with disabling hearing loss (HL). Current treatments for HL are limited to hearing aids and cochlear implants, with no FDA-drugs available. Patients who lack adenosine deaminase (*Ada*), the enzyme that degrades adenosine, have high levels of adenosine that yield severe health problems, including HL.

Previous studies have shown noise-exposed mice have elevated cochlear adenosine, but the pathogenic mechanisms behind these phenomena remain elusive. Our lab has found a HL phenotype in *Ada*-deficient mice (*Ada*$^{-/-}$) that parallels *Ada*-deficient humans. We also identified an accumulation of metabolites paired with elevated cochlear adenosine, acyl-carnitines, succinate, and glutamate, using unbiased high-throughput metabolomics profiling in *Ada*$^{-/-}$ mice. Elevated levels of succinate, acyl-carnitines, and glutamate imply a perturbation of the TCA cycle, beta-oxidation, and glutamate uptake, respectively. Additionally, out of all the four adenosine receptors, adenosine a_2b (ADORA2B) was found to have the highest genetic and protein expression in *Ada*$^{-/-}$ mice. On a cellular level, there is an increase in hair and neuronal cell loss that is commonly found in other models of sensorineural HL in mice, and in humans with age-related HL. In addition, lowering adenosine levels in the *Ada*$^{-/-}$ mice attenuated hearing deficiencies, decreased the aforementioned levels of metabolites, and reduced hair and neuronal cell losses. With these findings, we hypothesize that elevated adenosine-mediated hearing loss is dependent on ADORA2B signaling that leads to mitochondrial damage and excitotoxicity. Identifying the pathological signaling pathway induced by elevated cochlear adenosine will expand treatment options for millions of individuals suffering from HL.

Title: Both lemniscal and non-lemniscal pathways define auditory responses in the mouse orbitofrontal cortex (OFC)

Authors: *H. K. SRIVASTAVA[1], S. BANDYOPADHYAY[2]
[1]Advanced Technol. Develop. Ctr., [2]Dept. of E & ECE, Indian Inst. of Technol. Kharagpur, Kharagpur, India

Abstract: OFC, a part of the prefrontal cortex (PFC), is involved in assigning value to a stimulus depending upon the behavioral or contextual demands in a dynamic environment. Our studies show presence of auditory responses in the OFC of an anesthetized and awake mouse to pure tones as well as to low probability oddball sounds in a sequence of repeating sounds showing

pure deviance detection. The sources of the auditory inputs to and the mechanism of deviance detection in the OFC are unclear. We show that both of the two parallel auditory pathways, lemniscal and non-lemniscal, operating in tandem with different response characteristics to auditory stimulation participate in creating responses and deviance detection in the OFC. The differential contribution of both lemniscal and non-lemniscal pathways to the auditory response profile of OFC neurons are presented. Irreversible blocking (with muscimol and baclofen) of the lemniscal ventral division of the medial geniculate body, (MGBv) completely abolishes responses in the OFC. On the contrary blocking the non-lemniscal medial division (MGBm) and also subsequently blocking only the basolateral amygdala (BLA; receiving projections from MGBm and projecting to OFC) cause auditory responses in the OFC to become persistent, a usual response pattern known to be involved in working memory in the PFC. These results suggest that an MGBm driven inhibitory input from the BLA controls the temporal response profile of OFC auditory responses. Further, blocking primary (lemniscal) auditory cortex (A1, ACX) has no significant effect on OFC auditory responses, whereas blocking secondary ACX (thought to be non-lemniscal) areas abolishes auditory responses in the OFC. We show that non-primary ACX regions receiving MGBv projections (and hence lemniscal) and also projecting to the OFC contribute to the main auditory responses in the OFC, which are temporally sharpened to provide deviance detection through the non-lemniscal pathway. Together these findings suggest a critical interplay of lemniscal and non-lemniscal auditory pathways underlying the mechanism of creation and shaping of auditory sensory responses in the OFC and hence subsequently should be involved in value assignment to auditory stimuli in the OFC.

Title: Plasticity in the ventral cochlear nucleus in response to age-related hearing loss

Authors: *K. M. SCHRODE[1], H. JAVAID[2], J. ENGEL[2], A. M. LAUER[2]
[1]Baltimore, MD; [2]Sch. of Medicine- Otolaryngology, Johns Hopkins Hosp., Baltimore, MD

Abstract: The central auditory system shows a remarkable ability to compensate in response to insults to the inner ear, such as exposure to noise or ototoxic drugs. However, it is not known whether the auditory system reacts similarly to age-related hearing loss. Previously, we have

shown that young adult mice exposed to damaging noise exhibit sound-evoked hyperactivity in bushy-cell driven pathways, indicative of an increase in central gain. Furthermore, immunolabeling indicated that this hyperactivity was not associated with much change in excitatory terminals, but rather with a widespread loss of inhibitory terminals in the ventral cochlear nucleus (VCN). In the present study, we investigate whether similar changes occur in the aging auditory system. We allowed adult CBA/CaJ mice to age to at least 20 months. We measured auditory brainstem responses (ABRs) to assess auditory sensitivity and processing. To investigate synaptic plasticity in the brainstem, we labeled excitatory and inhibitory terminals in the VCN. We found that ABR thresholds were mildly increased at about 20 months compared to young animals (~10 week old), but that thresholds increased quickly at older ages. Similarly, the amplitude of the ABR was slightly decreased at 20 months, but decreased rapidly as a function of age thereafter. While inhibitory labeling in the VCN was approximately halved in animals over 20 months compared to young animals, the ABR did not provide strong evidence of hyperactivity. This dissociation may be explained by a parallel loss of excitatory labeling in animals over 20 months of age. Loss of synapses was confirmed with transmission electron microscopy. We also generally find that many of these changes in the auditory system are accelerated in males compared to females. The data in older animals suggest that aging may not initiate the same compensatory mechanisms as acute trauma to the auditory system.

Title: Descending projections from the auditory cortex and inferior colliculus contact GABAergic cells in the ventral nucleus of the trapezoid body

Authors: *N. L. BEEBE, W. A. NOFTZ, B. R. SCHOFIELD
Anat. and Neurobio., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: The ventral nucleus of the trapezoid body (VNTB), an auditory nucleus in the superior olivary complex (SOC), is a major target of descending projections from the auditory cortex (AC) and inferior colliculus (IC). Previous investigators reported that these descending projections contact cholinergic olivocochlear cells in the VNTB (Mulders and Robertson, 2000; Suthakar and Ryugo, 2017). The VNTB also contains GABAergic cells, which can project to the cochlear nuclei or IC. Here, we asked whether GABAergic cells of the VNTB are contacted by

descending projections from the AC and the IC.
We injected traditional tracers (e.g. FluoroRuby) or adeno-associated viruses carrying fluorescent protein genes (e.g., AAV2-hSyn1-EYFP) into the AC and/or IC of pigmented guinea pigs and Long-Evans rats. After 5-28 days, we perfused the animals and stained brain sections for glutamic acid decarboxylase (GAD) to label GABAergic cells.
Injections of anterograde tracer into the IC labeled axons and boutons in the thalamus, nuclei of the lateral lemniscus, SOC, and cochlear nucleus. In the VNTB, we saw many putative contacts onto GAD+ cells in both guinea pigs and rats. Injections of anterograde tracer into the AC labeled axons and terminals in the auditory thalamus, IC, and SOC. In the VNTB, putative contacts were present on GABAergic VNTB cells in both guinea pigs and rats, although these contacts were fewer than those observed after IC tracer injections. In animals with injections of different tracers into AC and IC, we observed convergence of AC and IC inputs onto single GABAergic cells of the ipsilateral VNTB.
These results show that descending projections from the AC and the IC contact VNTB GABAergic cells. Both AC and IC projections arise from excitatory cells, so their targeting of VNTB GABAergic cells could provide for top-down inhibition of nuclei innervated by the VNTB. Moreover, the convergence of AC and IC projections onto individual VNTB cells suggests integration of these descending inputs. Thus, the VNTB is well-situated to act as an inhibitory hub of the descending auditory system. It is possible that activation of these descending pathways contributes to habituation or attentional mechanisms to suppress or facilitate processing of auditory stimuli based on salience.

Abstract: Various types of information are associated with auditory information in auditory perception. However, the neuroanatomical mechanisms for such association are unclear. We challenged to reveal neuroanatomical mechanisms for associating emotional meaning with auditory information. We visualized mesoscopic- and synaptic-scale connective patterns between the amygdala and auditory cortex in mice by neural tracer injection. The mouse auditory cortex, which can be functionally identified using flavoprotein fluorescence imaging, has at least four tonotopic regions including the secondary auditory field (A2). Injection of cholera toxin subunit b (CTB) revealed that A2 had strong reciprocal connections with the lateral amygdala (La). The primary auditory cortex (A1) had only weak connections with La, and other tonotopic fields had no connections with the amygdala. Further investigation using a confocal microscope revealed that the feedback loops running through A2-La-A2 were directly connected by axosomatic excitatory synapses at La neurons: numerous glutamatergic axon terminals derived from A2 make synapses directly with somas of excitatory La neurons that project back to A2. These data suggest that the feedback loops relayed in La must be inevitably activated by A2 activities, and signals come back to A2 rapidly. Moreover, similar rapid feedback loops were projected from A2 to various other subcortical structures and relayed back to A2. Together, these findings suggest that the precise feedback loops which are relayed in subcortical structures including the amygdala operate as functional units, and the current study revealed the presence of potential anatomical platform, which associates non-auditory activities with auditory information, with a hub in A2.

Title: Control of firing of dorsal cochlear nucleus cartwheel neurons by ATP-sensitive K^+ channels

Authors: *R. M. LEAO[1], P. S. STRAZZA, Jr.[2]
[1]Fisiologia, [2]Physiol., Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: Glycinergic cartwheel neurons from the dorsal cochlear nucleus (DCN) provide a strong inhibitory force on the glutamatergic DCN fusiform neuron. Most cartwheel neurons present spontaneous action potential firing contributing to most of inhibitory post-synaptic currents on fusiform neurons. Several evidences suggest that a decrease in the inhibitory drive in the DCN could be related to the increased in the firing of fusiform neurons observed in animal models of tinnitus. We performed whole-cell patch-clamp recordings of DCN cartwheel neurons of young rats (p18-22) in order to investigate the ion channels influencing spontaneous firing of cartwheel neurons, and consequently the tonic inhibition on fusiform neurons. Most of cartwheel neurons (>80%) fired action potentials spontaneously at rest (active) while the other present a stable resting membrane potential (quiet). The spontaneous firing was not abolished by perfusion of glutamatergic or glycinergic synaptic blockers. Active neurons had bigger membrane input resistances and longer membrane time constants. Application of barium chloride (0.1 mM) a blocker of inwardly rectifying potassium channels (K_{ir}), which controls spontaneous firing of fusiform neurons, depolarized the membrane of both active and quiet cartwheel neurons, and induced firing of quiet neurons. Interestingly, the current blocked by barium had a similar conductance in the non-rectifying part, but in quiet neurons we observed a smaller rectification. ATP-sensitive K^+ channels (K_{ATP}) are formed by the K_{ir6} subunits and have small rectification. Application of the K_{ATP} blocker tolbutamide (0.2 mM) depolarized quiet neurons, leading to spontaneous firing, and inhibited a non-rectifying potassium conductance. In active neurons tolbutamide did not have any effect on both firing and membrane currents. On the other hand, the K_{ATP} activator diazoxide hyperpolarized the membrane potential of both quiet and active neurons, and silenced active neurons. Thus, K_{ATP} channels have an active role in controlling the spontaneous firing of DCN cartwheel neurons. Because K_{ATP} channels couple membrane potential with the energetic status of the cell and continuous action potential firing is energetically demanding, these channels can be an important mechanism to decrease tonic firing in cartwheel neurons in response to decreased ATP levels during situations of high intensity firing.

Title: Inhibition differentially affects auditory evoked P1-N1 response generation in a morphologically realistic model of auditory cortex

Authors: *D. BEEMAN[1], P. KUDELA[2], D. BOATMAN-REICH[3], W. S. ANDERSON[2]
[1]Univ. of Colorado Boulder, Boulder, CO; [2]Neurosurg., Johns Hopkins Univ., Baltimore, MD; [3]Neurol. and Otolaryngology, Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The ACnet2 GENESIS model of primary auditory cortex (AI) has been used to reproduce and understand adaptation, as measured by cortical surface electrodes in an 'oddball paradigm' experiment. Both the vertex-positive P1 peak in the evoked potential (EP) and the vertex-negative N1 peak were found to arise from excitatory currents in the pyramidal cells (PCs). This study uses the model to understand how basket cell (BC) inhibition of PCs affects the shape of the P1 and N1 peaks in the EP. Bruyns-Halett et al. (Neuroimage 2017) recorded EPs from rat barrel cortex and applied a GABA antagonist to vary the amount of inhibition. Panel (A) of the figure shows that decreasing inhibition (dark red) widens N1, but has no effect on P1 or the initial portion of N1. For the AI layer 2/3 model, tone pulses were applied to PC basal dendrites, as if they were coming from layer 4, as in the two-layer version of the model. Inhibition from the BCs was applied to a proximal apical dendrite compartment of the PCs. EPs were calculated from a trial-averaged sequence of short 1000 Hz tones. Panel (B) shows that decreasing the maximal inhibitory conductance widens the latter part of N1, with minimal effect on P1. Features of the EP are explained by the orientation of electric dipoles that are formed when synaptic currents enter or leave the cell at one point and compensating leakage and capacitive return currents flow through other dendrite sections. A multi-compartmental PC model that accurately reproduces these spatially separated currents is essential for computing and understanding effects of inhibition on evoked responses. Here, BC inhibition produces delayed outward inhibitory currents and return currents in the lower dendrites, resulting in a dipole that is oriented oppositely to that produced by PC-PC excitation, reducing the late contribution to N1.

Title: Voltage-sensitive potassium currents contribute to sound processing during prepulse inhibition in the goldfish startle circuit

Authors: *D. R. BRONSON[1], T. PREUSS[2]
[1]The Grad. Center, CUNY, New York, NY; [2]Psychology, City Univ. of New York, Hunter Col., New York, NY

Abstract: In fish, a pair of reticulospinal decision neurons, the Mauthner cells (M-cells), initiate startle in response to auditory stimuli. The experimental accessibility of the M-cells for *in vivo* intracellular recordings makes them ideally suited to study mechanism/s of prepulse inhibition (PPI). M-cell PPI is partly mediated by a voltage-dependent conductance that has been indirectly linked to a potassium current. However, the latter notion has yet to be tested. Potential candidates include voltage-gated Kv1.1 and inward rectifying potassium (GIRK) channels. Thus, we used here brainstem applications of a specific antagonist for Kv.1.1 (DTX-K 10 nM, n=10) or a general GIRK channels blocker (Tertiapin-Q, 2 µM, n=5) and assessed their effect on baseline M-cell membrane properties, auditory evoked post synaptic potentials (PSPs) and PPI. DTX-K and Tertiapin-Q decreased M-cell firing threshold in current ramp experiments by 64.2 ± 12.3 nA ($p < .01$, paired t-test, n=9) and 59.3 ± 7.9 nA ($p < .01$, paired t-test, n=5), respectively, with no effect on RMP. The antidromic action potential (AP) exhibited differential effects to the antagonists. Specifically, blocking GIRK increased AP magnitude (4.5 mV ± 1.7, paired t-test, $p < .05$, n=5), whereas blocking Kv1.1 increased AP width (0.13 ± .03 ms, paired t-test, $p < .05$, n=9). Both antagonists also modulated the waveform of sound-evoked PSPs, as indicated by a lingering membrane depolarization that persisted up to 150 ms. This was quantified by an increase in the membrane decay constant (τ) (increase in τ DTX-K = +17.7 ± 4.7 ms, $p < 0.01$, n=9, Tertiapin-Q = +31.6 ± 5.7 ms, $p < 0.01$, n=5, paired t-tests). The lingering depolarization added to the depolarization of secondary auditory PSPs in a prepulse/pulse stimulus paradigm, particularly at shorter interstimulus intervals (membrane depolarization increase at 50 ms, DTX-K = +0.49 ± 0.2 mV, $p<0.05$, n=9, Tertiapin-Q = +0.42 ± 0.1 mV, $p<0.05$, n=5, paired t-tests). Consequently, functional PPI, as quantified by the reduction in PSP height induced by the preceding prepulse, was reduced (DTX-K, $F(1,105) = 4.7$, $p<0.05$, n=8, Tertiapin-Q, $F(1,60) = 9.251$, $p < .05$, n=5, two-way repeated measures ANOVAs). Our results suggest that both Kv1.1

and GIRK conductances play a partially overlapping role in sensory processing, which indirectly affect functional aspects of PPI.

Title: Auditory representation in cortex and striatum during audiomotor learning

Authors: *K. A. MARTIN[1,2,3], R. C. FROEMKE[2,3,4]
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Skirball Inst. of Biomolecular Med., [3]Neurosci. Inst., New York Univ. Sch. of Med., New York, NY; [4]HHMI Fac. Scholar, Chevy Chase, MD

Abstract: Animals respond to sensory stimuli with appropriate motor actions. Some of these actions are innate, while others are learned. Models of sensorimotor learning argue that to learn the association between a sensory input and a motor output, the sensory stimulus must be reliably represented in the brain. Previous work in the auditory system has focused on how learning influences the representation of behaviorally-relevant auditory stimuli in auditory cortex (Polley, et al., 2006; Reed, et al., 2011; Takahashi et al., 2010). However, it is unclear how this information is represented in downstream areas and influences behavioral performance. The auditory striatum, a posterior area of striatum, receives input from the auditory system (via auditory cortex) and is required for audiomotor association tasks (Znamenskiy and Zador, 2013; Guo, et al., 2018). Are sensory representations affected by learning similarly or separately in the auditory striatum and cortex?
To address these questions, we developed a two-alternative forced-choice head-fixed audiomotor association task for mice. Animals report tones as either target or foil tones by licking right or left water ports, respectively, after a delay. If the animal is correct, it receives a small water reward from the same port. Animals reached criterion (80% correct) in this task after 9-21 days. In trained animals, we injected muscimol in either auditory cortex or auditory striatum bilaterally. Muscimol infusions in either area substantially reduced behavioral performance. Using *in vivo* whole-cell recordings, we measured the representation of auditory stimuli before and after learning in auditory striatum. The target tone was overrepresented in trained animals, but not in naive animals. This could arise from increased excitatory input from cortex, increased intrinsic excitability, or decreased inhibition within striatum. Based on previous literature,

dopamine can impact corticostriatal plasticity (Reynolds, et al., 2001), intrinsic excitability, and/pr inhibition within striatum (Dobbs, et al., 2016). Additionally, auditory striatum receives strong innervation from dopaminergic areas (the ventral tegmental area and substantia nigra pars compacta). However, dopamine antagonists in both either auditory cortex or auditory striatum in trained animals did not affect performance. This might suggest that if dopamine is playing a role, it may be during learning. Taken together, these results indicate that auditory representation in auditory striatum is important for audiomotor learning and imply that dopamine receptor signaling is not required to maintain these learned representations.

Title: Contributions of feedforward inhibition to feature selectivity and critical period plasticity in primary auditory cortex

Authors: *S. MASRI[1], S. BAO[2]
[2]Physiol., [1]Univ. of Arizona, Tucson, AZ

Abstract: Thalamocortical projections conveying sensory stimulus information activate pyramidal neurons in Layer 4 of cortex while also recruiting strong bursts of disynaptic feedforward inhibition from Parvalbumin-expressing interneurons (PV cells) which attenuate the magnitude of the sensory response. This canonical microcircuit provides the first cortical transformation of sensory information. Studies using optogenetic stimulation to activate fast spiking PV cells have failed to achieve a consensus with regards to their influence on tuning properties and feature selectivity in sensory cortex. Conversely, similar studies performed on slow spiking Somatostatin-expressing interneurons have returned generally consistent results. Hypothesizing that these inconsistencies may arise from time dependent dynamics of fast spiking interneurons and inconsistent experimental stimulation protocols, we investigated the impact of optogenetic activation of PV cells on acoustic response propterties in Primary Auditory Cortex in a time dependent fashion. We show that activating PV cells causes significant suppression of stimulus evoked activity in putative pyramidal neurons and an increase in feature selectivity, but that these effects are time dependent.
Critical period plasticity is functionally distinct from adult cortical plasticity, but models of its neural underpinnings are still being developed. While PV cells are playing an increasingly important role in that story, their contributions to the process have not been demonstrated. We used these experiments to explore the neural basis of critical period plasticity by exposing mouse

pups to pure tone pips of a single frequency, producing distortions in the normal development of tonotopy in A1. We show that changes in feature slectivity occur in an idiosyncratic fashion relative to naive mouse pups.
Overall these experiments have new implications for the effects of feedforward inhibition on sensory processing and provide support for a new methodology when using optogenetics to study fast spiking neurons.

Title: Layer 6b modulation of sensory processing in the adult mouse auditory cortex

Authors: R. J. MORRILL[1], *A. R. HASENSTAUB[2]
[1]Univ. of California, San Francisco, San Francisco, CA; [2]Otolaryngology / Ctr. for Integrative Neurosci., UCSF, San Francisco, CA

Abstract: At the base of the cortical sheet lies a band of cells that is well-known for its crucial role in development as a transient relay for thalamic input. While many of these cells die off early in development, a fraction persists into adulthood, becoming the layer 6b (L6b) sublamina. In the adult animal, layer 6b cells receive input from thalamic and cortical sources, send processes all the way to layer 1, and are highly responsive to neurotransmitters of arousal. As such, these cells are well-situated to sculpt activity in the cortical column. To investigate the role of L6b in sensory processing, we made use of the Ctgf-T2A-dgCre mouse line, in which Cre recombinase is expressed in the subset of Ctgf+ L6b cells. Ctgf is thought to define a large class of morphologically heterogeneous excitatory L6b cells. To achieve optogenetic control over L6b, we crossed this line with reporter mice expressing Cre-dependent opsins. We then performed acute extracellular recordings in awake mouse auditory cortex using multichannel probes to span many cortical layers. From these recordings, we identify L6b based on responsiveness to light stimulation, and show that this sublamina exhibits atypical and often reduced responses to tones

when compared with more superficial responses. We further show that light activation of Ctgf+ cells elicits both increases and decreases in firing rate at varying cortical depths, suggesting that these cells make multiple types of functional connections within the cortex. L6b light activation also affects responses to sounds, both enhancing and suppressing tone responsiveness relative to the light-off condition. We interpret these results in the context of a circuit model in which L6b cells sculpt sensory responsiveness through both excitation and inhibition, and speculate about their influence on sensory processing and their behavioral relevance.

Title: The cerebellar vermis robustly modulates neural activity in the inferior colliculus

Authors: *R. J. SIMA[1], T. KODAMA[2], H. FUJITA[2], S. DU LAC[1,2,3]
[1]Neurosci., [2]Otolaryngology-HNS, [3]Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: Accumulating lines of evidence from anatomical, functional, and imaging studies indicate that the cerebellum is involved in sensory processing, including in the auditory domain. However, how the cerebellum affects auditory processing is understudied. To investigate how the cerebellum influences the auditory system, we performed extracellular recordings from neurons in the inferior colliculus (IC) of awake, moving, head-fixed mice while optogenetically stimulating the contralateral cerebellar vermis. We discovered that 20 ms photoinhibition of Purkinje cells robustly excited approximately half of all recorded IC units with response latencies of ~45ms (Type 1) and ~92ms (Type 2) following stimulation onset. A smaller subset of IC neurons (~8%) was inhibited. Type 1 units were found preferentially in the dorsal cortex of IC, though were also present in the IC external cortex and central nucleus. Type 2 units were more abundant in IC external cortex and central nucleus. These results indicate that the cerebellar vermis is functionally connected to the IC, potentially through polysynaptic circuits. The functional significance of cerebellar influence on IC remains to be determined, but this circuit could serve as a channel for the auditory system to integrate sensorimotor and internal state information processed in the cerebellar vermis.

Title: Central auditory pathway corticotropin releasing factor signaling elements and their correlation to known regional and cellular markers in central auditory target regions

Authors: *K. T. YEE[1], S. G. COLLINS[3], J. S. GILBERT[2], D. E. VETTER[2]
[1]Neurobio. & Anatom. Sci., [2]Neurobio. and Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [3]Neurobio. and Anatom. Sci., Murrah High Sch. / Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: We have previously identified corticotropin releasing factor (CRF) and CRF receptor (CRFR)1 and CRFR2 in the cochlear epithelium (Graham et al 2010), and CRF in spiral ganglion neurons which innervate the cochlear nucleus (CN). Using two reporter mice, tdTomato CRF-Cre and BAC Tg CRFR1-GFP (Justice et al, 2008), we visualized CRF and CRFR1 expression patterns, respectively, over the dynamic postnatal maturational process in the central auditory pathway. There is broad CRFR1 expression in the developing CN that is down-regulated to the mature expression pattern, suggesting a transitory role for CRFR1 signaling during early dynamic synapse formation within various CN cell types. In the inferior colliculus (IC), CRFR1 is detected throughout the main subdivisions. In the medial geniculate nucleus (MGN), CRFR1 fibers exist as a meshwork and CRFR1 cell bodies are located ventral and medial to the ventral MGN (vMGN).
CRF is also expressed across the central auditory pathway. In the CN, CRF is expressed in neurons with varied morphologies and in distinct regions within the ventral and dorsal subdomains. In the IC, CRF expression consists of a small number of neurons in each of the major subdivisions, with a heavy axonal terminal field in a sub-region of the central nucleus of the inferior colliculus (CIC). In the MGN, CRF terminals exist, but are sparse centrally, and many positive neurons are positioned ventral and medial to the vMGN.
To correlate CRF expression with known regional demarcations and cellular populations, we double-labeled with cytochrome oxidase (CO) in IC and MGN and with the calcium-binding proteins, calbindin (CB), calretinin (CR) and parvalbumin (PV) from the cochlear nucleus through auditory cortex. The heavy field of CRF-positive terminals in CIC lies within an area of strong CO staining. CRF-positive terminals are also evident in the CO-positive domain in the vMGN while CRF-positive cells are positioned outside of the heavy CO domain of vMGN.

Further, few CRF-positive neurons are double labeled with CB, CR, or PV in the CN and IC. Relative to other auditory regions, the MGN shows the most CRF- calcium-binding protein double labeled cells. Within auditory cortex, a subset of CRF-positive neurons show double labeling with CR. CRF-positive terminals, however, appose soma that are positive or negative for CB, CR or PV.
In summary, CRF signaling across the central auditory pathway does not share common rules for correlation to CO, CB, CR, or PV, suggesting that CRF elements may 1) represent a unique population of neurons and 2) perform unique functions along the central auditory pathway.

Title: Modulation of auditory responses by visual inputs in the mouse auditory cortex (ACX)

Authors: *S. SHARMA[1], H. K. SRIVASTAVA[1], S. BANDYOPADHYAY[2]
[1]Advanced Technol. Develop. Ctr., [2]Dept. of E and ECE, Indian Inst. of Technol. Kharagpur, Kharagpur, India

Abstract: Multisensory (MS) integration allows seamless assimilation of information from different sensory modalities in order to better perceive the environment. Cross-modal interaction of incoming sensory information is important since each sensory system is capable of encoding the same stimulus in uniquely advantageous way. For example, the auditory system has better temporal resolution whereas the visual system has better spatial resolution and each may influence the other depending on context or requirement. Circuit and synapse based mechanism of visual input based modulation of responses in the ACX is poorly understood. We first elucidate the local broad cortical circuitry that could be involved in the above through neuroanatomical experiments. Retrograde tracer injections in the ACX show labelled cell bodies in both primary and secondary visual cortices indicating a direct interaction between the two sensory systems at the earliest stages of the sensory cortical hierarchy. Previous studies show the presence of single neuron responses to visual stimulus in infragranular layers but rare in supragranular layers of ACX. Using two-photon calcium imaging with GCaMP6s in awake

mouse we probed layer 2/3 (supragranular) of ACX with auditory, visual and audio-visual stimuli. In addition to responses to auditory stimulation (tone based tuning and broadband noise), we found robust Ca^{2+} based responses to visual as well as MS stimulus in layer 2/3 of auditory cortex in subpopulations of both excitatory (EXN) as well as inhibitory (IN) neurons. Most of the neurons show differential responses to multimodal stimulus as compared to their unimodal counterparts with linear as well as non-linear additive and suppressive effects. Noise correlations between pairs of neurons, a measure of functional connectivity, are significantly lower for the multimodal stimulus compared to that of unimodal stimuli suggesting better fidelity in population coding of multimodal stimuli as compared to that of unimodal stimuli. This decrease in noise correlations is strongly evident in similarly tuned EXN-EXN connections where as EXN-IN and IN-IN connections are less affected. The results have strong implications in coding of sounds in the mouse early auditory cortical regions.

Title: An atlas of the subcortical auditory system from post mortem human MRI

Authors: *K. R. SITEK[1], E. CALABRESE[2], G. A. JOHNSON[3], S. S. GHOSH[1]
[1]MIT, Cambridge, MA; [3]Radiology, [2]Duke Univ., Durham, NC

Abstract: Investigating the subcortical auditory system is challenging, particularly in humans, due to the technical difficulty of in vivo MR imaging: the small brainstem auditory nuclei require high spatial resolution, but decreasing voxel sizes reduces the signal-to-noise ratio, making the nuclei difficult to identify. A priori information about the location of auditory structures can focus in vivo investigations in the appropriate anatomical locations and reduce the number of voxels being analyzed, improving the statistics of detecting meaningful signal from auditory nuclei. In this study, we created an atlas of subcortical auditory structures based on high resolution, high quality anatomical MRI of a post mortem human brainstem and thalamus. The specimen was imaged at the Duke Center for In Vivo Microscopy in a 7-Tesla small-bore MRI scanner at 50 μm isotropic voxel sizes. This resolution allows for identification and segmentation of substructures along the entire subcortical auditory pathway, from the root of the cochlear nerve and the dorsal and ventral cochlear nuclei, through the superior olivary complex and

inferior colliculus, to subdivisions of the medial geniculate of the thalamus. By registering the atlas to a common reference space, we can apply the atlas to standard in vivo human MRI. In addition, registering the atlas to diffusion-weighted images (200 μm) from the same post mortem specimen allows us to constrain tractography to streamlines between specific auditory subnuclei, yielding the highest quality, highest resolution connectivity map of the subcortical auditory pathway. Auditory pathway streamlines were still visible after downsampling the diffusion images to resolutions feasible in vivo (1 mm), suggesting in vivo identification of subcortical auditory streamlines should be possible with high quality data. In total, this work contributes novel information about the auditory pathway using high resolution, high quality ex vivo MRI and facilitates further in vivo research on the structure and function of the human auditory system.

Title: The effects of early postnatal noise exposure on the development of perineuronal nets inthe rat auditory cortex

Authors: *J. SVOBODOVA BURIANOVA, J. SYKA
Dept. of Auditory Neurosci., Inst. of Exptl. Medicine, CAS, Prague, Czech Republic

Abstract: In the rat auditory system, a period of increased vulnerability to external stimuli (known as the critical period, CP) starts with the onset of hearing (PD 12) and ends around three weeks later. It is expected that the closing of the critical period is paralleled with the maturation of perineuronal nets (PNNs); lattice-like extracellular matrix structures that appear around the soma and proximal dendrites of mainly parvalbumin expressing inhibitory neurons. Exposure to loud sound during the CP, can significantly affect the neuronal morphology and electrophysiology of neurons in the rat auditory cortex. Whether the exposure can also change the pattern of PNN maturation remains unknown. Long-Evans rats were exposed at PD14 to a 125 dB SPL broad-band noise for 8 min. The content of PNNs was evaluated in brain sections, stained for Wisteria floribunda agglutinin in exposed rats aging from PD14 to PD106, and compared with non-exposed controls. We observed no visible nets at PD14, either in the exposed animals or in the controls. The first signs of PNN appeared at PD21 in both groups however, they were more expressed in the exposed animals. In principle, the development of PNNs appeared to be more accelerated in the noise-exposed animals than the non-exposed controls. These results suggest that noise exposure may lead to the premature closing of the CP window, thus limiting the plasticity of early postnatal development in the auditory cortex.

Abstract: Information processing in the brain is based on the interactions of distributed neuronal populations. However, studying neuronal networks at single-cell resolution across the entire adult brain has so far been impossible in vertebrates due to their size and opacity. Here, we address this challenge by introducing a new model organism to neuroscience. The freshwater fish Danionella translucida (DT) combines small size and near complete transparency even in the adult when neural circuits and behaviour have matured. We found this close relative of the zebrafish to have the smallest known adult vertebrate brain (0.6 mm^3), containing over one order of magnitude fewer neurons than zebrafish. DT adults display a rich set of complex behaviors, including courtship, shoaling, schooling and, remarkably, acoustic communication. To enable optical network activity measurements and perturbations, we established CRISPR/Cas9 genome editing and Tol2 transgenesis techniques that allowed us to image neural activity in response to acoustic stimuli, including mimics of DT's own vocalizations. Small size, transparency, genetic access and rich behavior make Danionella translucida a highly promising model organism for the study of adult vertebrate brain function at single-cell resolution.

Title: Presynaptic modulation and inhibitory feedback in the avian cochlear nucleus angularis

Authors: *K. M. MACLEOD, S. L. EISENBACH, S. E. SOUEIDAN
Univ. of Maryland, College Park, MD

Abstract: Inhibition plays a critical and varied role in auditory processing, ranging from sound level gain control, sculpting frequency tuning, and enhancing temporal processing. The cochlear nuclei in the avian brain are unusual in that they lack local inhibitory circuitry, and instead receive feedback from the superior olivary nucleus, a third order brainstem area. Cochlear nucleus angularis (NA) is a key encoder of overall sound level for gain control, but also subserves spectrotemporal processing. Since NA encodes multiple aspects of sound intensity, the nature and dynamics of the inhibitory feedback are of keen interest, as well as how feedback mechanisms might differ from the timing pathways of the brainstem. Using whole cell patch clamp recordings from NA neurons in brainstem slices, we investigated the short-term synaptic plasticity of fast, mixed $GABA_A$- and glycine-receptor mediated currents, presynaptic inhibition of excitatory and inhibitory inputs, and the effects of presynaptic inhibition on synaptic dynamics. Trains of IPSCs elicited by electrical stimulation showed substantial transient and sustained facilitation across a wide range of frequencies (5-200 Hz). In addition, trains of stimulation elicited numerous asynchronous events that contributed substantially to the overall current. Summation of facilitated synchronous events and increased frequency of asynchronous events resulted in total inhibitory current that showed >50% enhancement over that expected from trains of IPSCs without facilitation. Presynaptic inhibition via GABA-B receptors ($GABA_BR$) suppressed inhibitory synaptic transmission, but also shifted the dynamics further toward facilitation. Presynaptic modulation of excitatory transmission via $GABA_BRs$ also suppressed glutamatergic responses, but had little effect on the synaptic plasticity of these inputs. At inhibitory synapses, basal spontaneous release of GABA/glycine may be at sufficient levels to tonically suppress release. These results suggest that both excitatory and inhibitory synapses in the avian cochlear nucleus angularis can be strongly modulated via presynaptic metabotropic $GABA_BR$. The modulation of excitatory and inhibitory inputs of NA neurons via $GABA_BR$ activation appears to parallel that in the timing pathway.

Title: Modulation of auditory cortical information processing by movement and VIP interneuron activation

Authors: *J. BIGELOW, J. DEKLOE, R. MORRILL, A. HASENSTAUB
UCSF, San Francisco, CA

Abstract: Information processing in sensory cortex is highly sensitive to contextual variables such as anesthetic state, arousal, and task engagement. Recent work in visual cortex (VCtx) has established that local circuitry responsible for extracting information from visual environment is highly sensitive to inputs originating from motor circuits activated during locomotion, finding that evoked firing rates and stimulus information increase when animals are engaged in movement. A specific inhibitory interneuron circuit appears to be critical for this change. Inhibitory interneurons expressing vasoactive intestinal peptide (VIP) are differentially activated during movement, which typically suppress other inhibitory interneurons, ultimately disinhibiting excitatory pyramidal cells. Although VIP activation has been observed during movement in somatosensory and auditory cortices, it remains unclear whether these activations similarly elevate evoked responses and stimulus information. The present study examined auditory cortical (ACtx) responses evoked by tone cloud stimuli in awake, headfixed mice during spontaneous movement and still conditions. To test the role of a VIP-mediated circuit in motor-related activity modulation, we crossed VIP-Cre mice with Ai32 mice to express channelrhodopsin in Cre-expressing VIP interneurons. VIP+ cells were optogenetically activated for half of the stimulus presentations, permitting independent analysis of the consequences of movement and VIP activation, as well as their intersection. Preliminary analyses suggest heterogeneous influences of both movement and VIP activation on ACtx responses. In contrast to VCtx, stimulus-evoked spike counts tend to decrease during movement in our neuron sample. Loss of spikes during movement appears to be associated with a reduction in total information (bits) as well as information efficiency (bits/spike). Consistent with the disinhibitory circuit observed in VCtx, VIP interneuron activation tends to elevate evoked firing rates in ACtx

neurons. Importantly, however, the additional spikes produced by VIP activation seem to be unrelated to the stimuli, usually contributing zero additional information (bits), thus undermining information efficiency (bits/spike). The effects of simultaneous movement and VIP activation appear to sum linearly: although evoked spike counts during locomotion generally return to baseline levels with concurrent VIP activation, information remains abnormally low. Our findings raise intriguing possibilities about asymmetric consequences of motor circuit activation on information propagation in VCtx and ACtx.

Title: Short-term synaptic plasticity evoked by electrical and optical stimulation in neurons of the gerbil medial geniculate body

Authors: A. MILLER, K. V. NGUYEN, C. MARTINEZ, J. BRODEUR, A. J. CARRERA, D. MANDALAPU, S. GOOCH, M. HOOPER, L. A. MORENO-ELLIS, S. D. STOLLE, L. E. WAGNER, B. WILKINS, L. J. KREEGER, D. B. HAIMES, *N. L. GOLDING
Dept. of Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: The dynamics of synaptic transmission plays a critical role in shaping the encoding of auditory information to the cortex from the medial geniculate body (MGB). However, due to the extensive convergence of multiple ascending and descending auditory inputs to the MGB, it is not clear whether the release properties of excitatory and inhibitory terminals on MGB neurons are dictated by the target or source neurons. To understand whether the properties of short-term plasticity depend on input pathway, we made whole-cell current clamp recordings from MGB neurons in thalamocortical brain slices of Mongolian gerbils (30-38 days old, ~35°C). In initial experiments, we activated pharmacologically isolated excitatory or inhibitory synaptic inputs to thalamic neurons through local electrical stimulation. In a second set of experiments, we injected the inferior colliculus of P23-25 gerbils with an adeno-associated virus (synapsin promoter driving GFP and channelrhodopsin-2 (ChR2)), 13 days prior to electrophysiological slice experiments in which ChR2 was activated with 470 nm field illumination. Recorded MGB neurons were labeled with biocytin and slices were processed for streptavidin conjugated to Alexa-568 for subsequent morphological analysis and localization within the MGB. Labeling with an antibody against calretinin was used to distinguish the dorsal from the ventral

subdivisions of the MGB. For electrical stimulation experiments, most recorded neurons were from the ventral MGB, and exhibited electrophysiological properties consistent with prior studies in mouse and rat. Resting potentials were maintained between -60 and -65mV with direct current injection. In response to paired electrical stimuli, excitatory inputs exhibited strong short-term potentiation (2.99±0.33 fold change, n=6), whereas inhibitory inputs exhibited short-term depression (0.58 to 0.72 fold change, n=3). By contrast, in preliminary recordings, cells subjected to optical activation of both excitatory and inhibitory IC inputs to thalamic neurons all exhibited short-term depression (n=4). Taken together, our results in gerbils are in agreement with data from studies in rats and mice demonstrating there is input specificity in the release properties of synapses. The strong short-term potentiation observed during intra-thalamic stimulation is consistent with predominant activation of descending corticothalamic inputs, which may be preferentially preserved in these slices.
slices.

Title: Vagal nerve stimulation strongly activates cortical networks, centered around sensorimotor cortex

Authors: L. N. COLLINS[1], *L. J. BODDINGTON[1], P. J. STEFFAN[1], D. NESTVOGEL[1], S. JO[1], R. C. FROEMKE[2], M. J. MCGINLEY[3], D. A. MCCORMICK[1]
[1]Inst. of Neurosci., Univ. of Oregon, Eugene, OR; [2]Neurosci. Inst., New York Univ. Sch. of Med., New York, NY; [3]Duncan Neurolog. Res. Inst., Baylor Col. of Med., Houston, TX

Abstract: Stimulation of the vagus nerve is used for treatment of some forms of epilepsy and depression, although the mechanisms of these effects are not well known. Many forms of epilepsy are state-dependent, occurring more prominently at some states (e.g. drowsiness, transition between sleep and waking, etc.) than others. We hypothesized that vagal nerve stimulation may alter the state of the brain, perhaps through the activation of ascending sensory or modulatory pathways. Indeed, activation of ascending neuromodulatory pathways is known to

strongly influence arousal state, which in turn substantially alters sensory processing, task performance, and propensity to generate epileptic seizures. For example, our lab has previously demonstrated that when in an intermediate state of arousal (as determined by pupil size), mice perform significantly better on an auditory detection task than mice in either low or hyper-aroused states (McGinley et al., Neuron, 2015). We hypothesize that vagal nerve stimulation may strongly control the state of activity in the forebrain through activation of either ascending neuromodulatory pathways involved in arousal, or through activation of sensorimotor cortical regions, or both.
To test this hypothesis, we performed wide-field imaging of the entire dorsal surface of the mouse brain in awake, behaving mice, monitored pupil diameter (arousal) and walking while periodically delivering varying intensities of vagal nerve stimulation. Our data demonstrate that vagal nerve stimulation reliably induces pupil dilation (arousal), with the magnitude of the pupillary response being directly related to stimulus intensity. Increasing the intensity of vagal nerve stimulation also leads to a dose-dependent increase in neuronal activity (calcium signals) in widespread cortical regions, centered around motor and sensory areas, even in the absence of walking (measured using widefield imaging of Thy1-GCaMP and CamKII-GCaMP mice). Ongoing work is underway to examine these effects in detail at the neuronal and neuromodulatory level and how they affect the ability of the mouse to learn, retain, and perform detection and discrimination tasks.

Title: Inactivation of primary auditory cortex decrease the overall cortical burst activity in isoflurane-induced burst suppression state

Authors: *M. J. ROJAS, M. D. SUAREZ
Salud Animal, Univ. Nacional De Colombia, Bogota, Colombia

Abstract: Cortical Burst suppression (BS) is an electroencephalographic pattern present under a number of conditions such as deep isoflurane-induced anesthesia. The BS pattern shows very low amplitude EEG (silent EEG periods) followed by bursts of very high amplitude, and the ratio of these periods is the burst suppression ratio BSR. Auditory stimulation during isoflurane-induced BS evoke burst activity modifying the BSR. It might be an intracortical transmission of this signals from the auditory primary cortex (APC), but there is no data about the role of the APC in the generation of cortical BS. The aim of this exploratory study was to unveil the role of APC on BS, thus, we performed a bilateral reversible inactivation of the APC in 4 male Wistar rats under isoflurane anesthesia while recording temporal and frontal electroencephalogram (EEG). The animals were instrumented with frontal and temporal EEG electrodes, and a reference electrode was inserted into the neck muscles. A cooling technique was used to inactivate the APC by positioning a 3.5mm diameter cryoloop on the surface of each APC (AP: -4.5mm to Bregma, DV: 5mm); also, body temperature, and the surface cortical temperature was monitored while EEG recordings were carried out prior to cooling down the APC, during, and after the cooling procedure. The results from this study showed that inactivation of PAC significantly increased the BSR from 56.3% (±14.2) to 94.3% (±6.6) ($p=0.002$), and this effect was reversible after cooling when BSR went back to 70% (±9.8) ($p=0.01$). These results indicate that the PAC plays a key role in the generation of burst activity during isoflurane-induced BS. However, there is still the need of research the mechanisms involved in this phenomenon.

Title: Cholecystokinin neurons of the inferior colliculus provide direct and powerful excitation and inhibition to the medial geniculate body of the gerbil

Authors: *L. KREEGER, P. MEHTA, B. V. ZEMELMAN, N. L. GOLDING
Inst. for Neurosci., The Univ. of Texas At Austin, Austin, TX

Abstract: Neurons in the central nucleus of the inferior colliculus (ICC) exhibit diverse morphologies, electrophysiological properties, and projection targets. To understand whether molecular-genetic classes of ICC neurons form distinct cell classes, we targeted neurons with interdependent adeno-associated viruses and evaluated their anatomy, physiology, and neurochemical markers. This technique enabled us to label and optogenetically activate

cholecystokinin (CCK) expressing neurons in the ICC of the Mongolian gerbil. Using patch-clamp recordings in slices, we found that CCK neurons comprise two classes, one excitatory and one inhibitory, which can be distinguished by endogenous neurochemical markers and electrophysiological properties. Excitatory CCK neurons comprise 30% of ICC excitatory neurons, whereas inhibitory CCK neurons comprise 20% of ICC inhibitory neurons.
To characterize the relationship between neurochemical markers and electrophysiology, we targeted CCK neurons in the ICC for *in vitro* whole-cell current clamp recordings (P35-50 gerbils, 35°C). Excitatory and inhibitory CCK neurons have an adapting firing pattern. However, the inhibitory group exhibited more moderate levels of adaptation and an additional slow phase of spike after-hyperpolarization. To determine the connectivity of CCK neurons, we made recordings from non-CCK (non-fluorescently labeled) ICC neurons, and activated channelrhodopsin-expressing CCK neurons and axons with blue light. Evoked excitatory and inhibitory post-synaptic potentials (PSPs) were small (<2 mV) and widespread, making connections with >50% of recorded ICC neurons of all firing phenotypes.
To assess the role of CCK neurons in the ascending pathway, we activated channelrhodopsin-expressing CCK axons to putative medial geniculate body (MGB) targets. CCK neurons in the ICC exclusively target the ventral division of the MGB, suggesting a role in the thalamocortical pathway. Interestingly, terminal fields of virally labeled axons were highly branched and polymorphic, consisting of both small boutons with *en passant* swellings, as well as medium to large axons with large complex endings. Optogenetic activation of CCK inputs evoked large suprathreshold EPSPs and IPSPs (10-15 mV). Large EPSPs and terminal sizes are consistent with proposed models of thalamic drivers.
Taken together, our results indicate that excitatory and inhibitory CCK neurons are functionally distinct cell types. CCK neurons comprise a large proportion of ICC neurons and are well positioned to drive and shape thalamocortical activity.

Title: Amygdala-TRN projections amplify tone-evoked activity in auditory thalamus and cortex

Authors: *S. ROLÓN-MARTÍNEZ[1], M. AIZENBERG[2], M. N. GEFFEN[1,2]
[1]Neurosci., [2]Dept. of Otorhinolaryngology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Many forms of behavior require selective amplification of neuronal representations to relevant sensory signals. Associating emotional responses with sensory cues can lead the nervous system to alter behavior to future representations of these cues. Here, we identify a novel pathway between the baso-lateral amygdala (BLA), an emotional learning center in the mouse brain, and the inhibitory nucleus of the thalamus (TRN), and demonstrate that activation of this pathway amplifies sound-evoked activity in the central auditory pathway. We stimulated BLA using channelrhodopsin (ChR2) with a laser via implanted optic cannulas, while recording neuronal activity in the auditory cortex (AC) in response to a presentation of random tone sequences in awake, head-fixed male or female mice. Optogenetic activation of the BLA suppressed spontaneous activity (*paired t-test, p=0.0007*), while amplifying tone-evoked response magnitude in AC (*paired t-test, p=8.5e-5, n= 8 mice*). Inspection of fluorescence following RetroBead injections in TRN revealed direct projections from BLA to TRN. These projections were further confirmed by retrograde labeling of neurons in the BLA using a CAV-2 virus in TRN. We next directly activated projections from the BLA to TRN by repeating the initial experiment, but positioning the optic cannula over TRN. We found that there was a significant suppression of spontaneous activity (*paired t-test, p=0.003, n= 7 mice*), and a significant increase in tone-evoked responses in AC (*paired t-test, p=3.9e-8*). We found that activation of the BLA projections to TRN also led to inhibition of spontaneous activity (*paired t-test, p=4.3e-9*) and an increase in tone-evoked responses in auditory thalamus (Medial Geniculate Body, MGB) (*paired t-test, p=3.4e-7, n = 5mice*), consistent with the hypothesis that the changes in AC responses with BLA activation are a result of projections from BLA to TRN via MGB. These results demonstrate a novel circuit mechanism for amplification of sensory representation of behaviorally relevant signals and provide a potential target for treatment of neuropsychological disorders, in which emotional control of sensory processing is disrupted.

Title: Pharmacologic and optogenetic manipulation of the dopamine system alters auditory processing in the inferior colliculus

Authors: *J. M. HOYT[1], D. J. PERKEL[3], C. V. PORTFORS[2]
[1]Integrative Physiol. and Neurosci., [2]Washington State Univ. Vancouver, Vancouver, WA;
[3]Depts. Biol. & Otolaryngology, Univ. of Washington, Seattle, WA

Abstract: Background: The ability to understand speech relies on accurate auditory processing of complex sounds. Individuals with Parkinson's disease suffer from speech perception deficits, suggesting that dopamine is involved in the encoding of complex sounds. Recent studies from our lab demonstrated that dopamine has heterogeneous effects on the responses of many neurons in the inferior colliculus (IC) of mice, although the strongest effect is to suppress neural activity. It is currently unknown, however, which dopamine receptors are involved in modulating neuronal responses, and whether the observed preponderance of depressive effects reflects the endogenous dopamine system in the IC. In this study, we tested whether dopamine acts via D1- and/or D2-like receptors to alter responses of IC neurons, as well as tested the effect of optogenetically induced dopamine release on auditory responses in the IC. **Methods:** *Iontophoretic experiments*: We recorded extracellular responses of single neurons in the IC of awake, restrained mice. We compared neuronal responses to tones and mouse vocalizations before and after iontophoretic application of dopamine and D1- or D2-like agonists or antagonists. *Freely behaving experiments*: We recorded multi-unit activity in the IC of freely behaving mice. We compared global response to tones and mouse vocalizations before and after pressure injection of dopamine or a D2-like agonist or antagonist into the IC. *Optogenetic experiments*: We created a DAT/ChR2 mouse line and recorded extracellular responses of single neurons in the IC of awake, restrained mice. We compared neuronal responses to tones and mouse vocalizations before and after stimulation with blue light pulses through an optrode to evoke local dopamine release. **Results:** In iontophoretic and freely behaving experiments, both the single-unit and global effects of dopamine and a D2-like agonist were heterogeneous as both either increased or decreased responses of IC neurons to tones and vocalizations, while a D2-like antagonist had opposite effects. Similar to the effects of exogenous dopamine application, optogenetic induction of endogenous dopamine release via blue light decreased responses to tones and vocalizations in the majority of cells in mice expressing ChR2. **Conclusions:** We found that dopamine alters auditory responses in the IC, and that such modulation occurs via D2-like receptors. We also found that activation of the endogenous dopamine system in the IC suppresses responses of auditory neurons. Understanding how dopamine modulates auditory processing will ultimately inform therapies targeting mechanisms of auditory and communication disorders.

Title: Connectional modularity within the lateral cortex of the mouse inferior colliculus gives rise to partially segregated processing streams for auditory and multisensory information

Authors: *A. M. LESICKO, D. A. LLANO
Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The lateral cortex of the inferior colliculus contains a network of modules characterized by dense staining for glutamic acid decarboxylase-67 (GAD-67) and other neurochemical markers. Previous studies from our laboratory have shown that the extrinsic sensory inputs to the lateral cortex are patterned: somatosensory inputs terminate within these neurochemical modules, while auditory inputs target the extramodular regions of the lateral cortex. While the topography of extrinsic inputs to the lateral cortex is well defined, it is unknown whether the intrinsic connections in the lateral cortex also exhibit connectional modularity. In the present study, we sought to characterize the intrinsic inputs to GABAergic and non-GABAergic neurons in both modular and extramodular regions of the lateral cortex. Experiments were performed in brain slices from the GAD-67-GFP knock-in mouse, in which modular and extramodular areas of the lateral cortex can be clearly distinguished. GABAergic and non-GABAergic cells in both regions were filled and recorded from in either a single or dual-channel whole-cell voltage clamp configuration while potential pre-synaptic sites throughout the ipsilateral colliculus were stimulated using laser photostimulation of caged glutamate. Morphological reconstructions of biocytin-filled cells revealed that the dendrites of neurons in the lateral cortex are largely confined to the domain (modular or extramodular) in which their cell body resides, with the exception of GABAergic modular cells. Photostimulation maps generated under synaptic blockade further support these results; direct stimulation of extramodular cells is elicited from extramodular sites, direct stimulation of non-GABAergic modular cells arises from modular sites, but direct stimulation of GABAergic modular cells can be driven from both domains. Pre-synaptic photostimulation and spatial analysis revealed that extramodular cells receive input almost exclusively from the extramodular domain, non-GABAergic modular cells receive mixed input from both domains, and GABAergic modular cells receive the majority of their input from the extramodular domain. Overall, these results indicate that there is a unidirectional flow of information within the lateral cortex, such that

modular cells receive inputs from auditory-recipient (extramodular) and somatosensory-recipient (modular) areas of the lateral cortex, while extramodular cells only receive input from the extramodular domain. This modularity in the intrinsic connectivity of the lateral cortex may give rise to partially segregated processing streams for auditory and multisensory processing.

Title: Astrocytes and potassium buffering at a fast auditory synapse

Authors: *B. J. LUJAN, H. VON GERSDORFF
Vollum Inst., OHSU, Portland, OR

Abstract: The nerve terminals of auditory neurons are responsible for the efficient release and recycling of synaptic vesicles that enable the secure chemical transmission that underlies auditory perception. The fidelity and modulation of these synaptic events is important in the superior olivary complex (SOC) of the mammalian brainstem, which is involved in sound source localization. The calyx of Held nerve terminal is an integral component of this afferent projection pathway and a hallmark of this synapse is the ability to maintain synaptic fidelity during high frequency transmission (i.e. at frequencies ≥ 800 Hz *in vivo*), a range at which conventional synaptic boutons cannot reliably fire. The regulation of local ionic environments in the extracellular spaces during synaptic transmission is not well understood. Because of the high-fidelity necessary for the functional output of this synapse, extracellular K^+ accumulation is likely higher at auditory synapses than traditional synaptic boutons during persistent spiking activity. Astrocytes probably play a major role in the homeostatic maintenance of extracellular K^+ concentration; implicating the tripartite synapse as an important regulator of synaptic strength. Using the mature mouse brainstem slice preparation containing the calyx of Held-MNTB synapse as a model of tripartite synaptic function, we investigated the functional role of compromised K^+ buffering on synaptic vesicle release. We inhibited extracellular K^+ uptake produced as a byproduct of synaptic firing by antagonizing inward rectifying K^+ channels with Ba^{2+}. Bath application of Ba^{2+} increased evoked excitatory postsynaptic current (EPSC) amplitudes and led to a concomitant increase in the frequency of spontaneous EPSCs. Additionally, paired-pulse ratio was decreased after Ba^{2+} application, suggesting an increase in

presynaptic release probability (Pr). Finally, we made whole-cell patch clamp recordings from astrocytes juxtaposed to synapses, and observed an inward current in the astrocyte immediately following high-frequency synaptic firing. The amplitude of the inward current was dependent on the synaptic firing frequency and was completely blocked by Ba^{2+}, implicating astrocytes as a major regulator of extracellular K^+ concentration. Our data suggest that astrocyte K^+ buffering plays a putative role in the maintenance of extracellular K^+ concentration and loss of K^+ homeostasis increases presynaptic Pr in a mouse auditory synapse.

Title: Ca^{2+}-dependent vesicle replenishment in inhibitory synapses in the auditory brainstem allows for faithful and robust inhibition during high frequency activity

Authors: *D. J. WEINGARTEN[1,2,3], N. MÜLLER[3], E. FRIAUF[3], H. P. VON GERSDORFF[2]
[1]Kaiserslautern, Germany; [2]Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR; [3]Biol., Univ. of Kaiserslautern, Kaiserslautern, Germany

Abstract: A key function of the auditory brainstem is the precise localization of sound sources in the horizontal plane. For the ascending auditory pathway to perform this feat, a system which is able to distinguish minute intensity and timing differences at high frequencies is needed. Indeed, reliable synaptic transmission is a hallmark of the highly specialized excitatory synapses of this system, which allow the processing of auditory information with exquisite temporal precision. However, less is known about how inhibitory synapses shape the processing of sound signals and if they further develop after hearing onset. Here, we investigated synapses of the lateral superior olive (LSO) in the mouse auditory brainstem. A speeding of evoked excitatory and inhibitory postsynaptic currents has been observed in the LSO during postnatal development. Yet, if changes occur in the presynaptic parameters of vesicle release remains unknown. Using whole-cell patch clamp recordings in acute brainstem slices we characterized inputs from the medial nucleus of the trapezoid body (MNTB) and the cochlear nucleus (CN) to principle neurons of the LSO (MNTB-LSO and CN-LSO synapses) via electrical afferent fiber stimulation. Recordings were done at 36±1°C from pre-hearing mice at postnatal day P10-12 and young adults at P28-34. Using high-frequency stimulation (50 stimuli of 50, 100, and 200 Hz), synaptic parameters could be determined. After hearing onset CN-LSO synapses showed an

increase in their number of readily releasable vesicles (RRP), which has also been previously described for other excitatory synapses in this system. Surprisingly, the RRP of MNTB-LSO synapses dropped from 600 vesicles at P10-12 to below 300 vesicles at P28-34. To counteract this reduced number of RRP vesicles, after hearing onset these synapses develop a frequency-dependent vesicle replenishment. While the slow Ca^{2+}buffer EGTA and the K^{+}-channel blocker TEA had little effect on vesicle replenishment in young mice, mature animals showed a twofold higher vesicle replenishment with increased Ca^{2+} and a drop to ~50% compared to P10-12 under EGTA. To investigate how this activity-dependent replenishment affects recovery after depression, gaps of 10 ms to 5 seconds were introduced in between stimulation trains. In the absence of activity the time constant of recovery of MNTB-LSO synapses was significantly slower (2.7 ± 0.4s) than that of CN-LSO synapses (1.2 ± 0.4s). In summary, mature MNTB-LSO synapses develop a remarkably fast vesicle replenishment specialized for faithful and sustained inhibition during high-frequency activity.

Title: Development of functional responses to sound in primary auditory cortex

Authors: *K. SHILLING-SCRIVO[1], K. SOLARANA[2], N. A. FRANCIS[3], X. MENG[4], P. O. KANOLD[4]
[1]Program in Neurosci., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Office of Sci. and Engin. Labs/CDRH, U.S. Food and Drug Admin., Silver Spring, MD; [4]Biol., [3]Univ. of Maryland, College Park, MD

Abstract: Early sensory experience is critical for normal structural and functional neural development. Altricial animals are born with closed ears and so ear opening is thought to be the earliest time point at which auditory stimuli can shape sensory circuits. However, recent reports from ferret (Wess et al. 2017) indicate that auditory cortex can respond to sound over one week before ear opening. These responses emerged in a deep cortical layer, the subplate, which is known to receive thalamic projections before thalamorecipient layer 4 circuits. We therefore investigated if mouse auditory cortex(ACX) responds to sounds before ear opening (~P11) using

neonatal transgenic Thy1-GCaMP6s mice to track the evoked calcium fluorescence of neurons during sound presentation.
To image activity in these young mice we head-fixed the animal and exposed their skull. GCaMP fluorescence was elicited through a 473nm LED located above the skull surface. Emitted fluorescence was collected by a CMOS camera (ThorCam), allowing for recording of calcium activity across ACX fields. We presented broadband white noise (4-48kHz) or single tones (4-48kHz). Since the ear canals are closed at young ages we presented sounds at 90dB. Sounds were presented for 2 seconds in separate blocks of 30 trials each. Fluorescence data were then extracted and the time-courses of the 25th percentile most responding regions were plotted for each animal. Our analysis revealed an increase in GCaMP fluorescence during the period of sound presentation. Acute widefield imaging in anesthetized animals also showed evoked fluorescence signals before ear opening. To confirm that these responses were coming from single neurons, we used 2-photon in-vivo calcium imaging of ACX in mice before the ages of ear opening. We found that neurons in both layer 2/3 and layer 4 show sound-evoked activity. These results indicate that the ascending auditory pathway is functional in mice before ear opening. Therefore, studies of experience-dependent development of the auditory system have to take into account early auditory experience through closed ears.

Title: Neural indices of auditory reflective attention during word-in-noise identification

Authors: *T. M. V. CHAN[1,2], C. ALAIN[1,2]
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Rotman Res. Inst., Baycrest, Toronto, ON, Canada

Abstract: Speech-in-noise (SIN) comprehension is greatly enhanced when semantic context is provided prior to degraded speech. Evidence suggests that semantic context can also help identify words-in-noise even when the context is provided after. The latter is attributed to attention being retrospectively allocated to representations in short-term memory. However, it is unclear whether the use of context following degraded speech employs the same neural mechanisms as contextual cues prior to degraded speech. Here we present EEG findings from 15

healthy young adults using a word-in-noise identification paradigm. Participants listened to a target word embedded in speech-shaped noise that was either preceded (pre-cued) or followed (retro-cued) by one of three auditory cue conditions: a word related to the target, a word unrelated to the target, or a burst of white noise. Event-related potentials time-locked to retro-cue onset showed an effect of relatedness at about 400-700 ms over bilateral parietal scalp areas. These data are consistent with a proposed model of the employment of auditory reflective attention in the ongoing comprehension of SIN, where context provided after a degraded speech target engages attention to short-term memory representations of speech.

Title: Functional polymorphism of MMP9 and BDNF as a potential biomarker of neuroplasticity in prelingual deafness treatment with cochlear implantation - A retrospective cohort analysis

Authors: *M. E. MATUSIAK[1,2], A. OBRYCKA[1,2], D. OZIEBLO[1,2], M. OLDAK[1,2], L. KACZMAREK[3], H. SKARZYNSKI[1,2]
[1]Inst. of Physiol. and Pathology of Hearing, Warsaw, Poland; [2]World Hearing Ctr., Nadarzyn, Mokra 17, Poland; [3]Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Aims: Genetic biomarkers of neuroplasticity in prelingually deaf children treated with cochlear implantation could facilitate their clinical management, giving higher chances for development of robust proficiency of spoken language. We investigated whether carrying of a certain variants of genes encoding matrix metaloproteinase *MMP-9* and neurotrophin *BDNF* is a prognostic marker of auditory skills acquisition outcome. Method: We performed a retrospective analysis of functional *MMP9* variant (rs3918242, c.1562 C>T) known to affect *MMP-9* gene expression level and *BDNF* variant (rs6265, c.196G>A, p.Val66Met) known to affect the protein function in a group of 106 deaf children, aged below 2, treated with unilateral cochlear implantation. We studied associations between the presence of relevant *MMP9* and *BDNF* genotypes and auditory development of the implanted children. Language acquisition was assessed with Little Ears Questionnaire (LEAQ) over 14 months post intervention. Results: Prevalence of *MMP-9* variants in the studied group was C/C - 66%, C/T- 34%, *BDNF* - G/G - 75,5%, G/A- 24,5% and this data are consistent with Caucasian population dispersion. In the subgroup of subjects implanted below 1 year, showing no response in pre-implant Auditory

Brainstem Responses median rate of auditory development for carriers of rs3918242 C/T genotype (median 5.0, IQR 4.0-.9.0) 1 month after CI activation is statistically significantly higher than for carriers of rs3918242 C/C (median 2.0, IQR 1.5-5.0) (p=0.0102). This predominance remains in 5th month of auditory development (p=0.0424), but not in further follow up. (U Mann Whitney test). Applied regression model predicating LEAQ score after 1st month of CI use in this subgroup includes genetic status of both *MMP9* and *BDNF* (p<0.0001). It reveals that, assuming the same pre-implant LEAQ score, 1 month post CI a subject carrying both rs6265 G/G genotype and rs3918242 C/T genotype will score 7.6 points in LEAQ higher than a carrier of both rs6265 G/A genotype and rs3918242 C/C genotype, 4.1 points in LEAQ higher than a carrier of rs6265 G/G genotype and rs3918242 C/C genotype, and 3.5 points higher than a carrier of rs6265 G/A genotype and rs3918242 C/T genotype.
Conclusions: rs6265 G/G genotype and rs3918242 C/T genotype predisposes their deaf carriers to better response to a sensory stimulation delivery to cochlea in first months after CI activation than carriers of the rs6265 G/A and rs3918242 C/C genotypes. Further studies should address potential biomarker value of those genetic variants as well as possible functional role of *MMP9* and *BDNF* in neuroplasticity evoked by cochlear implantation in the prelingually deaf children.

Title: PET and MR evidence of functional connectivity between hearing and working memory in rat model

Authors: *M.-H. PARK[1,2], H. LEE[1], J. KIM[3]
[1]Otorhinolaryngology, Boramae Med. Center, Seoul Metropolitan Governm, Seoul, Korea, Republic of; [2]Otorhinolaryngology, Col. of Medicine, Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Mol. Imaging Res. Center, Korea Inst. of Radiological and Med. Sci., Seoul, Korea, Republic of

Abstract: Purpose: The effect of hearing loss on memory area of brain and is still not completely understood. Recently, several studies suggested that hearing loss aggravated decline of cognitive and memory function. In this present study, changes of cerebral volume and glucose metabolism were evaluated using PET, MR and RT-qPCR study in deafened animal model.

Materials & Methods: Twenty rat of F-18 FDG PET and T2W MR were scanned using Siemens Inveon PET scanner and agilent 9.4T MR scanner (baseline study). Single sided deafness (right sided deafness) model (n=10) and bilateral deafness model (n=10) were constructed. One month and 3 month after deafness induction, FDG PET and T2W MR were acquired. To perform SPM and VBM analysis, brain was extracted using rectangular masking. Individual PET and MR data was spatially normalized onto template and smoothed with 2 mm Gaussian kernel. To conserve gray matter concentration, modulated VBM was performed. Two sample t-test was performed ($p < 0.005$). Another sets of animals (n=42) were sacrificed for RT-qPCR at 1 and 3 month after deafening procedure. Age-matched normal hearing animals were also included for control. After sacrifice, entorhinal cortex was quickly harvested. Quantitative RT-PCR was performed for measuring mRNA expression of aldehyde dehydrogenase 1 family member L1 (ALDH1L1), glial fibrillary acid protein (GFAP), oligodendrocyte transcription factor 2 (OLIG2), and neurofilament heavy chain (NEFH).

R**esults:**

SPM analysis shows that cerebral glucose metabolism was decreased in the region of bilateral primary auditory cortex compared to that of baseline after 1 month of deafness for both single sided / bilateral deafness group. After 3 months of deafness, additionally, cerebral glucose metabolism was decreased in the region of medial entorhinal cortex compared to that of baseline for both single sided / bilateral deafness group. VBM analysis shows that regional gray matter concentration was decreased in the region of left medial entorhinal cortex for single sided deafness group and bilateral medial entorhinal cortex for bilateral deafness group. ALDH1L1 mRNA expression was significantly decreased at both entorhinal cortices after 1 month later in both single sided and bilateral deafness group.

Conclusions: SPM and VBM analyses showed decreased metabolic activity and volume of gray matter and an astrocyte marker mRNA expression was also decreased in medial entorhinal cortex. Entorhinal cortex is located between auditory cortex and hippocampus and known to relate to working memory. So these findings suggest a functional connectivity between hearing and working memory.

Title: Dopaminergic modulation of noise vocoded speech learning in patients with Parkinson's disease

Authors: *C. M. THIEL[1,2], M. CONTY[1], L. WURST[1], A. PFEIFFER[1], A. ENGELHARDT[1], S. PUSCHMANN[1,3]

Abstract: Human and animal studies provide evidence for a central role of the dopaminergic neurotransmitter system in auditory learning and brain plasticity (Bao, Chan, & Merzenich, 2001; Knecht et al., 2004; Weis, Puschmann, Brechmann, & Thiel, 2012). We here aimed to test the role of dopamine in learning noise vocoded speech, which consists of spectrally degraded signals and is commonly used to simulate the sensation after cochlear implantation. To investigate the role of the dopaminergic system, we used a between subject design and patients with Parkinson's disease (male/female; age range:42-83 yrs) on (n=10) or off (n=11) their regular l-dopa medication and an age-matched healthy control group (n=10). Subjects were presented with 60 noise vocoded sentences taken from a matrix test (Uslar et al., 2013) and asked to repeat back what they heard. In addition, they underwent neuropsychological and motor assessment. We found significantly reduced learning rates in patients off l-dopa as compared to on l-dopa. Our findings in this sample of patients with Parkinson's disease provide first evidence that dopamine promotes adaptation to degraded speech which may be of relevance for auditory rehabilitation after cochlear implantation.

Title: Reorganization of cortical population neuronal activity following auditory fear conditioning

Authors: *K. WOOD[1], R. BETZEL[2], D. S. BASSETT[2], M. N. GEFFEN[1]
[1]Dept. of Otorhinolaryngology, [2]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Auditory perception relies on learning-driven neuronal plasticity within the auditory pathway. Here, we investigated how associative learning, differential auditory fear conditioning (DAFC), affects neuronal population responses to sounds in auditory cortex (AC). In DAFC, the subject is presented with two different frequency tones, one of which is paired with a foot-shock. Previously, we found that AC is required for expression of DAFC-driven changes in sound-frequency discrimination acuity (Aizenberg and Geffen, 2013) and that modulating inhibitory neuronal activity in AC leads to similar bi-directional changes in discrimination acuity (Aizenberg, 2015). However, how DAFC affects tone-evoked population neuronal activity remained unknown. We hypothesized that DAFC would drive changes in population tone-evoked neuronal activity corresponding to either and increase or a decrease in neurometric frequency discrimination acuity, as a function of fear learning specificity.
To understand the transformation of sound representation in AC before and after DAFC we imaged calcium activity in hundreds of neurons simultaneously in AC of awake, head-fixed mice, tracking the same neurons over days under a two-photon microscope before and after two DAFC sessions. We quantified changes in tone frequency-dependent responses of individual neurons, as well as in population functional connectivity. DAFC drove heterogeneous changes in individual neuronal responses for either shock-paired or unpaired tone frequencies. At the same time, mean population neuronal response strength to tones across frequencies was preserved. However, neuronal responses to tones following DAFC became more consistent after DAFC. Neuronal populations formed clusters driven by correlated activity, neurons within clusters exhibit heterogeneous response patterns. The neuronal cluster structure changed between days in the absence of DAFC, but the network structure became more consistent over days following DAFC. These findings suggest that DAFC drives cortical population activity toward a more stable state.

Title: Effects of auricular vagus nerve stimulation on novel orthography acquisition

Authors: *T. M. CENTANNI[1], V. THAKKAR[1], A. JEFFERSON[1], C. STACEY[1], N. KHODAPARAST[2]
[1]Psychology, Texas Christian Univ., Fort Worth, TX; [2]Nexeon MedSystems, Inc., Dallas, TX

Abstract: For typically developing adults as well as for children with dyslexia, the acquisition of a novel orthography is a difficult task and fluency is often unattainable. While the brain is hardwired for language, the reading network must be allocated and optimized from scratch in every individual brain. In dyslexia, the visual word form area is often hypoactivated and recent studies suggest this lack of involvement may lead to poor fluency. Invasive cervical vagus nerve stimulation (cVNS) can drive plasticity in the adult brain and has shown recent promise in the treatments of tinnitus and post- stroke motor impairment. This invasive approach is not practical for reading-based interventions. However, the auricular nerve, a branch of the cervical vagus nerve, innervates the cymba conchae region of the outer ear and projects to similar brain regions as cVNS. This study evaluated whether this non-invasive form of vagus nerve stimulation could be useful in driving plasticity for newly learned letter-to-sound correspondences. Adults between the ages of 18-24 years old completed ten 30-minute training sessions in which they learned letter-to-sound correspondences in Hebrew. Participants were randomly assigned to one of two control conditions (training with an in-person tutor vs. a customized computer program) or the active stimulation group. In the active group, participants completed the computer-based training program while receiving low levels of electrical stimulation to the left cymba conchae. Participants were tested at 3 time points to track progress on letter identification, rapid letter reading, and pseudoword reading: once at the halfway point, (on Day 6) once on the final day of lessons (on Day 10), and once more at least a week following their final lesson (retention). Participants receiving stimulation were monitored daily to ensure no adverse reactions to the intervention and to ensure the level of current was well within tolerable levels. There were no differences in performance between the two control groups, so these groups were combined for comparison with the active stimulation group. The active stimulation group exhibited faster reading times and higher accuracy on pseudoword reading compared to the control group as early as day 6. We present these findings as well as the longer-term performance of the stimulation group and possible behavioral predictors of individual success in the training

program. This study demonstrates for the first time that non-invasive auricular vagus nerve stimulation may be a valuable tool in improving reading acquisition and fluency. Ongoing research is evaluating the neural correlates of this approach.

Title: Brain activities under culturally familiar and unfamiliar music: fMRI evidence of musical culture effect

Authors: S. GUO, Y. HE, *J. LU
UESTC, Sichuan, China

Abstract: Musical culture is an important aspect of musical cognition that affects our understanding of music, as well as our daily lives. Although previous studies have provided culture-related evidence on neural activities, the influence of musical culture on neuroplasticity has been scarcely considered. In this work, 20 pianists and 20 Chinese traditional instrument players were recruited as the musician group for the experiment, while 20 non-musicians were recruited as the baseline group. Using a paradigm of listening to culturally familiar and unfamiliar music under functional magnetic resonance imaging (fMRI) technology, we found that greater activation of the superior temporal gyrus was elicited by culturally unfamiliar music. The result showed that culturally unfamiliar music might strengthen the abilities to judge melodic familiarity. These findings, which provide evidence for functional neuroplasticity based on the familiarity of musical culture, could enrich our insights into the musical brain.

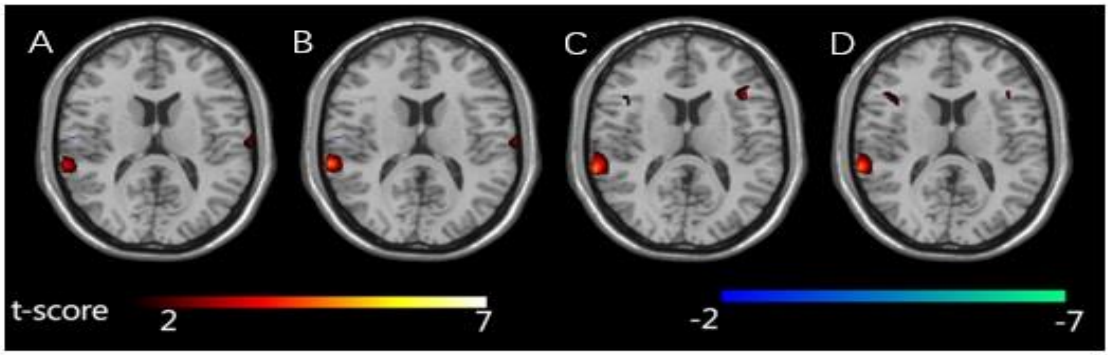

Figure1. The difference of brain activities when musicians listen to music compared with non-musicians. Superior temporal gyrus was significantly different in all conditions. A: the result of Chinese traditional musicians listening to Chinese music vs. non-musicians listening to Chinese music; B: the result of Chinese traditional musicians listening to western music vs. non-musicians listening to western music; C: the result of western musicians listening to Chinese music vs. non-musicians listening to Chinese music; D: the result of western musicians listening to western music vs. non-musicians listening to western music. Moreover, we also found that the greater activation of the superior temporal gyrus was elicited when subjects listening to the culturally unfamiliar music.

Title: Predictive coding on auditory processing: Spatio-temporal structure of signal flow in whole-cortical electrocorticograms

Authors: *M. KOMATSU[1], N. ICHINOHE[1,2]
[1]RIKEN Ctr. for Brain Sci., Saitama, Japan; [2]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

Abstract: To acquire a model of external world into our brain, the brain encodes sensory inputs by constracting generative model of the external world via synaptic modulations. Recently, this process is referred as "predictive coding (PC)", and some kinds of PC models inspired by the brain have become basis of the deep learning models in terms of the machine learning. However,

it remains unclear how the brain updates its generative model incessantly. In this study, we investigated the spatiotemporal structure of neuronal signal flow in a whole cortical level, which related to PC on auditory processing. We recorded the electrocorticograms (ECoGs) from three common marmosets with epidurally implanted electrodes covering entire hemispheres. The 85-96 channel ECoG array was epidurally implanted on the left or right hemisphere of each marmoset. ECoG recordings were conducted in passive listening condition with " roving oddball sequences" of 20 types of pure tones (250-6727 Hz with an interval of 1/4 octaves). Repetitive sequences of each 20 tone were randomly presented. We considered the last tones of sequences as standard, and the first tones of sequences as deviants. First, we investigated spatiotemporal propagation of auditory evoked potentials. We firstly observed significant activity in primary auditory area. And then, the activity moved to higher auditory areas, parietal, and frontal corteces. Second, we investigated brain regions correlated with prediction errors. The significant corelations firstly appeared in auditory belt regions, and then the corelations observed in frontal cortex. Third, we inferred functional connectivity by calcurating corretions of neuronal signals aligned on onset of standard and deviant stimuli, and compared the connectivity between standard and deviant stimuli at 50 msec time window with 10 msec step. The significant diffenrences of the connections were observed between temporal and frontal corteces. As results, a cortical processing model of auditory predictive coding have arrised. Information of auditory stimuli travels in wide range of cortical areas including temporal, frontal, and parietal areas. Onece stimulus comes into the brain, prediction errors firstly occure auditory belt regions, then propagate to other higher areas including frontal and parietal regions. Then, those signals update the generative model via changes of functional connectivities within auditory areas, and between auditory area and higher brain areas.

Title: Effects of peristimulus vagal nerve stimulation on responses in ferret auditory cortex

Authors: *J. B. FRITZ[1,2], A. MOHAMMED[2], J. VISWANATHAN[2], P. YIN[2], D. ELGUEDA[2], E. CAUSEY[2], J. LAI[3], S. V. DAVID[3], S. A. SHAMMA[2]

Abstract: Vagal nerve stimulation (VNS) has been shown to be an effective therapy for treatment of anxiety, epilepsy, inflammation and improves rehabilitation following stroke or brain injury. VNS is known to activate the Nucleus Tractus Solitarius which elicits CNS release of the neuromodulators acetylcholine (Nucleus Basalis) and norepinephrine (Locus Coeruleus), each of which are known from previous studies to affect responses in auditory cortex and enhance neuroplasticity. The goal of the present research was to explore the cortical effects of VNS in the awake animal, which could provide the neurobiological basis for VNS targeted neuroplasticity training – the use of VNS to enhance auditory learning. In the present study, we investigated the effects of VNS on auditory cortical responses in the awake, quiescent ferret to tonal, noisy and Mandarin Chinese phonemic stimuli with or without pairing with peristimulus VNS. We varied VNS duration, interstimulus interval, current amplitude and stimulation rate to explore parameter space for optimal stimulation effects. We also varied the site of VNS stimulation, using either cuff stimulation of the cervical vagus (c-VNS) or transdermal stimulation of the concha of the external ear, known to be innervated by the auricular branch of the vagus (a-VNS). We recorded from 120 neurons in primary auditory cortex (A1) and found that 32/120 cells showed response enhancement of 30% or more and 12/120 showed suppression effects of 30% or more. In some neurons, VNS lead to striking enhancement of cortical responses by 100-200%. Effects lasted for minutes and sometimes for up to one hour post-VNS, but gradually decreased and cell responses returned to baseline. Effects could be replicated with a second application of VNS. A parallel set of effects was observed with pupillary responses which were also modulated by VNS. In addition to measuring effects of VNS in a quiescent, listening animal, we also measured responses to VNS during active auditory task engagement in auditory go-nogo tasks, pairing target stimuli with or without peristimulus VNS. We shall describe the differences between the effects of a-VNS and c-VNS on cortical responses to acoustic stimuli during active behavior and passive listening.

Title: Neuromodulation and plasticity for a rodent model of cochlear implant use

Authors: *E. G. GLENNON[1,2], J. MULTANI[2], I. CARCEA[3], M. SVIRSKY[4,2,5,6], R. C. FROEMKE[4,3,2,5]
[1]New York Univ., New York, NY; [2]Neurosci. and Physiol., [3]Skirball Inst., [4]Otolaryngology, [5]Neurosci. Insititute, [6]Ctr. for Neural Sci., NYU Med. Ctr., New York, NY

Abstract: Cochlear implants are neuroprosthetic devices that can provide hearing to deaf patients. However, learning rates and peak performances of speech perception with cochlear implants are highly variable (Blamey et al. 2013). Adaptation to cochlear implants is believed to require neuroplasticity within the central auditory system (Fallon et al. 2009). However, mechanisms by which behavioral training enables plasticity and improves outcomes are poorly understood. Here we investigate the hypothesis that neural mechanisms that promote plasticity in the rodent auditory system are key to optimizing cochlear implant usage, and might be especially helpful in cases of poor performance. We focus on noradrenergic modulation of rat auditory cortex by the locus coeruleus, which can enable robust and long-lasting neural and behavioral changes (Manunta and Edeline 2004; Martins and Froemke 2015; Sara 2015).
We developed a new surgical approach for cochlear implantation in adult rats (King et al. 2016). Our approach optimizes insertion depth of an 8-channel electrode array and allows rats to freely behave while using the implant to perform auditory tasks. Normal hearing rats are trained on a go/no-go task, and self-initiate trials to respond to a target tone. Previously, we showed that this task requires auditory cortex, and that this task is sensitive to cortical modulation and plasticity (Carcea et al. 2017).
We tested if changes in locus coeruleus activity affect or improve auditory learning in normal hearing and cochlear-implanted rats. Prior to each daily behavioral training session, rats underwent a 5-10 min locus coeruleus pairing session. We examined how locus coeruleus stimulation might affect reversal learning when a new sound became the target. The new target was paired with locus coeruleus stimulation as for cochlear-implanted animals. Locus coeruleus stimulation accelerated learning in each case. We used fiber photometry to monitor neural activity of noradrenergic locus coeruleus neurons, showing strong responses to novel auditory stimuli and noxious stimuli. These studies indicate that neuromodulation can play a powerful role in shaping outcomes with cochlear implant use and training.

Title: Binaural interactions in the inferior colliculus following unilateral noise induced hearing loss

Authors: J. NGUYEN, J. W. MORLEY, *C. H. PARSONS
Western Sydney Univ., Sydney, Australia

Abstract: The auditory system is a bilateral system, integrating information from both ears to perform auditory functions such as sound localisation and detection of signals within noisy environments. The binaural functioning of the auditory pathway implies a balance of excitation and inhibition between inputs from either ear. Disruption of this balance, as may occur following unilateral noise-induced hearing loss (NIHL), may profoundly affect the normal functioning of the auditory system. There is growing consensus that the imbalance of excitation and inhibition due to hearing loss may contribute to the perception of tinnitus. Investigating changes in binaural processing following NIHL may aid us in understanding the neural basis of tinnitus. We investigated the consequences of unilateral NIHL on the response properties of cells in the inferior colliculus (IC). Four normal hearing Wistar rats were used as controls and four were unilaterally exposed to 115 dB SPL of 16 kHz for 1-hour. ABRs confirmed permanent threshold shifts. Using 32-channel, single shank electrodes, we simultaneously recorded from left and right ICs. We characterized the monaural response properties of IC neurons from normal hearing and NIHL animals, and investigated responses due to contralateral (dominant) and ipsilateral (non-dominant) stimulation. In these same neurons, we characterized binaural response profiles. Overall, in both normal (61%) and NIHL (71%) animals, the dominant binaural response was EI. Interestingly, the underlying monaural response properties of these EI neurons differed between the controls and NIHL groups. In the controls, the majority of EI neurons were derived from a population of V-shaped neurons, whilst in the NIHL group the EI responses were distributed amongst O and V-shaped neurons. We also examined the change in output of ipsilaterally driven IC neurons in response to introduction of contralateral stimulation. Under these conditions, introduction of contralateral stimulation produced an increase of excitatory responses. This was the dominant output in control (91%) and NIHL (61%) animals. In the control group, there was little inhibitory effect from contralateral stimulation with 4% of neurons being inhibited by contralateral input. However, in NIHL group, a significantly higher proportion of neurons were inhibited by contralateral stimulation. This result was consistent in the lesion (20%) and the intact ear (27%). These results show specific changes occur in the monaural and binaural response properties of IC neurons following unilateral NIHL. Moreover, the majority of binaural changes occur in a defined population of IC neurons.

Abstract: Listening and understanding our sound environment is a behavior that requires training and relies on our past experience. Auditory-cued behavioral training can alter neural circuits in primary auditory cortex (A1), but the mechanisms and consequences of experience-dependent cortical plasticity are far from being fully understood. This work addresses the following open questions: is there a general pattern of changes in the neuronal properties of A1 local networks when a sound becomes behaviorally relevant? Does the representation of a sound depend on whether it is associated with reward or punishment? Are there different circuits recruited during these opposite motivation auditory learning, and can we identify them? We explore these issues with mice that learn to perform two tasks with the same acoustic discrimination but with differential reward valence—one with water reward and the other with shock punishment. By taking advantage of the imaging capability of two-photon microscopy, we follow the same GCaMP6f expressing neurons in A1 throughout successive learning. Awake head-fixed recordings provide a rich observation of A1 activity in its layer 2/3. We find that in A1 superficial layers, both learning tasks induce strong patterning of neuronal sound selectivity, with an increase of marked spatial contrasts between zones representing the target sound and the surrounding areas. Neuronal assemblies representing the target sounds after learning the two tasks are distinct but overlapping. Finally, we apply approaches inspired by statistical physics to analyze our optical recordings and infer the underlying functional connectivity. They suggest that internal connectivity within A1 and external connection onto A1 are both reshaped by learning, and contribute to the observed modifications of sound selectivity. This work will

improve our understanding of the various circuits involved in learning associated with opposite values.

School, EwhaWomans Univ., Seoul, Korea, Republic of

Abstract: P300 (P3) wave is an event-related potential (ERP) recorded approximately 300 ms after stimulus in electroencephalography (EEG). P3 waves have been considered as a potential marker for cognitive brain function. Also, it is known that the P3 component may reflect information processing and consecutive decision making. However, there have been few studies for P3 waves using a rodent animal model due to the difficulty in dealing with animals' cognitive behaviors. In this study, we recorded P3-like ERPs from rats after behavior training during oddball paradigm. After the animal is trained to respond to a specific auditory stimulus, distinct P3 ERPs were successfully obtained. Further investigation is performed to propose the underlying mechanisms of P300 ERP component. We observe the aspects of P3-like ERP components under several different auditory target stimuli to accumulate the results from different cases and verify further underlying mechanisms of auditory cognitive perception in the rodent model.

Abstract: Cortical encoding of sound sequences with embedded rare stimuli, used in animal behavior of detection/discrimination/working memory tasks, can play a role in perception and behavior associated with streams of sounds. We investigate auditory cortical representation of deviant/rare stimuli in different long-term contexts using single unit extracellular recordings and 2-photon Ca^{2+} imaging in the mouse ACX. We use stimuli that are either periodic with a fixed relative location of the oddball sound (FF) or randomized location of the deviant (RF) with both tonal (T) and broadband noise (N) stimuli. Single unit recordings in Layer 2/3 show distinct patterns of response adaptation in the ACX over repetitions of stimuli in the two contexts. In the FF stream case (FF) ACX responses adapt to the entire sequence while in the RF case with an unpredictable deviant location there is a general increase followed by the adaptation of responses. Further, the adaptation observed in the FF case with T as deviant is absent with N as deviant amidst T sound stream. In order to understand the mechanisms underlying the differential adaptive coding of sound sequences, we hypothesize a role of inhibitory interneurons (INNs). Using 2-photon Ca^{2+} imaging, we probe coding of such sound sequences in excitatory and inhibitory neurons. We find differential selectivity of parvalbumin+ (PV) and somatostatin+ (SOM) INNs to N and T stimuli and thus further hypothesized that they play a differential role in the coding of Tone as deviant and Noise as deviant stimuli. We find the differential nature of adaptation of the PV and SOM neurons to the different contexts and types of sound sequence stimuli compared to excitatory neurons (EXNs) underlie the differential coding of sound sequences by EXNs in the supra-granular layers of the mouse ACX.

Title: Auditory oddball response in dorsolateral prefrontal cortex and basolateral amygdala is distinct from that in auditory cortex of macaque

Authors: *C. R. CAMALIER[1], K. SCARIM[2], M. MISHKIN[3], B. B. AVERBECK[4]

Abstract: The mismatch negativity (MMN) is an event-related potential component seen in response to unexpected "novel" stimuli, such as in an auditory oddball task. The MMN is of wide interest and application, but a key limitation of current understanding is that neural responses that generate it are poorly understood. This is in part due to differences in design and focus between animal and human oddball paradigms. For example, one of the main explanatory models, the "predictive error hypothesis", posits differences in timing and selectivity between signals carried in auditory and prefrontal cortex. However, these predictions have not been fully tested because 1) noninvasive techniques used in humans lack the combined spatial and temporal precision necessary for these comparisons, and 2) single neuron animal models of oddball, which combine spatial and temporal precision, have not focused on higher order contributions to novelty signals. In addition, accounts of the MMN traditionally do not address contributions from subcortical areas known to be involved in novelty, such as the amygdala. To better constrain hypotheses and to address methodological gaps between human and animal studies, we recorded single neuron activity from the (AC, n=690), dorsolateral prefrontal cortex (PFC, n=598) and the basolateral amygdala (AMY, n=627) of two macaque monkeys during an auditory oddball paradigm modeled after that used in humans. Consistent with predictions of the predictive error account, novelty signals in prefrontal cortex were generally later than in auditory cortex, as well as abstracted from stimulus specific effects seen in auditory cortex. However, we found signals in amygdala that were comparable in magnitude and timing to those in prefrontal cortex, and both prefrontal and amygdala signals were generally much weaker than those in auditory cortex. These observations place useful quantitative constraints on putative generators of the auditory oddball-based MMN, and indicate that subcortical areas, such as the amygdala, may need to be included in future explanatory accounts.

Title: Ensemble encoding of redundant and novel stimuli in auditory cortex

Authors: *Y. SHYMKIV[1], J. P. HAMM[2], R. YUSTE[2]
[1]Biol. Sci., [2]Columbia Univ., New York, NY

Abstract: Processing of sensory information in the brain strongly depends on prior context, whereby repetitive (redundant) stimuli are ignored, while novel (deviant) stimuli are amplified. The peak response to deviant stimuli also typically shows a delay relative to the redundant response, suggesting that deviance detection involves additional local or top-down feedback. To explore this we imaged the activity of neuronal populations in both primary and higher order auditory cortices and examined the dynamics of population activity involved in context processing and deviance detection. First, we mapped the auditory cortex with wide-field calcium imaging to locate primary auditory cortex (AI), anterior auditory field (AAF), and secondary auditory cortex (AII). Then, we focused on layer 2/3 of each area and record neuronal activity with volumetric two-photon calcium imaging. Awake mice were presented with an acoustic "oddball" paradigm, where a given stimulus was displayed in three contexts, repetitive, deviant, and neutral. The types of stimuli were either simple amplitude modulated tones of different frequencies (2-80 kHz), or more complex frequency grating of different orientations and mouse vocalizations. The population average of neuronal responses in each cortical area showed context dependency, where they were attenuated to redundant stimuli, i.e. stimulus specific adaptation, and amplified to deviant ones, i.e. deviance detection. We used cluster analysis and identify ensembles of neurons encoding context across levels of auditory cortex and as a function of stimulus complexity. We find elements of hierarchical organization, where context encoding is more complex in higher order cortex. We conclude that neuronal ensembles can specifically code

redundant or deviant stimuli, consistent with the hypothesis that they are involved in primary and higher order processing of sensory information.

Title: Vagus nerve stimulation modulates cortical activity in the common marmoset

Authors: *S. D. KOEHLER[1], L. SANTOS[2], X. WANG[2]
[1]Dept. of Biomed. Engin., The Johns Hopkins Sch. of Med., Baltimore, MD; [2]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Vagus nerve stimulation (VNS) has been shown to modulate resting state cortical activity and induce cortical plasticity in motor and sensory cortex. These observations motivate VNS as a treatment modality for epilepsy and a neuromodulation modality for enhancing rehabilitation and learning. While a number of studies have investigated VNS stimulation effects in rodents, there is currently little data from non-human primates. The common marmoset, a highly vocal and social monkey species, has emerged in recent years as a promising model for neuroscience research. We have established the first marmoset model for studying the effects of VNS on cortical physiology and plasticity. Chronic cuff electrodes were implanted around the left cervical vagus nerve, and electrode status was monitored chronically with electrode impedance spectroscopy. We recorded electroencephalography (EEG) and local field potential (LFP) and single-unit activity from auditory cortex of awake marmosets in response to parametric variations of VNS pulse train parameters including current amplitude (0 - 2 mA), pulse duration (50 - 600 us), and pulse train frequency (10 - 100Hz). We observed that VNS modulated EEG power, predominantly in the alpha (8-12Hz), beta (13-30Hz), and gamma (30-75Hz) bands with modulation strength increasing with pulse train frequency. High frequency pulse trains also suppressed spontaneous activity in some cortical neurons. These data provide the first evidence for VNS modulation of physiological and cortical responses in the marmoset.

Title: Recalibration of excitatory and inhibitory local cortical networks supports neural and perceptual recovery of simple - but not complex - sound processing

Authors: *J. RESNIK, D. B. POLLEY
Otolaryngology, Harvard Med. Sch., Boston, MA

Abstract: The auditory system employs a variety of rapid gain control mechanisms to adjust neural coding sensitivity to match transient shifts in acoustic signal energies. In addition to these "fast acting" gain control systems, central auditory neurons also exhibit slower gain control that adjusts neural excitability following long lasting reductions in auditory input strength, for example, deprivation of afferent inputs from the ear. While there is a general notion that increased neural amplification following a partial blockade of input from the ear is enabled by changes in inhibitory strength, the time course and cell type specific circuitry modifications that underlie slow changes in auditory gain remain unknown.
We performed chronic, cell type specific 2-photon calcium imaging to simultaneously visualize sound evoked GCaMP signals in genetically identified inhibitory PV (parvalbumin expressing) neurons alongside neighboring PPy (putative pyramidal) cells in the auditory cortex of awake adult mice, before and after a controlled loss of afferent input from the cochlea. This approach allowed us to track the daily dynamics in identified cell types, at different spatial scales - single cell to network activity, and temporal scales - hours to weeks following peripheral insult. We found an increase in spontaneous activity in PPy cells on the day of the insult followed by an increase in PV spontaneous activity 24 hrs later. Both excitatory and inhibitory cells exhibited a major decrease in toned evoked responses, which recovered almost back to baseline levels two weeks post injury. For more temporally complex stimuli, such as tones embedded in background noise, both PPy and PV cells showed an increase in response thresholds that didn't recover. Network activity showed a permanent increase in noise correlation between PV cells during complex, but not simple, sound presentations.
Our imaging data demonstrated complete cellular and network recovery for simple stimuli, but persistent coding deficits for more complex stimuli such as tones in noise. To explore the perceptual implications of these observations, auditory operant behavioral measurements were performed in head-fixed mice before and following damage to cochlear nerve afferents. As

predicted from our imaging data, mice showed complete perceptual recovery for detecting tones in silence despite a massive loss of auditory nerve input. However, tone detection in noise remained impaired.
Collectively, our work provides new insight into slow compensatory plasticity in PV and PPy neurons in the auditory cortex that restores neural encoding of rudimentary, but not complex, sounds after peripheral deafferentation.

Abstract: Speech communication in real-world conditions requires a listener's auditory system to continuously adapt to sudden changes in the acoustic environment and selectively suppress the noise features relative to speech. How adaptation occurs in the human auditory cortex and how it affects the representation and perception of phonetic features as a new noise source appears in the acoustic scene remains unclear. We directly measured neural activity in perisylvian cortical regions of six human subjects as they listened to speech in abruptly changing background noise. We found rapid and selective suppression of acoustic features of noise in the neural responses, which resulted in enhanced representation and perception of spectrotemporal and phonetic features of speech. We further show that the degree of adaptation to different background noises varied across electrodes and was predictable from the tuning properties and speech-specificity of electrodes. Finally, electrical brain stimulation of highly adaptive electrodes significantly improved the perceived quality and the intelligibility of speech in noise. The convergence of these neural, perceptual, and stimulation effects reveal novel representational properties for speech processing in human perisylvian areas and shed light on intrinsic dynamic mechanisms that enable a listener to filter out irrelevant sound sources in a changing acoustic scene.

Title: Dissociation in behavioral effects of perineuronal net degradation in premotor nuclei of adult songbirds

Authors: *L. DARKWA[1,2], V. NERURKAR[2], D. SEMU[2], T. M. OTCHY[2,3]
[1]2018, Boston, MA; [2]Dept. of Biol., [3]Ctr. for Neurophotonics, Boston Univ., Boston, MA

Abstract: During sensitive periods, enhanced neural plasticity enables environmental factors to shape developing circuits and behavior. In primary visual cortex, where developmental regulation of plasticity has been studied most extensively, the absence of perineuronal nets (PNNs), extracellular matrix containing chondroitin sulfate proteoglycans, is thought to be a key permissive factor for experience dependent plasticity. The assembly of PNNs around parvalbumin (PV)-expressing inhibitory interneurons is thought to contribute to critical-period closure, and consistent with this notion the degradation of PNNs in adults returns primary visual cortex plasticity and dynamics to a less mature state. In contrast to these sensory circuits, relatively little is understood regarding the regulation of plasticity in sensorimotor circuits and the behaviors they underlie. Song learning in the zebra finch (*Taeniopygia guttata*) occurs during a sensitive period, and it has been previously shown that PNN formation around PV-expressing interneurons in key song system nuclei is correlated with song stereotypy. Drawing an analogy with primary visual cortex, we hypothesized that the degradation of PNNs in premotor nuclei would similarly revert the adult song system to a state more characteristic of the juvenile songbird. To test this hypothesis, we compared the song structure before and after degrading PNNs in either HVC (used as a proper name) or the robust nucleus of the arcopallium (RA) in adult zebra finches by bilateral injections of chondroitinase ABC (ChABC), an enzyme shown to digest PNN proteoglycans *in vivo*. For birds receiving injections targeting RA, we found no significant difference in song structure following PNN degradation, nor between ChABC-injected birds and sham controls. In contrast, birds receiving ChABC injections targeting HVC showed significant and persistent increases in spectral and temporal variability in comparison to both pre-injection songs and sham controls. A subset of these birds also showed elevated syntactic variability. The elevated behavioral variability we observed in birds receiving HVC-targeted injections was reminiscent of the song structure of uncrystallized juvenile birds and is

consistent with prior mechanistic studies showing a correlation between song maturation and the increase of inhibitory tone within HVC. Whether degradation of PNNs in HVC additionally recapitulates other aspects of juvenile song system structure and function remains to be determined. Future experiments will focus on understanding the role of PNNs in shaping singing-related neural dynamics and behavioral flexibility.

Abstract: Vagus nerve stimulation is a medical treatment for severe epilepsy and depression, but the mechanisms underlying the neural effects are poorly understood. The vagus connects essentially all peripheral organs to the brain via afferents through the nucleus tractus solitarius to several neuromodulatory centers. Vagus nerve stimulation has been shown to produce long-lasting plasticity in the cerebral cortex to improve sensory processing after stroke (Boreland et al. Brain Stimul 2016). Additionally, recent work has shown that neuromodulatory signaling via the cholinergic and noradrenergic systems lead to enhanced learning (McGinley et al. Neuron 2015). Understanding the circuit mechanisms by which vagus nerve stimulation modulates neural plasticity is important for developing non-invasive neuromodulatory therapies and expanding their application to learning.
Mice provide an opportunity to monitor and manipulate neural circuits during stimulation but vagus nerve cuff electrodes are not available for mice due to their small size. We first designed a novel cuff electrode for mice and demonstrated reliable low-impedance measurements and stimulation for months during behavior in chronically implanted animals. Vagus nerve stimulation was calibrated to transiently reduce respiration without affecting heart rate or blood

oxygen saturation levels. We next wanted to see if vagus nerve stimulation could affect neural representation and behavior. During two-photon calcium imaging in auditory cortex, we found that pairing a tone with stimulation led to a short-term enhancement of auditory representation. After several days of pairing sessions, the representation of the paired tone increased across the population. The observed changes in neural activity following pairing are reminiscent of the effects of basal forebrain stimulation (Froemke et al. Nature 2007). To test if neural changes could influence behavioral performance, animals were trained on either a paired go/no-go or two-alternative forced choice auditory discrimination task (Martins & Froemke Nat Neurosci 2015; Kuchibhotla et al. Nat Neurosci 2017). We are now investigating how vagus nerve stimulation might lead to direct or indirect activation of central modulatory systems to enable plasticity and improve learning.

Title: Interhemispheric projections regulate sensory processing in primary auditory cortex

Authors: *B. J. SLATER, J. S. ISAACSON
UCSD, La Jolla, CA

Abstract: Interhemispheric (callosal) connections between the right and left auditory cortex are proposed to participate in sound localization and speech processing. Intriguingly, pathophysiology of auditory callosal projections has also been proposed to underlie language deficits and auditory hallucinations in disorders such as autism and schizophrenia. Despite the potential importance of cortical callosal projections in auditory processing, the functional properties of interhemispheric connections are not well understood. Here we combine reversible optogenetic silencing of the left auditory cortex with linear silicon probe recordings in the right primary auditory cortex (A1) of awake, head fixed mice to determine how one cortex influences tone-evoked responses in the other. Pure tones (4-60 kHz) were applied free field to the left ear and the right ear was plugged. Under these conditions, cortical silencing caused a rapid and sustained reduction in spontaneous firing of fast spiking units preferentially located in deep layers. Cortical silencing caused a slow increase in spontaneous firing of regular spiking cells

across all layers and suppressed tone-evoked responses in the majority of cells (39/52) with classical v-shaped tuning curves. The suppressive action on evoked responses scaled with firing rate and there was no consistent change in best frequency. These findings indicate that interhemispheric connections provide both subtractive and multiplicative operations on sensory processing. Thus, cortical callosal projections regulate both the signal to noise ratio and gain control of sound representations in A1.

Title: Brain state-dependent modulation of sensory representations in layer 2/3 of primary auditory cortex

Authors: *P.-A. LIN[1], S. K. ASINOF[2], J. S. ISAACSON[3]
[1]Neurosciences, Univ. of California San Diego, San Diego, CA; [2]Neurosciences, Univ. of California San Diego, La Jolla, CA; [3]UCSD, La Jolla, CA

Abstract: Sensory processing in the neocortex is continuously modulated by changes in behavioral and cognitive state. Thus, deconstructing the complex and multi-faceted relationship between brain state and sensory responses is key to understanding how our brains represent the world around us. In deep layers of the primary auditory cortex (A1) of mice, the magnitude and reliability of sound-evoked responses have been shown to be maximal at intermediate states of arousal (McGinley et al., 2015). However, the manner in which brain state modulates sensory responses in superficial layers of A1—where the bulk of intracortical auditory processing is thought to occur—is less well understood. To address this question, we monitored pure tone-evoked responses using two-photon calcium imaging of GCaMP6s-expressing layer 2/3 (L2/3) pyramidal cells in awake, head-fixed mice situated on a linear treadmill. We simultaneously measured fluctuations in arousal and locomotion via pupillometry and treadmill activity tracking, respectively. In contrast to previous observations in deep layers of A1, we found that the magnitude and reliability of L2/3 tone-evoked responses increased linearly with arousal, peaking at high states of arousal in the absence of locomotion. Thus, the relative sparseness of sensory representations rapidly changed depending on the level of arousal. Furthermore, although

changes in arousal did not alter the best frequency of individual cells, increases in arousal broadened frequency tuning. Taken together, our results suggest that arousal alters the density of population responses and tuning broadness in L2/3 on a moment-by-moment basis. We are currently examining responses of local interneurons to explore potential mechanisms underlying arousal-dependent changes in L2/3 activity.

Title: Adaptive efficient coding of correlated acoustic features in primary auditory cortex of the awake ferret

Authors: *K. LU, W. LIU, J. B. FRITZ, S. A. SHAMMA
Inst. for Systems Res., Univ. of Maryland, College Park, MD

Abstract: Natural sounds such as vocalizations often have co-varying acoustic attributes where one acoustic feature can be predicted from the other. In such cases, neural encoding of one acoustic feature would overlap with that of the other, resulting in coding *redundancy*. It has been proposed that sensory systems are able to detect such covariation and adapt so as to reduce redundancy leading to more efficient neural coding (Barlow and Földiák, 1989). Recent psychoacoustic studies provide evidence supporting this Efficient Coding Hypothesis (Stilp et al., 2010, Stilp and Kluender, 2011, 2012, 2016). Following passive exposure to a set of complex sounds in which the waveform amplitudes and the spectral envelopes covaried in a correlated fashion,,subjects' discriminability for sounds along the correlated dimensions remained intact. However, their discriminability of sounds on the orthogonal dimension was significantly impaired. These results suggest that passive exposure induced the auditory system to efficiently encode the two co-varying dimensions as a single dimension, at the cost of lost sensitivity to the orthogonal dimension. Here we explore the neural underpinnings of this phenomenon by recording single-unit responses from neurons (n=80) in the primary auditory cortex (A1) in awake ferrets (n=4) following a similar passive exposure procedure The stimuli in our study were harmonic tones with two correlated stimulus attributes - amplitude modulation (AM) rate and peak frequency of the spectral envelope (SP). We found that: (1) cortical responses driven by

sounds with correlated attributes rapidly became adapted to these stimuli, (2) while their neuronal spike rate coding signal-to-noise ratio remained unchanged along the covaried dimension, the SNR along the orthogonal dimension decreased, (3) correlation between neurons tuned to the two covarying attributes decreased after exposure, (4) these exposure effects still occurred if sounds were correlated along two acoustic dimensions (AM and SP), but varied randomly along a third dimension (pitch). These neurophysiological results support the Efficient Learning Hypothesis and deepen our understanding of how the auditory system represents acoustic regularities and covariance.

Title: Brain state regulates network-level control of the strength and tuning of tone-evoked responses in primary auditory cortex

Authors: *S. K. ASINOF[1], P.-A. LIN[2], J. S. ISAACSON[3]
[1]Neurosciences Grad. Program, Univ. of California San Diego, La Jolla, CA; [2]Neurosciences, Univ. of California San Diego, San Diego, CA; [3]UCSD, La Jolla, CA

Abstract: Recent rodent studies demonstrated that brain state, as measured by changes in pupil diameter or behaviors like whisking or running, can have profound effects on the cortical encoding of sensory stimuli. However, the synaptic mechanisms underlying brain-state dependent changes in cortical sensory processing are unclear. Here we combine pupillometry and whole-cell recording in awake, head-fixed mice to determine how arousal modulates sensory-evoked activity in layer 2/3 cells of primary auditory cortex (A1). We studied responses to pure tones (100-200 ms duration) over a range of frequencies. In current-clamp, we found that increases in arousal enhanced the amplitude and duration of tone-evoked excitatory postsynaptic potentials (EPSPs). Furthermore, subthreshold responses were tuned to a broader range of frequencies as arousal increased. We next used voltage-clamp recordings to study the excitatory and inhibitory postsynaptic currents (EPSCs and IPSCs) underlying tone-evoked responses. Surprisingly, increases in arousal were associated with modest decreases in short-latency, evoked EPSCs and IPSCs locked to tone onset. However, we observed that lateral inhibition generated

by a slow, tone-evoked withdrawal of ongoing, recurrent excitation ("network suppression", Kato et al., 2017) was strongly suppressed as arousal increased. These results reinforce the notion that A1 operates as an inhibition stabilized network and show that the modulation of recurrent activity underlies stronger and more broadly tuned tone-evoked membrane voltage responses in aroused brain states.

Title: Functional investigation of a brainstem excitatory connection relevant to sensorimotor gating

Authors: *L. E. MARTINETTI, E. PERU, A. TENA, C. D. LOYOLA, K. FÉNELON
Biol. Sci., The Univ. of Texas At El Paso, El Paso, TX

Abstract: In order to focus attention, the brain has to "gate" or block irrelevant sensory information that could lead to cognitive overload. This is done by way of a neuronal pre-attentive mechanism termed sensorimotor gating (SG). Therefore, deficits in the SG mechanism prevent patients from focusing attention. SG deficits have been observed in patients suffering from various neurological disorders, and it is a hallmark of schizophrenia. Previous work has identified key brain areas, such as the pedunculopontine tegmental nucleus (PPTg), that send inputs to the brainstem caudal pontine reticular nucleus (PnC). The PNC is the area at the center of the SG circuitry. However, there is still a knowledge gap concerning what cell types are involved and what other brain areas could potentially contribute to SG. It has been long known that the PPTg contains cholinergic, glutamatergic and GABAergic neurons and sends direct inputs to the PnC which contains large glutamatergic neurons as well as glycinergic neurons. These projections are known to modulate SG. Recently, the contribution of PPTg cholinergic neurons to SG was debated. Therefore, it is not known whether other PPTg neurons project to the PnC and whether they contribute to SG. We investigated the role of the PPTg glutamatergic inputs onto the PnC as well as the possible role of glycinergic neurons present in PNC in the context of SG in mice, which had not been demonstrated before. To test our hypothesis, we used neuronal dyes to label cellular pathways, immunohistochemistry to reveal cellular

neurochemistry and *in vivo* optogenetics to functionally study the contribution of the PPTg-PnC glutamatergic connection as well as the possible role of glycinergic interneurons present in the PNC in SG. Additionally, whole cell recordings were obtained from glycinergic PNC neurons in order to characterize their intrinsic and synaptic properties. Our data show for the first time that there is a direct bilateral glutamatergic connection between the PPTg and the PnC. In addition, silencing these PPTg excitatory fibers in the PnC lead to altered prepulse inhibition (PPI), showing a contribution to SG *in vivo,* possibly via glycinergic PnC neurons.

Title: Shining light on a key amygdala-brainstem connection important for attention processing

Authors: J. CANO, *K. FENELON
Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: Sensorimotor gating is a pre-attentive neural filtering mechanism that prevents sensory or cognitive overload, and contributes to attention processing. Patients suffering from neuropsychiatric disorders, such as schizophrenia and anxiety, present sensorimotor gating deficits that greatly impact their daily lives. Clinically, sensorimotor gating can be assessed using the prepulse inhibition (PPI) of the acoustic startle reflex task. During PPI in healthy subjects, a non-startling sound (prepulse) will inhibit the startling effect of a subsequent startling sound (pulse). Numerous *in vivo* and *in vitro* animal studies have shown that the brainstem caudal pontine reticular nucleus (PnC) is at the core of the PPI pathway, relaying sensory inputs from several brain regions directly to spinal and cranial motor neurons. In fact, the PnC has been shown to receive cholinergic inputs from the pedunculopontine tegmental nucleus (PPTg). However, recent *in vivo* rat and fish studies suggest that different neurotransmitters released from other brain regions might be more critical for PPI. The amygdala is another region directly connected to the PnC. Interestingly, the amygdala modulates PnC neuronal activity, and lesions to the amygdaloid complex can disrupt PPI. Furthermore, anatomical and functional abnormalities of the amygdaloid complex are a phenotypic marker of schizophrenia. However, the potential role of the amygdala-PnC connection in sensorimotor gating remains to be further investigated. We previously showed that the amygdala sends monosynaptic and glutamatergic

inputs to the PnC, using mice. Therefore, here, we investigated the functional contribution of this excitatory connection to sensorimotor gating *in vivo* using an optogenetic approach. We show that silencing this connection significantly affects PPI. Furthermore, we performed tract-tracing, immunohistochemical and *in vitro* electrophysiological experiments to further identify the PnC neurons targeted by this amygdala glutamatergic input. These results will contribute to better understand the neural pathways underlying PPI, and allow us to identify potential therapeutic targets for diseases associated with sensorimotor gating deficits.

Title: Habituation of neural responses to complex sounds in secondary auditory cortex of ferrets reflects long-term auditory memory

Authors: *W. LIU[1], K. LU[2], S. V. DAVID[3], P. ZAN[4], J. B. FRITZ[2], S. A. SHAMMA, 20740[2]
[2]Inst. for Systems Res., [1]Univ. of Maryland, College Park, MD; [3]Oregon Hearing Res. Ctr., Oregon Hlth. and Sci. Univ., Portland, OR; [4]Electrical and Computer Engin., Univ. of Maryland, Colleg Park, Greenbelt, MD

Abstract: Auditory neurons encode sound features and also stimulus history (Ulanovsky et al., 2003, 2004). The most commonly reported time course for context or history effects on auditory responses in mammalian auditory cortex ranges from a few hundreds ms up to minutes (Yaron et al., 2012). In the secondary auditory areas in the forebrain of songbirds (Chew et al., 1995, 1996), however, stimulus-specific habituation to acoustic stimuli has been shown to last for hours, even days. This long-term habituation effect in the songbird requires RNA synthesis and is also correlated with behavioral responsiveness to familiar sounds. It is correlated with immediate gene expression and is believed to be a form of long-term auditory memory. However, such long-term habituation effects in the mammalian auditory system have not been previously described. In the current study, we investigated the long-term effect of stimulus history on single-unit responses in secondary auditory cortex (areas PPF and PSF in the dorsal PEG (posterior ectosylvian gyrus)) of awake ferrets (n = 3). We used standard neurophysiological technique and recorded from neurons (n=81) while the animal was repetitively presented with short clips (duration of 2-5 seconds) of novel complex sounds in blocks of 50 same-sound repetitions. Sounds were diverse (n = 73) and included music samples,

animal vocalizations and human speech, For all stimuli we consistently observed marked habituation which decreased the response to asymptote after ~20-30 repetitions. Responses to the same stimuli were then measured again after a delay. We found habituation to stimuli persisted, demonstrating that stimulus habituation could last for at least 20 minutes, thus reflecting a form of long-term memory. With a parallel set of pupillometric studies in the ferret (n=3) we compared pupillary size in response to familiar and novel stimuli and plotted habituation curves for pupillary responses that were similar to the neural habituation curves. The correlated neural and pupillary indices showed that long-term habituation to passively presented repeated stimuli was correlated with recognition of familiar sounds.

Title: The protective effects of ferrostatin-1 (fer-1) in response to excitotoxicity in mouse hippocampal slices

Authors: *V. I. NAVARRO[1], M. N. RAMIREZ[2], C. D. LOYOLA BALTAZAR[2], R. SKOUTA[3], K. FENELON[2]
[1]Biol. Sci., Univ. of Texas At El Paso, El Paso, TX; [2]Biol. Sci., [3]Chem., Univ. of Texas at El Paso, El Paso, TX

Abstract: The development of different neurological disorders has been associated with the accumulation of reactive oxygen species (ROS). This phenomenon has been seen during epilepsy and neurodegenerative diseases like Parkinson's disease. Furthermore, an excess of ROS and the development of such disorders have been linked to neuronal cell death partly due to excessive, non-physiological glutamate release. Ferroptosis is a defined iron-dependent cell death mechanism. Interestingly, both ferroptosis and glutamate excitotoxicity are associated with an increase in ROS levels. Ferroptosis and glutamate-induced cell death can be inhibited by another small molecule named Ferrostatin-1 (Fer-1). This suggest that both cell death mechanisms share a similar lethal pathway that can be rescued by Fer-1. The goal of the present study is to better understand the neuroprotective properties of Fer-1. To test our hypothesis, we bath applied glutamate in order to induce epileptiform activity in an *in-vitro* brain slice model. Extracellular field electrophysiological recordings were then performed on hippocampal slices in the presence

and absence of Fer-1. In addition to these studies immunohistochemical experiments were used on 150 µm thick mouse hippocampal slices in order to assess soma size of CA3 region neurons exposed to glutamate-induced excitotoxicity, in the presence and absence of Fer-1. Preliminary data show that Fer-1 decreases the frequency of the glutamate-induced epileptic-like events and prevents the morphological changes subsequent to the exposure to an excess of glutamate.

Title: Cortical network topology across awareness states during sleep and anesthesia: An intracranial electrophysiology study

Authors: *M. I. BANKS[1], K. V. NOURSKI[2], H. KAWASAKI[2], M. A. HOWARD, III[2]
[1]Dept. of Anesthesiol., Univ. of Wisconsin, Madison, WI; [2]Dept. of Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA

Abstract: Introduction: The sharing of information between nodes in the cortical network plays a central role in leading theories of consciousness, and disruption in connectivity has been proposed to occur upon loss of consciousness (LOC) during anesthesia and sleep. However, whether LOC during these two conditions shares a common mechanism is unclear. To investigate this issue, resting state network topology was compared across brain states during natural sleep and propofol anesthesia.
Methods: Subjects were neurosurgical patients implanted with intracranial electrodes placed to identify epileptic foci. A combination of subdural grids and depth electrodes provided dense coverage of temporal, parietal and frontal cortex. We focused on nodes in the cortical hierarchy activated during both pre-attentive and conscious auditory novelty detection: core and non-core auditory cortex on the superior temporal gyrus including the superior temporal plane, auditory-related cortex on the middle temporal and supramarginal gyrus, and prefrontal cortex. Resting state data were recorded in the same subjects during overnight natural sleep and during induction

of general anesthesia with incrementally titrated propofol infusion. Six brain states were compared: wake (WS) and NREM stages 1 and 2 (N1, N2) during natural sleep, and pre-drug wake (WA), sedated/responsive (S) and unresponsive (U) during propofol anesthesia. Adjacency matrices (A), computed as thresholded, weighted, alpha (8-13 Hz) phase lag index, were compared pairwise for brain states using the operator norm of the difference between adjacency matrices (i.e. $d_{i,k} = ||A_i - A_k||_{op}$).
Results: Changes in network topology were more dramatic for transitions into the unconscious states (N2, U) than for transitions into states of diminished but maintained awareness (S, N1) (i.e., $d_{WA,S} < d_{S,U}$ and $d_{WS,N1} < d_{N1,N2}$). Network topology was most similar between brain states hypothesized to be equivalent under sleep and anesthesia (i.e. WA vs. WS, S vs. N1, U vs. N2); d values comparing hypothesized equivalent states (i.e. $d_{WA,WS}$, $d_{S,N1}$, $d_{U,N2}$) were smaller than d values for corresponding non-equivalent states (e.g. $d_{S,N2}$).
Conclusions: Pronounced changes in network topology for the transitions S -> U and N1 -> N2 likely reflect changes in cortical connectivity mediating transition between conscious and unconscious states. The similarity in network topology between equivalent brain states during anesthesia and sleep suggests common mechanisms in transitions to and from unconsciousness.

Title: Auditory and premotor cortex connectivity in the rat brain

Authors: *C. I. DE LEÓN-ANDREZ[1], G. ROJAS-PILONI[3], L. CONCHA[1], P. GARCÍA[2], H. MERCHANT[4]
[1]Inst. de Neurobiología, UNAM, Queretaro, Mexico; [2]Inst. de Neurobiología, UNAM, Qro, Mexico; [3]Univ. Natl. Autonoma Mexico, Queretaro, Mexico; [4]Inst. de Neurobiologia UNAM, Queretaro, Mexico

Abstract: Sensorimotor synchronization (SMS) is the coordination of rhythmic movements with an external rhythm. This SMS ability is essential for a number of human behaviors such as

language comprehension, dance and music performance, activities that depend on a dynamic interaction between the auditory and motor system. Neuroimaging and electrophysiological studies have shown that the motor cortico-basal ganglia-thalamocortical circuit (mCBGT), which includes SMA, pre-SMA and putamen, is involved in rhythm, perception and motor execution or rhythmic behaviors. Although it has been demonstrated that neurons in premotor regions (SMA and preSMA) respond to the presentation of auditory stimuli it is not clear how the auditory cortex reach this premotor area. Before the characterization of the audio-premotor pathway in the monkey, we standardized the neuronal tracing technique in the rat brain to elucidate the auditory-premotor cortex circuit in this model. Using the retrograde fluorescent tracer Fluoro-Gold (FG) and the anterograde tracer Dextran Tetramethylrhodamine (TMR), we found that neurons in superficial and deep layers of the auditory cortex (A1) project directly to the supplementary tor cortex (M2), and axons of other areas such as motor, visual and somatosensory cortex also target M2 with different magnitudes. Preliminary data also propose that this pathway M2-A1 is reciprocal. These findings were corroborated using high field 7T magnetic resonance tract-graphs in the same animals. Hence, these results suggest a strong and direct audio-premotor loop in the rat.

Title: Oscillatory correlates of auditory working memory as revealed by electrocorticography

Authors: *T. D. GRIFFITHS[1], P. GANDER[2], K. V. NOURSKI[2], C. KOVACH[2], H. OYA[2], H. KAWASAKI[2], M. HOWARD, III[2], S. KUMAR[1]

Abstract: Working memory is the capacity to hold and manipulate behaviourally relevant information in mind in the absence of ongoing sensory input. Here we explored the hypothesis that working memory for tones requires a network of oscillatory activity in auditory cortex, frontal cortex, and hippocampus, and examined the form of such activity in neuronal ensembles. We recorded local field potentials from six human subjects undergoing invasive monitoring for pre-surgical localization of epileptic foci. The subjects were implanted with depth electrodes

along the axis of Heschl's gyrus (HG) containing primary cortex in the medial part, subdural electrodes over temporal and frontal cortex, and hippocampal depth electrodes. Following a visual cue, subjects were presented with a pair of tones (0.5 s duration, 750 ms inter-stimulus interval) belonging to one of the two different categories ('Low': 300-570 Hz; 'High': 2000-2800 Hz). A visual cue (750 ms) then informed the subjects which tone (first or second) to remember. A 3 s retention period was followed by a tone which could be the same or different (frequency difference ±20%) from the tone held in mind. The subjects made a same/different judgement over a total of 160 trials (80 each of 'Low' and 'High' tone retention). We measured averaged evoked potentials and carried out single-trial time-frequency analysis using a wavelet transform. During retention, a sustained increase (compared to rest period) in power in the beta band (15-20 Hz) was observed in the lateral part of HG. Increase in power in the gamma band (60-100 Hz) was observed in recording sites on the posterior superior temporal gyrus (pSTG) and inferior frontal gyrus (IFG). In the hippocampus, power increase in low frequencies (less than 10 Hz) in the retention period was observed. The data demonstrate a network of brain regions during auditory working memory that includes auditory, frontal, and hippocampal cortex and is consistent with the network shown in our previous functional neuroimaging study (Kumar et al., J Neurosci 2016 36:4492-505). The results provide a foundation for analysis of effective connectivity to test the hypothesis that the auditory cortex activity during retention is driven by the activity in inferior frontal gyrus or hippocampus.

Title: Modulation of low frequency oscillations by human speech control

Authors: *A. RAMÍREZ-CÁRDENAS[1], D. R. PETERS[2], R. BEHROOZMAND[3], R. M. KELLEY[2], C. KOVACH[1], H. KAWASAKI[1], M. A. HOWARD, III[1], J. D. W. GREENLEE[1]
[1]Dept. of Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [2]Carver Col. of Med., Univ. of Iowa, Iowa City, IA; [3]Speech Neurosci. Lab., Univ. of South Carolina, Irmo, SC

Abstract: Speech motor control requires the timely integration of vocal-motor and sensory information. Particularly, auditory feedback is crucial for online monitoring of speech production. To study the neural networks involved in speech control, we introduced a sudden and short perturbation in the auditory feedback that human subjects received when speaking. Particularly, feedback was shifted in time (delayed) by 200-300 ms for a variable short period in

pseudorandomized trials. Voice was recorded and subsequently played back to the subjects for comparisons between auditory and motor activity. Fifteen surgical epilepsy patients performed the task while we recorded local field potentials from multicontact intracranial electrodes implanted for clinical purposes. All subjects exhibited some degree of speech disruption in trials with delayed auditory feedback. Moreover, significantly more utterances were rated as abnormal in trials in which feedback was disrupted. The abnormalities more frequently identified in these trials were utterance prolongation and a change in speech rate. Consistently across patients, the perturbation in auditory feedback induced modulation of high gamma power (HGP, 70-150 Hz) and ERPs (filter <30 Hz) in the posterior superior temporal gyrus (STG) during vocal production. Other high-order auditory (MTG, SCG) and prefrontal also showed modulation by the disrupted feedback. During vocal production, ERPs were more rapidly and specifically modulated by disrupted feedback than HGP. Both HGP and ERPs were also modulated in these areas when subjects listened to their delayed vocalizations. However, during listening, HGP exhibited a larger and faster modulation by the disruption than ERPs. Indeed, ERPs were minimally modulated in non-disrupted trials and while listening disrupted utterances, but exhibit a strong response in the speaking phase of disrupted trials. A suppression of beta power (12-20 Hz) seems to drive this effect, which is specific of vocal motor control. These preliminary results show how a sudden and short delay in auditory feedback affects speech production and reveal the neural mechanisms of speech control in the human brain.

Title: Alpha oscillations index the temporal dynamics of exerted cognitive effort during listening

Authors: *B. HERRMANN[1], B. MAESS[2], I. S. JOHNSRUDE[3]
[1]Dept. of Psychology, The Univ. of Western Ontario, London, ON, Canada; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [3]Psychology / Comm Sci. Disorders, Univ. of Western Ontario, London, ON, Canada

Abstract: The ability to exert cognitive effort during listening is crucial for speech perception in the presence of background sound, and may be an important factor that determines listening success in older people with hearing difficulties. Neural alpha oscillations in parietal cortex may provide a promising index for the assessment of effort as its power increases when individuals listen for subtle acoustic changes in sounds. It is, however, less clear how alpha oscillations are modulated by prior knowledge about when in time cognitive effort must be exerted during listening. In electroencephalography (EEG) and magnetoencephalography (MEG) experiments (N>100), we investigated how alpha power in a gap-detection task is affected by knowledge about when a near-threshold gap occurs within 10-s white noise sounds. Within one recording block, the gap occurred either within the first or the second half of the sound, and participants (21-33 years) were informed prior to each block. The precise position of the gap within the specified half was unknown to participants. Reaction times indicate that participants shifted their attention to either the first or second half of the sound, depending on the anticipated gap occurrence. EEG data showed a peak in alpha power at parietal electrodes either within the first or the last 5 seconds after sound onset, depending on whether participants were instructed to focus on the first versus second half of the sound. When detecting supra-threshold gaps, reaction times again indicated that participants shifted their attention to either the first or second half of the sound, but alpha power was less sensitive to this manipulation. These results suggest that investment of effort is needed to modulate alpha power. MEG data show that alpha power in parietal cortex was sensitive to the manipulation of gap occurrence (first vs. second half), but that alpha-power in auditory cortex remained enhanced throughout sound presentation (relative to baseline), independent of gap occurrence. MEG data from older people (54-72 years) show similar patterns of brain activity, but also subtle differences. The data show that alpha oscillations in parietal cortex are sensitive to when in time cognitive effort is exerted during listening.

Title: Cross-frequency coupling in human auditory cortex measured by complex modulation

Authors: U. MALINOWSKA[1], M. ZIELENIEWSKA[3], *D. F. BOATMAN[2], P. J. FRANASZCZUK[4]

[1]Neurol., [2]Johns Hopkins Sch. of Med., Baltimore, MD; [3]Physics, Univ. of Warsaw, Warsaw, Poland; [4]Human Res. and Engin. Directorate, US Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: Human electrophysiology studies have demonstrated that interactions between low-frequency and high-frequency cortical oscillations are important for sensory processing, including auditory perception. Prior studies in humans have focused mainly on phase-amplitude coupling (PAC) between cortical frequencies, leaving other potential cross-frequency interactions, such as power coupling, largely unexplored. Here we implemented a novel method, complex modulation, to measure stimulus-related changes in power coupling between theta (4-7 Hz) and high-gamma (70-150 Hz) frequency bands. We analyzed electrocorticographic (ECoG) recordings to tone and speech stimuli from three right-handed epilepsy patients (ages 24-56 years; 3 female) who had subdural electrode arrays implanted over lateral left temporal cortex for clinical purposes of seizure localization. The ECoG time-series was frequency-shifted by complex demodulation transform. Cross-frequency power coupling was then quantified using linear coherence measures. To compare results with established phase-amplitude coupling measures, we computed the phase-locking values of theta phase and high gamma amplitude from the same ECoG recordings. Results from the complex modulation method showed significant increases in cross-frequency power coupling (Wilcoxon sign test) at electrode sites in auditory responsive cortex for tones (N=5) and speech (N=11), comprising a subset of sites that showed significant increases in PAC (tones: N=10; speech: N=12). These results suggest that cross-frequency interactions during auditory perception are not limited solely to changes in phase-amplitude coupling, but also involve changes in power coupling. These findings underscore the complexity of cortical frequency interactions as well as the potential utility of the complex modulation method.

Title: Neural oscillations predict stuttering disfluency on a single trial basis

Authors: *J. MYERS, J. MOCK, E. GOLOB
Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Fluent speech requires precise coordination between sensory processing and motor planning areas in the brain. Impaired communication between sensory and motor areas may underlie stuttering disfluency. Most stuttering events occur at the beginning of an utterance, so, in principle, the state of the speech network before speaking should differ between fluent and stuttered speech. Here we provide evidence that neural oscillations during speech preparation predict stuttering on a single trial basis. Brain activity was recorded with EEG in people who stutter (n = 3) in two sessions on separate days. Subjects read aloud pseudo-word pairs during 4 different 'Cue-Go' behavioral tasks (n=100 trials/task/session) and each trial was classified as either a fluent or stutter trial by a speech-language pathologist. Independent component analysis (ICA) identified neural sources underlying speech preparation. For each neural source, a custom algorithm extracted event-related spectral perturbation and neural coherence (i.e., phase synchrony between sources) data from the time window of maximum activation. During the speech preparation phase of stuttering trials, we observed abnormal coherence between independent components localized to speech/motor planning (e.g., inferior frontal gyrus) and sensory regions (e.g., auditory cortex) ($p < 0.001$). In all three subjects, a discriminant function fitted to the spectral and coherence data predicted fluent vs. stuttered speech on > 80% of the trials. These results support the feasibility of developing a brain-computer interface (BCI) system to detect stuttering before it occurs, with potential for therapeutic application.

Title: Neural substrates of auditory rhythm processing and language skill in early-to-mid adolescence

Authors: *M. GRUBE[1,2], F. SMITH[2], S. KUMAR[2], H. SLATER[2], T. D. GRIFFITHS[2]
[1]Aarhus Univ., Aarhus C, Denmark; [2]Auditory Group, Inst. of Neurosci., Newcastle Univ., Newcastle, United Kingdom

Abstract: This study seeks the neural substrates of auditory-sequence processing skills in the adolescent brain by seeking correlation between grey matter density and a systematic battery of tests to measure timing and rhythm skill. The study is part of a large initiative at a local high school where we carry out extensive behavioral testing to assess auditory skills and literacy skills on whole-year group cohorts (see PMID 22951739 for initial report). This study was carried out

on subgroups form the larger study. Previous work in 42 twelve-to-fourteen year-olds suggested a correlation between grey matter density in the left intra-parietal sulcus (IPS) and the first principal components of both auditory and language skills (Grube et al., Society for Neuroscience 2011: XX27 509.10). We also found a correlation between rhythm processing and grey matter density in the right cerebellum. The current work assesses rhythm and language skill and their corresponding structural correlates of in two separate, new cohorts of mean age 12 (n = 20) and 14 (n = 24), respectively. Structural MRI was carried out at 3T on a Phillips xxx scanner, and voxel-based morphometry (VBM) implemented in SPM 8 sought correlation between grey matter density and auditory and language skill, taking non-verbal intelligence into account. We test the hypotheses: i) there is a critical correlation between left IPS grey matter density and both sound sequence and literacy skill; ii) there is a correlation between cerebellar grey matter density and skill in rhythmic perception; iii) the alteration in the behavioral link between auditory sequencing and language skill from early to mid-adolescence that we have observed (Grube et al., Society for Neuroscience 2016: HHH3 85.07) is reflected in altered correlations between grey matter density and the sequence and rhythm measures.

Title: Dissociating task acquisition from expression during learning reveals latent knowledge

Authors: *T. HINDMARSH STEN[1], K. KUCHIBHOTLA[2], E. PAPADOYANNIS[3], R. KUMAR[4], Y. BOUBENEC[4], P. C. HOLLAND[2], S. OSTOJIC[4], R. C. FROEMKE[5]

Abstract: Performance on cognitive tasks during learning is often used to measure progress and intelligence, yet remains controversial since such testing is susceptible to contextual factors. To what extent does performance depend on the testing context, rather than underlying knowledge? Here, we report that acquisition and expression of task knowledge can be dissociated during learning by manipulating the testing context. We trained head-fixed mice to discriminate between a "target" tone to which the animal was trained to lick for a water reward provided through a licktube, and an unrewarded "foil" tone to which the animal was trained to withhold licking (Kuchibhotla et al., Nat Neurosci 2017). To examine how testing context impacts acquisition versus expression, we interleaved the reinforced context with a smaller number of trials without reinforcement by removing the licktube ("probe context"). Surprisingly, in probe trials, all mice (n=14) discriminated between the tones much earlier in learning than in reinforced trials (trials to expert: reinforced=4728±647; probe=1765±108; n=7, t(6)=4.359, p=0.0055). Moreover, the inter-animal variability in learning curves was strikingly reduced in the probe context showing that the underlying acquisition of sensorimotor associations is highly stereotyped across mice. These results generalized to other species (rats and ferrets), motor action (licking and lever press), animal restraint (head-fixed and freely moving), sensory modality, and task structure. A computational model that explicitly dissociates between reward-driven plasticity of sensorimotor projections (representing task knowledge) and expression modulated by context in a decision circuit parsimoniously captured all aspects of these observations. These results suggest that reinforcement is critical for learning but paradoxically masks underlying task acquisition. Probing behavior in the absence of reinforcement, therefore, uncovers latent knowledge and identifies testing context, rather than sensorimotor abilities, as the critical driver of individual variability.

Title: Gender differences in DPOAE in mice

Authors: *T. MAKISHIMA, T. SUZUKI, J. MARUYAMA, S. PAESSLER
Univ. of Texas Med. Br. at Galveston, Galveston, TX

Abstract: Mice have become the model animal of choice for studying the inner ear auditory and vestibular system due to its ease of genetic manipulations. Auditory testing in mice have been extensively done using methods such as auditory brainstem response (ABR), otoacoustic emission (OAE), or acoustic startle reflex (ASR). Although there is a large amount of reports using these methods in association with different auditory function altering conditions, not much has been reported on gender differences. Most studies have traditionally not taken into account gender differences, which in recent years have been identified as a major factor affecting outcome in most studies. Our goal was to determine whether there were gender differences in DPOAE in several different mice strains used as infectious disease model mice. We tested wild type C57BL6J mice (n=3 each males and females), Stat1 mice (n=5 each males and females), Stat1 wt mice (n=5 each males and females) and IFNa/bg mice (n=3 each males and females). The mice were age 6 weeks to 14 weeks. We performed ABR with 8, 16, 24 and 32kHz tone pip and click stimulus. We tested DPOAE with F2 value of 8kHz - 16kHz. Weekly recordings were done and results of males and females were compared. We observed significant difference in ABR and DPOAE results between males and females in the Stat1 mice ($p<0.05$), but not in the other mice tested. We conclude that there is a gender difference in auditory function in mice frequently used in infectious disease models. Therefore, the results of any auditory test must be interpreted with caution, and needs to account for gender differences at the planning stage of experiments to study this effect.

Title: Sensory-evoked cholinergic dynamics in auditory cortex during sensorimotor learning

Authors: *K. KUCHIBHOTLA[1], T. DESBORDES[2], S. OSTOJIC[2]
[1]Psychological and Brain Sciences, Neurosci., Johns Hopkins Univ., Baltimore, MD; [2]Ecole Normale Superieure, Paris, France

Abstract: The basal forebrain cholinergic projection system modulates behavioral state and signals reinforcement feedback in fully trained animals. To date, however, the sensory-evoked

dynamics of cholinergic projections are unknown and whether and how these representations change during learning has never been recorded. Here we use two-photon calcium imaging in head-fixed behaving mice to monitor the activity of cholinergic axons in auditory cortex in response to conditioned auditory stimuli during learning. We find that cholinergic axons in naïve mice exhibit robust, broadly tuned, and spatially homogeneous sound-evoked responses. We next trained mice to lick for a water reward in response to a "target" tone and withhold licking to an unrewarded "foil" tone. We interleaved the reinforced context with a smaller number of trials without reinforcement by removing the licktube ("probe context"). Surprisingly, in the probe context, mice discriminated correctly between the tones far earlier than in reinforced context pointing to two distinct timescales of learning: rapid acquisition and slower expression. We then monitored cholinergic dynamics daily during learning. Remarkably, the population-level representation by cholinergic axons rapidly discriminated between target and foil tones on the fast learning timescale of sensorimotor acquisition with individual axons exhibiting selectivity for the conditioned stimuli. This simple behavioral dissociation points to a novel role for phasic, sensory-evoked cholinergic signaling during sensorimotor acquisition. Moreover, these results suggest that cholinergic projections may play a critical role in opening up a plasticity window in sensory circuits during real-time learning.

Title: Understanding word representations in the brain using ECoG

Authors: S. RAHIMPOUR[1], M. M. HAGLUND[1], S. R. SINHA[2], C. R. MUH[1], *G. B. COGAN[1]
[1]Dept. of Neurosurg., [2]Dept. of Neurol., Duke Univ., Durham, NC

Abstract: Understanding speech forms the basis for complex language functioning in the human brain. In milliseconds, the brain effortlessly transforms sound into words. The first contact that sound has with cognition is through words: words, but not sound, interface with representations of meaning. We still do not however, understand how sounds are transformed into words nor how words are processed in the brain. Here, therefore, we studied word representations in the brain using 5 patients undergoing phase II monitoring for pharmacologically intractable epilepsy (4 sEEG, 1 Grid - 515 electrodes total). We had subjects perform a task in which there were 2 conditions: a lexical decision condition in which after a short delay, subjects were asked to state whether the auditory stimulus was a word or not (yes or no) and a repetition condition in which

subjects were to repeat the word or nonword after a delay. In both conditions, we presented subjects with 41 words and 41 nonwords that also varied in their sublexical properties (phonotactic probability/neighborhood size - high vs. low). We first assessed significance of the high-gamma neural responses using a permutation test with the baseline period for each electrode (189/515 electrodes - 37%). We then used the significant electrodes in a linear model with lexicality (words vs. nonwords), phonotactic probability/neighborhood size (high vs. low), and task (decision vs. repeat) as predictor variables. We find that 59 electrodes demonstrate a significant effect of lexicality, with the majority (45 - 76%) showing greater high-gamma power for words as compared to nonwords. We find that 52 electrodes demonstrate a main effect of sublexicality, with the majority demonstrating greater high-gamma power for low phonotactic probability/low neighborhood size (41 - 79%). Finally, wefind89 electrodes demonstrating a significant effect of task with a majority demonstrating higher power for decision (67 - 75%) as compared to repetition. An analysis of the time course of the beta weights for each factor reveals that the processing of sublexical properties arises first (100 ms) while lexical processing and task processing occur later (~400ms). Taken together, these results suggest that word representation is a sequential process involving sublexical, lexical, and task representations.

Title: The neural processing of phonemes is shaped by linguistic analysis

Authors: *J. C. LEE, T. OVERATH
Duke Univ., Durham, NC

Abstract: Speech perception entails the mapping of the acoustic waveform to stored linguistic representations, such as phonemes, syllables, or words. Recent evidence suggests that different phoneme classes (e.g. plosives, fricatives, etc.) have characteristic neural signatures, or phoneme-related potentials (PRPs; Khalighinejad et al., 2017). What remains to be understood is the extent to which the temporal scale of linguistic analysis, and linguistic knowledge, influence the processing of this fundamental linguistic unit.
To control the scale of linguistic analysis, we used a modification of our speech quilting algorithm (Overath et al., 2015) to generate stimuli that maintain linguistic structure at one of 4 linguistic units: phoneme, syllable, word or sentence; to control for linguistic knowledge, we constructed speech quilts from both familiar (English) and foreign (Korean) languages.

We recorded EEG from 28 native English speakers (with no knowledge of Korean); data were epoched to the phoneme onset boundary. Grand average PRPs across all phonemes showed a similar sequence of P50, N100, and P200 components at fronto-central regions. Comparisons between linguistic-unit levels (phoneme, syllable, word, sentence), showed significant differences ($p < 0.05$) at time points corresponding to the P50 and N100 components for English, but not for Korean. In addition, the N100 component showed a main effect of language and an interaction between language and linguistic unit. The classification of phonemes based on articulatory manner revealed unique PRPs for each of these classes, and forms were similar between the two languages. The similarity in articulatory-class responses across languages suggests that acoustic features play an important role in the processing of phonemes. However, the main effect of language and the interaction with linguistic unit suggest that the processing of a fundamental linguistic unit, the phoneme, is already shaped by linguistic analysis as early as 100 ms after phoneme onset.

Title: Electrocorticographic (ECoG) analysis of dialog-based paradigms for assessing speech, language and cognitive functions: A case report

Authors: *M. STEINSCHNEIDER[1], K. V. NOURSKI[2]
[1]Neurol., Albert Einstein Col. of Med., Bronx, NY; [2]The Univ. of Iowa, Iowa City, IA

Abstract: Acquisition of ECoG data while subject/patients engage in a dialog-based study permits high resolution analysis of multiple speech, language and cognitive functions in a concise question/answer format. Analysis focuses on neural processing associated with listening, performing mental calculations, and verbal responses. Here, we demonstrate the utility of this paradigm by presenting data from a single neurosurgical subject with normal hearing and cognitive functions, and who had extensive right hemisphere electrode coverage of temporal,

temporo-parietal, and frontal cortices. The paradigm was an expanded version of the Mini-mental State Examination, which included additional spelling, naming, and memory-based tasks. Recording of the verbal exchange was parsed using Praat software based upon natural articulatory breaks in the conversation. Cortical recording sites were categorized based upon their location, within anatomically defined regions of interest (ROIs), including e.g., Heschl's gyrus, posterior, middle and anterior portions of the lateral superior, middle and inferior temporal gyri (STG, MTG). A key analysis was the degree of high gamma (70-150 Hz) activation during listening to the interviewer vs. during one's own speech (Nourski, Steinschneider, Rhone, Front Hum Neurosci 2016 10:202). ROIs where listening was associated with stronger high gamma activity than speaking were restricted to the posterior and middle portions of the STG. ROIs where speaking was associated with stronger high gamma activity than listening included Heschl's gyrus, planum polare, anterior STG, middle/anterior MTG, ITG, supramarginal gyrus and the temporal pole. A second analysis examined the relationship between high gamma and activity in lower ECoG frequency bands. In all ROIs, there was a positive correlation between high and low gamma (30-70 Hz). Relationships between high gamma and alpha (8-14 Hz) and theta (4-8 Hz) bands were inconsistent across ROIs. Largest high gamma responses were generally associated with relatively difficult tasks, naming favorite items and task completion. We conclude that monitoring one's own speech can extend beyond the classically defined dorsal auditory-motor speech pathway into the ventral pathway involved in listening and decoding speech at progressively higher processing levels. A consistent relationship between high and low gamma activity supports the utility of low gamma acquired in non-invasive studies as a proxy for high gamma activity. Comparing neural activity across subjects may assist in defining the natural variability in language and cognitive processing strategies utilized by individuals.

Title: Resting-state functional imaging of chronic tinnitus

Authors: *L. B. HINKLEY[1], A. FINDLAY[2], D. MIZUIRI[2], S. W. CHEUNG[4], S. S. NAGARAJAN[3]
[1]Radiology, UC San Francisco, San Francisco, CA; [3]Radiology and Biomed. Imaging, [2]UCSF, San Francisco, CA; [4]Otolaryngol-Head & Neck Surg, UCSF Otolaryngology, San Francisco, CA

Abstract: In chronic tinnitus, both intraoperative electrical stimulation and resting-state functional connectivity studies have shown that the caudate nucleus maintains an abnormal relationship with auditory cortex, possibly by acting as a dysfunctional gating mechanism to modulate auditory phantom perception. The specific sub-regions of the caudate that act as this gating mechanism have yet to be defined. Here, we use high-resolution resting-state functional MRI (rs-fcMRI) at both 3T and 7T in patients with tinnitus and/or hearing loss. We hypothesize that abnormal functional connectivity within specific sub-regions of the basal ganglia and the central auditory system will be unique to patients with tinnitus. MRI was performed on a 3.0T or 7.0T MR950 scanner (GE Healthcare) in the same group of subjects. Spontaneous fMRI data (eyes closed) were collected using a gradient echo planar pulse sequence for both 3T and 7T data acquisition. Resting-state fMRI data was spatially preprocessed and analyzed using the CONN toolbox (https://www.nitrc.org/projects/conn/). Seeds were placed in nine specific predefined subdivisions of the caudate. Data from four cohorts were enrolled: 28 patients with tinnitus plus hearing loss (TIN+HL), 12 patients with hearing loss and no tinnitus (HL), 14 patients with tinnitus and no hearing loss (TIN) and 8 healthy controls with no hearing loss or tinnitus (CON). Comparisons were made between groups using unpaired t-tests for each seed implemented in CONN. Nine seeds were placed in both the left and right subdivisions of the caudate. For comparisons between the TIN+HL and HL cohort, only 2/7 subdivisions of the caudate showed significant ($p<0.0005$) increases in functional connectivity isolated to sub-regions of auditory cortex. Both regions fell within the dorsal aspect of the caudate head and anterior body. Both seeds showed increased connectivity with the ipsilateral posterior middle temporal gyrus. Dorsal/posterior subdivisions of the caudate did not show any increases in functional connectivity in the TIN+HL group. Decreased resting-state functional connectivity in the TIN+HL group were identifiable and fell outside of primary or secondary auditory regions. These findings support a growing body of evidence that suggest the basal ganglia is integral to the perception of auditory phantoms. More specifically, increased patterns of resting-state functional connectivity are not found across the caudate, but only within specified subregions. A greater understanding of how specific sub-regions of the caudate are attached to auditory perceptual regions in tinnitus can lead to more targeted strategies for intervention, such as DBS.

Title: Changes in the grey and white matters in the human auditory system due to presbycusis and tinnitus

Authors: *O. PROFANT[1,2], J. SYKA[1], A. SKOCH[3], J. TINTERA[3], V. SVOBODOVA[4], D. KUCHAROVA[4]
[1]Dept. of Auditory Neurosci., Inst. of Exptl. Medicine, Acad. of Sci., Praha, Czech Republic; [2]Otorhinolaryngology, 3rd Fac. of Med. of Charles University, Fac. Hosp. Kralovske Vinohrady, Prague, Czech Republic; [3]MR Unit, Inst. of Clin. and Exptl. Med., Prague, Czech Republic; [4]Otorhinolaryngology and Head and Neck Surgery, 1st Fac. of Med. of Charles University, Univ. Hosp. Motol, Prague, Czech Republic

Abstract: Presbycusis and tinnitus are two of the most common hearing related pathologies. Although both presumably originate in the inner ear, there are several reports about their central components. Central pathologies caused by presbycusis are associated with degraded ability to detect fast temporal changes, related in case of tinnitus to increased spontaneous activity at several levels of the auditory system and in both pathologies to hypofunction of the inhibitory system.
The aim of our project is to identify age, hearing loss and tinnitus related changes within the auditory system and associated structures.
A group of patients with presbycusis and tinnitus (40 subjects), group with presbycusis only (28 subjects) and a group of young controls (19 subjects) underwent audiological examination to characterize the degree of presbycusis and tinnitus. MR morphometry and tractography were acquired using a 3 T Siemens Tim Trio system (Siemens), with a 12-channel head coil. For MR morphometry cortical reconstruction and volumometric segmentation were performed with the aim to evaluate surface and thickness of the grey matter. DWI acquisition of the pathway from the inferior colliculus to auditory cortex was performed by spin-echo EPI sequence. A statistical analysis of fiber density (FD), fiber cross-section (FC) and fiber density and cross-section (FDC) was performed by fixel-based analysis framework (FBA) using mrtrix3 framework. Statistical analysis using R framework was done by linear mixed-effects models with explanatory variables (fixed effects) age, tinnitus, laterality, hearing and random subject-wise intercept.
Significant decrease of cortical thickness occurred in all examined cortical regions (planum temporale, Heschl gyrus (HG), anterior insula, parahipocampal gyrus (PH), primary visual cortex (V1)) as a result of aging. The surface area was significantly affected by laterality (left vs. right hemisphere) in the PH and HG. Tinnitus caused increase in cortical thickness of V1 and PH, however the significance of the tinnitus effect didn't survive the multiple comparisons correction. The analysis of the auditory pathway showed only significant effect of ageing in all three variables (decrease of FD, FC and FDC), whereas hearing loss and tinnitus had no effect. We can conclude that tinnitus and hearing loss have only marginal effect on the structural parameters of the human auditory cortex and pathway from the inferior colliculus to auditory cortex compared to the effect of ageing. Our data also show different effect of ageing on examined cortical regions with a more pronounced decrease of the cortical thickness in the more frontal regions.

Title: Anticipated ITD statistics built-in human sound localization

Authors: *J. L. PENA[1], R. PAVÃO[2], E. S. SUSSMAN[3], B. J. FISCHER[4]
[1]Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Ctr. de Matemática, Computação e Cognição, Univ. Federal do ABC, Sao Paulo, Brazil; [3]Dept of Neurosci., Albert Einstein Col. of Med., Bronx, NY; [4]Seattle Univ., Seattle, WA

Abstract: The variability of natural scenes places perceptual processes in the realm of statistical inference. Perceptual tasks may be optimized if the invariant statistical structure of sensory cues is built into the neural processing. We investigated this question in human sound localization. Localizing sounds in the horizontal plane relies on interaural time differences (ITD). We estimated the ITD statistics from human head-related transfer functions (HRTFs). ITD varied with azimuth following a sigmoid relationship, whose slope was steepest at the center. In addition, ITD was more variable over time for sounds located in the periphery compared to the center, in a frequency-dependent manner. We tested the hypothesis that these statistics are anticipated by the human brain, influencing spatial discriminability and novelty detection. Thresholds for discriminating ITD changes reported by classical studies (Mills, 1958) were predicted by a model that considered both ITD slope and ITD variability. To further test our hypothesis, EEG novelty responses were recorded in human subjects undergoing an oddball stimulation sequence, where repetitive (“standard”) tones of a given ITD were combined with sporadic (“deviant”) tones of a different ITD. By using insert earphones, ITD was shifted with zero variability across time and location. Mismatch negativity (MMN) brain signals were used as an index of discriminability between standard and deviant stimuli. We found that MMNs were weaker for standards in the periphery, where the ITD slope is lower and the ITD variability is higher. Overall, the amplitude of novelty EEG signals was predicted by the difference in ITD between the standard and deviant normalized by the anticipated discriminability of the standard location, indicating that change detection is weighted by expected statistics of the sensory input. These results show that spatial discriminability thresholds and novelty detection are consistent

with a representation of anticipated ITD statistics in the brain, supporting the hypothesis that high-order statistics are built into human perceptual processes biasing behavior.

Title: Electrocorticographic responses to vowel sequences in awake and anesthetized states

Authors: *K. V. NOURSKI[1], M. STEINSCHNEIDER[2], A. E. RHONE[1], R. N. MUELLER[1], H. KAWASAKI[1], M. A. HOWARD, III[1], M. I. BANKS[3]

Abstract: Elucidating neural signatures of sensory processing across conscious states is a major focus in neuroscience. Clinically relevant conditions of altered awareness include sedation, loss of consciousness (LOC) under general anesthesia, natural sleep and disorders of consciousness. Non-invasive studies in human subjects using the general anesthetic propofol to induce sedation and LOC have shown differential effects on auditory cortical activity, with a greater impact on non-primary and auditory-related areas than primary auditory cortex. High spatiotemporal resolution of electrocorticography can further extend results of non-invasive studies in delineating hierarchical organization of human auditory cortex (e.g., Nourski et al., NeuroImage 2017, 152:78-93). The present study examined changes in cortical responses to vowel sequences during sedation and LOC with propofol. Subjects were adult neurosurgical patients with intracranial electrodes placed to identify epileptic foci. Data were collected prior to electrode removal surgery. Stimuli were sequences of five 100 ms vowels separated by 50 ms silent intervals presented during an awake baseline state and during propofol administration. Subjects were asked to press a button in response to occasional target stimuli. Depth of anesthesia was monitored using the Observer's Assessment of Awareness Scale and bispectral index. Regions of interest included core and non-core auditory, temporo-parietal auditory-related and prefrontal cortex. Activity was measured as averaged evoked potentials (AEPs) and high gamma (70-150

Hz) event-related band power. Vowel stimuli elicited AEPs throughout studied brain areas in the awake state; high gamma activity was restricted to core and non-core auditory cortex. AEPs and high gamma activity within core auditory cortex persisted after LOC. In non-core auditory cortex, propofol administration led to a progressive decrease in the spatial extent and amplitude of AEPs, and increases in onset latency. The spatial extent of AEPs within auditory-related and prefrontal cortex progressively decreased with sedation, and responses were abolished upon LOC. Overall, sensitivity of cortical responses to propofol increased along the ascending cortical processing hierarchy. Loss of responses to sound in auditory-related and prefrontal cortex may represent a biomarker of general anesthesia. The findings serve as a foundation for probing changes in sensory processing associated with general anesthesia induced by other agents, as well as natural sleep and disorders of consciousness (e.g., chronic vegetative state and coma).

Title: Experience-dependent tuning of song discrimination in *Drosophila*

Authors: *X. LI, H. ISHIMOTO, A. KAMIKOUCHI
Div. of Biol. Sci., Nagoya Univ., Nagoya, Japan

Abstract: The language skill of human beings is built on the genetic predisposition and further through postnatal learning. Like humans, many mammals and birds have a critical period in youth when hearing the vocal cues of their parents helps them to learn the specific features of their communication sounds. However, wherever in human beings or other animals, the mechanisms remain mysterious. Although the hearing study in *Drosophila* has attracted huge attention in recent years, little is known how auditory experience contributes to perception of

courtship song in fly mating and whether there is also a critical period for it, because for a long time most processes in courtship behavior of *Drosophila* are thought to be innate.>
In this study, we exposed flies to artificial courtship song before behavioral tests and examined whether the perception of inter-pulse interval in *Drosophila melanogaster* was tuned by the auditory experience. We discovered that both male and female fruit flies (*Drosophila melanogaster*) learned to discriminate the species-specific song from early auditory experience and tuned their mating preference in later sexual behaviors. Females who were raised with the auditory experience of their species-specific song later in life rejected conspecific males presented with artificial playback of another species' song. Similarly, males raised with the experience of hearing conspecific song later in life ignored another species' song, which usually increased the mating drive of naïve males. However, song discrimination of both male and female flies was not altered by exposure of another species' song. We further identified the mechanism of experience-dependent acquisition of the song discrimination. This experience-dependent song discrimination relied on GABA synthesis, and the ionotropic $GABA_A$ receptor in a small group of central neurons called pC1 neurons (command-like neurons in mating) gated this tuning. In addition, we found this auditory learning not only occurred in the early adult stage, but also extended to the mature adult stage, suggesting a long critical period for this acquision.>
Here our study gives the hint that simple animals like flies can also tune their perception of specific auditory feature by learning. Our discovery establishes a new and simple system to study how the experience-dependent auditory plasticity is incorporated into higher-order integration center to modulate sensory-motor behaviors at the molecular and cellular levels. A better understanding of how fruit flies learn and discriminate sounds may bridge knowledge gaps in research using humans and other animals.

Title: How do neurons overcome developmental hearing loss induced deficits during auditory learning?

Authors: *T. M. MOWERY[1], N. PARAOUTY[2]
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: Developmental hearing loss leads to deficits in the auditory perceptual abilities of children and these arise from peripheral and central changes along the auditory neuraxis. When peripheral deficits are treated through resolution of ear canal blockage, surgery, hearing aids or cochlear implants, perceptual thresholds often return to control values. On many non-perceptual (cognitive) tasks, some individuals who have recovered from hearing loss (HL) perform at normal hearing (NH) levels while others remain impaired. This suggests that regions down-stream of the perceptual processing centers of the primary auditory neuraxis are sensitive to developmental HL. One such region, which is highly involved in language development, is the auditory striatum. We have recently reported that animals that have recovered from HL continue to show significant changes in cellular properties in the cortex and striatum. Thus we asked how these changes to cellular and synaptic properties affect the learning of an auditory task. We used the gerbil and a brain slice preparation to assess how changes to synaptic excitation, inhibition, and cellular firing rates correlate with behavioral performance in animals as they learn to discriminate two amplitude-modulated tones. We found that the synaptic and cellular changes that occur in NH and HL recovered animals are extremely polarized, but change in such a way that permits learning in both groups of animals. Delays to this learning-induced progression could account for the shallower learning curves observed in both NH and HL animals with impaired acquisition. Precocious onset of this progression could like-wise account for the steeper learning curves observed in animals with faster task acquisition. These results demonstrate a central learning mechanism that emerges during auditory learning, and reveals how the brain can overcome permanent cellular deficits induced by developmental deprivation.

Title: Central mechanism of thermoregulation via the vestibular system in mice

Authors: *C. ABE, Y. YAMAOKA, H. MORITA
Physiol., Gifu Univ. Grad. Sch. of Med., Gifu, Japan

Abstract: The vestibular system is one of the sensory systems which contributes to the sense of balance and spatial orientation. The vestibular system is also participating in the autonomic nervous response, which stimulation to the peripheral vestibular organs induces sympathoexcitation. This response is observed in both rodents and human beings, and we have reported that vestibular system contributes to the arterial pressure response during postural change as one of the feedforward control system (Morita, Abe et al., Sci Rep, 2016). In the other autonomic nervous responses, there is a hypothermic response induced by stimulation to the otolith organs in the inner ear; exposure to the hypergravity environment decreases body temperature by 8 degree Celsius in mice. This response was attenuated by vestibular lesion or genetic deletion of otolith. In order to elucidate the central mechanism of hypergravity-induced hypothermia, we examined the role of Vglut2, Vgat and ChAT positive neurons in vestibular nucleus complex (VNC) on thermoregulation in mice. We used Vglut2-cre, Vgat-cre, and ChAT-cre mice to manipulate each neuron in VNC. AAV-DIO type viral vector was injected in VNC to express photo sensors (channelrhodopsin (ChR2) or archaerhodopsin (Arch)) for optogenetics or hM3D for chemogenetics, which the methods were modified from the previous work (Abe et al., Nat Neurosci, 2017). Unilateral photostimulation of the Vglut2 neurons in VNC induced body tilt to the ipsilateral side, while photoinhibition induced body tilt to the contralateral side. In Vgat-cre mice, opposite response was observed compared with Vglut2-cre mouse. Photostimulation of ChAT neurons did not show any responses. Chemogenetics stimulation of Vglut2 neurons showed hypothermic response with increasing in activity, while Vgat stimulation increased body temperature with decreasing in activity. Deletion of Vglut2 neurons in VNC using AAV2-DIO-taCasp3-TEVp attenuated hypothermia induced by hypergravity exposure. On the other hand, hypothermia was still observed by deletion of Vgat neurons in VNC. Interestingly, chemogenetics stimulation of Vglut2 neurons in VNC 2 days before hypergravity exposure, the hypothermia was attenuated. Taken together, hypothermic response by hypergravity exposure is due to activation of Vglut2 positive neurons in VNC.

Title: Peripheral mechanism of thermoregulation via the vestibular system in mice

Authors: *Y. YAMAOKA, C. ABE, H. MORITA
Dept. of Physiol. Gifu Univ. Grad., Gifu, Japan

Abstract: The vestibular system is one of the sensory systems to sense the gravity and rotation. Eye movement (vestibulo-ocular reflex) and posture maintaining (vestibulo-spinal reflex) are well known to be controlled via the vestibular system. Autonomic nervous system is also partially dominated by the vestibular system, i.e., stimulation to the peripheral vestibular organs induces sympathoexcitation. This reflex works as a feedforward control system for arterial pressure response in rodents and human beings (Morita et al., Sci Rep, 2016, Abe et al., J Appl Physiol, 2011). Interestingly, the vestibular system participates in the thermoregulation; exposure to the hypergravity environment decreased body temperature (BT) in mice (Fuller et al., PNAS, 2002). This response was attenuated by genetic deletion of the peripheral vestibular organ, suggesting that otolith is important in the afferents for hypothermic response. However, the mechanism of the efferents in this response is still unclear. To examine this, we conducted the experiments focusing on increase in heat loss and/or decrease in heat production during exposure to hypergravity in mice. We used two groups of mice; vestibular lesion (VL) and their sham-operated (Sham) mice. We measured skin temperature using a thermography camera as evaluation for heat loss and temperature of brown adipose tissue (BAT) as evaluation for heat production. Sham mice showed decrease in BT (-6.5 ± 0.5°C), and this response was attenuated by VL (-3.2 ± 0.3°C). Although increase in tail temperature was observed, tail sympathetic denervation did not improve the hypothermic response, suggesting that hypothermia is not due to increase in heat loss. On the other hand, pretreatment with isoprenaline (10 mg/kg i.p.), nonselective β agonist, significantly attenuated the hypothermic response (-1.8 ± 0.5°C). Furthermore, decrease in sympathetic tone seems to be involved in hypergravity-induced hypothermia because hexamethonium administration decreases BT (-5.0 ± 0.4°C) with increase in tail temperature and decrease in BAT temperature. Accordingly, it is possible that hypergravity-induced hypothermia is due to decrease in heat production through the sympathetic nervous system, probably hypometabolism including BAT might be occurred in 2 G.

Title: Anatomical and functional convergence of otolith afferents onto vestibulospinal neurons in larval zebrafish

Authors: *Z. LIU[1], J. ELSNER[1], Y. KIMURA[3], S.-I. HIGASHIJIMA[4], D. G. HILDEBRAND[5], J. L. MORGAN[2], M. W. BAGNALL[1]

Abstract: Vestibulospinal (VS) neurons influence posture by transforming sensory inputs from vestibular afferents into motor outputs. VS neurons display more complex spatiotemporal tuning than their afferents, suggesting sensory convergence is important for computing head motion signals. However, it has not been possible to directly measure this convergence, limiting our understanding of central vestibular computations. We addressed this question in larval zebrafish, first demonstrating that bilateral ablation of VS neurons resulted in severe deficits of body balance. Therefore, VS neurons serve a postural function in fish as in other vertebrates. Next we developed a technique to intracellularly record sensory responses of VS neurons *in vivo* on a moving table. Recordings from VS neurons in voltage clamp revealed that synaptic transmission from vestibular afferents is mediated by mixed synapses with both chemical (AMPA) and electrical components. The electrical component is usually larger, producing a stereotyped EPSC waveform for each afferent. Therefore we can distinguish inputs from distinct afferents converging onto one VS neuron. Each VS neuron usually received inputs from 2-3 potential afferents. During application of a translational sinusoidal stimulus, EPSCs from vestibular afferents exhibited tuning to specific phases of linear acceleration. EPSCs from most afferents are phase-led relative to peak acceleration, which indicates they encode a mixture of jerk and acceleration, similar to mammalian otolith afferents. Afferent convergence exhibited a range of properties: in some cases, afferents with highly similar tuning converge on one VS neuron; in other cases, directional tuning varied across afferents. Similar results were seen in current clamp measurements of VS membrane potential and firing rate. Serial electron microscopy of vestibular afferents confirmed that on average 3 afferents, out of 17 total, converge onto each VS neuron. By combining EM and electrophysiology, we can reveal a complete map of both connectivity and function from afferents to central vestibular neurons.

Title: Spatial tuning for translation in the posterior cerebellar vermis across changes in head-re-body and body-re-world orientation

Authors: *C. MARTIN, J. X. BROOKS, A. M. GREEN
Neurosciences, Univ. de Montreal, Montreal, QC, Canada

Abstract: Many daily tasks (e.g., postural control, reaching, navigation) rely on estimates of body motion with respect to specific body axes (body-centered estimates) and/or with respect to gravity (world-centered). Our vestibular sensors are among the most important sources of self-motion signals. However, they encode motion in head-centered coordinates. To contribute to such tasks, vestibular signals must thus be transformed into body- and world-centered reference frames. Recently, we showed that neurons in the rostral fastigial nucleus (rFN) encode the spatially transformed vestibular signals in 3D required to compute estimates of body motion (Martin et al., 2018). Furthermore, while individual rFN cells reflect a distribution of reference frames, specific aspects of their tuning properties suggest that the rFN reflects a late or "output" stage of the head-to-body reference frame transformation, with the bulk of the computations likely occurring upstream in the cerebellar cortex. Most rFN cells also preferentially encode translation as compared to tilt. This suggests a potentially important role in the head-to-body transformation for regions of the posterior cerebellar vermis (nodulus/uvula, NU, lobules 9 and 10) which have been implicated in computing translation estimates from ambiguous sensory vestibular signals (Yakusheva et al., 2007; Laurens et al., 2013). The goal of this study was to investigate the reference frames in which such translation estimates in the NU are encoded. We recorded NU Purkinje cells in a rhesus monkey during translational motion (0.5 Hz, +/-9 cm) delivered along 13 directions in 3D space. Cell tuning was characterized with the head and body upright and after static reorientation of the head relative to the body in the vertical plane (toward nose- or ear-down) and horizontal plane (leftward). In addition, we characterised the spatial tuning of a subset of cells after static reorientation of the body relative to gravity and after combined head-re-body and body-re-gravity reorientations. The majority of NU cells recorded to date (84%) exhibited spatial tuning across head and body orientations that was consistent with a predominantly head-centered encoding of translation. Our present results are thus compatible with theoretical models (e.g., Green et al., 2004, 2007) proposing that the NU combines spatially-transformed canal signals with head-centered otolith signals to compute a head-centered representation of translation. In addition, they suggest that the bulk of the computations necessary to construct body-centered translation estimates occur elsewhere, likely within parts of the anterior vermis (Manzoni et al., 1999).

Title: Vestibular neurons mediating the vestibulo-ocular reflex optimally encode natural self-motion through temporal whitening

Authors: *I. MACKROUS[1], J. CARRIOT[1], K. E. CULLEN[2], M. CHACRON[1]
[1]Physiol., McGill, Montreal, QC, Canada; [2]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Understanding how the brain encodes natural vestibular stimuli has become of great interest since prior studies have demonstrated that neural responses cannot be predicted from responses to artificial stimuli. It is generally accepted that sensory systems have adapted their coding strategies by matching their tuning properties to the statistics of natural stimuli, which results in a neural response that is independent of frequency (i.e., are temporally whitened). The vestibular system encodes head motion in a complex 6D trajectory (3 rotational and 3 translational) and mediates vestibulo-driven reflexes and spatial perception. While the statistics of natural self-motion have been measured recently, how neurons within the vestibular system respond to naturalistic self-motion has for the most part not been investigated to date. Here we investigated how Position Vestibular Pause neuron (PVP) and Floccular Target Neuron (FTN), vestibular neurons that mediate the vestibulo-ocular reflex VOR, respond to naturalistic self-motion. Because of the remarkable properties of the VOR, which requires knowledge about the detailed time course of the head motion, we expected that PVP and FTN neurons would preserve the statistics of natural stimuli in their spiking activities and thus not implement temporal whitening. In contrast, we found that both neural classes displayed temporally whitened responses to naturalistic self-motion. These responses could be well-predicted from the tuning properties to head velocity alone. Thus, our results demonstrate for the first time that both PVP and FTN neurons are tuned such as to optimize information transmission about the detailed time-course that is necessary in order to mediate the VOR.

Title: Thalamus coding strategies for representing natural self-motion

Authors: *J. CARRIOT[1], I. MACKROUS[3], G. MCALLISTER[2], H. HOOSHANGNEJAD[4], A. DALE[2], C. MCNICOLL[2], K. E. CULLEN[4], M. J. CHACRON[2]
[1]Physiol., [2]McGill Univ., Montreal, QC, Canada; [3]Physiol., McGill, Montreal, QC, Canada; [4]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Self-motion is sensed by the vestibular system, contributing to automatic reflexes and spatial perception. While it is generally accepted that sensory systems have adapted their coding strategies to the statistics of natural signals, how the vestibular system processes natural self-motion is largely unknown because artificial (e.g., sinusoidal) stimuli have been typically used to date. Natural stimuli frequently display complex spatiotemporal characteristics. It is commonly assumed that, through both evolutionary and developmental processes, sensory neurons are adapted to the statistical properties of the stimuli to which they are exposed. This has led to the proposal that sensory systems optimally process natural stimuli by removing redundancy which is commonly referred to as whitening as the neural response then contains equal power at all frequencies (i.e., is “white”). While we have shown that VN neurons optimally encode natural self-motion through temporal whitening, how this information is decoded remains poorly understood. Here, we investigated how neurons within the ventral posterior lateral (VPL) Thalamus, which receive direct input from neurons within the vestibular nuclei (VN) and project to cortical structures respond to natural self-motion stimuli. Our results show that vestibular Thalamic neurons, contrary to VN neurons, do not display whitening. Indeed, their response power spectra were not constant as a function of frequency and instead resemble those of afferents, showing that information as to the head motion’s detailed timecourse is transmitted to cortical structures as required for accurate self-motion perception.

Title: Adaptation to the distribution of vestibular stimuli in the thalamus

Authors: *G. MCALLISTER[1], J. CARRIOT[1], J. X. BROOKS[1], K. E. CULLEN[2], M. J. CHACRON[1]
[1]Physiol., McGill Univ., Montreal, QC, Canada; [2]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Growing evidence shows that neural sensory systems actively adapt their responses to efficiently encode the full range of changing stimulus distributions. Adaptive encoding has been demonstrated in many sensory systems and species, most extensively in studies of rapid contrast gain scaling in retinal and visual thalamic neurons. Previous studies have found that vestibular stimuli in natural contexts are highly non-stationary and have a large dynamic range, suggesting that such adaptation may also occur in the vestibular system. Here, we investigated adaptation to changes in vestibular stimulus intensity in the thalamus. We recorded extracellular single-unit neural responses in the ventral posterior lateral thalamus of rhesus macaque monkeys, to sinusoidal head rotation with steps in peak rotational velocity (amplitude). We found that the neural response to amplitude steps was strongly nonlinear. For frequencies from 0.5-8Hz, gain increased sub-proportionally when peak amplitude was increased. This change occurred rapidly, consisting of an initial overestimation followed by a gradual reduction in gain. We described the pattern of adaptation by fitting a divisive normalization model that resembles models of adaptive gain scaling in the visual thalamus. Furthermore, we found that the observed adaptation significantly increased mutual information between stimulus and response when compared to a fully linear model, suggesting that this adaptation improves information transmission. In conclusion, we found that adaptive gain scaling does occur in vestibular thalamus neurons in healthy subjects, supporting the view that adaptation is a fundamental aspect of sensory processing. The findings also provide insight into how the posterior ascending vestibular pathway provides an accurate signal to the cortex for reliable perception in varying sensory contexts.

Title: Complete and irreversible unilateral vestibular loss induces reactive neurogenesis in the vestibular nuclei in adult rats

Authors: *G. RASTOLDO, D. PERICAT, I. WATABE, N. EL MAHMOUDI, C. CHABBERT, B. TIGHILET
Sensory and Cognitive Neurosci. Lab., Aix-Marseille Univ., Marseille, France

Abstract: Apart from two specific structures: the subgranular zone of the dentate gyrus of hippocampus and the subventricular zone of the lateral ventricles, the adult mammalian brain is considered non-neurogenic. Neurogenesis in other brain regions is limited under normal physiological conditions but could be induced after injury or pathological conditions. This is what happens after unilateral vestibular neurectomy (UVN) in adult cats: our work revealed for the first time the existence of adult reactive neurogenesis in deafferented vestibular nuclei (VN) located in the brain stem. Even more surprisingly, we have shown in an original way that most of the newborn cells are functional and contribute to the recovery of the posturo-locomotor functions in adult cats. We recently switched to the rodent model by replicating the same surgery (UVN) resulting in the same posturo-locomotor and oculomotor syndrome. The objective of this study is to verify whether the reactive neurogenesis observed in the cat model is also expressed in the rodent model after UVN. We used specific markers of cell proliferation (BRDU), stem cells (GFAP and SOX2) and cell differentiation (GFAP: astrocytes, NEUN: neurons, GAD67: GABAergic neurons and IBA1: microglia). The results showed a significant cellular proliferation with a peak of proliferation 3 days after UVN exclusively on the deafferented side in all VN. Most of the newly generated cells survived up to 1 month after UVN and differentiate into astrocytes and microglial cells but also into GABAergic neurons. We also observed SOX2/GFAP-immunoreactive cells in UVN rats and surprisingly in control animals. We observed the same reactive neurogenesis phenomenon in all VN in adult rats. The presence of SOX2 and GFAP co-localization attests to the presence of probably quiescent stem cells in the VN in the intact animal. Our perspectives are: i) to specify the origin of stem cells: birth in vestibular nuclei or migration from brain neurogenic zones, ii) to demonstrate the involvement of this neurogenesis in vestibular compensation and iii) use pharmacological agents that impact on neurogenesis to accelerate the vestibular function recovery.

Title: Stochastic noise alters the sensitivity of medial vestibular nucleus neurons *in vitro*

Authors: S. STEFANI[1], P. BREEN[3], J. SERRADOR[4], M. SCHUBERT[5], *A. J. CAMP[2]
[1]Univ. of Sydney, Sydney, Australia; [2]Univ. of Sydney, Sydney University, Australia; [3]Univ. of Western Sydney, Sydney, Australia; [4]Rutgers Univ., New Jersey, NJ; [5]Johns Hopkins Med. Inst., Baltimore, MD

Abstract: Background: Stochastic resonance is a phenomenon whereby sensitivity to sub-threshold signals is modified via low frequency noise. Application of stochastic noise has been shown to improve visual, auditory, balance and cardiovascular functions within humans. A key feature of stochastic noise is the low frequency and amplitude of the stimulus- that is, it remains imperceptible to the participant. This means that rather than eliciting a profound habituation or hyperstimulationreflex responses on the back of neuronal activation, stochastic noise presumably exerts its effect by subtlely altering neuronal sensitivity to incoming signals.
Objective: Here we aim to determine how the gain (sensitivity) of individual medial vestibular nucleus (MVN) neurons is modified by the application of stochastic noise.
Methods: All experimental materials and procedures were approved by the University of Sydney Animal Ethics Committee (protocol 2018/1308). All experiments were performed in 3 - 4 week-old male and female C57BL/6 mice. Whole-cell current-clamp recordings of individual neurons in the medial vestibular nucleus (MVN) were made at room temperature from 250 µm tissue slices. Recordings were made in response to a suite of depolarising current steps (10 steps, 10 pA/step) with or without (control) sStochastic noise. The stochastic noise protocol was produced using MATLAB with a maximum amplitude of ± 120 pA. To maintain average background neuronal discharge during stochastic noise, stimulus amplitudes of between 5-20 % of the maximum amplitude were used (i.e. 5 % = ± 6 pA). Spike rate vs current plots were produced and the slope of the line of best fit used to quantify neuronal gain.
Results: In 4/6 MVN neurons stochastic noise produced a significant alteration in neuronal gain when compared with the no noise control condition (all p-values < 0.001). In two of the neurons this difference was expressed as an increase in neuronal gain (46.10 % and 8.50 %) and in two of the cells, neuronal gain was reduced (72.35 % and 28.82 %). However, the neuronal gain of the remaining two neurons was unaffected by stochastic noise.
Conclusion: These results indicate that the sensitivity of MVN neurons are can becan be influenced by the application of stochastic noise. Importantly this preliminary data suggests that the impact of stochastic noise is variable? differential- that is, in some neurons the impact is an

increase in gain while in others it is a reduction. This differential may provide a “normalisation” mechanism to modulate the overall sensitivity of the vestibular system and as such may be useful in the development of therapeutic devices to treat those suffering from balance dysfunction.

Title: Pulsed infrared neural stimulation of vestibular system endorgans evokes sinusoidal vestibulo-sympathetic reflex responses

Authors: D. RICE[1], W. JIANG[1], G. P. MARTINELLI[3], G. R. HOLSTEIN[4], *S. RAJGURU[2]
[1]Biomed. Engin., Univ. of Miami, Miami, FL; [2]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL; [3]Dept. Neurol., [4]Depts Neurol, Neurosci, Anat/Cell Bio, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The vestibulo-sympathetic reflex (VSR) plays a role in modulation of heart rate (HR) and blood pressure (BP) with changes in posture and head position. Previous experiments have demonstrated that the activation of VSR pathway via galvanic electrical stimulation and tilt. In the present study, we have investigated the effects of pulsed infrared radiation (IR) focused on individual vestibular endorgans, either the vertical semicircular canals or the otolith endorgans *in vivo*in a rat model and characterized the resultant physiological modulation of HR and BP.The focused, pulsed IR stimulation allows a detailed characterization of the contributions of individual endorgans to the resultant HR and BP changes. Long wavelength pulsed IR (1863nm) was targeted towards individual vestibular endorgans using custom optical fibers. The cardiovascular responses evoked via the activation of the VSR were measured using a small animal, single-pressure implantable device (DSI Inc.) inserted into the femoral artery.To confirm the site of stimulation and the endorgans affected, the distance of the fiber from target structures and orientation of the beam *in vivo*were determined using micro-computed tomography. Stimulation of the posterior semicircular canals using frequency-modulated IR resulted in significant cardiovascular responses. Overall, the HR dropped between 10 to 40 bpm below baseline (a change of up to 16%) whereas the BP dropped between 5 to 10 mmHg below baseline (a change of up to 11%, n=14). The IR parameter space including irradiance and

modulation frequencies was explored. Light directed at the utricular macula evoked the characteristic upward-torsional movements of ipsilateral eye with a downward rotation of the contralateral eye. However, IR stimulation of utricular macula in the rats failed to evoke changes in HR or BP. In the companion abstract, we present resulting distributions of activated vestibular nuclei neurons following IR of an individual end organs. Combined with previous studies utilizing tilt or galvanic vestibular stimulation, these results are suggestive of selective activation of the vestibular system by pulsed infrared, and an important role of vertical canals in the activation of the VSR pathways. Title: Vestibular nucleus neurons that activate vestibulo-sympathetic reflex pathways following single end organ labyrinthine stimulation

Authors: *G. R. HOLSTEIN[1], E. K. CHAPMAN[2], D. L. RICE[4], W. JIANG[5], S. RAJGURU[6], G. P. MARTINELLI[3]
[1]Depts Neurol, Neurosci, Anat/Cell Bio, [3]Dept. Neurol., [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Biomed. Engin., U. Miami, Miami, FL; [5]Biomed. Engin., Univ. of Miami, Miami, FL; [6]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL

Abstract: The vestibulo-sympathetic reflex (VSR) pathway can alter blood pressure and heart rate in response to changes in head position with regard to gravity, as occurs when humans rise from a seated or supine position and when quadrupeds rear, climb or burrow. We have previously demonstrated that sinusoidal galvanic vestibular stimulation and tilt can be used to activate central vestibular neurons of the VSR pathway in rats. The activated vestibular neurons were identified by cFos labeling and retrograde tract tracing, and were classified by neurotransmitter phenotype, projection target, and laterality of the projections.
The goal of the present study was to identify the locations of vestibular neurons of the VSR pathway that were activated by pulsed infrared laser stimulation (pIR) of individual vestibular end organs. To achieve this, pIR at 1863 nm, 250 pps baseline pulse frequency, and 200 μs pulse

duration was directed through the round window toward vestibular end organs in rats using polished optical fibers with core diameters of 200 or 400 µm. Changes in blood pressure and heart rate were detected using a telemetric sensor implanted in the aorta via the femoral artery, and recorded using Ponemah software (DSI Inc.; MN). Evoked eye movements were recorded using video-oculography. Cells that were activated by pIR were identified by cFos/DAB immunohistochemistry. Labeled cells were counted in skip-serial sections through the caudal vestibular nuclei that were separated by at least 100 µm. The cell counts from each rat were mapped onto 16 representative rostro-caudal Bregma levels and normalized for comparison across subjects. In some animals, the retrograde tracer FluoroGold was placed in the pre-sympathetic medullary region (RVLM) two weeks prior to pIR stimulation.
Results indicate that blood pressure and heart rate are highly sensitive to unilateral pIR activation of the posterior canal, but not unilateral activation of the utricle. Nevertheless, following unilateral activation of the posterior canal, the highest density of cFos-positive cells is located in a narrow rostrocaudal belt between Bregma levels -11.40 and -11.88, and the highest density of cFos-positive cells resulting from unilateral pIR of the utricle is observed between Bregma levels -11.76 and -12.12. In both stimulus conditions, the highest densities of activated neurons are present in the caudal medial vestibular nucleus. Together with the results of previous studies utilizing tilt or sinusoidal galvanic vestibular stimulation stimuli, the present study suggests that there are subpopulations of VSR neurons in the caudal vestibular nuclei that receive differential end organ input.

Title: The effect of dynamic upper limb movements on perception of gravitational direction during prolonged whole-body tilt

Authors: *K. TANI[1], S. YAMAMOTO[2], Y. KODAKA[3], K. KUSHIRO[4]
[1]Hamamatsu Univ. Sch. of Med., Hamamatsu City, Japan; [2]Nihon Fukushi Univ., Chita-gun, Japan; [3]Natl. Inst. AIST Tsukuba Central 2, Ibaraki, Japan; [4]Kyoto Univ., Kyoto, Japan

Abstract: Prolonged whole-body tilt, keeping the body tilted for certain time, gradually shifts the perceived direction of gravity toward the direction of body tilt (Wade 1970). The present

study investigated how upper limb movements during body tilt influence the effects of prolonged whole-body tilt in the roll plane on the perception of gravitational direction. Fifteen healthy subjects participated in this study. First, subjects which sat on the tilting chair, were moved toward left-side-down 16 degrees, they were instructed to perform visual vertical (VV) task, in which they adjust a white line presented on the display in front of their head to the perceived direction of gravity. After that, they were asked to perform any of three following action tasks without vision; 1) non-movements, 2) static movements, pointing with their right index finger ahead the center of the eyes and keeping this upper limb position, and 3) dynamic movements, moving their right upper limb up and down along their longitudinal axis for ten times. After the action task, they performed VV task again. We compared subjective visual vertical (SVV) angle between before and after action task for each movement condition. Results show that SVV after action task were significantly tilted toward the direction of body tilt (i.e. leftward) compared with SVV before action for non-movement and static movement conditions. And, in contrast, we found no significant angular difference between SVV before and after the action task for dynamic movement condition. These results suggest that additional spatial cues (i.e. dynamic proprioceptive feedback from muscle spindles and skin receptor, and effect copy) occurred during dynamic upper limb movements contribute to the accurate estimation of gravitational direction.

Title: Vestibular adaptation time constants to mechanical and virtual rotation

Authors: *A. CHEN, N. KHOSRAVI-HASHEMI, J. L. K. KRAMER, J.-S. BLOUIN
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The semicircular canals in our vestibular system detect angular acceleration of the head in space, providing us with information for spatial orientation and balance. Activation of primary canal afferents result in oculomotor responses (vestibulo-ocular reflex; VOR) and motion perception. For mechanical rotations, a step change in head velocity generates primary canal afferent activity that decays with a time constant of ~4s. Central multisensory integrative processes, however, prolong responses evoked by such mechanical stimuli. Electrical vestibular stimulation (EVS) may mimic the neuronal activity of the primary vestibular afferents despite

the lack of any associated head motion. Using previously reported transfer functions from animal models, a mathematical conversion model was developed to estimate the equivalent electrical current profile for a given head motion. The goal of this study was to determine whether this electrically equivalent stimulation profile was processed differently in the central neurons eliciting the VOR and perceptual responses. Subjects were seated with their head pitched down in a rotary chair that delivered whole-body yaw rotations. Illusionary yaw rotations were created by electrodes placed bilaterally on the mastoid processes that provided EVS in a binaural-bipolar configuration. Within a darkened room, stimuli were delivered to the seated subject while extraneous somatosensory cues were attenuated with padding. To quantify adaptation time constants, we rotated the chair at a constant velocity (*±10o/s*) over 60s or delivered an electrically equivalent profile with a maximum current amplitude of ±4mA. For perceptual responses, twenty subjects (11 females) were asked to turn a handle corresponding to their perceived position. In a second session, VOR-evoked ocular torsion was recorded using an infrared camera placed in front of the subject. Position signals were processed offline and adaption time constants were determined by fitting the differentiated position signal with an exponential function. Preliminary results based on perceptual responses showed that the time constant under physical stimulation 13.8±2.2s was longer than that evoked by EVS (7.4±1.0s; Wilcoxon Rank-Sum p=0.006). Preliminary observations from the VOR (n=2, 1 female) support our perceptual findings but additional testing is required. Altogether, these results suggest that activation of primary vestibular afferent by EVS are integrated differently from mechanical stimuli in the central vestibular system. Application of EVS to mimic real world motion perception would require further modeling of central processing not yet accounted.

Title: Multisensory signals underlie self-motion representation in the retrosplenial cortex

Authors: *S. KESHAVARZI, C. V. ROUSSEAU, S. LENZI, T. W. MARGRIE
Sainsbury Wellcome Centre, Univ. Col. Lond, London, United Kingdom

Abstract: Any neuronal representation of one's location, heading direction or motion with respect to the surrounding scene and objects is generated using internal and external sensory cues. These may include motor, somatosensory, visual and vestibular signals that combine to form a coherent representation of the external world, and the location and motion status of the observer within it. The retrosplenial cortex (RSP) is a multimodal cortical region involved in encoding and storage of spatial information. It receives substantial inputs from the ascending vestibular and head-direction pathways as well as visual cortical areas. However, it is not known whether individual RSP cells signal multimodal information, or whether functionally diverse populations of unimodal cells provide a combinatorial signal. We examined this question by recording responses of RSP cells during passive rotation (yaw) in awake head-fixed mice in the absence and presence of visual cues. Using a custom-built two-photon calcium imaging setup and extracellular recordings with a high-density silicone probe (Neuropixels), we observed neurons in superficial and deep layers of RSP to be modulated by rotation in the dark. Preliminary results showed changes in firing in both excitatory and inhibitory RSP cells evoked by clockwise and/or counter-clockwise rotations. Across the population, the presence of visual cues led to an increased directional tuning suggesting that, at least in some cells, both visual and vestibular inputs underlie the representation of self-motion in the RSP.

Title: You must stop the postural control of balance before you can move

Authors: *R. TISSERAND[1], C. J. DAKIN[2], M. H. F. VAN DER LOOS[1], E. A. CROFT[3], T. J. INGLIS[1], J.-S. BLOUIN[1]
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Utah State Univ., Logan, UT; [3]Monash Univ., Clayton, Australia

Abstract: The neural control of transition between posture and movement is dependent upon regulation of reflex-stabilizing mechanisms to enable motion. Optimal feedback control theory postulates that specific postural configurations, such as standing balance, or a movement pattern, such as locomotion, operate under distinct control policies, and that transitions between posture

and movement require disengagement of the current control policy before the engagement of a new one. We investigated this hypothesis by examining the continuity of the vestibular control of balance during transitions between standing balance and locomotion and between two states of standing balance. Sixteen healthy subjects initiated and terminated locomotion, at their preferred walking speed (Experiment 1) or shifted their weight from 50% to 90% on their left leg (Experiment 2), while exposed to a continuous electrical vestibular stimulus (EVS). Ground reaction forces (GRFs) were recorded before, during and after the different transitions. The relationship between the EVS and GRFs was quantified using time-frequency coherence. We observed a coherence null period preceding the onset of anticipatory postural adjustments during both the initiation of locomotion and the weight shift, as well as during the step prior to the termination of locomotion. These results highlight a down-regulation of the balance-correcting mechanisms to enable the transition between posture and movement that is not only related to locomotion. Our results suggest there is a discrete change between motor control policies to disengage the current motor policy to make way for the next, as predicted by optimal feedback theory. Ultimately, we demonstrate that humans must “stop balancing” before they can move and “stop moving” before they can reinitiate standing balance.

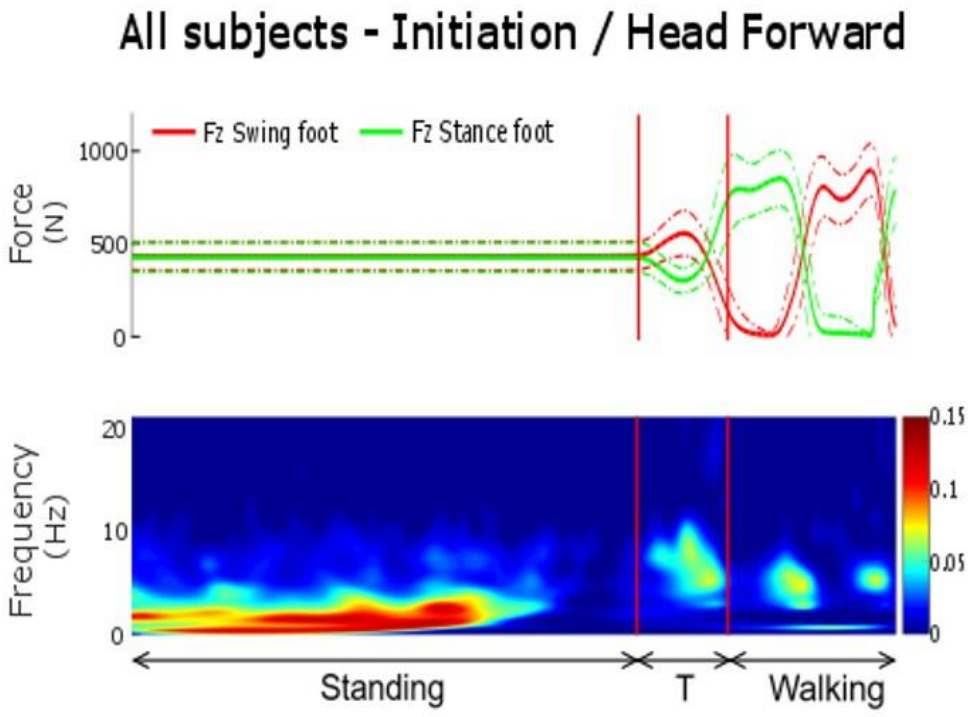

Figure 1: Evidence for a suspension of the vestibulomotor control of balance during locomotion initiation in healthy young adults (n = 10). Graphs represent the average vertical forces ± one standard deviation (top, red and green traces) and the average time-frequency coherence results between vestibular stimulus (EVS) and muscular responses in the mediolateral direction (bottom, colored graph). On the coherence graph, a dark blue color indicates a non-significant coherence. In both graphs, from left to right, the first vertical red line delimits between quiet standing and transition (T) periods and the second vertical red line delimits between transition (T) and walking periods.

Abstract: Galvanic Vestibular Stimulation (GVS) evokes virtual head motion. It has been used to diagnose vestibular disorders and to experimentally manipulate the vestibular afferents. However, the physiological mechanisms underlying GVS are not yet well understood.
GVS-induced motion has been explained as a vectoral summation of the motion direction synchronously signalled by both vestibular organs. This approach has three critical assumptions. First, the electrical current equally activates both otoliths and canals (*non-specificity*). Second, the activation pattern of the vestibular organs is defined by the polarity of the electrodes stimulating the organs (*polarity dependency*). Third, the overall signal information is summed to calculate the net motion direction (*vector summation*).
Here we show evidence that GVS may activate specific vestibular organs (*specificity*), independently from electrode polarity (*polarity independence*). Five participants were administered with a novel GVS electrodes configuration, in which the current was applied between electrodes on the mastoid and on the neck. Critically, the polarity of the electrodes on mastoids was always identical. According to the traditional theory, GVS will activate both otoliths and canals, and the vectoral summation of the signal should lead to forward and backward sensation. In contrast to this prediction, they perceived upwards or downwards sensations, without any rotation or forward-backward sensations. This indicates otoliths dominant activation was induced by this stimulus. Importantly, they were also administered with the same GVS configuration while facing the ground. In this posture, upward and downward otoliths contribution should be translated to forward and backward postural sway. Participant's postural sway direction was forward and backwards, confirming our prediction. Taken together, our results indicate that depending on the configuration of the electrodes, GVS can specifically activate the otoliths in a polarity-independent manner.
The impedance of the skull bone is well above that of the other tissues. Thus, the path that the GVS current can flow to affect the vestibular organs are restricted. Depending on the electrodes configuration, the current 's path can differ. We propose a novel Current Path Account to explain the physiological effects induced by GVS, where the direction of the current defines the activation pattern of the vestibular organs. We believe that the motion sensation triggered by GVS reflects a specific activation pattern in the vestibular organs, not the biased direction calculated from the non-specific overall activation.

Title: The effects of repetitive subconcussive head impacts on vestibular processing and balance during walking

Authors: *J. B. CACCESE, F. V. SANTOS, M. GONGORA, I. SOTNEK, E. KAYE, F. YAMAGUCHI, J. J. JEKA
Univ. of Delaware, Newark, DE

Abstract: Humans require precise integration and modulation of visual, vestibular, and proprioceptive feedback to control balance during walking. Using galvanic vestibular stimulation (GVS), a tool used to probe the vestibular system, our laboratory has demonstrated that repetitive subconcussive head impacts (RSHI) from soccer heading may lead to vestibular dysfunction during quiet stance. However, it is unknown if RSHI disrupt vestibular processing during walking and how vestibular dysfunction affects balance mechanisms during walking. The purpose of this study was to compare changes of balance mechanisms in response to GVS during walking following RSHI. Twenty adult amateur soccer players (10 males and 10 females, 22.3±4.5years, 170.5±9.8cm, 70.0±10.5kg) were randomly assigned to a soccer heading or a control group. Participants in the soccer heading group performed a controlled soccer heading paradigm. All participants underwent balance testing at baseline (PRE), immediately after the soccer heading paradigm (POST-0h), and 24 hours later (Post-24h). During balance testing, participants walked along a foam walkway with the eyes closed under two conditions: with GVS (~40 trials) and without GVS (~40 trials). Outcome measures included mediolateral center-of-mass (COM)-center-of-pressure (COP) separation, and four balance mechanisms: foot placement, mediolateral ankle modulation, hip adduction, and ankle push off. For each balance mechanism, a GVS response was calculated (GVS - mean (without GVS)). Repeated measures ANOVAs were used to compare between group responses across time points, while controlling for concussion history and sex. There were no significant group x time interaction effects for any of the balance measures (COM-COP separation: $F_{2,15}$=2.330, p=0.131; foot placement: $F_{2,15}$=1.448, p=0.266; ankle modulation: $F_{2,15}$=3.405, p=0.060; hip adduction: $F_{2,15}$=2.330, p=0.749). The results of this study suggest that although there may be a disruption in vestibular processing following RSHI, this disruption does not lead to measurable changes in balance during walking. While there were subtle, individual changes in balance mechanisms across time,

these changes may be an indication of the sensitivity of these measures and not of the clinical implications of RSHI.

Title: The effects of subconcussive head impacts on vestibular processing and balance during walking

Authors: *F. V. SANTOS[1], J. B. CACCESE[1], M. GONGORA[1], I. S. SOTNEK[1], F. S. YAMAGUCHI[1], J. J. JEKA[2]
[2]Kinesiology, [1]Univ. of Delaware, Newark, DE

Abstract: Gait is a primordial human function that requires sensory integration of visual, vestibular, and proprioceptive systems. In traumatic brain injury there are profound deficits in sensorimotor function. In addition, previous research has suggested that even mild traumatic brain injury/concussion and repetitive subconcussive head impacts (RSHI) may lead to subtle balance disturbances during standing and walking. We proposed to use galvanic vestibular stimulation (GVS), a technique used to study vestibular contributions to balance, to determine the effect of concussion history and exposure to RSHI on vestibular processing and balance during walking. Twenty adult amateur soccer players (10 females, 22.3±4.5years, 170.5±9.8cm, 70.0±10.5 kg) walked along a foam walkway with the eyes closed under two conditions: with GVS (~40 trials) and without GVS (~40 trials). Peak mediolateral center-of-mass (COM)-center-of-pressure (COP) separation response (GVS - mean (without GVS)) was used as the main outcome measure. Independent variables included self-reported years of soccer participation, age of first exposure to soccer heading, and concussion history. Linear regression models were used to determine if measures of RSHI exposure or concussion history were related to balance response to GVS. The COM-COP separation response was not associated with RSHI exposure or concussion history (age of first exposure to soccer heading, R^2=0.028, p=0.477; years of soccer participation, R^2=0.012, p=0.652; concussion history, R^2=0.139, p=0.105). Although previous research has speculated that there are possible long-term neuropathological consequences associated with RSHI and concussion, including chronic traumatic encephalopathy, our results suggest that years of participation in soccer and a history of concussion are not related to

vestibular processing and balance dysfunction during walking. Moreover, recent literature has suggested that age of first exposure to tackle football leads to later-life cognitive, behavioral, and mood changes. However, we found no evidence of balance dysfunction in those with earlier exposure to soccer heading. Our cohort consisted exclusively of current adult amateur soccer players, and thus, our findings cannot be extended to later-life, retired soccer players.

Title: Customizing galvanic vestibular stimulation amplitude using postural sway: Sensitivity thresholds are reduced without vision and disrupted proprioceptive feedback

Authors: M. MURARIK[1], S. B. DOUGLAS[1], E. R. STEELE[1], M. M. FEYRER-MELK[1], H. S. LEE[1], J. M. SERRADOR[2], *S. J. WOOD[1]
[1]Azusa Pacific Univ., Azusa, CA; [2]Pharmacology, Physiol. & Neurosci., Rutgers, Newark, NJ

Abstract: Neuromodulation using low levels of noisy galvanic vestibular stimulation (GVS) is being explored as a treatment to improve balance function. High intersubject variability in GVS sensitivity suggests that the treatment can be enhanced by customizing the stimulus level to individual sensitivity thresholds. We have developed an objective procedure for determining thresholds using postural sway induced during increasing levels of sinusoidal GVS. One complication is that the target patient population will have varying levels of postural instability prior to and during treatment. The purpose of this study was to compare sensory sensitivity thresholds in 27 healthy subjects across four conditions that represent increasing postural challenge: eyes open on stable surface, eyes closed on stable surface, eyes open on unstable surface, and eyes closed on unstable surface. Inertial motion sensors on the head and torso recorded sway while subjects stood with feet together for 20 sec during sinusoidal 0.1 Hz GVS over a 0.1 - 0.9 mA range in 0.1 mA steps. Both the amplitude of sway as well as the percentage of falls increased from fixed to unstable conditions, and from eyes open to eyes closed conditions. Sinusoidal curve fits were used to characterize sway modulation as a function of the sinusoidal-varying stimuli. Sensitivity thresholds were derived from the lowest stimulus level where the sinusoidal response amplitude exceeded the baseline sway amplitude without GVS

stimulation. Thresholds were significantly reduced during the condition without vision and disrupted proprioception. Sensitivity thresholds determined by this technique are influenced by the feedback available to the participant. Visual and/or proprioceptive feedback may elicit compensatory reflexes that inhibit sway, thus increasing the sensitivity thresholds. These compensatory strategies may be greater in patients with vestibular loss, and therefore need to be considered when determining a threshold-based stimulus level for treatment.

Title: Neural correlates of vestibular processing during exposure to a spaceflight analog with elevated carbon dioxide

Authors: *K. E. HUPFELD[1], J. K. LEE[1], N. E. GADD[3], I. S. KOFMAN[4], Y. E. DE DIOS[4], J. J. BLOOMBERG[3], A. P. MULAVARA[3], R. D. SEIDLER[2]
[1]Applied Physiol. and Kinesiology, [2]Univ. of Florida, Gainesville, FL; [3]NASA Johnson Space Ctr., Houston, TX; [4]KBRwyle, Houston, TX

Abstract: Spaceflight negatively affects central vestibular processing and performance of vestibularly-mediated behaviors such as balance and gait. Head-down-tilt bed rest (HDBR) is commonly used as a spaceflight analog to examine effects of body unloading, fluid shifts, and other consequences of spaceflight unrelated to gravitational changes. HDBR paired with elevated atmospheric carbon dioxide (CO_2) to mimic conditions on the International Space Station has been shown to positively influence cognitive performance; however, effects of combined HDBR and elevated CO_2 on vestibular processing have not yet been studied. Here, we examine how a 30-day HDBR intervention with elevated (0.5%) CO_2 influences the neural correlates of vestibular processing in 11 participants (6 males, mean age = 34 years). Over six sessions (twice before, twice during, and twice after CO_2-HDBR) we used fMRI to measure brain activity in response to pneumatic cheekbone taps, a validated method of vestibular stimulation, in addition to assessing balance and mobility. This allowed us to examine immediate and cumulative changes due to CO_2-HDBR and the time course of recovery. We found that frontal,

sensorimotor, temporal, and occipital cortices showed increases in brain activation during vestibular stimulation immediately after starting CO_2-HDBR, with recovery after stopping the intervention. Opposite patterns of immediate decreases in activation after starting CO_2-HDBR followed by recovery were observed in the brainstem. Slower cumulative increases in activation across CO_2-HDBR followed by recovery were seen in occipital cortex. In comparison to another cohort exposed to 70 days of HDBR with ambient air (n = 13; all males; mean age = 29), CO_2-HDBR participants showed multiple regions with a greater degree of activation change from baseline to the end of the intervention, including regions in frontal, parietal, and occipital cortices. CO_2-HDBR participants also showed multiple regions with a smaller degree of activation change from baseline, including in the thalamus, cerebellum, and temporal cortex. These results suggest that CO_2-HDBR may be associated with reduced neural efficiency and/or sensory reweighting in comparison to HDBR alone. Further, the observed differences in the neural vestibular changes between ambient air-HDBR and CO_2-HDBR participants suggest that CO_2-specific effects, such as hypercapnia-induced cerebrovascular reactivity, or the interactive effects of CO_2 and HDBR may uniquely affect central vestibular processing. These findings have implications for better understanding the neural mechanisms of spaceflight-related changes in vestibular processing.

Abstract: To maintain posture, the visual, vestibular and proprioceptive sensory information are utilized. In dizziness patients, posturography is used to measure variations in center of gravity(COG) to assess postural instability. The VR technology can be applied to create real-life 3D environments where the user can navigate. In this study, we introduce the development of VR immersion contents with varying degrees of visual sway components, and evaluate their validity in assessment of postural control. Three conditions of VR immersion scenarios(VR1-3)

were created and operated on commercially available head mount devices. Ten healthy subjects were instructed to maintain upright posture during exposure to different visual conditions. Posturography data of COG sway during test trials of 30 seconds were collected. Subjective symptoms were measured using visual analog scale and the simulator sickness questionnaire. Mean COG sway velocities were 0.17±0.38 deg/sec and -1.51±0.86 for x- and y-axis directions for VR1, 0.24±0.52 and -1.88±0.75 for VR2, and 0.11±0.53, and -1.94±0.68 for VR3. Mean VAS scores 0.1±0.32, 0.4±1.27, and 2.0±3.09 for VR1-3 respectively. Mean total SSQ scores were 0.37±1.18, 1.5±4.73, and 7.48±11.56 for VR1-3, showing that even healthy subjects showed wide range of VAS and SSQ during VR immersion. Tailored VR immersion scenarios were developed and their applications in assessment of posture control showed that increased visual-vestibular conflict resulted in postural instability. Addition of VR immersion conditions would be helpful to discern minute but significant deficits in patients who experience dizziness but can perform conventional posturography tasks.

Title: Vestibular contribution to balance control during stair negotiation and locomotion vestibular contribution to balance control during stair negotiation and locomotion

Authors: *C. DAKIN, M. ELWOOD, A. KERN, E. BRESSEL
Utah State Univ., Logan, UT

Abstract: The vestibular system is an important source of motion and orientation information, and is essential for the control of our posture in space. Generally, the vestibular contribution to the control of posture increases as the balance demands of a task increase, resulting in some tasks seemingly having greater vestibular involvement than other tasks. Here we ask whether this is true for stair negotiation compared to treadmill walking with the long-term goal of understanding how changes in vestibular function with aging may contribute to falls on stair. **Methods:** Fifteen young adults and six older adults walked over a nine-step staircase and on a treadmill (300 steps each for ascent, descent and treadmill) with a cadence of 76 steps/minute (treadmill speed of 0.4m/s) while receiving a small continuous random electric current (0-25hz bandwidth) to their mastoid processes. Electromyography was recorded from eight muscles (soleus, medial gastrocnemius, tibialis anterior, biceps femoris, semitendinosus, vastus medialis, rectus femoris and gluteus medius) and body kinematics recorded from the left leg and trunk. We quantified the relationship between the vestibular stimulus and behavior across conditions using time-

dependent measure of coherence and cross-correlation. **Results:** Preliminary results suggest older adults exhibit greater vestibular influence over muscle activation in the soleus and medial gastrocnemius than young adults during treadmill walking, and in the biceps femoris during stair ascent. Vestibular influence appears to decrease in the soleus, medial gastrocnemius, biceps femoris and semimembranosus during stair descent versus ascent whereas in older adults vestibular influence increases in the tibialis anterior during stance in stair descent. **Conclusions:** Stair negotiation requires changes in how vestibular cues are used to control balance compared to locomotion and much like during locomotion these changes depend on the muscle and phase of the gait cycle. More generally, these results provide a first proof of concept demonstrating the ability to identify subtle changes in vestibular feedback driven control of balance in dynamic and potentially compromising environments.

Title: Statistical characterization of heading stimuli in natural environments using SLAM

Authors: *C. SINNOTT, T. DANG, C. PAPACHRISTOS, K. ALEXIS, P. MACNEILAGE
Univ. of Nevada Reno, Reno, NV

Abstract: Heading is the direction of linear self-motion in head coordinates. It may be estimated based on vestibular signals that provide information about linear acceleration and based on visual optic flow signals that provide information about linear velocity. Prior psychophysical studies have documented significant repulsive biases in perception of both visual and vestibular heading (Cuturi & MacNeilage 2013), meaning that heading azimuth angle is perceived to be more eccentric than the presented stimulus. Theoretical work suggests that such biases may result from a combination of efficient encoding and probabilistic decoding, where both encoding and decoding mechanisms are constrained based on natural stimulus distributions (Wei & Stocker 2015). To our knowledge, these distributions for heading stimuli remain undocumented, so we set out to characterize them. Tracking linear head velocity in natural environments using a head-based system is challenging. Recording of linear head acceleration using an inertial measurement unit (IMU) results in velocity estimates subject to drift, while optic flow analysis of video from a head-mounted camera is subject to ambiguity due to superposition of linear and angular flow and unknown scene scale. To overcome theselimitations we adopted visual-inertial odometry

technology developed for autonomous robots that perform localization and mapping (SLAM). Subjects wore a head-mounted device with calibrated, integrated camera and IMU.The data fusion pipeline yielded robust estimates of linear and angular position (in world-frame coordinates) and velocity (in head-frame coordinates) as subjects moved freely. The distribution of heading azimuth and elevation was peaked near straight ahead, as expected based on natural walking with head facing forward. These highly peaked distributions are qualitatively consistent with predictions of repulsive biases based on efficient encoding and probabilistic decoding.

Title: A novel apparatus for open- and closed-loop vestibular stimulation in head-fixed mice

Authors: *E. A. RANCZ, B. A. HOROBET, A. P. TRAN-VAN-MINH, Z. YE
The Francis Crick Inst., London, United Kingdom

Abstract: Visual virtual reality (VR) is used successfully to study cortical processing in awake, behaving mice. It not only allows for tight control of animal driven visual stimuli, but also has the ability to change the coupling between stimulus and behaviour. However, most visual VR approaches use head-fixed animals, where one important sensory modality, the vestibular system, is taken out of play. Vestibular information is important for many cognitive processes, including spatial navigation. So-called head-direction cells, found in several cortical areas associated with spatial navigation, are primarily driven by vestibular input. Here we present a novel experimental apparatus, in principle compatible with visual VR systems, using a yaw rotational motor which can be used in both open- and closed-loop configuration, allowing animals to navigate in rotational, directional space.
We show that animals adapt to the new environment quickly and behave in a natural way when the motor is engaged. We further show that our approach is compatible with both electrical and optical recording of brain activity at the cellular level. We are currently conducting experiments to establish the degree and nature of recruitment of the head-direction system as well as suitability for behavioural tasks requiring directional information.

We present a novel experimental apparatus, which combines the advantages of head fixation (access to electrical and optical signals from the animal's brain) and rotational vestibular input. It can be used in an open-loop mode to study vestibular sensory representation and processing, while in closed-loop mode allows animals to navigate in rotational space, providing a better substrate for 2D navigation in virtual environments.

Abstract: One of the most common forms of degenerative retinal diseases and leading cause of human blindness is age-related macular degeneration (AMD). The objective of this project is to develop an innovative line of research dealing with the use of light-sensitive organic nanoparticles (NPs) as smart materials for bio-hybrid interfaces that can fully integrate with retinal neurons. Recently, we introduced organic conjugated polymers (CPs) as interfaces for neuronal photostimulation. We developed a planar fully organic device composed of a flexible and highly conformable silk substrate covered with photoactive layers of CPs that, once implanted in the subretinal space of Royal College of Surgeons (RCS) rats, was able to rescue light sensitivity and visual acuity (*Nature Materials 2017, 16(6): 681*). With the aim of improving the spatial resolution of the CP-based organic device to target AMD, by scaling down photoactive devices to the cellular size, we engineered and tested subcellular size CP

nanoparticles (CP-NPs) as a "liquid high-resolution prosthesis" that can be implanted in the degenerate macula with a non-invasive injection. CP-NPs were prepared from freshly prepared poly(3-hexylthiophene) (P3HT) using the re-precipitation technique. We found that P3HT-NPs, injected in the eyes of blind RCS rats, covered most of the subretinal space but remained restricted to the outer retina, in place of the degenerate photoreceptors. Interestingly, the analysis of the light-driven behavior revealed a significant light-sensitivity rescue in dystrophic blind RCS rats injected with P3HT-NPs with respect to control glass spheres of the same size. The recovery of both spatial acuity and of the pupillary reflex was also observed in P3HT-NPs treated animals. Our results highlight a potential clinical relevance of this low-invasive approach in retinal degenerative blindness.

Abstract: Retinitis Pigmentosa (RP), or inherited retinal degenerations, are genetically inherited retinal dystrophies characterized by progressive loss of photoreceptor cells and represent one of the most prevalent causes of blindness among working age populations. Much currently remains unknown regarding the underlying mechanisms of photoreceptor death. We have previously shown that the transmembrane protein Neogenin is involved in regulating cell survival in the CNS. Here we show that Neogenin expression is induced in degenerating photoreceptors in two mouse RP models (Rd1 and Rd10). Degenerating photoreceptors can have abnormally high

levels of cGMP and cAMP, and here we demonstrate that 8-Bromo-cAMP administration was sufficient to induce Neogenin expression in-vivo, in wild type mouse photoreceptors, and in-vitro in human photoreceptor surrogate cells. Using targeted in-vivo electroporation, we then demonstrate that i) overexpressing Neogenin in mouse photoreceptors induces cell death and ii) that silencing Neogenin in degenerating Rd1 photoreceptors promotes survival. This suggests Neogenin acts as a previously unidentified pro-death signal in RP. To develop a potential therapeutic approach for targeting Neogenin in RP, we utilized our Neogenin function blocking peptide (4Ig) that is capable of blocking Neogenin's pro-apoptotic activity. Intravitreal injections of 4Ig were administered at the onset of photoreceptor degeneration in Rd1 and Rd10 mice. When assessed at advanced stages of disease progression, 4Ig treatment significantly improved i) rod photoreceptor survival and ii) cone photoreceptor survival. Photoreceptor function was also shown to be significantly improved following 4Ig treatment as demonstrated by i) improved light-evoked retinal ganglion cell recordings, ii) improved scotopic/photopic electroretinogram recordings and iii) improved visual acuity (OptoMotry; CerebralMechanics). Targeting Neogenin therefore represents an exciting new approach for the treatment of RP.

Title: Protective effects of zinc and cAMP against A2E-induced toxicity in ARPE19 cells: Possible involvement of lysosomal acidification

Authors: *J. CHOI[1], B.-R. SEO[2], J.-Y. KOH[3], Y. YOON[4]
[1]Neural Injury Res. Ctr., Asan Inst. For Life Sci., SEOUL, Korea, Republic of; [2]Neural Injury Res. Ctr., Asan Inst. for Life Sci., Seoul, Korea, Republic of; [3]Neurol., ASAN Med. Center, Col. of Medicine, Univ. of Ulsan, Seoul 138-040, Korea, Republic of; [4]Ophthalmology, ASAN Med. Center, Col. of Medicine, Univ. of Ulsan, SEOUL, Korea, Republic of

Abstract: Dry age-related macular degeneration (AMD) is characterized by accumulation of drusen and degeneration of photoreceptor cells and retinal pigment epithelial (RPE) cells. It has been proposed that dysfunctional lysosomes in RPE cells contribute to dry AMD pathology by hindering the degradation of shed photoreceptor membranes. We have previously shown that raising intracellular zinc levels can restore lysosomal acidity, and several studies have shown that

raising cAMP levels may restore acidity and degradative functions of lysosomes. In the present study, we examined the effects of zinc and cAMP on lysosomal alkalization and dysfunction in an *in vitro* model of AMD. To induce lysosomal dysfunction in ARPE19 (human RPE cell line), we used A2E (lipofuscin derivative). We quantitatively assessed A2E-induced cell death by measuring the amount of lactate dehydrogenase (LDH) released into the culture medium. In addition, we observed the effects of zinc and dibutyryl cAMP on lysosomal acidity and degradative functions in A2E-treated ARPE19 cells. Lysosomal pH of the cells treated with cAMP or clioquinol (ClioQ, zinc ionophore) was measured by using LysoTracker. Twenty-four hours after A2E treatment, ARPE19 cells exhibited autofluorescence throughout the cell body, and showed significant amount of cell death (69.2 ± 4.9 % LDH release). Addition of clioquinol or dibutyryl cAMP significantly reduced cell death by 20 - 50% in both cases ($P < 0.05$). A2E was seen to accumulate in endosomes and lysosomes, and LysoTracker signals faded, signifying lysosomal alkalization. Moreover, both zinc and cAMP decreased A2E autofluorescence and restored lysosomal pH back to the acidic range. Our results support the possibility that adequate levels of zinc or cAMP may help overcome A2E-induced toxicity in ARPE19 cells that contribute to the pathogenesis of AMD.

Title: A subpopulation of GABAergic intrinsically photosensitive retinal ganglion cells in the mouse retina

Authors: *T. SONODA, T. M. SCHMIDT
Neurobio., Northwestern Univ. Dept. of Neurobio. and Physiol., Evanston, IL

Abstract: The mammalian retina contains three classes of photoreceptors: rods, cones and intrinsically photosensitive retinal ganglion cells (ipRGCs). ipRGCs directly project to over 10 brain areas to mediate a wide range of visual behaviors such as circadian photoentrainment, pupil constriction, and contrast detection. Current evidence points to ipRGCs executing these functions by primarily releasing the excitatory neurotransmitter glutamate and the peptide transmitter pituitary adenylate cyclase-activating peptide (PACAP). Here, we report that a small population of ipRGCs are GABAergic. This population of GABAergic ipRGCs project to the

suprachiasmatic nucleus (SCN) and the intergeniculate leaflet (IGL), which suggests that they are primarily involved in circadian photoentrainment. These results identify a novel inhibitory circuit mediated by retinal ganglion cells in the mouse visual system.

Title: Effect of long-term iron administration on retinal photoreceptor cells

Authors: *P. KUMAR[1], T. C. NAG[1], T. S. ROY[1], T. VELPANDIAN[1], S. WADHWA[2]
[1]ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI, India; [2]NORTH DELHI MUNICIPAL CORPORATION MEDICAL COLLEGE, NEW DELHI, India

Abstract: Iron accumulates in many organs with age. Iron overload is a causative factor in several neurodegenerative diseases. In this study, we investigated the effect of long-term, oral iron administration on the photoreceptor cells in rat retina. At 2 months of age, rats were treated orally with ferrous sulphate (500 mg/kg body weight/week), which was continued up to 17.5 months. Electroretinography (ERG), photoreceptor ultrastructural changes and markers of mitochondria (SOD-2 and VDAC1) and autophagy (LC3-II and beclin-1) were examined at different ages (8, 14 and 20 months). In contrast to controls, in iron-accumulated retina, the mitochondria of photoreceptor inner segments were highly disorganized, which also showed a decrease in the expression of SOD-2 and VDAC1 in retinal extracts, in 14 month- and 20-month-old rats. Electron microscopy revealed signs of autophagy in photoreceptor inner segments in both groups, which paralleled with the increased expressions of LC3-II and beclin-1, as detected by immunoblotting. Together with the earlier findings, the present data indicate that photoreceptor damage due to iron accumulation involves not only the outer segments, but also the inner segment mitochondria and that autophagy is induced in photoreceptor inner segments to maintain tissue homeostasis in the iron-accumulated aged retina.

Title: Differential distribution of molecularly distinct M1 intrinsically photosensitive retinal ganglion cells in mouse retina

Authors: *S. LEE, T. M. SCHMIDT
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Melanopsin-expressing, intrinsically photosensitive retinal ganglion cells (ipRGCs) are a class of atypical, ganglion cell photoreceptor. The M1 subtype of ipRGCs serves ambient irradiance detectors mediating non-image forming visual behaviors such as circadian photoentrainment and the pupillary light reflex. Despite initial reports of homogeneity within the M1 population, recent reports have suggested that M1 ipRGCs can be molecularly subdivided based on whether they express the transcription factor Brn3b (Brn3b+ M1 and Brn3b- M1). The distribution of RGCs in retina is correlated with what environmental light they encode for visual behaviors. Although reports have shown the distribution pattern of M1 ipRGCs in retina, how Brn3b+ and Brn3b- M1 ipRGCs are distributed has not been determined yet. We therefore performed immunohistochemistry for Brn3b and beta-galactosidase in a whole-mount retina of *Opn4*$^{LacZ/+}$ mouse to identify the location of Brn3b+ and Brn3b- M1 ipRGCs. The retinal location was identified by unbiased poking before enucleation. The number of Brn3b+ M1 ipRGCs are 3-fold lesser than Brn3b- M1 ipRGCs. Brn3b+ M1 ipRGCs are significantly more distributed in the ventrotemporal retina than the dorsonasal retina. In contrast, Brn3b-expressing cell are significantly more found in the dorsonasal retina than in the ventrotemporal retina. Brn3b- M1 ipRGCs are found every region in the retina but with a significantly lesser distribution in the ventronasal retina than dorsonasal retina. Collectively, these results suggest that Brn3b+ and Brn3b- M1 ipRGCs have distinct distribution pattern in the retina, preferring to the ventral and dorsal region, respectively, and that Brn3b expression pattern in M1 ipRGCs does not parallel to typical Brn3b expression pattern in retina.

Title: The role of syntaxin 3 in the human retina

Authors: *R. JANZ, S. PUNURU, X. LIU, R. HEMMATI, R. HEIDELBERGER
UT-Houston Med. Schl, Houston, TX

Abstract: Syntaxin 3 is a t-SNARE protein, thought to be involved in the trafficking of vesicles in epithelial cells, the exocytosis of secretory granules in mast cells and pancreatic beta cells, as well as the exocytosis of synaptic vesicles in ribbon synapses of the retina. Previous studies in mouse and goldfish have shown that the syntaxin 3 gene expresses two major transcripts by differential splicing named syntaxin 3A and 3B. Syntaxin3B is expressed in photoreceptor and bipolar cells of the retina, while syntaxin 3A is expressed in non-neuronal cells. Patients with mutations in the human syntaxin 3 gene suffer from microvillus inclusion disease (MVID), a disorder of the intestinal epithelium (Wiegerinck et al., 2014). There have also been reports that MVID patients with mutations in the syntaxin 3 gene suffer from vision defects, indicating a role of syntaxin 3 for normal retina function. As a prerequisite for a better understanding of the role of syntaxin 3 in the human retina, we first investigated the expression of the syntaxin 3 gene in different human tissues using RT-PCR analysis. We demonstrated that syntaxin 3B is expressed at high levels in the human retina but only expressed at very low levels in other human tissues. In contrast, syntaxin 3A is expressed at high levels in most human tissues, including small intestine and retina, with the exception of the brain and muscle where the transcript is only expressed at very low levels. Next, we investigated the distribution of syntaxin 3 in the human retina by immunolabeling with antibodies that recognize both syntaxin 3A and 3B. Similar to the pattern found in the mouse and goldfish retina, syntaxin 3 was detected in the ribbon synapses of photoreceptors and bipolar cells. However, in contrast to the mouse where the majority of syntaxin 3 is found in the ribbon synapses with some weak labeling of the photoreceptor inner segments, we detected strong labeling with different syntaxin 3 specific antibodies in the outer segments of the rod and cone photoreceptors. This indicates that in the human retina, syntaxin 3 is probably also involved in trafficking processes in the outer segments of the photoreceptors in addition its role in synaptic vesicle exocytosis at ribbon synapses.

Title: Effect of electrical stimulation on mouse retinal tissues via microelectrode array

Authors: *H. YOO[1], H. YOON HEE[1], H. JEONG[1], S. HWANG[1], S. JUN[1,2]
[1]Dept. of Electronic and Electrical Engin., [2]Dept. of Brain and Cognitive Sci., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Recently, the restoration of sight has been enabled by implantable visual prosthetic system for patients blinded by retinal degeneration. The visual prosthetic system, also known as retinal prostheses, delivers electrical stimulation via microelectrode array attached on the surface of retina, evoking action potentials of surviving retinal neurons even though there exists no photoreceptors. Although the retinal prostheses have been applied for clinical applications, there still exist remaining challenges. One of them is the uniform and loose attachment of electrode arrays on to the retinal surface mostly due to the curvature of the retinal surface. To investigate this issue, in this study, as a first step, electrical stimulation is applied to retinal tissues on microelectrode array to simultaneously monitor the evoked activity from multiple locations at different distances between retina and electrode. The distance between the stimulating electrode and the retinal tissue varied to mimic the irregular electrode attachment of implanted artificial retina. It is expected that the results help establishment of safe and effective electrical stimulation parameters in retinal prosthetic devices.

Title: Changes in photoreceptor synapses and expressions of BDNF and Trk-B in postnatal chick retina exposed to light of variable photoperiods

Authors: *M. MAURYA, T. C. NAG, T. S. ROY
All India Inst. of Med. Sci. New Delhi, New Delhi, India

Abstract: Synaptic ribbons (SR) are unique structural features of photoreceptors that enable them to encode and transmit light response. Alterations in photoperiod and light intensities cause damage to the photoreceptor synapses, though the detailed mechanisms of retinal synaptic degeneration after light stress are unclear. The aim of this study was to understand the effect of bright light and photoperiod on SR length in cone dominated retina. Role of brain derived neurotropic factor (BDNF) and its receptor (Trk-B) was also evaluated. One day-old chicks (*Gallus gallus domesticus*) were acclimated in normal 12 h light –12 h dark cycle (12L: 12D) for 7 days (400 lux), followed by exposure to high intensity light (5000 lux, experimental) and 400 lux (control) at 12L: 12D, 18L: 6D and 24L: 0D conditions. Chicks were sacrificed and their eyes enucleated at 24h and 168h intervals. Transmission electron microscopy (TEM) of SR at 168h revealed that SR length was reduced significantly from 0.374 to 0.348 µm in 12L:12D vs 18L:6D, while the number of cone SR was reduced from 509 to 478 between the two groups and in constant light group, the values were 0.324 µm and 452. Retinal cryosections, immunolabelled with BDNF and Trk-B antibodies showed the significantly high number of BDNF immunoreactive neurons in inner nuclear ($p = 0.03$) and photoreceptor layer ($p = 0.03$) after exposure to 400 lux for 24h duration in 18L: 6D group compared to that in 12L:12D group, whereas after 168h interval, it increased in photoreceptors in 18L:6D ($p = 0.01$) and 24L:0D ($p = 0.01$) groups, compared to that in 12L:12D group. Immunoblotting revealed a reduction in BDNF level in retinas exposed to 5000 lux light for 24h interval under 24L:0D photoperiod ($p = 0.04$). Similarly, a decrease in Trk-B level was also noted in retinas exposed to 5000 lux for 24h duration under 18L:6D photoperiod ($p = 0.01$) and 24L:0D photoperiod ($p = 0.03$). These results indicate altered regulation of synaptic transmission due to changes in ribbon morphology and number. Increased number of BDNF positive photoreceptors and inner nuclear layer cells in 18L: 6D group and in photoreceptors in 24L: 0D group implicate a role for BDNF and its receptor (Trk-B) in neuroprotection against light induced stress in the retina.

Title: Histology of the eye of the crepuscular crab

Authors: *J. R. BARRADAS[1], E. VALERO-PACHECO[3], M. ALVARADO[2], P. PACHECO[4], F. ROJAS[5], F. ALVAREZ[6]

Abstract: Ocypode quadrata is a semi-terrestrial coastal crab, with crepuscular habits, which is active 19 hours a day. It has pedunculated eyes with a 360 ° vision. You can appreciate the flight of insects and capture them in the air. It has been proposed that this crab has compound eyes. However, so far the eyes of this species have not been studied in detail. The compound eyes can be of two types: of apposition, present in diurnal species and of superposition present in nocturnal species. O. quadrata is exposed to light variations and intermittent changes from an aquatic to a terrestrial environment. So it is conjectured that the cellular structure of the eye of this species is of intermediate type to eyes composed of apposition and superposition. In the present work, the cellular structure of the eye of O. quadrata was described by the Histological Technique of Paraffin, Hematoxylin and Eosin Stain, and Scanning Electron Microscopy. The tissue subjected to the Paraffin Technique and Hematoxylin & Eosin Stain. It was processed for longitudinal and transverse histological sections of 10 μm with a crank microtome. The permanent preparations of these cuts were observed, photographed and analyzed by means of an optical microscope with a digital camera. It was identified that the ocular structure of O. quadrata is composed of four layers of tissues: the cornea, the lens, the rhabdomoma and the dendrites. The cornea is divided into three layers: the cuticle, the corneogena cuticle and the distal pigment cells. The cone-shaped lens possesses: interomatidial pigment, retinal cell pigment and retina cells. The Rabdon has: proximal pigment cells, cone cells in process, basal membrane and basal pigment. Finally, the dendrites are responsible for taking the captured information to the tapetum region, where ganglion cells are found responsible for sending information to the brain ganglion through a set of axons that make up the optic nerve. According to the ocular structure observed, it is described as an eye composed of interposition type, considering that there are gradual steps between apposition and superposition.

Title: Unique dual rhabdom organization in the fusion stemmata of the firefly (Photuris sp.) larval visual system

Authors: *F. L. MURPHY, A. MOISEFF
Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: Fireflies, as holometabolous insects, have distinctly different visual systems as larvae compared to adults. Adults have a pair of extensively studied compound eyes. Larvae, by contrast, have a pair of stemmata, whose structure and function are unknown. Here, we present the structure of the firefly (*Photuris* sp.) larval stemmata.
Firefly stemmata (i.e., eyes) were located bilaterally on the antero-lateral surface of the head. Each eye had a single, simple lens (diameter ~130µm) and a densely pigmented, asymmetrical eye cup. At its widest point, the diameter of the eye cup was ~150µm, which tapered towards the base of the eye. The optic nerve, originating from the base of each eye, was ~30µm diameter and contained 88 axons (± 0.87, n=4).
Within the eye cup, dense pigmentation surrounded two regions, which we referred to as lobes. Each lobe was asymmetric in size (~256µm; ~189µm cross sectional perimeter of each lobe's superior surface) and devoid of pigment granules. Of particular note, a septum, consisting of a dense band of screening pigment perpendicular to the inferior surface of the lens was oriented along the antero-posterior axis and separated the two lobes.
Ultrastructure of the stemmata revealed that each lobe was a large rhabdom composed of multiple retinula cells. Retinula cells were arranged in pairs where the microvilli of neighboring rhabdomeres interlocked. These photoreceptor (PR) pairs were arranged radially within each rhabdom. The gross anatomy of the visual neurons was accomplished by backfilling of the optic nerve with texas red. 3D reconstruction of texas red labelled neurons revealed that PRs were arranged in vertical columns which extended the depth of each lobe.
The identification of this dual rhabdom system with 88 PRs is consistent with the eye being formed as a fusion-stemmata, an occurrence in holometabolous evolution where multiple ommatidia conjoin forming the larval eye. We believe that the anatomy of the firefly *Photuris* larval stemmata, specifically the rhabdom organization within the dual lobes and PR structure is unique among holometabolous stemmata.

Title: The cytoarchitecture of the degenerating eye if the blind cavefish Astyanax mexicanus

Authors: *D. SOARES[1], M. YOFFE[2], Z. TANVIR[2], S. ALI[3]
[1]Biol. Sci., [3]Biol., [2]NJIT, Newark, NJ

Abstract: Astyanax mexicanus is a teleost that has adapted to cave environments approximately 2 mya. Its closest living ancestor is still extant on the rivers outside the caves. During development, cavefish larvae develop retinas and lenses, but as the larva grows the lenses which subsequently undergo apoptosis and the eyes sink into the orbits. Embryonic lens transplantation from a surface larva donor onto a cavefish eye cup rescues the eye. Retinas that have been

rescued are generally presumed to be functional, and that all components are present and normal. Here we use comparative immunohistochemistry, expansion microscopy and transmission electron microscopy to show that the retinal layers is already disorganized. Retinal ganglion cells do not form a tightly organized layer and are intertwined with other cell types. Their projections onto the Optic Tectum follow the same timeline. The plexiform layer has synapses in both forms of the fish, and we have quantified smaller differences. The photoreceptor layer is particularly misshapen, with fewer cells that have much longer outer segments. The discs are not stacked but there are similar numbers of mitochondria in the inner segment. It appears that the cytoskeletal structure of the photoreceptors is malformed. We propose that the retinal organization is already lost in early stages of development and that at closer scrutiny; lens transplantation will likely not completely restore the retina.

Title: Presaccadic modulation of sensory responses in primary visual cortex

Authors: *J. YATES[1], S. H. COOP[3], J. F. MITCHELL[2]
[2]Brain and Cognitive Sci., [1]Univ. of Rochester, Rochester, NY; [3]Brain and Cognitive Sci., Univ. of Rochester - River Campus, Rochester, NY

Abstract: Primates actively sample visual input using rapid eye movements (saccades). This active sampling means that during natural vision, stimuli typically enter the receptive fields of visual neurons because they were brought there by eye movements. This is in contrast to most visual experiments, where visual stimuli appear de novo at locations in visual space. Despite half a century of research on the response properties of neurons in primary visual cortex (V1), we do not fully understand how saccadic eye movements modify the processing and transmission of sensory signals. Here, we studied the representation of visual input in V1 of marmoset monkeys freely viewing visual stimuli. We measured the selectivity of V1 neurons to orientation and spatial frequency, as well as their response gain, immediately before and after saccadic eye movements. We found that saccades produced substantial post-saccadic firing rate modulations in almost all neurons recorded. These modulations resulted from changes in response gain as well as additive increases in spike rate. Importantly, some neurons exhibited pre-saccadic

response gain, implying extraretinal signals can modify encoding in V1 immediately prior to eye movements. Ongoing work is quantifying the nature of this presaccadic gain and its consequences for the cortical representation of visual input.

Title: Visual strategies of elite athletes during attacks

Authors: *M. TAKAYOSE[1], Y. SATO[2], M. FUKAMI[2], H. SATO[3], T. HIRAKI[4], R. KOSHIZAWA[4], S. UMESHITA[5], S. SHIROMA[6]

Abstract: The information obtained from the visual system contributes to optimal motor control. An athlete must have a visual strategy to obtain valuable information and apply it to achieve an effective performance. Further, elite athletes may employ characteristic visual strategies. However, visual strategies used during dynamic movement has not yet been revealed. The purpose of this study was to clarify the visual strategies of elite athletes from eye movement patterns and cerebral activity recorded while attacking.
The participants were six female elite fencers, including an Olympian, and two male elite boxers. In Experiment 1, the participants in a standing state gazed at a fixation point 3 meters away from them (gaze condition) and then looked at the same point in an unfocused manner (fuzzy condition). In Experiment 2, the participants played competitively in the game style. Eye tracking, electroencephalography (EEG), electromyography (EMG), and a high-speed camera were used to record eye movement patterns, cerebral activity, muscle activity, and body motion during the tasks. Five successful attacks that won a point were analyzed in Experiment 2.
The peak frequency of the EEG power spectrum in cortical visual areas was lower during the fuzzy condition than the gaze condition in Experiment 1. In Experiment 2, beta power during attacks was equivalent to that during the fuzzy condition and lower than that in the gaze condition. The theta power during attacks was equivalent to that during the fuzzy condition and greater than that during the gaze condition. In the attack phase, the eye movement patterns of the

elite athletes showed that they directed their gaze to the specific points of the opponent. Although elite athletes aim their line of sight to important places for successful attacks, the results suggest that they look at the opponent with a peripheral field of view rather than gazing at a particular object or position.

Title: Active task engagement and congruent visuomotor feedback enhance experience-dependent network activity in mouse primary visual cortex

Authors: *J. M. PAKAN[1,2,3], E. DYLDA[4], J. U. HENSCHKE[1,2], S. P. CURRIE[4], N. L. ROCHEFORT[4,5]

Abstract: Constant adaptation to the environment is vital for survival throughout an animal's lifespan. Accordingly, various forms of adult experience-dependent plasticity have recently been demonstrated even in early sensory processing pathways. However, the extent to which neuronal activity is altered when an animal is actively learning to map sensory stimuli to behaviour compared to passively experiencing stimuli, remains controversial. In the primary visual cortex (V1), several recent studies have reported either a stimulus-specific response potentiation to a repetitively presented stimulus (without any associated reward or aversive stimuli), stimulus-specific decreases in the number of visually responsive neurons in both passive and active learning tasks, or conversely, an increase in the number of visually selective neurons to

behaviourally-relevant stimuli during active learning. Part of the inconsistency in these results may stem from the presence or absence of congruence between an animal's self-motion and optic-flow information. In this study, we performed two-photon calcium imaging of layer 2/3 neurons in awake-behaving head-fixed mice to assess population activity in V1 before, during and after both passive and active learning tasks. Mice were able to freely run on a circular treadmill and visuomotor feedback was either matched (motor output congruent with optic-flow information) by utilizing a virtual reality environment, or mismatched by passively presenting visual stimulation at a fixed temporal frequency regardless of the animal's speed. We found that active learning in a visuomotor matched task increased the proportion of neurons that were responsive to a repeatedly presented behaviourally relevant stimulus; conversely, this effect was not seen during passive viewing of a repeatedly presented stimulus. While the accuracy of a decoder to determine stimulus identity from V1 population activity for the visuomotor matched and mismatched conditions was equivalent, we found that overall neuronal activity as well as the average pairwise correlation between neurons was increased during the mismatched condition. Therefore, experience-dependent changes in V1 are facilitated by active task-engagement and visuomotor congruence to efficiently alter the representation of a behaviourally-relevant visual stimulus across learning. Altogether, these results support the view of a dynamic regulation of visual information processing in V1 based on the behavioural and ecological relevance of the sensory input.

Title: Measuring mouse vision using innate behavioral responses

Authors: *R. STORCHI
Univ. of Manchester, Manchester, United Kingdom

Abstract: Optogenetics and stem cell based treatments provide new opportunities for treating retinal dystrophies [1, 2]. An important step in evaluating treatment effectiveness is represented by behavioural assays of mouse vision. Many commonly used tests are based on sub-conscious, reflex responses [3, 4] whose activity is only indirectly related to perceptual vision. More relevant tests largely rely upon learned associations between visual stimuli and conditioned

stimuli [5] and are inherently throughput because they require long training periods and only allow association with single visual stimuli.
An alternative and more humane approach to assess vision relies on measurements of mouse spontaneous behaviour. These tests rely on the hypothesis that when mice detect a change in their visual environment they naturally change their behaviour. However they are currently low throughput as they rely on very simplified measures of behaviour such as average distance moved [1] or time required to move from a light to a dark area [6].
Here we show that combining a better experimental design with more sophisticated behavioural measures based on changepoint analyses [7] we can obtain reliable high throughput readouts of mouse vision. We designed an open field apparatus to capture mouse behaviour simultaneously with multiple cameras while stimulating the upper visual field and to perform reliable tracking of multiple body parts. We performed three series of experiments designed to capture a large repertoire of innate behavioural responses that allowed us to measure contrast sensitivity and visual acuity. In order to validate the method we repeated the same experiments in visual intact mice and in a mouse model of retinal degeneration (rd1). Results indicate that our method can capture the limit of mouse visual acuity in intact animals and also detect residual cone function in animals affected by severe retinal degeneration.

Title: Visuomotor reflexes differ across *Drosophila* species

Authors: I. D'ALESSANDRO, E. J. PARK, *S. M. WASSERMAN
Wellesley Col., Wellesley, MA

Abstract: To generate adaptive behavior, an organism must identify and assign subjective value to salient sensory information. However, what stimuli are deemed salient could change depending upon the local environment. Insects, such as fruit flies (*Drosophila*), for example, rely upon olfactory cues to locate food and oviposition sites. However, not all *Drosophila* species find the same sensory stimuli to be salient. Work done investigating host preferences of four geographically isolated populations of *Drosophila* mojavensis, cactophilic flies that feed and oviposit on necrotic cacti, has revealed olfactory driven behavioral preferences for host cacti specific to the local environment of each population. Similar to olfactory adaptations driven by the variation of host plants across different ecological environments, we wondered whether visual features specific to certain environments could drive divergent visuomotor responses. To examine this, we compared the visuomotor reflexes of D. melanogaster, a cosmopolitan generalist, found in visually dense environments, with D. mojavensis, a cactophilic specialist found in comparatively sparse visual landscapes. We used an electronic flight simulator in which flies are rigidly tethered to a pin and suspended in an LED arena and their steering direction and magnitude measured. Our results reveal the first evidence to suggest variability in visuomotor reflexes across *Drosophila* species.

Title: Learning from the past and predicting the future: The role of auditory and retrosplenial cortex input on coding in visual cortex during associative learning

Authors: *A. R. GARNER, G. B. KELLER
Friedrich Miescher Inst. for Biomed. Resear, Basel, Switzerland

Abstract: How does information from the past affect processing of information in the present in sensory cortex? Primary visual cortex (V1) receives afferent fibers from a number of classically non-visual regions including auditory cortex and retrosplenial cortex, a region known to be involved in associative and contextual learning. Using 2-photon calcium imaging in mice engaged in an auditory-visual classical conditioning paradigm in a virtual reality environment we investigated the functional input patterns in V1 of auditory and retrosplenial afferent axons. We then optogenetically stimulated axons from these regions in V1 to measure which V1 soma could be functionally influenced by the long-range fibers, and compared activity of influenced soma

with the rest of the population during learning. Our results revealed strong visual responses in afferent axons and these responses were modified with learning. Additionally, auditory-influenced and retrosplenial-influenced V1 populations changed activity patterns differentially with learning. Finally, V1 population activity specifically during the visual stimulus could be used to decode whether or not the visual stimulus had been preceded by an auditory stimulus. Our results suggest that long-range input is converted into local processing coordinates and allows coding of sensory stimuli as a function of their relationship to other stimuli and the context in which they are presented already at the level of primary sensory cortex. Moreover, our results suggest that auditory cortex input aids V1 in predictive coding of visual stimuli using auditory cues, while retrosplenial input specifically facilitates coding of stimuli with learned relevance.

Title: Visual psychophysical measurements in head-fixed mice with classical conditioning

Authors: O. ARROYO, Jr[1], *N. W. OESCH[2]
[2]Dept. of Psychology, [1]Univ. of California San Diego, La Jolla, CA

Abstract: One of the main goals of retinal neurophysiology is to understand how physiological mechanisms in the retinal contribute to visual processing and perception. Progress has been made by simply inferring how retinal mechanisms contribute to visual perception; however, the ability to directly measure visual behaviors is ideal in the identification of supporting mechanisms. Previously, this has been problematic as visual psychophysics in non-human species traditionally requires extensive training and noisy responding requires many trials to get good psychometric curves. In rodents, the current animal of choice for retinal neurophysiological studies, visual psychophysics has been particularly challenging. Here we developed a simple, classically conditioned visual detection task in head-fixed mice that can be trained in less than 3 days. Water deprived mice learn to associate water reward (US) with a visual stimulus (CS+), and developed an anticipatory licking response (CR) in response to the conditioned CS+. Anticipatory lick responses emerged within one hundred pairings. The anticipatory lick response followed psychometric visual detection curves comparable to prior mouse visual detection behavior tasks, hence providing a sensitive detection measure of the visual stimulus. Multiple aspects of anticipatory licking behavior, such as lick probability, lick rate, delay to lick, and lick rate acceleration are continuously modulated over a range of visual stimulus discriminability.

These multiple measures provide a robust examination of visual stimulus discriminability, and psychometric curves can be determined from a single session of less than 1.5 hours in duration. In addition, the CS+ is readily generalized to other similar stimuli, thereby allowing us to examine a variety of different visual stimuli without extensive retraining. Together, this technique represents a flexible behavioral tool to examine visual perceptual behavior in mice, with relatively little training and high signal to noise minimizing the number of trials needed. The head-fixed preparation allows for tight control of the stimulus inputs and can easily be combined with a variety of in vivo manipulations and ex vivo mechanistic assessments.

Title: Neural variability quenching increases with learning

Authors: *A. ARAZI[1,2], I. DINSTEIN[3,2,1]
[1]Dept. of Brain and Cognitive Sci., [2]Zlotowski Ctr. for Neurosci., [3]Dept. of Psychology, Ben Gurion Univ., Beer Sheva, Israel

Abstract: Background: Neural responses to an identical sensory stimulus vary across trials. This trial-by-trial variability is relatively large before stimulus presentation and significantly reduced (i.e. quenched) after stimulus presentation. Greater magnitudes of variability quenching were previously reported in trials where weak sensory stimulus was accurately detected, in trials with shorter reaction times, and in subjects with better perceptual thresholds. These studies suggest that reduced neural variability following stimulus presentation is associated with better perceptual performance. However, other studies have reported that individuals with larger overall moment-to-moment variability throughout the entire experiment exhibit faster learning of new motor skills and better cognitive performance. These studies have suggested that more variable neural networks can move flexibly and explore different states more effectively. Here, we examined the magnitude of neural variability as subjects learned to perform an orientation discrimination task with improved accuracy and speed. **Methods:** Twenty-seven subjects performed a forced-choice orientation discrimination task while their neural activity was recorded with EEG. In each trial, a circle with black and white stripes appeared on the screen and subjects were asked to report whether the stripes were oriented to the right or left. The angle of orientation changed across trials using a staircase procedure such that performance was set to

70% accuracy. Subjects completed 10 blocks of 120 trials and we quantified the mean angle, reaction time, and trial-by-trial EEG variability, for each of the blocks. **Results:** Subjects exhibited significant improvement in orientation angle and reaction time between the first and last block of the experiment demonstrating that they learned the task. The magnitude of neural variability quenching was significantly larger in the last block as was the magnitude of pre-stimulus variability. **Conclusions:** Subjects improved their performance throughout the experiment, exhibiting lower discrimination thresholds and shorter reaction times. This improvement was accompanied by an increase in pre-stimulus trial-by-trial variability and an increase in variability quenching, suggesting a possible link between perceptual learning and the magnitude of neural variability.

Title: All-optical stimulation and imaging in macaque V1 reveals neural and behavioral masking effects of optogenetic stimulation in a threshold detection task

Authors: *S. C.-Y. CHEN, G. BENVENUTI, M. P. WHITMIRE, Y. CHEN, W. S. GEISLER, E. SEIDEMANN
Univ. of Texas At Austin, Austin, TX

Abstract: To understand the neural basis of perception, we need tools for measuring and manipulating neural population responses in behaving animals. Optical-genetic methods provide a powerful tool for achieving this goal, but the use of these techniques in behaving macaques, an important animal model for studying human perception, has been limited. Here we used rAAVs to co-express a red-shifted opsin (C1V1) and a calcium indicator (GCaMP6f) in excitatory neurons in macaque V1. We then used widefield imaging to measure GCaMP6f response to visual stimuli and to C1V1 optogenetic stimulation. Robust response was recorded to 0.6 mW/mm^2 stimulation, a level much lower than previously reported. Even at this low light level, stimulation-evoked response could be larger than visually-evoked response to optimal stimuli. We hypothesized that the stimulation evoked-activity will interact in V1 in a sublinear way with visual responses, thereby reducing neural and behavioral sensitivity in visual detection tasks. To test this hypothesis, we applied optogenetic stimulation while a monkey detected a small Gaussian target (0.33° FWHM) at a retinotopic position corresponding to a co-expression site

(ecc. ~1.5°). The monkey indicated the presence of the target (50% of the trials) with a saccade to the target location. We compared the monkey's performance in separate blocks with stimulation (in all trials) and with no stimulation. Visual and optogenetic stimulation lasted up to 250 ms, and were terminated as soon as the monkey initiated a saccade. Our behavioral and neural measurements were consistent with our hypothesis. Across several experiments using light intensities between 0.6 to 2.2 mW/mm^2, we found that the monkey's detection threshold with stimulation was significantly higher than without stimulation; this masking effect increased with light intensity. Stimulation reduced hit rates but had no effect on false alarm rates, which were near zero. Similarly, we observed that the detectability of the target-evoked calcium response decreased in the presence of optogenetic stimulation. We repeated the experiment with the target placed about 1° away at a location corresponding to a V1 site expressing only GCaMP6f. At this site (~4 mm from the co-expression site), we recorded a small stimulation-evoked response but found no behavioral or neural effects on target detectability. Overall, our results reveal neural and behavioral effects of sublinear summation in V1, and represent a first step toward an all-optical platform for manipulating population activity in behaving macaques and studying the effect of these manipulations on visual processing and behavior.

Title: A framework to interpret population activity of neurons tuned to multiple signals: Visual speed and self-motion

Authors: *A. B. SALEEM[1], E. A. B. HORROCKS[1,2], I. MARESCHAL[2]
[1]Univ. Col. London, London, United Kingdom; [2]Biol. and Exptl. Psychology, Queen Mary Univ. of London, London, United Kingdom

Abstract: Neural populations commonly encode multiple signals. The implications of this encoding on a downstream area interpreting one of the signals remains unclear. Indeed, how do we interpret neurophysiological and psychophysical experiments where responses to a single signal are studied in isolation? To gain an insight into this, we developed a new modelling framework. We focused our analysis on visual coding, which is often studied under stationary

conditions, although animals spend large periods of time moving around in a naturalistic setting. In addition, an increasing number of studies find that visual cortical neurons are strongly influenced by self-motion signals (Busse et al., 2018). We therefore applied our framework to the paradigm of visual speed encoding during self-motion.
We generated populations of 50 Poisson-spiking model cells with tuning for both visual speed and self-motion speed. Based on previously reported data from mouse visual cortex, we modelled cells to respond to different weighted combinations of visual and self-motion speed (Saleem et al., 2013). We then trained separate spike count based Bayesian decoders on visual speed using population spiking generated under either a coupled condition, where visual speed and run speed observed a fixed linear relationship, or an uncoupled condition, where visual speed and run speed varied independently. We then tested their ability to discriminate visual speeds based on decoding spiking activity generated under a range of conditions.
Within our framework we find that visual speed discrimination is strongly affected by test condition. Specifically, we find that performance is reduced under stationary conditions, which is consistent with reports in human psychophysics (Durgin et al., 2007). Conversely, visual speed discrimination performance is stable for textures moving at different distances from the observer, which alters the relationship between run speed and visual speed or gain. Interestingly, we find that the population biased towards equal weightings of visual speed and run speed reported (Saleem et al., 2013) performs visual speed discrimination better in most cases compared to a population with a uniform distribution of weightings. This was true when tested under the conditions where run speed and visual speed are linearly coupled, but not when stationary. We also find that a decoder trained on the coupled condition performs better at all gains tested except when stationary.
We conclude that our model provides an accessible framework for interpreting population activity of neurons tuned to multiple signals, and generates predictions which can be tested experimentally.

Title: V1 layer 6 corticothalamic feedback encodes behavioral state by complementary activity of two neuronal populations

Authors: *S. AUGUSTINAITE, B. KUHN
Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan

Abstract: Layer 6 (L6), the deepest lamina of cerebral cortex, is one of the key structures regulating behavior state related information processing within cortex and various subcortical areas. However, very little is known about the functional significance of different L6 circuits in vivo. Here, we focus on primary visual cortex L6 feedback projections to visual thalamus (dorsal lateral geniculate nucleus, dLGN) which regulate visual signal transmission from retina to cortex. After injecting fluorescent microspheres into dLGN and AAV.CAG.flex.GCaMP6f into cortex, calcium imaging of retrogradely marked L6 corticothalamic (CT) neurons was performed in vivo with 2P microscopy in a head-fixed Ntsr1-cre mouse. The neuronal activity from the same neurons was recorded for several hours and / or repeatedly recorded during different days while presenting full-screen drifting gratings and monitor mouse activity state with electrocorticogram, pupil size and locomotion speed recordings. This allowed us to study the corticothalamic feedback during different behavior states, ranging from full alertness to sleep. We found that the strength of feedback to lateral geniculate nucleus depends on state: neuronal activity is stronger during more active / alert behavior. Moreover, feedback is composed of two complementary signals mediated by two different neuronal populations: visual stimulus (i) activated or (ii) suppressed CT neurons. Visual stimulus activated neurons respond to a particular orientation / direction stimulus while remaining quiet during other orientation / direction stimuli and the dark periods, that is, in the absence of visual stimulation. Visual stimuli suppressed neurons, on the contrary, are active during the dark periods, but get inhibited with visual stimulation. Encoding behavioral state by this complementary neuronal activity, corticothalamic feedback can regulate thalamocortical transmission in a state - related manner continuously, in the presence or absence of visual input. The functional role of the feedback, however, might be different. Visual signal processing might get facilitated by visual stimuli activated CT neurons, while visual stimulus suppressed CT neurons might prime dLGN neurons to a certain behavioral state - related activity level in the absence of visual stimuli.

Title: Pathological cortical regions in patients with refractory epilepsy display normal physiological responses during cognitive tasks

Authors: *S. LIU, J. PARVIZI
Neurol. and Neurolog. Sci., Stanford Univ., Palo Alto, CA

Abstract: High frequency oscillation (HFOs, 80 - 500 Hz) are known to be a reliable biomarker for the delineation of pathological epileptic foci in patients with refractory epilepsy. By contrast, high frequency broadband (HFB, 70 - 180 Hz) signal is a reliable biomarker for the local physiological responses in a given cortical site during cognitive and behavioral tasks. To date, however, it remains unclear whether epileptic cortical tissue, with abundant intrinsic HFO activity, is also capable of generating normal functional HFB responses during a cognitive task. A systematic comparison of temporal and spectral properties of epileptic HFO and functional HFB is also lacking. Here, we recruited three patients with anatomically similar electrode coverage in the lateral occipital and posterior ventral temporal cortex. Patients participated in the same visual cognitive task. We mapped the occurrence of HFOs during rest and during the experimental task and computed the stimulus-locked HFB responses during the experimental task. We discovered that, in all three subjects, the epileptic brain sites with abundant pathological HFOs were capable of generating physiological functional responses during the presentation of visual stimuli. In addition, we noticed a clear difference in the profile of pathological and cognitively-induced physiological high frequency signals. The average duration of high-band poweraugmentation for HFOs was 82 ms whereas that of HFB was significantly longer (501 ms, $P < 0.05$). The spectral width of spontaneous HFOs was 32 Hz, substantially smaller than that of task-driven HFBs (92 Hz, $P < 0.05$). A significant change in the slope of power spectral density was found only in HFO ($P < 0.05$) but not in HFB activities. Further, visually induced HFOs were temporally discordant with HFBs induced by the same tasks ($P < 0.001$). Our findings clearly demonstrate that brain structures involved with epileptogenicity may elicitnormal physiological responses to cognitive stimuli. The pathological HFOs and task induced HFBs that are originated from the same cortical tissue exhibit different temporal and spectral characteristics, and do not coincide in time. Since the use of intracranial EEG in human cognitive neuroscience has mainly been restricted to the clinical circumstances of patients with drug resistant epilepsy, investigating the connection and distinctions between HFB and HFO has its practical implications, and should shed light on the cognitive reserve function of epileptic neuronal populations.

Title: The functional role of human early visual areas during blinks and saccades as revealed by intracranial EEG

Authors: *M. J. KERN
Epilepsy Ctr., Univ. Med. Ctr. Freiburg, Freiburg, Germany

Abstract: Introduction: In natural viewing conditions, eye movements like blinks and saccades are ubiquitous, they take place roughly three times per second in natural viewing conditions, even so they are hardly consciously perceived. However, little is known about how the early visual areas of the human cerebral cortex operate during such natural performed events and how information processing in these areas is reflected in neural population activity. Hence, the aim of this study was to characterize the brain activity pattern in early visual areas during blinks and saccades.
Methods: In the present study we used intracranial EEG from implanted electrodes covering early visual areas in human cerebral cortex of four patients to investigate blink- and saccade-related brain activity during natural, non-experimental viewing conditions. In this way, a large number of eye movements (~3000 per patient) could be used without additional burden on the patients. Intracranial EEG is an optimal candidate for this kind of study since it offers a temporal resolution in millisecond-time scale and is less susceptible to ocular artifacts compared to standard EEG (Ball et al., 2009). The spectral composition of the recorded ECoG signals was calculated using a complex Morlet wavelet.
Results: We clearly show that both blinks and saccades were accompanied by a biphasic broadband gamma decrease-increase pattern in all studied visual areas (V1, V2, V3d, V3v, V4d, V4v and Fusiform Gyrus). In contrast to blinks, saccades additionally elicited a late, narrower-banded gamma increase starting after eye movement offset. Astonishingly, a significant decrease in gamma power was observed even before eye movement onset, especially notable during saccades in V1.
Conclusions: Since the timing of the gamma suppression is in line with psychological studies and in case of saccades starts even before eye movement onset, we think that this strongly indicates active top-down mechanisms from higher brain areas. The subsequent gamma power increase that starts around eye movement offset may reflect an amplified re-uptake of visual information, supporting uninterrupted visual perception. Finally, the late gamma power increase after saccades may reflect the greater amount of visual information that has to be processed compared to blinks.

Title: Predicting perceptual decisions using visual cortical population responses and choice history

Authors: *A. I. JASPER[1], S. TANABE[1], A. KOHN[1,2,3]
[1]Dominick Purpura Dept. of Neurosci., [2]Ophthalmology and Visual Sci. Dept., [3]Systems and Computat. Biol. Dept., Albert Einstein Col. of Med., Bronx, NY

Abstract: Our understanding of the neural basis of perceptual decision making has relied largely on relating fluctuations in single neuron responses to perceptual decisions, on a trial-by-trial basis. We sought to extend our understanding of perceptual decision making in two ways. First, we asked how our ability to predict animals' decisions would be improved by considering small simultaneously-recorded neuronal populations rather than individual units. Second, we asked how predictions would be improved by taking into account the animals' choice and reward histories. It is well known that perceptual decisions can be strongly affected by these factors, but their influence is seldom considered when relating neuronal responses to decisions.
We trained two macaque monkeys to perform a fine orientation discrimination task while we recorded from small neuronal populations in early (V1) and midlevel (V4) visual areas using multi-electrode arrays. Responses of individual V4 neurons were weakly predictive of decisions, but only in the post-stimulus fixation period and only in one animal; in V1, only a few neurons showed significant decision-related activity. To relate population activity to decisions, we trained a linear classifier. The classifier predicted choice slightly better than the best single unit in the recorded population and revealed limited, but more robust choice-related information. Including choice- and reward-history information in the model had a modest influence on performance, except when the recorded populations contained little decision-related information. We conclude that fluctuations in small neuronal population responses in early and mid-level visual cortex are only weakly related to perceptual decisions, even when choice and reward histories are taken into account.

Title: Suppression & sparsification of visual responses during perceptual learning

Authors: *P. THAMIZHARASU, C. V. TOGT, E. RUIMSCHOTEL, I. F. PICA, L. D. KRAKER, C. LEVELT
Netherlands Inst. For Neurosci., Amsterdam, Netherlands

Abstract: In order to understand how neurons in primary visual cortex change their activity patterns during perceptual learning, we developed a two-alternative forced choice behavior paradigm for head-fixed mice allowing us to chronically monitor calcium responses of the same neurons in visual cortex by two-photon microscopy. During the task, the mice learn to discriminate between different visual stimuli and respond by licking a left or right lick spout in order to receive reward. Once the mice learn the task, the visual stimuli are partially changed forcing the mice to relearn the task. We observe that neurons in V1 start to anticipate the visual stimulus and reward with training. Improvements in behavioral performance were closely associated with reduced number of visually responsive neurons. In fact, V1 becomes suppressed upon visual stimulation after training. These effects are partially reversed with relearning. Our findings suggest that scarification improves coding efficiency in V1 but interferes with learning new associations.

Title: Two complementary population coding schemes in primate V1 contribute to scale-invariant pattern discrimination

Authors: *G. BENVENUTI[1], Y. CHEN[2], W. S. GEISLER[2], E. SEIDEMANN[2]
[1]Ctr. For Perceptual Systems, The Univ. of Texas At Austin, Austin, TX; [2]The Univ. of Texas at Austin, Austin, TX

Abstract: Humans can discriminate fine differences in orientation of visual patterns over a wide range of spatial scales. How does our brain carry out such a challenging, scale-invariant computation? Neurons in primary visual cortex (V1) are selective to the orientation of visual stimuli within their receptive fields (RFs) and are organized in cortical columns, based on their orientation preferences. Therefore, the brain might be expected to carry out orientation discrimination by comparing the orientation-specific columnar response patterns in V1. However, at every visual field location, V1 neurons have a limited range of RF sizes. As a consequence, the quality of the discrimination information at the columnar level and at the level of single-cells will decrease rapidly once the scale of the oriented stimuli on the retina exceeds this range of RF sizes. Thus, a simple decoder of the orientation column or single-cell responses cannot easily explain why behavioral discrimination thresholds are relatively constant across spatial scale. To investigate this puzzle, we used voltage-sensitive dyes to image V1 responses over an area of 8x8 mm^2 while two monkeys carried out a fine orientation discrimination task with oriented Gabor stimuli. We found that, like humans, monkeys' orientation discrimination performance is relatively scale-invariant. We then determined the orientation discrimination performance of the columnar responses for a wide range of spatial frequencies (SFs). As expected, we found that the orientation discrimination performance of the columnar responses is relatively constant for medium and high stimulus SFs, but drops substantially for low SFs, unlike behavioral performance. However, we also found a surprising coarse-scale signal that corresponds to the projection of the luminance layout of low SF stimuli to V1's retinotopic map. This homeomorphic and distributed representation, which carries high quality orientation information through variations in the level of population activity across the retinotopic map, can explain the behavioral performance at low spatial frequencies. We conclude that two separate decoders, one operating at the fine orientation column scale for medium and high SFs, and one operating at a larger retinotopic scale for low SFs, are likely to contribute to ours and monkeys' striking scale invariant pattern discrimination capabilities.

Title: Visual responses are more robust during navigation than passive viewing

Authors: *E. M. DIAMANTI, K. D. HARRIS, A. B. SALEEM, M. CARANDINI
Univ. Col. London, London, United Kingdom

Abstract: Neurons in visual cortex are involved in the processing of visual inputs, but during behavior their responses are also modulated by task-related factors. Yet, little is known on whether sensory processing remains the same across conditions of increased behavioral complexity, from passive viewing of simple visual stimuli to navigation in visually rich environments. Are visual responses during passive viewing as strong as during navigation ? Do the same cells respond across all conditions?
We used 2-photon calcium imaging to record neural activity across primary visual cortex and 6 higher visual areas. Head-restrained mice either passively viewed drifting gratings or ran along a corridor in virtual reality (VR). The VR corridor contained two landmarks (a vertical grating or a plaid) repeated after 40 cm. We ran the VR sessions in two modes: closed-loop, where the speed of the virtual corridor matched the animal's run speed; open-loop, where previous closed-loop visual scenes were played back to the animal regardless of its running speed.
In closed-loop mode, neurons responded strongly to the landmarks in the corridor. Based on a measure of variance explained, these responses were highly reliable for most cells. In open-loop, however, there were fewer responsive cells, and the reliability of their responses was markedly reduced. The reduced responsiveness observed in open-loop could not be explained by differences in running behavior. In addition, cells did not simply become silent in open-loop mode: many cells maintained their selectivity to the visual landmarks, but the variance explained by their response profile was lower than in closed-loop. Responses in VR were not well predicted by responses to grating stimuli: for example, an independent population of neurons responded to vertical drifting gratings when mice viewed stimuli passively, than when the same gratings appeared as landmarks in VR.
We conclude that visual processing during active navigation is more reliable than during passive viewing, and involves a neuronal population that is not driven by passive grating stimuli. These

findings suggest that the difference in sensory responses between active behavior and passive viewing is beyond a mere modulation by task-related factors.

Title: Effects of single-cell stimulation in macaque V1 on performance in a threshold detection task

Authors: *N. J. PRIEBE[1], B. LI[2], E. SEIDEMANN[2]
[1]Univ. Texas, Austin, Austin, TX; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Cortical microstimulation has played a critical role in establishing causal links between sensory processing, network activity and perceptually guided behavior. Such microstimulation alters the activity of large populations of neurons, however, and it remains unclear how single sensory neurons contribute to behavior. Even if perception is based on a large population of neurons in sensory cortex, the response of single cells can be amplified by the highly interconnected local cortical network, particularly when the sensory input is weak or ambiguous, thereby affecting behavior. To assay the impact of activity in single neurons on network activity and perceptual judgments, we stimulated single neurons in V1 of three macaque monkeys while they performed a threshold detection task. Single cell stimulation was performed using patch electrodes either in the whole cell (n=15) or loose patch (n=14) configuration. We hypothesized that placing the animal in a threshold detection task would increase the impact of the activity of single V1 neurons. The animal was required to report whether a small, low contrast and briefly presented Gabor target appeared at one of two possible locations by making a saccade toward the target location. In half of the trials (randomly selected) with target at zero and low contrast levels (~3%), depolarizing current that coincided with the timing of the visual target (0.1-0.2 nA for whole cell, and 1-3 nA for loose patch, respectively) was injected to evoke action potentials (between 21-240 spikes/s). If single-cell stimulation has a large effect on the animal's perception, we would expect to observe a bias in the animal's choice toward the location of the cell's receptive field or a change in the reaction time. Single-cell stimulation, however, did not induce a discernible shift in the animal's psychometric function or change the latency of saccades toward either of the target locations even when the contrast of the target was

0% and even when the cell was highly sensitive to the target. Our results suggest that the impact of the activity of single cells on network activity in macaque cortex is relatively small, that the role of single V1 neurons in perceptual tasks is limited, and that perceptual judgements are based on the concerted action of large population of neurons.

Title: Behavioral state and experience modify natural behavioral responses to visual stimuli in mice

Authors: *R. IJEKAH, J. HOY
The Univ. of Nevada, Reno, Reno, NV

Abstract: The ability to use vision to rapidly identify and respond to suddenly appearing biologically relevant stimuli is vital to survival and highly conserved across species. Recent studies of ethological visual behaviors such as predator avoidance and prey capture in mice have helped in understanding the neural basis of this type of visual processing in mammals. Here, we follow up on our original studies of visually-guided prey capture in the mouse to show that mice respond in an ethologically appropriate way towards simple virtual stimuli with prey-like features. In particular, C57BL/6J mice approach, orient without approach, or freeze in response to virtual stimuli presented in the lower to middle visual fields depending on the size and speed of the stimuli. Intriguingly, the sizes and speeds of virtual stimuli that reliably evoke each of these behaviors vary as a function of prey capture experience and hunger state. We show for the first time in the mouse, how specific internal states and experiences systematically modulate natural, visually-guided behavioral responses to simple stimuli. These observations suggest the animal's state influences both the salience and valence of visual stimuli presented in this context. Accordingly, we hypothesize that the cells and circuits which encode the behaviorally relevant stimulus features will also exhibit such state-dependent modulation. Our current and planned work investigates this possibility and should rapidly shed light on mechanisms underlying experience-dependent changes in selecting behavioral choices.

Title: Human detection of occluding targets is near optimal for natural scenes

Authors: R. C. WALSHE[1], *W. S. GEISLER[2]
[1]Ctr. for Perceptual Systems, The Univ. of Texas at Austin, Austin, TX; [2]Univ. Texas Austin, Austin, TX

Abstract: A fundamental visual task is separating relevant signals from background clutter. The natural-signals hypothesis suggests that perceptual systems exploit regularities in the statistical structure of natural scenes to solve this problem. Here, we study a novel class of target stimuli that fully occlude the background directly underneath the target. Despite the high prevalence of occlusion in nature nearly all studies on detection in humans and primates focus on additive targets. We provide psychophysical measurements for occluding target detection for a large range of background conditions and retinal eccentricities. We also describe a principled model for detection of occluding targets in naturalistic stimuli.
The psychophysical results were summarized by measuring eccentricity thresholds (retinal eccentricity for 70% correct detection) for four different occluding targets presented in natural backgrounds at different distances from the fovea. The luminance and contrast of the targets was fixed, and precise experimental control of the statistics (luminance, contrast and pattern similarity) of the natural backgrounds was obtained using a recently developed method known as constrained scene sampling. For luminance we found that performance was worst when the luminance of the background was close to the mean luminance of the target; whereas, performance declined with increasing background contrast and similarity.
To model the results we developed an ideal observer in which detection was limited by the approximate sampling density of ganglion cells in the human retina. To measure the scene statistics used by the model we first filter natural scene patches with and without the target by the optics of the human eye. We then simulate the output of the retinal ganglion cells by blurring and downsampling the image to match their sampling density at a given eccentricity. Next we decompose the information relevant for target detection into a luminance, boundary, and pattern components. The variances and covariances of the components are measured for a large set of backgrounds and retinal eccentricities. Finally, performance of the optimal classifier is measured in the set of background and eccentricity conditions for which we have measured human psychophysical responses. After applying a single scale parameter (efficiency), the model

thresholds were in close accordance with human thresholds. We conclude that much of the variation in performance for detecting occluding targets across the visual field arises from the stimulus uncertainty induced by the statistical structure of natural scenes and the limitations of retinal sampling.

Title: Hemodynamic response function (HRF) used to predict brain imaging responses from spiking switches sign and functional form between task-engaged and drowsy states

Authors: *A. DAS[1], M. M. B. CARDOSO[3], B. R. LIMA[4], Y. B. SIROTIN[2]
[1]Neurosci, [2]Neurosci., Columbia Univ., New York, NY; [3]Neurosci., New York Univ., New York, NY; [4]Inst. de Biofisica, Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: When interpreting hemodynamics-based brain imaging such as fMRI, the HRF is key to making predictions from modeled inputs and thereby relating the measured hemodynamics to the inputs. The HRF is taken as a proxy for neurovascular coupling to local neural activity. It is typically assumed to remain locally consistent although the coupling can change strength between drowsy and alert states (Schölvinck et al. 2010). Here we tested if the HRF remained consistent when switching between alert engagement in a task and states of drowsiness with eyes closed.
We recorded intrinsic-signal optical images (specifically, blood volume) with concurrent multi-unit spiking (MUA) from macaque primary visual cortex (V1). The animals performed a predictable, periodic fixation task for juice reward. This task elicits a powerful task-related hemodynamic response, entraining to task timing independent of visual stimulation (Sirotin and Das, 2009). Recording sessions extended over multiple hours in total darkness other than the

small (~2 arc min) fixation cue. Recordings thus included segments when the animal was actively engaged in the task, interspersed with segments when he shut his eye and appeared to drift asleep.
While the animal was alert and engaged in his task, the measured hemodynamics was dominated by the task-related response; the MUA showed weak task-linked fluctuations. During drowsy segments the hemodynamics showed large phasic fluctuations in local blood volume while the MUA showed large, multi-second bursts of activity. We used multilinear regression ('deconvolution': Dale 1999) to estimate the HRF over a moving window (typically 150 sec) traversing the entire session including alert and drowsy segments. The 'drowsy' HRF resembled a standard causal HRF kernel predicting an increase in local blood volume following the spiking, with typical times to peak and peak width. The 'alert' HRF was distinctly different, with an acausal temporal profile reflecting the periodic task timing, and a reversed sign predicting local decrease of blood volume following spiking. Cross validation between the two epochs was poor: the mean of the 'drowsy' HRF kernels gave consistently good predictions (quantified by Pearson's r) over the drowsy segments, but gave incorrect phase-reversed predictions in the alert segments. Neurovascular control thus likely involves very different neural mechanisms in drowsy vs. alert engaged states. These results should have considerable bearing on our understanding of the HRF, and the interpretation of fMRI in terms of local neural activation.

Abstract: A characteristic feature of neurons in primary visual cortex (V1) is their strong response to visual stimuli of a particular orientation (orientation selectivity). During natural

behavior animals move their eyes, but it remains unclear how these eye movements affects basic properties of the receptive fields. Most studies of visual response properties are performed in head-restrained or anesthetized animals, and it has been shown that the eye movements of freely moving rats are more complex and fundamentally different with regularly disconjugate and often asymmetrical movements. By experiments alone, it is problematic to determine the specific influence of eye movements on the receptive fields of simple cells in V1, because the activity is confounded by a lot of non-visual input. Thus, in order to determine how eye-movements (including torsional rotations of the pupil) affect the orientation tuning of typical V1 receptive fields, we used a computational model. In particular, we use experimentally measured eye movements in freely exploring rats (Wallace et al. 2013) to construct a drifting grating stimulus embedding the eye movements. This stimulus is then convolved with a Gabor-like receptive field consisting of two elongated ON and OFF subfields, and passed through a nonlinear function to estimate the firing rate of the neurons. This simple model for receptive fields of V1 simple cells predicts high degree of orientation tuning in spite of eye movements. This prediction is in accordance to recordings from the V1 of behaving rats where most units show impaired orientation tuning during movement while a small subset of units in layer VI retain a remarkable stable orientation tuning. However, a shift in preferred orientation was observed for movements involving torsional rotations of the pupil. This suggests that an explanation of the experimentally observed reduction in orientation tuning during movement, requires model mechanisms beyond linear receptive fields combined with a static nonlinearity.

Title: Stable orientation tuning in the freely moving rat: Movement-robust orientation selective neurons in the deep layers of the primary visual cortex

Authors: *M. B. RØE[1], I. E. AASEBØ[1], M. HOBBI MOBARHAN[1], K. K. LENSJØ[1], G. T. EINEVOLL[3], T. HAFTING-FYHN[2], M. FYHN[1]

Abstract: A hallmark of neurons in the primary visual cortex (V1) is their orientation selectivity. However, it remains elusive how orientation tuning is affected during natural movement as recordings have mostly been from restrained animals. In the present study, we implanted tetrodes in the deep layers of V1 and conducted extracellular recordings of single units in awake rats. The animals moved freely in an enclosure surrounded by monitors presenting visual stimuli. In accordance with previous findings, most orientation-tuned units showed a reduced or disrupted orientation selectivity during movement compared to sessile behavior. However, a subpopulation of units sustained a remarkably stable orientation selectivity also during movement. These movement-robust orientation selective (MROS) units were predominantly located in layer 6 (L6), and maintained their preferred orientation across multiple recording sessions in freely moving and sessile states. To examine the effect of head-rotation on orientation tuning, the awake animal was placed on a remotely controlled tilting platform, creating a misalignment between stimulus and head-angle. As predicted, the sharp tuning of the MROS to its preferred orientation remained stable during continuous change of the platform angle. Interestingly, a shift in preferred orientation was observed when the platform, and thus the animals head, was fixed at a specific angle over time. The stability of the MROS units may be partly due to lower inhibitory surround in receptive fields of deep layer neurons. Moreover, the MROS units likely receive inputs from vestibular or oculomotor systems, for instance via the recently reported pathway from retroplenial cortex to V1 that convey vestibular-mediated head-motion information onto V1L6 neurons. Taken together, the functional properties of these units suggests that specialized receptive field properties and compensatory mechanisms such as counter eye-rolling or vestibular input maintain stable orientation tuning during passive and natural behavior.

Title: Luminance enhances ON/OFF asymmetries in primary visual cortex by increasing the excitation/suppression ratio of the stimulus response

Authors: *R. MAZADE, J. JIN, C. PONS, J. ALONSO
Biol. and Vision Sci., State Univ. of New York Col. of Optometry, New York, NY

Abstract: ON and OFF thalamic afferents segregate in primary visual cortex making cortical neurons ON-dominated or OFF-dominated. It is currently unknown if the responses of ON- and OFF-dominated neurons are differently affected by luminance range, which can vary by more than two orders of magnitude in natural scenes. Here, we demonstrate that luminance strengthens both the excitatory response evoked by preferred stimuli and the response suppression evoked by preferred and non-preferred stimuli in both types of neurons. However, because the excitatory response is strengthened more, visual responses become stronger, faster, and more transient, and OFF-dominated neurons become faster and more sustained than ON-dominated neurons. We performed horizontal penetrations through cat primary visual cortex with multielectrode arrays and mapped cortical receptive fields with static grating stimuli, while varying the maximum luminance with neutral density filters (0.024 to 239 cd/m^2). Receptive-field polarity was measured as the (ON-OFF)/(ON+OFF) maximum responses (-1: OFF-dominated, +1: ON-dominated) and the response temporal profile as the average temporal response to the ten preferred grating stimuli. Cortical receptive fields showed a pronounced bi-modal distribution for contrast polarity with a dip centered at zero ($p<0.001$, Hartigan test), allowing us to split them into two groups. Our results demonstrate that the excitatory responses of ON- and OFF-dominated neurons to preferred stimuli increase with each luminance log-unit by ~8.5 spk/s (ON: $R^2=0.81$, $p<0.001$; OFF: $R^2=0.84$, $p<0.001$). In contrast, the response suppression increases only by ~1.3 spk/s for preferred stimuli (ON: $R^2=0.69$, $p=0.003$; OFF: $R^2=0.79$, $p=0.001$) and ~3.0 spk/s for non-preferred opposite-phase stimuli (ON: $R^2=0.88$, $p<0.001$; OFF: $R^2=0.91$, $p<0.001$). The increase in the response strength reduced the response latency per luminance log-unit by ~7.0 ms for OFF- ($R^2=0.97$, $p<0.001$) and ~6.0 ms for ON-dominated neurons ($R^2=0.98$, $p<0.001$). In addition, the increased excitation/suppression ratio reduced the response duration per luminance log-unit by ~9.0 ms in ON- ($R^2=0.96$, $p<0.001$) and ~7.5 ms in OFF-dominated neurons ($R^2=0.93$, $p<0.001$). As a result, OFF-dominated responses became faster (OFF vs ON latency at 239 cd/m^2: 49.5 ± 0.52 vs 54.0 ± 0.58 ms, $p<0.001$, Wilcoxon test) and more sustained (OFF vs ON width at 239 cd/m^2: 25.4 ± 0.59 vs 22.5 ± 0.76 ms, $p<0.001$, Wilcoxon test) than ON-dominated neurons. We conclude that luminance speeds up stimulus detection and enhances the temporal differences between darks and lights by increasing the excitation/suppression ratio of cortical responses.

Title: High-accuracy decoding of complex visual scenes from neuronal calcium responses

Authors: *R. J. ELLIS[1], M. MICHAELIDES[2]
[1]Friedman Brain Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Biobehavioral Imaging & Mol. Neuropsychopharm., NIDA IRP, Baltimore, MD

Abstract: The brain contains billions of neurons defined by diverse cytoarchitectural, anatomical, genetic, and functional properties. Sensory encoding and decoding are popular research areas in the fields of neuroscience, neuroprosthetics and artificial intelligence but the contribution of neuronal diversity to these processes is not well understood. Deciphering this contribution necessitates development of sophisticated neurotechnologies that can monitor brain physiology and behavior via simultaneous assessment of individual genetically-defined neurons during the presentation of discrete sensory cues and behavioral contexts. Neural networks are a powerful technique for formulating hierarchical representations of data using layers of nonlinear transformations. Here we leverage the availability of an unprecedented collection of neuronal activity data, derived from ~25,000 individual genetically-defined neurons of the parcellated mouse visual cortex during the presentation of 118 unique and complex naturalistic scenes, to demonstrate that neural networks can be used to decode discrete visual scenes from neuronal calcium responses with high (~96%) accuracy. Our findings highlight the novel use of neural networks for sensory decoding using neuronal calcium imaging data and reveal a neuroanatomical map of visual decoding strength traversing brain regions, cortical layers, neuron types, and time. Our findings also demonstrate the utility of feature selection in assigning contributions of neuronal diversity to visual decoding accuracy and the low requirement of network architecture complexity for high accuracy decoding in this experimental context.

Title: Interrelated gradients of orientation, spatial frequency, and ON/OFF selectivity in primary visual cortex

Authors: *E. KOCH, J. JIN, Q. ZAIDI, J. ALONSO
Biol. and Visual Sci., SUNY Optometry, New York, NY

Abstract: The cat primary visual cortex has a map for different stimulus features whose topographic relations remain poorly understood. Here we demonstrate a systematic relationship among spatial frequency resolution, orientation selectivity and ON/OFF response balance in the cortical map. We then show, with computational modeling, that these relations originate from the cortical clustering of ON and OFF thalamic afferents. We performed tangential penetrations in cat visual cortex with linear multielectrode arrays (32 recording sites separated by 0.1 mm). We frequently found systematic gradual changes in spatial resolution (spatial frequency cutoff) with cortical distance. Spatial resolution was strongly correlated with cortical map location ($r=0.464$, $p<0.0001$, $n=239$ units, 7 penetrations, 4 animals) being high in iso-orientation domains and low in pinwheel centers. Because iso-orientation domains tend to cross the border between ocular dominance columns, the binocular border often had high spatial resolution. Because iso-orientation domains also tend to cross the border between ON and OFF domains, monocular iso-orientation domains at the ON/OFF border also had high spatial resolution. Importantly, spatial resolution was low for pinwheels near the binocular regions indicating that it is more closely associated with high orientation selectivity than binocularity. Finally, the ON/OFF response balance of the receptive field was correlated with orientation selectivity ($r =0.391$, $p < 0.0001$, $n = 153$ units, 12 animals), being more balanced in cortical regions with narrowly tuned neurons than broadly tuned neurons. A simple computational model demonstrates that a cortical gradient for ON/OFF response balance can reproduce the relationships between orientation and spatial frequency measured experimentally. In the model, thalamic afferents project within a cortical sheet of 1x2 mm that has two ocular dominance columns, two OFF and two ON domains. The afferents compete to find the cortical region with the best-matched retinotopy, ocular dominance and ON/OFF polarity (axon separation: 50 microns, arbor spread: 0.5 - 1 mm). We show that the resulting clustering of ON and OFF afferents produces ON and OFF domains with low orientation selectivity and low spatial resolution at the center of ocular dominance columns. It also produces ON/OFF balanced cortical domains at the binocular border and ON/OFF border. We conclude that the structure of cortical orientation and spatial frequency selectivity gradients emerges from the segregation of thalamic afferents by eye input and ON/OFF polarity in primary visual cortex.

Title: Human amblyopia increases perceptual dark dominance

Authors: *C. PONS, R. MAZADE, J. JIN, M. DUL, Q. ZAIDI, J.-M. ALONSO
Biol. Sci., State Univ. of New York, New York, NY

Abstract: Visual information reaches the cerebral cortex through four parallel pathways that originate in ON and OFF retinal ganglion cells from the contralateral and ipsilateral eyes. During brain development, depriving one eye of visual input weakens its impact on visual cortex (Wiesel and Hubel, 1963), a process that is thought to equally affect ON and OFF pathways. Our results indicate that this assumption needs to be reconsidered. We have previously shown that optical blur reduces the visual salience of lights more than darks (Pons et al., 2017) and, therefore, it should reduce ON cortical responses more than OFF (Komban et al., 2014). Based on these results, we hypothesized that sustained optical blur during brain development should weaken ON cortical pathways more than OFF, thus permanently increasing perceptual dark dominance in visual salience. To test this hypothesis, we recruited 18 human subjects diagnosed with amblyopia in one eye and normal visual acuity in the fellow eye. Visual acuity was measured with a Snellen chart and was 20/25 or better for the fellow eye and up to 20/400 for the amblyopic eye. Subjects were asked to count as fast as possible the number of light or dark targets (1, 2 or 3) embedded in binary noise and perform this task monocularly using the refraction that provided the highest visual acuity for each eye. Consistent with our hypothesis, amblyopia affected the visual salience of light targets more than dark. On average, the dark-light difference in performance was ~3 times larger for the amblyopic eye than the fellow eye (dark-light difference in percent correct: 11.46 ± 1.15% for amblyopic eye; 3.87 ± 0.50% for fellow eye, $p < 0.001$, two-sided Wilcoxon tests, n=18 subjects). The average light-dark difference in reaction time was also ~1.3 times larger for the amblyopic eye (reaction time: 1.61 ± 0.10 sec for amblyopic eye; 1.25 ± 0.07 sec for fellow eye, $p < 0.001$; two-sided Wilcoxon tests, n=18 subjects). The dark dominance in visual salience not only increased with amblyopia but was strongly correlated with the reduction in visual acuity ($R^2=0.75$, $p < 0.001$). Unlike for visual salience, however, the average dark-light difference in grating orientation discrimination at high spatial frequency was not significantly higher for the amblyopic eye (14.26 ± 3.93% for amblyopic eye, 9.13 ± 4.24% for fellow eye, p=0.36, two-sided Wilcoxon test, n=7 subjects). These results can all be explained by a computational model that uses greater luminance/response saturation for ON than OFF pathways. We conclude that the ON cortical pathway is more vulnerable to amblyopia than the OFF pathway, a finding that could have implications for future amblyopia treatments.

Title: Sub-millimeter resolution fmri reveals interdigitated body- and disparity-selective columns within macaque parietal cortex

Authors: *X. LI[1], Q. ZHU[1], W. VANDUFFEL[2,3,1]
[1]Res. Group Neurophysiology, KU Leuven, Leuven, Belgium; [2]Radiology, Harvard Med. Sch., Charlestown, MA; [3]A. A. Martinos Ctr. for Biomed. Imaging, MGH, Charlestown, MA

Abstract: The primate parietal lobe contains a heterogenous population of neurons and the first electrophysiology studies already suggested that different types of neurons may be grouped into distinct interdigitating functional modules (Mountcastle et al. 1975). However, unlike early visual cortex, the columnar organization of parietal cortex is surprisingly under-investigated. Here, we studied the mesoscopic functional organization of parietal cortex in awake rhesus monkeys using high resolution fMRI: ~0.6mm isotropic voxels with implanted phased-array coils at 3T (Janssens et al. 2012; Li et al. 2017). In a passive-viewing expt. 1, binocular disparity-defined radial sine-wave gratings and their size-matched monocular counterparts were presented to activate disparity-biased neurons. Two other experiments were conducted to identify body- and face-selective cortical clusters at the same resolution. In expt. 2, achromatic images from 10 different categories, as in Popivanov et al. (2012), were presented. Only common activations across the 3 contrasts (achromatic monkey bodies vs. size-matched fruits, objects and faces, respectively) and scan sessions were labeled as body-selective. Face patches were defined in the same way, but using fruits, objects and bodies as controls. In expt. 3, a completely different set of colorful face, body and object stimuli with different shapes and sizes (diameter ~ 24° of visual angle, matching that of the disparity stimuli, instead of < 15° of visual angle in expt. 2) were used. We tested the reproducibility of the category-selective activations across different stimulus sets of expt. 2 and 3. Our results show highly reproducible alternating patterns of disparity- and body-selective activations within cytoarchitectonically defined LIP (Lewis and Van Essen 2000) across different sessions and subjects (and different stimulus sets for body patches). Intriguingly, the body- and disparity-selective activations interdigitated, with multiple body patches located between disparity-selective activations. The results suggest a columnar organization of LIP

neurons for processing bodies (body parts) and disparity. Future studies are required to examine whether other columnar structures exist in the parietal lobe, besides the body and disparity columns.

Title: Expanding the luminance range increases ON/OFF response asymmetries in visual cortex

Authors: *H. RAHIMI NASRABADI, J. JIN, R. MAZADE, C. PONS, Q. ZAIDI, J. ALONSO
Biol. and Vision Sci., SUNY Optometry, New York, NY

Abstract: The visual cortex has two parallel pathways that signal local luminance increments (ON) and decrements (OFF) in visual scenes. ON cortical responses to light increments show a more pronounced saturation with luminance contrast than do OFF cortical responses to light decrements. This greater ON luminance response saturation is important because it reduces the spatial resolution of light targets, an effect that is thought to decrease on mid-gray backgrounds (Kremkow et al., 2014, Pons et al., 2017). The effect of mid-gray backgrounds was previously measured with standard monitors of ~200 cd/m^2 maximum luminance and could be due to an increase in background luminance, a reduction in luminance range or a combination of both. To distinguish among these possibilities, we measured ON and OFF luminance response functions using an LCD monitor of ~1,000 cd/m^2 maximum luminance (TRU-Vu, SRMH-15-AR series), which allowed us to use three luminance ranges (300, 600 and 1000 cd/m^2) and multiple combinations of background and target luminance for each range. ON and OFF luminance response functions were fit with Naka-Rushton functions to estimate the luminance that generated the half-maximum response (L_{50}) and the exponent of the function. Our results demonstrate that the L_{50} is consistently lower for ON than OFF responses across different luminance ranges and backgrounds (normalized ON and OFF L_{50} for 300, 600 and 1000 cd/m^2 luminance range averaged across backgrounds: 0.29/0.41, 0.28/0.41, 0.22/0.46; normalized ON and OFF L_{50} for 100, 400 and 600 cd/m^2 backgrounds at 300 cd/m^2 range: 0.28/0.41, 0.27/0.40, 0.31/0.43, $p<0.0001$, Wilcoxon tests). The difference between ON and OFF L_{50} increased by 92% when the luminance range was expanded from 300 to 1000 cd/m^2 (0.13 vs. 0.25, $p<0.0001$, Wilcoxon test), but remained roughly constant when the luminance range did not change (300 cd/m^2) and only the background luminance increased (0.13, 0.13, 0.12 for 100, 400 and 600

cd/m^2 background luminance, p>0.1, Wilcoxon tests). Expanding the luminance range from 300 to 1000 cd/m^2 also increased the maximum ON and OFF responses by ~4 spk/sec per 100 cd/m^2 and reduced the exponent by ~0.15 per 100 cd/m^2. Conversely, increasing the background luminance from 100 to 600 cd/m^2 (300 cd/m^2 luminance range) reduced the ON and OFF maximum response by ~4 spk/sec per 100 cd/m^2 and increased the exponent by ~0.17 per 100 cd/m^2. We conclude that expanding the luminance range from common laboratory values (~ 200 cd/m^2) to more natural values (~ 1,000 cd/m^2) enhances the ON-OFF differences in luminance/response saturation, maximizing spatial resolution for darks and low-contrast discrimination for lights.

Title: Functional organization of cortical maps for ocular dominance and light-dark polarity in primary visual cortex

Authors: *S. NAJAFIAN, J. JIN, Q. ZAIDI, J. ALONSO
State Univ. of New York Col. of Optometry, New York, NY

Abstract: The cat primary visual cortex has a map of retinal stimulus position (retinotopic map) that is split into four copies, two for each eye and two for each contrast polarity. These four copies are arranged in a grid (Kremkow et al., 2016) that aligns the eye and polarity axes with the axes of lowest and highest retinotopic gradient, probably to maximize the binocular retinotopic match needed for binocular vision and the light-dark retinotopic mismatch needed for processing stimulus orientation (Kremkow and Alonso, 2018). Here, we investigate the two-dimensional organization of the eye-polarity grid with computer simulations. We used a multivariate-normal-distribution filter to simulate the cortical spread of attraction-repulsion interactions that sort thalamic afferents by eye input during development. We then varied the geometry of the filter across cortical regions to reflect local variations in retinotopic gradients. The filter was convolved with a cortical patch of random binary noise representing the unsorted thalamic afferents (1: contralateral, 0: ipsilateral). By systematically varying the filter parameters (e.g. elliptical geometry with different spreads along major/minor axes), we generated a database of ocular dominance patches resembling those found in nature. We then took published ocular

dominance maps from different animals (cats, monkeys and humans), divided each map into 3 x 3 mm patches, and used our database to find the filters that best reproduced the geometry of each patch (i.e. best match in average width, length and orientation of ocular dominance stripes). This simulation generated a map of local retinotopic gradients that was used to generate the map for light-dark polarity and the eye-polarity grid for each animal (Figure 1). The predicted eye-polarity grids of cats, monkeys and humans shared the same general geometry but differed in the width and length of the eye-polarity stripes. We are currently investigating how the eye-polarity grid changes when OFF thalamic afferents occupy more cortical territory than ON thalamic afferents.

Title: Multimodal functional mapping of posterior parietal cortex in mice

Authors: *R. HIRA, L. B. TOWNSEND, I. T. SMITH, S. L. SMITH
UNC Chapel Hill, Chapel Hill, NC

Abstract: Posterior parietal cortex (PPC) in rodents plays a role in cognitive functions including navigation, multisensory integration, working memory, and decision making. However, its location has not been precisely determined in mice. PPC is bordered by the primary somatosensory cortex (S1), but other boundaries remain unclear. Higher visual areas (HVAs) could overlap with PPC in whole or in part. To precisely determine the location of PPC in mice, we performed a series of functional, multimodal intrinsic signal optical imaging experiments. First, we mapped HVA locations relative to cranial landmarks including lambda, which are commonly used for stereotaxic targeting. We found that, relative to cranial landmarks, the mouse-to-mouse variability in the locations of HVAs are large (mean ± S.D.: 10.0 % ± 12.1% overlap in HVAs across six adult mice). In comparison, when mapped relative to each other (e.g., using the centers of two HVAs as registration points), the locations of HVAs were more consistent across mice (46.4 % ± 16.8% overlap in HVAs across six adult mice). Thus, precise targeting of HVAs requires functional mapping in individual mice. Second, we used tactile stimulation of the tail, trunk, and ear to map parietal areas ~300 μm anterior from the anterior border of the Antereomedial (AM) HVA, and adjacent to the Anterior (A) and Rostrolateral (RL) HVAs. This mapping identified a cortical area between S1 and anterior HVAs, which we refer to as the Anterointermediate (AI) area. AI is likely a component of PPC. Third, we developed a multimodal mapping protocol to rapidly locate these areas adjacent to AI, based on simultaneously mapping HVAs and subregions of S1. The resulting maps provide functional landmarks for targeting PPC in mouse experiments. These findings also highlight the precise relative locations of cortical areas, despite variable relationships to cranial landmarks. We propose that subregions of mouse PPC have distinct integration roles such as tactile-visual, auditory-visual, visual-motor, and cognitive integration, similar to findings in primate PPC.

Title: A model for the development and dynamics of visual orientation selectivity

Authors: G. NGUYEN, *A. W. FREEMAN
Sch. of Med. Sci., Univ. of Sydney, Lidcombe, Australia

Abstract: Aims. Orientation selectivity, a major feature of primary visual cortex, depends on convergent input from on- and off-centre subcortical pathways. A cortical column receives input from highly overlapping on- and off-populations, and it is unclear how these inputs segregate into the separate on- and off-subfields of a simple cell receptive field. Orientation selectivity is refined by intracortical inhibition, but the mechanisms and extent by which inhibition shapes orientation tuning are still controversial. Our aim was to describe a model that, first, explains the segregation of on- and off-inputs to the cortex and, second, shows how inhibition contributes to the orientation tuning, contrast invariance and orientation mapping seen in real cortex. **Methods.** The model consisted of an array of subcortical channels, each of which included a photoreceptor, bipolar cell, ganglion cell and geniculate cell. These on- and off-channels converged onto two networks of cortical neurons, one excitatory and the other inhibitory. The inhibitory network then converged onto excitatory neurons. Each neuron in the model was modelled as a first-order low-pass temporal filter and represented by a nonlinear differential equation. Time courses of neuronal impulse rates were obtained by solving all equations simultaneously. Geniculocortical synaptic weights were initially all equal and then set through an iterative process representing visual development. The stimuli were drifting gratings with a range of orientations, and a synapse's strength was increased only if it enhanced the impulse rate of the target cortical neuron. **Results.** Cortical impulse rates were initially low because of destructive interference between neighbouring on- and off-inputs. The Hebbian development process favoured one sign of input over the other at any point in the visual field, resulting in the segregation of on- and off-inputs. As cortical contrast sensitivity grew so did inhibition. This favoured the response at the preferred orientation, shaping orientation tuning. At the end of development, orientation tuning bandwidth in some neurons was as sharp (15° half-width at half-height) as that seen in primate and carnivore primary visual cortex. This same *iceberg effect* also resulted in contrast invariance: increasing contrast increased inhibition, keeping tuning curves slim. Finally, maps of preferred orientation in the model are shown to have similar characteristics to measured maps. **Conclusion.** A model containing both Hebbian geniculocortical connections and feedforward intracortical inhibition can reproduce a number of the essential features of cortical orientation selectivity.

Title: Thalamic and feedback connections to mouse V1 differentially drive excitation and inhibition within distinct subnetworks

Authors: *R. D'SOUZA[1], P. BISTA[1,2], A. BURKHALTER[1]
[1]Dept of Neurosci., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Anat. and Neurosci., The Univ. of Melbourne, Melbourne, Australia

Abstract: The lateral posterior nucleus (LP) is a higher order thalamic structure that is involved in the contextual modulation of cortical visual representations (Roth et al., 2016). In mouse primary visual cortex (V1), axons originating in LP selectively target layer 1 (L1) and L5, which are also principal targets of feedback axons from higher cortical areas. Moreover, the dorsal lateral geniculate nucleus (dLGN), in addition to projecting to its primary target L4 in V1, also sends afferents into L1. It is unclear how diverse thalamic and cortical areas exert their respective influence on V1 function through the L1 neuropil. It was recently shown that projections from the dLGN and the higher visual lateromedial area LM, to L1 of V1, terminate preferentially in a non-uniform pattern of repeating regions termed 'patches', which interdigitate with regions termed 'interpatches' that are selectively avoided by these afferents (Ji et al., 2015). Given this organization, one way in which inputs from diverse sources could differentially regulate circuit output in V1 is through pathway-specific recruitment of excitatory and inhibitory actions within functionally and spatially distinct modules. To test this hypothesis, we mapped synaptic inputs from each of dLGN, LP, and LM to parvalbumin-expressing (Pv+) and pyramidal cells in L2/3 of V1 in Ai9 X Pvalb-Cre mice. Anterogradely labeled LP axons showed a remarkable propensity to target the interpatch zones in L1 of V1, thereby largely interdigitating with dLGN and LM axons. Pv+ dendrites and axon terminals in L1 showed a preference for localizing in patches, but Pv+ perisomatic baskets were denser in L2/3 modules aligned with interpatches. Channelrhodopsin2-assisted mapping in acute cortical slices showed that the inhibition/excitation (I/E) balance, defined here as the average ratio of the total EPSC recorded in a Pv+ cell to that recorded in a neighboring (< 50 μm) pyramidal cell upon presynaptic optogenetic stimulation, was pathway-specific. dLGN axonal inputs generated an I/E balance that was strongly tilted towards inhibition, unlike LP inputs which did not show any such bias in either patches or interpatches. LM axons showed a bias for recruiting inhibition in interpatches but not in patches, and exhibited an overall weaker tilt towards inhibition compared to dLGN inputs. Together, these results demonstrate fine-scale specificity with which diverse inputs to L1 control computations in V1. We propose that long-range excitatory afferents exploit the bimodular organization in V1, by differentially engaging the I/E balance within spatially segregated subnetworks, in order to modulate V1 at microcircuit-level precision.

Title: Excitatory and inhibitory presynaptic networks supporting orientation selectivity in primary visual cortex

Authors: *L. F. ROSSI, K. D. HARRIS, M. CARANDINI
Univ. Col. London, London, United Kingdom

Abstract: The response selectivity of neurons in the primary visual cortex (V1) stems from the integration of excitatory and inhibitory inputs from hundreds of presynaptic neurons across cortical layers. It remains unclear how this presynaptic network supports a neuron's orientation preference, and what differences exist between the inhibitory and excitatory presynaptic networks.

We targeted individual pyramidal L2/3 neurons in mouse V1, and identified their presynaptic network through single-neuron initiated monosynaptic tracing with an EnvA-dG-DsRed rabies virus. Mice expressed GCaMP6 in all excitatory neurons, so that we could perform two-photon microscopy to reconstruct the postsynaptic neuron and its local presynaptic network, and to measure their retinotopy and orientation tuning while the animal was passively viewing and free to run on spherical treadmill. For each postsynaptic neuron, we identified 132±41 (s.e., n = 13 mice) presynaptic partners across L1-5. On average, at least 49% of these presynaptic partners were excitatory, expressed GCaMP6 and displayed activity dependent fluorescence changes. The remaining cells were putatively inhibitory, as they did not express GCaMP6.

Presynaptic networks were not distributed uniformly in cortical space, but were elongated: in retinotopic space, this elongation matched the orientation preference of the postsynaptic neuron. Within this arrangement, there were striking differences between excitatory and inhibitory neurons: inhibitory neurons were concentrated locally around the postsynaptic cell, while excitatory neurons were distributed over a wider area. In retinotopic space, this distribution favored locations coaxially aligned with the orientation preference of the postsynaptic neuron. Differences extended also to the distribution across layers: inhibitory neurons constituted a majority in L2-3, while excitatory presynaptics dominated input from L4-5.

These results demonstrate that presynaptic networks support the orientation preference of L2/3 neurons through distributed, retinotopically elongated excitation balanced by local, dense,

retinotopically elongated inhibition. Moreover, they suggest feedforward excitation and local inhibition play a dominant role in the computation performed by L2/3 neurons.

Title: Modeling feedback for a large set of visual stimuli in a detailed, spiking model of macaque V1

Authors: *C. L. CHARIKER[1], L.-S. YOUNG[1], R. SHAPLEY[2]
[1]Mathematics, [2]Neurosci., New York Univ., New York City, NY

Abstract: A major challenge in understanding and modeling local networks of neurons in the cerebral cortex is trying to understand the network's interaction with its sources of feedback current. We report here a new approach to modeling feedback in a modified version of a previously constructed, biophysically detailed, spiking network model of macaque V1 input layer 4Cα (Chariker et. al. JNS 2016). The model consisted of ~41,000 excitatory and inhibitory integrate-and-fire cells in several hypercolumns of 4Cα. Model neurons had conductance based AMPA, GABA, and NMDA recurrent synapses, as well as sparse feedforward input from LGN and feedback from layer 6. While the original model successfully exhibited and made predictions about a number of important V1 phenomena simultaneously (e.g., orientation/spatial-frequency selectivity, simple/complex cells, gamma rhythms, firing rate distributions), the feedback component (layer 6) was only modeled for a specific set of visual inputs (background or full contrast drifting gratings ranging over several orientations and spatial frequencies). In order to study V1 phenomena involving a more general set of stimuli, we introduced and benchmarked a rate-dependent direct coupling of the feedback layer 6 to 4Cα. The feedback coupling scheme respects known anatomical features in the Layer 6-4Cα feedback circuit. The parameters of the coupling were chosen to replicate contrast response data in V1. With these parameters, we also studied V1 phenomena involving a wider range of visual stimuli (drifting gratings varying in contrast, orientation, spatial frequency, and temporal frequency). The phenomena included contrast invariance, spatial contrast sensitivity, and temporal frequency tuning. The new scheme of modeling feedback was judged to be successful based on how well the model matched experimental data. The particular detailed, mechanistic nature of the implementation of the

model allowed us to analyze the dynamical mechanisms underlying a wide range of visual cortical function.

Title: Specific intracortical connectivity rules reconcile push-pull and broad inhibition in V1 simple cells

Authors: *M. TAYLOR[1], R. BENOSMAN[2], D. CONTRERAS[1], A. DESTEXHE[3], Y. FREGNAC[3], J. ANTOLIK[2,3]
[1]Neurosci., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA; [2]Inst. de la Vision, Paris, France; [3]UNIC-CNRS, Gif-sur-Yvette, France

Abstract: Previous experimental studies have produced seemingly contradictory evidence on the nature of interaction between excitation and inhibition in simple cells of cat primary visual cortex (V1). Studies using drifting sinusoidal gratings have shown that both excitation and inhibition are modulated by the phase of the stimulus, and this modulation is anti-correlated, implying so called “push-pull” organization of the intra-cortical connectivity with respect to the functional properties of the neurons. Studies using flashed bar stimuli have shown that only excitation is locked to the phase (position) of the stimulus, while inhibition remains broad and phase unspecific across space.
Here we reconcile these experimental results by constructing a model of the granular layer of V1, with high biological fidelity, that exhibits both behaviors to the two different stimuli. We show that a moderate bias of excitatory neurons to synapse onto other neurons with correlated receptive fields (RFs), and a weak bias of inhibitory neurons to synapse onto other neurons with anti-correlated RFs can explain the V1 spike, Vm, and conductance dynamics under these different stimulation paradigms.
We explore a parameter space of RF-correlation-based bias for excitatory and inhibitory synapses and find surprisingly that a wide range of connectivity parametrizations give rise to experimentally observed spike and Vm dynamics in simple cells, suggesting that elementary

functional properties such as orientation tuning and its invariance to contrast, as well as the push-pull structure of RFs can arise robustly across a variety of connectivity schemes. However, the underlying conductance dynamics change dramatically across this parameter space: very different conductance dynamics can underlie the same functional properties. Experimental conductance data restrict the acceptable parameters to moderately biased excitatory connectivity and weakly biased inhibitory connectivity.
This work demonstrates that in complex dynamical systems such as cortex, it is dangerous to use restricted results from few different experimental conditions to make far-reaching conclusions on the nature of the underlying neural system. Only systematic, comprehensive treatment of the primary visual cortex, that incorporates a broad range of established constraints from different experimental designs, can lead to reconciliation of the often seemingly contradictory diversity of experimental findings, and in turn to accurate characterization of the system under study.

Title: Receptive field size and spatial phase organization in macaque V1 with two-photon imaging

Authors: *I. M. NAUHAUS[1], K. NIELSEN[4], E. M. CALLAWAY[5], H. KO[6], B. ZEMELMAN[2], E. SEIDEMANN[3], Y. Y. CHEN[3]
[1]Psychology, Room 4.208, [2]Neurosci., [3]Psychology, Univ. of Texas at Austin, Austin, TX; [4]Johns Hopkins Univ., Baltimore, MD; [5]Salk Inst., La Jolla, CA; [6]Psychology, The Univ. of Texas At Austin, Austin, TX

Abstract: Recent studies in macaque primary visual cortex (V1) have shown that maps of spatial frequency (SF), ocular dominance, orientation, and retinotopy, all co-exist to efficiently represent the visual scene (Nauhaus et al ‘16; *Efficient receptive field tiling in primate V1*). However, to establish a complete model of the functional organization of classic receptive field properties, along with corresponding coding limitations, we must also characterize the cell-by-cell organization of spatial phase and receptive field size. Here, we performed 2-photon imaging

in macaque V1 to accomplish this task. We used both synthetic (OGB) and genetically-encoded (GCaMP6) calcium indicators. Responses were measured to static sinewave gratings and sparse noise.
To begin, we find that RF width is homogeneous in each region-of-interest (ROI) - whereas the SF preference can systematically change by multiple octaves within a 500 μm field-of-view, the map of RF width (deg) is relatively flat when placed on a similar octave scale. Furthermore, we find that RF width is a poor predictor of preferred SF (cyc/deg). Our recordings are limited to upper layer 2/3, where the population has phase tuning curves with relatively low amplitude (i.e. they are more "complex" than "simple"). Overall, the results are consistent with prior studies showing that "complex cells" have a RF size that is poorly coupled to preferred SF (Movshon et al J. Physiol '78; Hubel and Wiesel '68 J. Physiol).
Next, our data shows that spatial phase is clustered in V1 - in each ROI, the population has a significant bias for the preferred phase of a given orientation and SF in the sinewave grating stimulus ensemble. We are continuing to investigate how this clustering relates to retinotopy and if it allows for complete tiling at each location of the visual field. In summary, we are continuing to identify a more complete model of the V1 functional architecture. Such a model is necessary for a descriptive understanding of the V1 population code. Furthermore, a complete model of V1 maps may provide important clues into the mechanisms that give rise to feature tuning in the cortex.

Title: Role of neuropilin-2 in the establishment of a functional neuronal connectivity in the mouse primary visual cortex

Authors: *H. KHDOUR[1,2], T. S. TRAN[3], P.-O. POLACK[4]
[1]Ctr. of Mol. and Behavioral Sci., Rutgers Univ. Newark, Newark, NJ; [2]Ctr. of Mol. and Behavioral Neurosci., [3]Biol. Sci., Rutgers Univ., Newark, NJ; [4]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. Newark Ctr. for Mol. and Behavioral Neurosci., Newark, NJ

Abstract: The establishment of cortical circuits during development is under the control of multiple signaling systems. One of these signaling systems is class 3 Semaphorins, more

specifically Sema3F. In the absence of the Sema3F signaling system during development will result in thalamocortical axons from the somatosensory and motor thalamic relay nuclei misproject to the visual cortex. As the presence of thalamocortical misprojections were only investigated during development, we ignore if abnormal thalamocortical wiring still exists in the adult. However, we know that the proximal part of the apical dendrite of layer 5 pyramidal neurons located in the adult primary visual cortex (V1) of mice knock-out for Sema3F or its obligate receptor Neuropilin-2 (Nrp2) present an abnormally high density of excitatory spines. These findings led to the hypothesis that Sema3F signaling plays a key role in the development of a functional network in V1 by pruning ectopic thalamocortical synapses. However, the identity of the presynaptic inputs rescinded under the control of the Sema3F signaling system as well as the gain of function achieved through this pruning were never established. To determine the identity of the neurons targeting erroneously the proximal dendrite of V1 L5 neurons in the absence of the Sema3F signaling**,** we injected either a retrograde tracer in V1 or an anterograde tracer in different thalamic relay nuclei of wild type (WT) and Npn-2 null mice. Then, using calcium imaging in awake mice, we compared the orientation tuning and the receptive field structure of V1 neurons of WT and Npn-2 null mice. Finally, we tested the effect of the absence of Sema3F signaling on visual perception by comparing the performance of WT and KO mice at visual discrimination tasks. We found that: [1] non-visual-specific thalamocortical inputs are still present in the V1 of adult Npn-$2^{-/-}$ mice; [2] the computational properties of L5 V1 neurons are negatively affected by the absence of Nrp-2 during development; [3] the receptive field structure of V1 neurons in Nrp2 null mice is degraded compared to WT; [4] Nrp2 KO mice showed lower visual discrimination ability compared to WT. Our results suggest that Sema3F signaling is implicated in the establishment of the thalamocortical connections in V1 and plays an important role in the emergence of the computational properties of V1 neurons.

Title: Spatial organization of simple and complex cells in the primary visual cortex

Authors: *G. KIM[1], J. JANG[2], S.-B. PAIK[2,3]
[1]Dept. of Physics, [2]Dept. of Bio and Brain Engin., [3]Program of Brain and Cognitive Engin., KAIST, Taejon-City, Korea, Republic of

Abstract: Selective response for various types of visual features is a hallmark of neurons in the primary visual cortex (V1), and great effort has been devoted to the classification of neurons depending on their functional tuning. As suggested in the pioneering study of Hubel and Wiesel (Hubel & Wiesel, 1968), one of the most studied criteria is the classification between simple and complex cells, where simple cells detect the edge in the visual stimulus, and the complex cells encode more integrated information. Conventionally, simple and complex cells have been considered two distinct classes of V1 neurons, based on the bimodal distribution of the modulation ratio (F1/F0; Skottun et al., 1991). On the contrary, later studies have suggested that these two types of cells are not clearly separated and can be considered as variations along a continuous spectrum (Mechler & Ringach 2002, Priebe et al., 2004). However, it is still unclear what induces such variation of the modulation ratio across V1 neurons. Here, we propose that the modulation ratio of V1 neurons is constrained by the spatial separation between ON and OFF retinal afferents to the neuron. Previously, we suggested that the spatial organization of ON and OFF retinal ganglion cells (RGCs) constrains the orientation preference of a V1 neuron, and the moiré interference between ON and OFF RGC mosaics can seed the hexagonal arrangement of orientation columns (Paik & Ringach, 2011). By extending this notion, we suggest that the distance between ON and OFF retinal receptive fields may constrain the modulation ratio of V1 cells. If ON and OFF retinal receptive fields are close to each other and highly overlapped, the connected V1 neuron shows nonlinear response dynamics of a complex cell. As ON and OFF retinal receptive fields become further apart from each other, the subregions of V1 become more separated, resembling the receptive field of a simple cell. Since the distance between ON and OFF retinal receptive fields periodically varies across the moiré interference, our model suggests a quasi-periodic arrangement of simple and complex cells. We observed such periodic variation of overlap between ON and OFF subregions in the animal data (Kremkow et al., 2016). We further predict that the spatial distribution of complex cells is correlated with the local structure of orientation maps because both structures are seeded by the common retinal organization. Overall, we suggest that the various functional tuning properties are determined by the retinal afferents, resulting in spatial correlation between different properties across the cortical surface.

Title: Cellular and circuit mechanisms underlying processing of binocular visual information in visual cortex

Authors: *S. HONNURAIAH, H. H.-Y. HUANG, G. TESTA-SILVA, W. M. CONNELLY, G. J. STUART
Australian Natl. Univ., Canberra ACT, Australia

Abstract: The binocular region of primary visual cortex plays a critical role in processing visual information received from the eyes. Recent work from our lab and by others demonstrates that this binocular visual information is integrated sub-linearly in layer 2/3 pyramidal neurons in binocular visual cortex. To better understand how binocular information is integrated in layer 2/3 of binocular visual cortex here we combine optogenetic and electrophysiological methods to identify putative binocular and monocular neurons in vitro and characterize their active, passive and morphological properties. We have identified two distinct populations of layer 2/3 pyramidal neurons in binocular visual cortex, one that receives long-range monosynaptic excitatory input from the contralateral visual cortex (putative binocular neurons) and one that does not (putative monocular neurons). In addition, we find that input from the contralateral visual cortex strongly excites a subset of fast-spiking, putative parvalbumin positive (PV) interneurons, activating feed-forward inhibition that could drive sub-linear synaptic integration in layer 2/3 pyramidal neurons. While we found no differences in passive and morphological properties of putative binocular and monocular layer 2/3 pyramidal neurons, the active properties of putative binocular neurons were significantly different from putative monocular neurons. Specifically, the slope of the input/output (f/I) curve generated during somatic current injection was lower in putative binocular layer 2/3 pyramidal neurons, leading to reduced action potential firing. These data suggest that binocular layer 2/3 pyramidal neurons are intrinsically less excitable than monocular neurons. This difference indicates that binocular layer 2/3 pyramidal neurons may have different cellular integration rules from monocular neurons during synaptic integration. Using a morphologically realistic active model of layer 2/3 pyramidal neurons, we demonstrate that differences in axonal potassium channels likely underlie the difference in input/output (f/I) curves of putative binocular and monocular neurons. In conclusion, we provide evidence that distinct populations of both excitatory and inhibitory neurons are involved in processing binocular visual input in binocular visual cortex. Furthermore, we show that these different neuronal populations have different active properties. These findings provide insight into the cellular and circuit mechanisms used by the cortex to process binocular visual information.

Title: Mapping cortico-cortical network activity with fmri elicited by optogenetic stimulation of primate v1

Authors: *M. ORTIZ-RIOS, M. HAAG, B. AGAYBY, F. BALEZEAU, M. C. SCHMID
Inst. of Neurosci., Newcastle Upon Tyne, United Kingdom

Abstract: Optogenetics in nonhuman primates have become an increasingly important resource to understand brain function and its relationship to behaviour in health and disease. However, approaches to influence behaviour using this method remain challenging in primates, in part due to a lack of detailed knowledge about how optogenetic stimulation affects neuronal activity across large-scale brain networks. Here we use fMRI to map the effective connectivity induced by optogenetic stimulation of primary visual cortex (V1). We injected 25.5 µl of *AVV9-hSyn-hChR2(H134R)-eYFP* across multiple depths and sites into the opercular part of V1 (at 5-7° visual eccentricity representation) of two monkeys resulting in an estimated virally transfected area of 12-20 mm^2. Opto-fMRI experiments were performed in a 4.7T vertical scanner and began at least eight weeks after construct injections. High-resolution images were taken from awake monkeys that remained seated inside the scanner in total darkness. LED stimulation (460 nm) was applied via a 1.5 mm diameter optical-fiber placed over the dura of V1; e.g. without penetrating brain tissue. Stimulation was performed in blocks of 30 seconds alternated with 30-second-long blocks without stimulation. To assess the effect of light stimulation on the BOLD response we used multiple power amplitudes (110mW, 90mW, 70mW as measured at the fiber tip), frequencies (40Hz, 10Hz and 5Hz) and intensity matched red light (625 nm) for control analyses. To assess the BOLD response modulation, we used a model-free assessment of the signal using the coherence measured between the BOLD response and the optical stimulation rate (e.g. 1/60 sec). In visual cortex, blue, but not red light resulted in coherent modulation of areas V1, V2, V3 and MT. The local BOLD response amplitude in V1 was incrementally modulated with increasing power and frequency. The distal cluster in MT/MST was mainly driven at the highest amplitudes and frequencies (e.g. 110-90mW, 40-10Hz). We also observed strong modulation in ventromedial V1 however with a phase lag, perhaps indicative of a negative BOLD response. Outside the occipital lobe, we also found reliable activation in the dorsal genu of the caudate nucleus and moderate modulation in the right ipsilateral frontal eye field (FEF) region most likely reflecting poly-synaptic modulation. Our results of V2 and MT activation are consistent with monosynaptic input to these areas via V1 layer 4B neurons (Nassi & Callaway, 2009) and as such provide a new perspective onto how optogenetic V1 stimulation might influence saccadic eye movements by eliciting perceptual changes (Jazayeri al., 2012) that involve large-scale cortical networks.

Title: Mapping functional synaptic weights with *in vivo* spine imaging and correlated ultrastructural anatomy

Authors: *B. SCHOLL[1], C. THOMAS[2], D. GUERRERO-GIVEN[2], N. KAMASAWA[2], D. FITZPATRICK[1]
[2]Electron Microscopy Core Facility, [1]Max Planck Florida Inst., Jupiter, FL

Abstract: Understanding how single neurons integrate synaptic inputs from myriad sources to generate somatic responses remains a challenge. Further adding to this challenge are recent studies revealing significant functional diversity in populations of synaptic inputs onto individual cortical cells. While organization motifs have been identified in the form of dendritic clustering of inputs aligned to the somatic output and local synaptic clustering of distinct properties, how this relates to unitary synaptic strength and whether clustered inputs result from individual axons remains unknown. To address these issues, we combined *in vivo* two-photon calcium imaging and serial block-face scanning electron microscopy (SBFSEM) to correlate ultrastructural and functional properties of the same subcellular features of individual cells. Here we focus on measuring orientation selectivity and ocular dominance of individual dendritic spines on the basal dendrites of cells sparsely labeled with GCaMP6s in ferret visual cortex. Following morphology-based correlation, we were able to quantify postsynaptic and presynaptic characteristics including spine morphology such as spine head volume, PSD length, bouton size, and vesicle pool size of functionally-identified spines. Furthermore, SBFSEM allows for reconstruction of presynaptic axons to examine whether functionally-defined clusters of spines are axon-coupled or have separate inputs. Comparing synaptic functional properties and ultrastructural properties, we find that spines are commonly connected to a single, exclusive axonal bouton, and exhibit a diversity of sizes (volume, PSD length) regardless of the degree of co-tuning with the soma orientation preference. Interestingly, larger presynaptic boutons form synapses onto spines with similar eye preference to that of the soma. Continued development and use of *in vivo* synaptic imaging and SBFSEM will be key to unravel how synaptic inputs and their functional properties are integrated within the dendritic tree of individual cortical cells.

Title: Propagation of "network belief" in the primary visual cortex: Synaptic contribution of the horizontal intrinsic connectivity

Authors: *M. PANANCEAU, B. LE BEC, C. DESBOIS, X. TRONCOSO, Y. FREGNAC
UNIC-CNRS, FRE 3693, Gif Sur Yvette, France

Abstract: Contextual long-range interactions involved in perceptual binding are generally thought to depend on cortico-cortical feedback (Gilbert and Li, 2013) and attention (Lamme & Roelfsema 2000). In contrast, the contribution of lateral diffusion mechanisms intrinsic to V1 is less known (review in Frégnac & Bathellier, 2015) We explore here the role of the "horizontal" long-distance intra-cortical connections in the dynamic emergence of facilitatory and predictive responses in the primary visual cortex (V1) of the anesthetized cat. .
A previous study of the spatiotemporal features of the subthreshold receptive field (RF) of V1 cells (Gerard- Mercier et al. 2016) showed that 1) synaptic responses to flashed 3-4° Gabor patches can be elicited from the far periphery (up to 15°) and most remarkably, exhibit a coherent organization reminding the grouping bias of the "perceptual association field" for collinear contours (Field et al, 1993) and 2) that presentation of centripetal apparent motion (AM) iso-oriented Gabor patches (GPs) induces a facilitatory modulation along the cell's preferred orientation axis.
Intracellular experiments were designed to further characterize the spatio-temporal coherence requirements of this facilitatory effect. We then used 6-stroke apparent motion (AM) concentric sequences of GPs at saccadic-like speeds (~200°/s) centered on the subthreshold RF. The motion path extended up to 25° into the periphery. The response to the RF center stimulation alone was compared to the one induced by the AM sequences, which were either centripetal or centrifugal, with GP collinear or cross-oriented to the motion path. Control conditions included randomized order of the GPs presentation and the change of the AM speeds. Sequences restricted to the silent periphery of the RF were also tested to reveal possible filling-in responses.
Our results shows that the contextual sequence originating from the far periphery has a strong

boosting effect on the evoked discharge, resulting in a significant phase advance (5-20 ms) of the synaptic response. The supra-linearity of the boosting is specific to centripetal collinear AM at saccadic speeds and could not be induced by either the centrifugal AM or random sequences or at low speed. These results are consistent with our hypothesis that “Gestalt-like” interactions are triggered when the visual input carries a sufficient spatiotemporal coherence matching the properties of the underlying V1 connectivity. We propose that horizontal connectivity participates to the propagation of a network-based belief, resulting in some kind of "prediction" process travelling through the V1 network.

Pierre Et Marie Curie, Paris, France

Abstract: Functional organization of primary visual areas in non-human primates has been massively studied using different imaging techniques as fMRI, optical imaging (calcium, VSDi) or electrophysiological methods with single electrodes or multielectrodes arrays. In the domain of vision, all these techniques allow studying functionality of visual cortex at different scale levels. However, mesoscopic and microscopic examinations of cortical activity in visual cortex have rarely been done simultaneously because of technical limitations. Common imaging techniques as fMRI present low temporal resolution although optical imaging techniques as VSDi are limited to the surface exploration. New functional ultrasound (fUS) imaging technique, which consists of recording cerebral blood volumes variations, overpasses several of these

limitations. Indeed, with this method, we obtained functional images with an high spatial resolution (~100µm) and an high temporal frequency (1Hz) even at deeper cortical locations (~1,5cm) that cannot be reached with other optical imaging methods (calcium imaging or VSDi), for example through the cortical sulci. In this study, the animals were performing a passive fixation task in which different types of visual stimuli were flashed briefly on a computer screen while we were recording functional ultrasound images of their visual cortex. We showed that using this innovative technique, we were able to reconstruct retinotopic and ocular dominance maps of primary visual areas (V1/V2/V3) with an high spatio-temporal resolution in awake behaving monkeys. Indeed, the results showed evidence of the retinotopic organization of the calcarin sulcus in V1, V2 and V3 areas. This technique also allows revealing the presence of ocular dominance bands in V1 cortex. Together, these results provide a novel perspective of using functional ultrasound imaging to study deep cerebral activity in different brain areas at the columnar or layer level.

Title: Prediction of future input explains lateral connectivity in primary visual cortex

Authors: *E. FRISTED, Y. SINGER, A. J. KING, M. F. IACARUSO, N. S. HARPER
Dept. of Physiology, Anatomy, and Genet. (DPAG), Univ. of Oxford, Oxford, United Kingdom

Abstract: Neurons in primary visual cortex (V1) show complex tuning properties[1] and functional specificity of local synaptic connectivity, whereby neurons with strong response correlations and similar spatial receptive field structure are more likely to be connected and to form strong connections[2][3]. However, it is not clear what is the functional significance of this

relationship between tuning properties and connectivity. We hypothesize that the connectivity of neurons in V1 is optimized to predict the immediate future of visual inputs from recent past inputs. To test this hypothesis, we implemented a temporal prediction model[4] in a one hidden layer recurrent neural network (RNN), which was trained to predict the next frame in movies of natural scenes from the recent past frames. Tuning properties were determined by measuring the network's response to drifting grating stimuli and natural visual scenes, and network connectivity was obtained from the recurrent weight matrix. The excitatory units of the network developed tuning properties resembling those of mouse V1 neurons[5], and were sparsely connected. The network showed functionally specific connectivity, whereby excitatory units were more likely to connect and form strong connections if they had similar orientation or direction tuning. Furthermore, connection probability between units increased with their response correlation to natural visual scenes. Finally, units with both simple- and complex-like tuning properties emerged in the network. Having validated the model, we used it to generate testable predictions of the lateral connectivity of inhibitory units in V1. Our results provide support for the hypothesis that the lateral connections in V1 are optimized for prediction of future visual input.

Title: Mapping thalamic projections onto L2/3 pyramidal neurons of visual cortex

Authors: *A. BALCIOGLU
Dept of Neurol, MIT, Cambridge, MA

Abstract: Cortical pyramidal neurons receive thousands of excitatory inputs from cortical, as well as subcortical sources. The relative numbers of these inputs, and their location across the arbor, and in relation to each other, determines the impact of each given source on action potential firing. Where inputs are situated on the arbor in terms of the apical vs basal tufts,

distance from the soma, branch points, and how they are distributed or clustered at these locations will significantly influence how they are integrated locally per dendritic segment, as well as across the entire cell. Unfortunately, we have little information regarding the mapping of different afferent inputs sources onto cortical pyramidal neurons. Using a thalamus specific Cre driver line crossed to a conditional synaptophysin Tdtomato (syn-Td) reporter line to specifically label thalamic afferents, in combination with a methodology for sparse labelling of cortical neurons and their excitatory synapses, we asked the following question: Do excitatory projections coming from thalamus differ in their distribution on L2/3 pyramidal arbors, as compared to intracortical excitatory inputs? L2/3 pyramidal neurons in pups expressing thalamic syn-Td were labeled by *in utero* electroporation with eYFP as a cell fill and teal-PSD95 to mark stable excitatory synapses. After cranial window implantation at 6 weeks, the entire cell volume was imaged *in vivo* at 8 weeks using multi spectral, high resolution, two-photon microscopy. PSD95-labeled excitatory synapses on imaged neurons were scored as either thalamic (syn-Td positive) or cortical (syn-Td negative) with a custom-written 4D point-tracking system implemented in Fiji. We found that: 1) The number of thalamic inputs onto the L2/3 neurons was much higher than expected considering L2/3 is not the primary recipient layer of thalamic innervation. 2) There was no preference for apical vs. basal distribution of thalamic inputs. 3) Thalamic innervation was not uniform across cells, with different cells receiving different degrees of innervation. 4) Distribution of thalamic vs. cortical afferents across individual dendritic branches was non-random. In conclusion, cortical L2/3 pyramidal neurons receive extensive cell type specific and structured thalamic innervation.

Title: Modelling contour integration in deep artificial neural networks

Authors: S. KHAN[1], A. WONG[1], *B. P. TRIPP[2]
[2]Systems Design Engin., [1]Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Contour integration is a phenomenon in V1 where stimuli from outside a neuron's classical receptive field have an influence over its responses. In particular, responses are enhanced if a preferred stimulus within the classical receptive field is part of a larger contour. Contour integration is thought to be mediated by intra-area lateral and higher-layer feedback

connections. Past computational models have tested potential mechanisms and replicated observed neurophysiological data. However, past studies have done little to explore the role of contour integration in the perception of naturalistic scenes.
In this research, we explore the integration of a computational model for contour integration into a deep artificial neural network, for the task of object classification, in order to investigate the relationships between low-level contour integration phenomena and complex perceptual functions. The computational model is trained to match empirical enhancement gains for several different contour configurations, including variations in contour length, spacing, and curvature. Unlike previous computational models, no predefined lateral connection structure is assumed, and the networks learns the patterns and weights of sparse lateral connections. These connection structures are compared with observed horizontal connections in the V1 cortex. Importantly for scaling the model to networks that perform sophisticated naturalistic tasks, the model works with learned feed-forward kernels, rather than idealized Gabor kernels. Future work will explore the effects of parameter variations on various perceptual contexts, such as recognition of partially occluded objects.

Title: Functional topography and synaptic targets of a new cell type in the primary visual cortex of the cat

Authors: *Z. F. KISVARDAY, M. SRIVASTAVA, C. ANGEL, S. MOHAMMED, A. NADHEM
Univ. Debrecen, Debrecen, Hungary

Abstract: Traditionally, neurons possessing spiny dendrites such as pyramidal, star-pyramidal and spiny stellate cells are considered excitatory in nature whereas smooth dendritic neurons are inhibitory. Here we report a smooth dendritic, i.e. spine free cell type in layer 6 of the adult visual cortex which shows, however, a host of morphological features typical for excitatory neurons. The neuron was selected from a large pool of intracellularly labelled cells based on its unique morphological features such as large soma size, numerous long and barely branching dendrites which were emitted in all directions from the cell body. The main axon entered the

white matter but also gave off long-range horizontal axons which extended up to 2.8 mm in layers 5/6. 3D-reconstruction of the cell revealed that the axon provided chiefly en passant boutons (n=1192) which were rather uniformly distributed without obvious spatial clustering. Dendritic length, surface and volume measurements revealed that these parameters are at least 3 times larger than corresponding parameters of any known neuron types in the cat visual cortex. Quantitative electron microscopy of the labelled boutons from projection zones representing proximal and distal parts of the axon showed that for both categories the postsynaptic targets are chiefly dendritic spines and dendritic shafts of other excitatory neurons while GABA immunopositive dendrites represent a minority of the targets. Superimposing the axonal field on the orientation map obtained with intrinsic signal optical imaging showed that the majority of connections prefer oblique orientations rather than iso-orientation. The data obtained for this novel cell type suggest that its likely role is integration of a broad range of cortical inputs.

Title: Mesoscale and cellular scale calcium imaging of the primary and secondary visual cortex in marmoset monkeys

Authors: *T. MATSUI, T. HASHIMOTO, T. MURAKAMI, M. UEMURA, K. KIKUTA, T. KATO, K. OHKI
Univ. of Tokyo, Tokyo, Japan

Abstract: Primate neocortex analyzes visual scenes with a hierarchical neuronal network consisting of multiple interactive functional structures spanning broad range of spatial scales,

such as cortical areas, columns and single cells. To understand how such cortical entities interactively process visual scenes, it is necessary to record neuronal responses at multiple spatial scales in a seamless manner. We are currently developing such a method applicable to primates using a combination of wide-field and two-photon calcium imaging (see for details Uemura et al., in this meeting). In this study, we report preliminary application of the method to marmoset monkeys. Neurons in the primary and secondary visual cortex (6.5 x 6.5mm field-of-view) were transduced with adeno-associated viruses carrying genetically encoded calcium indicator optimized for primates (see Sadakane et al., 2015 and Uemura et al., in this meeting). We then performed wide-field and two-photon calcium imaging in the same animal to seamlessly cover multiple spatial scales. Wide-field imaging revealed the orientation map in both V1 and V2 whose boarder was identifiable by the change in the size of the orientation columns. V2 was also identifiable by an alternating pattern of band-like regions with high and low orientation-tuning, likely corresponding to the cytochrome oxidase stripes. Subsequent two-photon imaging revealed orientation columns and pinwheels organized at the single cell level in V1 and V2. In V2, we also observed clustering of cells with low orientation-tuning and high orientation-tuning, consistent with the alternating pattern observed with wide-field imaging. Thus the present results demonstrate the usefulness of calcium imaging to understand the primate visual cortical network at multiple spatial scales.

Title: Contextual effects of high dynamic range (HDR) luminance flankers on orientation discrimination

Authors: *C. P. HUNG[1,3], A. V. HARRISON[2], A. J. WALKER[1,4], M. WEI[1,4], B. D. VAUGHAN[1]
[1]Human Res. and Engin. Directorate, US Army Res. Lab., Aberdeen Proving Ground, MD; [2]Computat. & Information Sci. Directorate, US Army Res. Lab., Adelphi, MD; [3]Dept. of Neurosci., Georgetown Univ. Sch. Med., Washington, DC; [4]DCS Corp, Alexandria, VA

Abstract: Computational models of visual search behavior include luminance normalization based on spatial context and laboratory conditions of ~100:1 luminance contrast ratio (standard dynamic range, SDR). How do feature and luminance context interact under real-world contrast ratios of up to 10^6:1? Recent reports of brightness perception have revealed non-linear effects of luminance normalization at contrast ratios over 1000:1 (high dynamic range, HDR), expanding the perceived shadings of gray at the mode of the luminance distribution. We hypothesize that, because visual neurons encode both luminance and orientation, luminance and orientation processing may interact non-linearly during visual recognition. We tested whether flanker effects on target orientation discrimination is stronger for the brightest flankers or for flankers that are similar to the target in luminance. We measured EEG, eye tracking, and visual recognition behavior under a two-alternative forced choice (2AFC) task and under rapid serial visual presentation (RSVP, 0.5-2 Hz). Stimuli consisted of 45- and 135-deg Gabors presented on a 5 × 5 grid of luminance patches (100:1 patch contrast, 10000:1 peak contrast including Gabors). The target was a contrast blend of Gabors at the two orientations, and subjects indicated via keypress the orientation with the higher contrast. In one condition, the co-oriented flanker patches were the brightest patches, and in the other condition, the co-oriented flanker patches were similar in luminance to the target patch. Dependent variables include behavioral response time and accuracy, stimulus and ocular-locked EEG amplitude, latency and frequency, and pupil size. Our results show that luminance-orientation context has a significant bias on orientation discrimination that is opposite across the two conditions. The bias is more robust for the second condition, favoring a luminance-similarity contextual effect. We are modeling the effect of luminance and shape interaction in visual search by manipulating the level of interaction between luminance adaption and local orientation based filtering. Standard models of visual search assume shape based filtering and luminance adaptation happen largely in parallel and independently, but nonlinear luminance adaption may directly affect the filtering of shapes with regard to the background.

Title: Establishing optogenetics in pigeons on a histological, physiological and behavioral level

Authors: *N. ROOK[1], J. TUFF[1], S. ISPARTA[1], O. MASSECK[2], S. HERLITZE[3], R. PUSCH[1], O. GUNTURKUN[1]
[1]Biopsychology, [2]Fac. for Biol. and Biotech., [3]Dept. for zoology and neurobiology, Ruhr-University Bochum, Bochum, Germany

Abstract: One of the major goals of neuroscience is to understand the function of specific cell types in micro- and macro-brain circuitry, in health, and disease. To study the function of neuronal networks, methods that are able to control neuronal activity precisely are indispensable. This ambitious goal was first achieved with optogenetics, allowing researchers to activate or silence specific networks with high temporal and spatial resolution through the integration of artificial light-sensitive ion channels into the cell membrane. Given those advantages it is not surprising that optogenetics has been established in a wide range of species such as rodents and primates in the last years. In contrast to the revolution optogenetics has brought to rodent research, only few studies have been reported in birds and none so far in pigeons. However, pigeons are a very valuable research organism as they offer a model with excellent visual capabilities for comparative research. Therefore, establishing optogenetics in pigeons is inevitable for future research. One crucial step of optogenetics is the integration of the light-sensitive proteins into the cell membrane of neurons mainly via viral vectors and cell type-specific promoter systems. A lot is known about those parameters in rodents, but this data cannot simply be transferred to another organism since viral transduction and transgene expression have been found to vary extensively across species. Therefore, in a first study, we compared the transduction efficiencies of three adeno-associated viral vector (AAV) serotypes AAV1, AAV5 and AAV9 either with the neuron-specific hSyn promoter or with the non-selective CAG promoter. We found that AAV1 was the most efficient serotype regardless of the utilized promoter system. Therefore, this construct was used for the following physiological and behavioral experiments. With simultaneous electrophysiological recordings and optical stimulation in the anesthetized pigeon, we could show that blue light at 480 nm reliably evokes action potentials in ChR2 expressing cells. Finally, stimulating ChR2 expressing cells in the entopallium of the pigeon brain (visual area) during a visual discrimination task significantly reduced the performance of the pigeons. Thus, this study successfully established optogenetics in pigeons offering a tool box for further optogenetic experiments in birds

Title: Age dependence of visual gamma oscillations elicited by Cartesian gratings in human EEG

Authors: DINAVAHI V P S MURTY, S. RAY
Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Gamma rhythms have been proposed to be abnormal in various neuropsychiatric disorders such as schizophrenia. Since these rhythms could be important for developing non-invasive and early diagnostic tools for such diseases, it is necessary to study their dependence on various demographic variables like age and gender. Recent studies have observed two different gamma oscillations (slow: 20-40 Hz and fast: 40-70 Hz) in human occipital cortex that are induced by visual gratings in EEG/MEG recordings. In this study, we explored the relationship between these oscillations and age, using full-screen static Cartesian gratings in 41 young-middle aged subjects (aged 20-48 years, mean age: 29.3 ± 6.2 years, females: 14) and 44 elderly subjects (aged 51-85 years, mean age: 64.3 ± 7.6 years, females: 18) with no known history of neuropsychiatric illness.

We found that ~80% of the subjects showed a change in power from baseline by 0.5 dB or more in at least one of the two gamma rhythms. Interestingly, we found that stimulus-induced change in fast, but not slow gamma power decreased significantly with age in both males and females. Further, females had significantly higher change in fast, but not slow gamma power compared to males in both young and elderly age groups. Moreover, the total number of bipolar electrodes in centro-parietal to occipital regions showing gamma activity decreased with age for fast gamma for both genders, but not for slow gamma.

Apart from gamma, we also tested responses of two other oscillations: steady-state visual evoked potentials (SSVEP) using gratings counterphasing at 16 Hz that generated a peak at 32 Hz, and suppression in alpha (8-12 Hz) power. Similar to slow gamma, SSVEP at 32 Hz did not differ with age, both in terms of power change or scalp distribution. However, suppression in alpha power to static gratings tended to decrease with age as in the case of fast gamma, although the results were weaker and not significant for males.

Our preliminary analyses show that both slow gamma oscillation and SSVEP in slow gamma range are more stable across age and gender compared to fast gamma or alpha suppression. These characteristics may make these oscillations desirable candidates for biomarker testing in diseases of the brain especially in elderly, like in the case of Alzheimer's disease.

Title: The cortical dynamics underlying contour integration in human visual system

Authors: *Y. LI[1], Y. WANG[2], S. LI[3]
[1]Shaanxi Normal Univ., Shaanxi, China; [2]Sch. of Psychology, Shaanxi Normal Univ., Xi'an, China; [3]Peking Univ., Beijing, China

Abstract: The human visual system efficiently extracts local elements from cluttered backgrounds and integrates these elements into meaningful contour perception. Contour integration is a critical step before object recognition, in which contours often play an important role in defining the shapes and borders of the to be recognized objects. Previous investigations have suggested that both striate and extrastriate visual areas are involved in the process of contour integration. However, the cortical dynamics of these areas in the human brain during contour integration is less understood.
The present study used fMRI to investigate the temporal evolvement of contour integration at different levels of the visual processing hierarchy. Specifically, using a sandwich masking paradigm, we combined psychophysics and fMRI to reveal how low-level (V1, V2, V3) and higher-level (V3B, LO) visual areas responded during the process of contour integration. In fMRI session, the Gabor filed with or without a contour embedded was presented with a duration of 33, 67, 133, 267 ms and was temporally sandwiched between masking stimuli. Human participants were required to indicate whether the contour was present or not. By contrasting BOLD responses between contour and non-contour (i.e. CI index) for all stimuli duration condition, we measured the psychophysical time course of contour integration and its underlying cortical dynamics.
The results showed that both low- and higher-level visual areas were involved in the process of contour integration, but they responded at different activation patterns. First, the first stimuli duration at which the visual areas revealed significant CI activation was earlier in LO than in other areas (LO: 33 ms; others: 67 ms). Second, we found that the CI index in higher visual areas (LO, V3B) increased as the stimulus duration increased, which was consistent with behavior

results. These results suggested that LO is critical involved in the processing of contour integration. However, the CI index in early visual areas (V1, V2) was significant at two separate stimulus duration: an early activation (67 ms) and a late reactivation (267 ms). This activation and reactivation pattern is consistent with previous EEG-fMRI study (Mijović et al., 2014). These results suggest the feedback from higher visual area to lower visual area is involved to contour integration. Our findings fit well with the incremental grouping theory (Roelfsema, 2006), in which a feedforward sweep generates a coarse template in higher visual areas with large receptive fields before the processing of detail information in lower visual areas with small receptive field through feedback mechanisms.

Title: Late positivity component as neural correlate of post-perceptual processing in different version of visual backward masking task

Authors: *M. DERDA, M. KOCULAK, K. GOCIEWICZ, M. WIERZCHON, M. BINDER
Jagiellonian Univ., Kraków, Poland

Abstract: The goal of the presented study is to disentangle electrophysiological correlates of visual awareness from other task-related processes through manipulating the level of processing of visual stimuli. Brain activity reflecting conscious perception should only be correlated with subjective visibility (measured with ratings on Perceptual Awareness Scale, PAS) and be independent of the perceptual task. Two experiments (E1 and E2) with a visual backward masking task were conducted. The design of both experiments was within-subject; each participants performed 420 trials with stimulus, location and condition order randomized. Thirty healthy participants (12 male, M=24.21) took part in E1. In each trial a stimulus (either a line or a letter, depending on condition) was shown randomly in one of four possible locations (2º from fixation). Stimuli, displayed for 16 ms, were followed by a fixed mask. Then, participants were asked to perform 2AFC task, either with line slope identification or letter classification. After each trial participants rated the visibility of stimulus on the PAS scale. In E2 36 healthy students participated in the experiment (15 male, M=23.41). This time, stimuli was the same in each condition (masked digit, either red or blue, presented for 50 ms). Similar to E1, every subject performed a 2AFC task (either discriminating the color or magnitude of the digit) and assessed

subjective visibility of it on the PAS scale. In both experiments EEG data were collected with 64-channel BioSemi System and preprocessed according to the same routine: filters: 0.1Hz-30Hz band (plus 50Hz notch filter); ICA Ocular Correction; visual inspection; re-referencing to average; baseline window: -200ms to 0ms pre-stimulus. Amplitude of two components: Visual Awareness Negativity (VAN: 140-240 ms, channels PO7, PO8, PO4, PO3, O2, O1) and Late Positivity (LP, 380-480 ms, Pz) was analyzed with weighted regression mixed model.In E1: for VAN component time window the mean amplitude correlated with condition. The mean amplitude in LP window correlated with PAS rating and condition (with no significant interaction between condition and PAS). In E2 the mean amplitude of VAN correlated with PAS rating in both conditions. The mean amplitude in LP window correlated with PAS rating in the magnitude judgement condition, but not in the color judgement condition.Both VAN and Late Positivity were observed, but their role was different depending on task that was performed. VAN amplitude was sensitive to PAS Ratings in E2, but not in E1. The pattern of LP was also different in E1 and E2. Therefore, our results contest the interpretation of LP and VAN as neural correlate of visual awareness.

Title: Two-photon imaging evidence for neuronal responses to superimposed cross-gratings in macaque V1

Authors: *S. GUAN[1], N.-S. JU[2], S.-H. ZHANG[1], S.-M. TANG[3], C. YU[4]
[1]Peking-Tsinghua Ctr. for Life Sci., [2]Sch. of Life Sci., [3]Sch. of Life Sciences, IDG-McGovern Inst. for Brain Res., [4]Peking-Tsinghua Ctr. for Life Sciences, IDG-McGovern Inst. for Brain Research, Dept., Peking Univ., Beijing City, China

Abstract: The responses of V1 neurons to a grating are suppressed by a superimposed orthogonal grating. This cross-inhibition effect suggests divisive normalization, a crucial computation that determines the non-linearity in neuronal contrast response functions. Previous studies investigated cross-inhibition through single-/multi-unit recording and functional brain imaging (e.g., fMRI). Here we used two-photon calcium (GCaMP5) imaging (Li et al., Neuron, 2017) to study this effect again, with the advantage to record simultaneously the responses of hundreds of neurons at single-neuron precision, and with relatively unbiased neuron sampling. We recorded the responses of superficial layer (2/3) V1 neuron (150 and 400-μm depths) at 4-5^{o}

eccentricity in an awake, fixating monkey. The stimuli were either a single Gabor or two orthogonal Gabors forming a plaid. Each Gabor drifted at 2-cycles/sec, with 6 orientations (30^o apart) and three SF ranged from 2-5 cpd. The contrast was either 0.32 (near the saturation contrast) or 0.08. Two types of V1 neurons responded to single and plaid gratings. The first type (~70%) was orientation-tuned, and the peak responses to a grating were overall suppressed by an orthogonal grating. The responses to a 0.32-contrast grating ($R_{0.32}$) were similarly reduced by an orthogonal 0.32-/0.08-contrast grating (median Cross Modulation index CM = ((R_{cross}-$R_{0.32}$)/((R_{cross}+$R_{0.32}$)) = -0.39/-0.43). $R_{0.08}$ were more suppressed by an orthogonal 0.08-contrast grating (median CM=-0.41), than by a 0.32-contrast grating (median CM=-0.23). A small portion of neurons showed enhanced $R_{0.08}$ by an orthogonal grating of either contrast (CM>0). We did not observe the winner-take-all effects, in which only $R_{0.08}$ would be suppressed by a 0.32-contrast orthogonal grating, but not $R_{0.32}$ by a 0.08-contrast grating. The second-type (~30%) showed previously unreported behaviors. These neurons showed weak and orientation non-selective responses to a 0.32-contrast grating, but strongly responded to 0.32+0.32 plaid gratings (median CM=0.58). The two types of neurons showed similar peak response strengths to their preferred single or plaid gratings. Our results provide more detailed and unbiased estimates of the cross-inhibition effects for first-type V1 neurons. The previously reported winner-take-all effect is not observed, which we suspect may result from higher stimulus contrasts placed in the saturation region of neurons' contrast response functions. The second-type V1 neurons' responses cannot be revealed via traditional single-unit recordings that first map the RFs with oriented stimuli, and then assess the responses to plaid gratings.

Title: Location-specific attentional modulation of neural representation of color in the human LGN

Authors: *S. PARK[1], S. HONG[2,3], Y. LEE[1,4], W. SHIM[1,4]
[1]Ctr. for Neurosci. Imaging Research, IBS, Suwon, Korea, Republic of; [2]Psychology, Florida Atlantic Univ., Boca Raton, FL; [3]Ctr. for Complex Systems and Brain Sciences, Florida Atlantic Univ., Boca Raton, FL; [4]Biomed. Engin., Sungkyunkwan Univ., Suwon, Kyunggi-Do, Korea, Republic of

Abstract: Previous work on the nonhuman primate visual system shows a distinction between two chromatic channels, parvocelluar (L-M) and koniocellular (S-(L+M)) in the lateral geniculate nucleus (LGN). Using fMRI in conjunction with encoding methods, we investigate how neural representations of L-M opponent and S-cone opponent colors are modulated by spatial attention in the human LGN. On each block, observers viewed expanding or contracting equiluminant concentric ring patterns with colors varying on either the L-M or S-(L+M) axis only or colors varying on both color axes. To manipulate spatial attention, participants were instructed to detect specific letters in an RSVP sequence presented at the foveal 0.5° or to detect a circular probe presented at an eccentricity of 5° from the central fixation point. The probe was defined by sudden chromatic contrast reduction in a circular region. We constructed an inverted encoding model of color (Brouwer & Heeger, JNeurosci, 2009) and reconstructed population-level color-selective response profiles in the LGN using a leave-one-run-out procedure. The result showed the effect of spatial attention on color-selective responses in the LGN. The color selectivity was more prominent when spatial attention was deployed to the foveal visual field, compared to when attention was directed to the parafoveal visual field. Crucially, however, the color-selective response to S-cone opponent colors was stronger when the parafoveal visual field was attended, whereas the color response to L-M opponent colors was stronger when the foveal visual field was attended . The distinct patterns of attentional modulation of the neural responses to L-M opponent and S-cone opponent colors may arise from the cone distribution on the retina, where S-cone populations spread more across parafovea compared to L and M cones, which are heavily concentrated in the central fovea (Ahnelt et al., 1987). This location-specific attentional modulation was absent in the early and high-level visual cortical areas (V1, V2, V3, V4v, and VO). Our results indicate that neural representations of colors in the human LGN are affected by spatial attention and that color-selective responses to L-M and S-cone can be distinctively modulated by location-specific attention.

Title: Spatio-temporal processing of rod and cone inputs to mouse V1

Authors: *I. RHIM[1,2], G. COELLO-REYES[1,2,3], I. NAUHAUS[1,2,3]
[1]Dept. of Psychology, The Univ. of Texas At Austin, Austin, TX; [2]Ctr. for Perceptual Systems, [3]Dept. of Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: Classic paradigms for parsing parallel inputs to visual cortex vary three stimulus dimensions: space, time, and color. Although channels in the mouse retina are also tuned to these dimensions, only achromatic spatio-temporal tuning based on rod inputs has been carefully investigated at the level of the cortex. Rod inputs are routed through relatively sluggish and spatially broad circuitry in the retina. The notion that cortical studies are based on rod inputs can be gleaned from the fact that visible wavelengths were able to drive all regions of the visual field; S-opsin dominates the cone mosaic in the ventral 2/3 of the retina and is only sensitive to UV wavelengths.
In our previous work, we showed that the dorsoventral opsin gradient in the mouse retina causes an "opsin map" in V1 and higher visual areas that correlates with the map of vertical retinotopy (Rhim et al., J. Neurophysiol. 2017). Our ongoing calcium imaging experiments measure the same opsin map in cortex as a means to determine graded levels of rod saturation, as a function of baseline luminance - as luminance falls, robust responses remain, yet the cone-opsin map is systematically lost. We will present data from this paradigm to show that standard in-vivo mouse vision experiments measure rod processing. We are also using this paradigm to measure differential contributions of rods and cones to spatio-temporal processing in V1. In addition to wild-type mice, rod-deficient KO mice (Gnat1 -/-) are being used in this series of experiments for a guaranteed pure cone condition. Under mesopic and photopic conditions, we are testing the hypothesis that color tuning is inseparable from spatio-temporal tuning, consistent with classical notions of color vs. form and motion. Our current results are that spatial frequency tuning is inseparable across both color direction and retinotopic location in mouse V1.

Title: Neuronal specialization for object size detection by higher order visual projection neurons in *Drosophila*

Authors: *C. STAEDELE, M. A. FRYE
Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Discerning an object from the visual panorama is essential for animal survival and a complex task that requires sophisticated neural algorithms. An important part of distinguishing objects from panoramic background is the extraction of salient features of objects such as size,

edges, contrast, and color. Feature-selective neurons seem to play a key role in this task and have been identified in several animals. Yet, how they detect and encode different attributes of objects such as object size is only partially understood. Despite possessing a low-resolution eyes and brains with fewer than a million neurons, *Drosophila melanogaster* shows superb capabilities for size-based classification of visual objects in that vertically elongated bars and small two-dimensional objects elicit behaviors of opposite valence. Our work focuses on Lobula Columnar (LC) neurons, a class of 22 anatomically similar visual projection neuron types in the fly lobula that have recently been suggested to be involved in higher order feature detection. We found that three out of 22 LC neuron classes show size-based responses to visual objects. Using two-photon optical imaging, we found that one is tuned to small two-dimensional objects (LC11), another is selective for elongated one-dimensional bars (LC15), and a third combines selectivity for both small objects and bars (LC12). None are excited by motion of the visual panorama. We hypothesized that this difference in size tuning is based on a unique channel composition and transcriptional profile of each LC type, plus different synaptic connectivity. Thus, we characterized the receptive field properties and found that all three LCs are tuned differently to e.g. vertical and horizontal object size, direction, motion, and contrast. Interestingly, blocking GABAergic inhibition abolished object selectivity in all three LC types and facilitated responses to panoramic gratings. We are currently testing the contribution of feed-forward inhibition to the size-based categorization of visual objects.

Title: Contribution of inhibitory cell types in mouse primary visual cortex to perceived contrast

Authors: *R. BLAZING, J. R. SIMS, R. KIRK, M. FOWLER, A. MCKINNEY, M. JIN, L. L. GLICKFELD
Duke Univ., Durham, NC

Abstract: Visual perception results from the concerted activity of functionally and morphologically diverse populations of neurons in the visual cortex. It is unclear, however, how the computations of distinct inhibitory cell types contribute to specific aspects of perception. The activity of parvalbumin-expressing (PV+) inhibitory interneurons regulates the gain of local

pyramidal cells in a manner that mimics changes in stimulus contrast (Atallah et al., 2012; Nienborg et al., 2013). In addition, the exogenous activation of PV+ cells in the primary visual cortex (V1) increases the threshold for detecting changes in contrast. Thus, we hypothesized that PV+ interneurons in V1 uniquely and specifically control perceived contrast. To test this hypothesis, we trained mice expressing the light-sensitive ion channel, Channelodopsin-2 (ChR2), in either PV+ or somatostatin-expressing (SOM+) interneurons in V1 on a head-fixed, two-alternative forced choice (2AFC) contrast discrimination task. In this task, the mouse is presented with two circular gabor stimuli of different contrasts in opposite visual hemi-fields, and must turn a wheel to indicate the higher contrast stimulus. We obtained a psychophysical readout of contrast discrimination by changing the relative contrast of the two stimuli. Regression analyses confirm that mice are performing the task by relying on the contrast ratio of the two stimuli, and not on the absolute target contrast. To determine the effect of the activity of specific interneuron classes on perceived contrast, we used blue light to stimulate ChR2-expressing PV+ or SOM+ cells in V1 during presentation of the visual stimuli. We found that activation of both PV+ and SOM+ interneurons in left V1 biased choice in the 2AFC task towards the left stimulus, indicating a decrease in the perceived contrast of the contralateral stimulus. Thus, we show that in the mouse, the contribution of V1 to contrast perception is not regulated by cell-type-specific mechanisms, but rather is generally mediated by inhibition. To assess whether the activity of these unique cell types specifically mediates the perception of contrast, we are currently training mice on a size discrimination task in which we vary the relative size of two same-contrast stimuli. We expect that if changes in PV+ and SOM+ activity specifically control perceived contrast, the effects of activation of these cell populations on behavior in the size task will be analogous to decreasing stimulus contrast. Together, these experiments will serve to elucidate the cortical computations underlying the perception of discrete visual features.

Title: Can the inclusion of a specialized sensory-preprocessing stage lessen the training requirements and improve the generalization behavior of a deep network?

Authors: *A. S. RIOS[1], G. C. MEL[2], V. AKOPIAN[1], L. ITTI[1], B. W. MEL[1]
[1]USC, Los Angeles, CA; [2]Stanford Univ., Palo Alto, CA

Abstract: Deep neural networks, which purport to represent the ventral visual processing stream, perform well at large scale object recognition benchmarks, yet exhibit several un-biological performance characteristics:
• They require massive quantities of human-labeled data
• Learning depends on high-precision mathematical operations
• Trained networks are highly susceptible to "adversarial" inputs
• Learning new material causes catastrophic forgetting of old material
Thus, modern neuromorphic software and hardware systems, while technically impressive, fall short of reproducing the remarkable learning capabilities and learning style of the human brain. The simplest theory to explain this constellation of undesirable traits is that modern neural network architectures lack the proper representational biases that would allow them to efficiently solve the biologically relevant problems given to them, particularly the specialized early sensory processing stages. In order to perform well on benchmark tests, therefore, these generic networks must be given too many parameters in too many layers, which leads to the demand for huge quantities of labeled data, and the need for high-precision gradient calculations during learning. At the behavioral level, these oversized and inefficiently parameterized models are slow to learn, are fooled by inputs that would never fool a biological vision system, and have difficulty incorporating new knowledge without destroying previously stored information [1,2].
Given the importance of contours for object classification [3], we hypothesized that pre-processing images with a commercial-grade contour detector that nominally replicates V1 functionality would simplify the learning task, such that attaining any given level of classification performance would require significantly less training data and time, and the resulting network would be less susceptible to egregious classification failures, catastrophic forgetting, etc. Our preliminary results indicate that the contour preprocessing does indeed significantly reduce network training requirements. Evaluation of the robustness of classification behavior under various challenges is ongoing.

Title: Disentangling feature complexity and pooling region size in metameric texture perception

Authors: *A. V. JAGADEESH, J. L. GARDNER
Psychology, Stanford Univ., Stanford, CA

Abstract: In peripheral vision, physically different images with similar high-order statistics can be indistinguishable, i.e. metameric. This suggests there are perceptual mechanisms that compute the presence of complex, high-order features and pool these over regions of visual space. Thus, stimuli with similar complex features can appear metameric even if those features are spatially scrambled within pooling regions. If so, both the complexity of features and the pooling region size should determine the degree of metamerism of visual textures. We tested this hypothesis by modifying an algorithm for generating textures using convolutional neural networks (CNNs) to allow control of both the complexity of matched features and the size of pooling regions. To control complexity, we generated stimuli that matched Gram matrices containing the inner product of pairs of filter activations across spatial locations at various CNN layers, since later layers compute more complex, nonlinear features. To control pooling region size, we divided the image into uniform sized square subregions and computed a Gram matrix within each subregion. Starting from a random image, we used gradient descent to generate textures that minimize the squared-error to the Gram matrices of an original image. We generated textures that were matched to 3 different layers of the VGG-19 network (pool1, pool2, pool4), at 4 different pooling region sizes (1.5, 2, 3, 6 degs width) for 20 natural images (6 degs). We conducted a visual search experiment to examine how these manipulations affect perceptual similarity. On each trial, subjects were shown the original image subtending 6 degs at fixation for 500ms. After a 500ms interstimulus interval, 4 images (the original and 3 textures generated to match a particular layer and pooling region size) were presented in each quadrant at an eccentricity of 10 deg for 2 s. During this time, subjects responded with a keypress to indicate which image was the original. Fixation on a centrally presented cross was enforced throughout the trial using eye-tracking. We found that both feature complexity ($F = 346.42$, $p < 0.001$) and pooling region size ($F = 68.59$, $p < 0.001$) had a significant effect on the percent of correct choices. Identification accuracy decreased monotonically with greater feature complexity and smaller pooling region size. These results suggest that both feature complexity and pooling region size contribute to visual metamerism and therefore suggest limits on the complexity of features accessible within regions of visual space in peripheral vision.
