Abstract: Shady is a software toolbox that enables precise visual stimulus presentation on mass-produced screens and video cards, without additional specialized hardware. It renders arbitrary stimulus patterns linearly with high dynamic range and high timing precision. It lets you manipulate them in real time while leaving the computer's central processor (CPU) free to perform other time-critical tasks. To do this, it provides a customizable, specialized "shader" program that runs on a graphics processor (GPU) and a high-level wrapper/programmer's interface in the Python programming language. It is available as open-source software: see http://shady.readthedocs.io
With increasing prevalence of multi-modal, integrative and real-time research approaches (such as those that hinge on neuro- and bio-feedback) specialized software components must evolve to avoid dominating users' programming environment, but rather to be good citizens. Shady is designed with this in mind. Its manifesto is:
(1) Precise control of every physical pixel of a display device (to avoid spatial artifacts);
(2) Minimization of "boilerplate" coding: it takes one short line of code to initialize the display and start the engine, one line to create a stimulus, and (often) one line to specify how some parameter of the stimulus should change over time; the housekeeping is done reliably and out of sight;
(3) Good citizenship I: minimization of CPU load. Shady pushes nearly the burden of frame-by-frame pixel-processing (including signal generation, animation, spatial windowing, contrast modulation in time and space, gamma correction, quantization, and dynamic-range enhancement tricks) onto the GPU, leaving the CPU largely free for other tasks; (4) Good citizenship II: compatibility. Shady's Python and C++ code has been confirmed to work on multiple platforms, including recent versions of Windows, macos and Ubuntu Linux. It does not require any proprietary software beyond the base operating system. Both Python 2 and 3 are supported, with graceful tolerance for variation in version-numbering, or even absence, of its few third-party dependencies;

(5) Good citizenship III: Windows-centricity. We bite the bullet and focus on Windows as our primary platform for performance optimization, because that is where support for specialized neuroscience hardware and novel human interaction devices is most prevalent.

Title: Curveball: A tool for rapid measurement of contrast sensitivity based on smooth eye movements

Authors: *G. T. PRUSKY[1,2], S. W. J. MOONEY[1,2], J. HILL[1,2], M. S. TUZUN[1,2], N. M. ALAM[1], J. B. CARMEL[1,2]

Abstract: The contrast sensitivity function (CSF) is a highly informative measure of visual system performance and is well correlated with many other measures of visual health and disease. Unlike other measures of spatial visual function, the CSF describes a contour in the two-dimensional space of contrast sensitivity and spatial frequency, and is consequently more challenging to assess than one-dimensional measures such as visual acuity. The time required to measure multiple contrast thresholds with conventional psychophysical staircase procedures is prohibitive in most clinical settings. Here, we describe an efficient new contrast sensitivity measurement tool, 'Curveball', that continuously infers stimulus visibility through smooth eye tracking instead of perceptual report. Curveball moves a band-limited image on a computer screen, measures gaze velocity with an eye tracker and employs an adaptive algorithm to determine the extent to which the eyes move in concert with the image. If a participant smoothly follows the image with their eyes, as most do instinctively, stimulus features are changed in real time to a lower contrast until they can no longer follow, which quantifies the limit of ability. Our findings provide strong evidence that Curveball is a reliable, accurate, and efficient objective measure of contrast sensitivity at working distance. Task repeatability was high, both within the same session (coefficient of repeatability of $\log_{10}$ threshold contrast was 0.275) and across different days (0.227). It was consistent across changes in room illumination suggesting that it is suitable for clinical settings. The procedure produces CSFs that are (a) systematically related to the CSFs obtained from both static and moving stimuli in a conventional staircase task and (b) highly predictive of the difference between corrected and uncorrected eye chart acuity. Curveball

contrast sensitivity estimates change in predictable ways as the user moves closer to the screen, and the algorithm's ability to detect smooth tracking appears to degrade only gradually as viewing distance varies between the optimal and maximum distance allowed by the eye-tracker. This suggests that the participant's distance can be continuously monitored using the eye-tracker and used to compute the true spatial frequencies being measured in each trial when estimating the CSF. The display-mounted eye tracker used here required only a 500ms one-point calibration at the start of the task for our smooth pursuit matching algorithm to perform well. Overall, our findings indicate that Curveball is a promising means of accurately assessing contrast sensitivity in previously neglected populations.

Title: Multiple sensory inputs modulate a short-lived sleep-like state in *C. elegans*

Authors: *D. L. GONZALES[1,2], J. ZHOU[3], J. T. ROBINSON[2,1,3,4]
[1]Applied Physics, [2]Electrical and Computer Engin., [3]Bioengineering, Rice Univ., Houston, TX; [4]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: To survive in complex environments, animals must evaluate information from multiple senses and select an appropriate behavioral response. Indeed, multisensory integration is a major function of the nervous system, but difficulties in simultaneously quantifying both the behavioral and neural state of an animal while controlling multiple sensory stimuli presents challenges in studying this phenomenon. Here, we describe a short-lived, sleep-like state in *C. elegans* that is amenable to whole-brain imaging, quantitative behavioral phenotyping, and microfluidic control of the external environment. When confined in microfluidic chambers for 1 hr, adult animals transition between periods of normal activity and short quiescent bouts hallmarked by a complete cessation of locomotion. The quiescent state, we call μSleep, begins and ends spontaneously, lasts an average of 1-2 min, and meets some of the basic criteria for sleep behavior. In addition, we have discovered that the geometry of the confinement chamber, available fluid volume, fluid flow rate, temperature, and satiation state can all increase and/or decrease the prevalence of quiescent bouts. These results suggest that multiple sensory pathways

converge to drive μSleep. To identify the circuits involved in regulating μSleep, we investigated how loss-of-function mutations in dopaminergic, serotonergic, octopaminergic and stress-related neural circuits affect the quiescent phenotype. Furthermore, we used whole-brain imaging to determine whether the global brain dynamics during μSleep, and other *C. elegans* sleep states, are independent of environmental cues. Together, these results shed light on how the nervous system integrates multiple sensory inputs to control transitions between behavioral states.

Title: The effects of early sensory deprivation on multisensory thalamocortical and intracortical connections

Authors: *J. HENSCHKE[1], T. MACHARADZE[2], A. M. OELSCHLEGEL[3], J. M. PAKAN[4], J. GOLDSCHMIDT[5], P. O. KANOLD[6], E. BUDINGER[7]

Magdeburg, Magdeburg, Germany

Abstract: The nervous system integrates information from multiple senses. This multisensory integration already occurs in primary sensory cortices like A1, S1, and V1 via direct cross-modal thalamocortical and corticocortical connections. In humans, sensory loss that occurs from birth results in functional recruitment of the deprived cortical territory by the spared senses during subsequent development. However, the underlying neural circuit changes accompanying this recruitment are poorly understood. Here, using anatomical tracer injections into three primary sensory cortices (A1, S1, and V1) in a rodent model (Mongolian gerbil), we show that early auditory, somatosensory, or visual deprivation increases the multisensory connections of these areas at the end of the critical period (P28). The anatomical changes encompass lemniscal, non-lemniscal sensory specific, as well as multisensory pathways and are due to axonal reorganization processes but not apoptosis or neurogenesis of projecting neurons. Furthermore, the axonal remodeling is mediated by non-lemniscal thalamic nuclei and the primary areas themselves. Functional single-photon emission computed tomography imaging (SPECT) of regional cerebral blood flow revealed a largely reduced stimulus-evoked activity but a higher functional connectivity specifically between primary areas in deprived compared to non-deprived

animals. Since supragranular pyramidal neurons are the main targets of intracortical and also some thalamocortical connections, we subsequently investigated their morphology in deprived vs. non-deprived animals at P28 using the Golgi-Cox method. Scholl and branch analyses showed that early sensory deprivation leads to a general increase of dendritic branching, i.e., to longer and more widely branched basal and apical dendrites in both the deprived and spared cortical areas. In contrast, the overall number of dendritic spines decreased and accordingly, overall spine density was also decreased. This suggests that the loss of early sensory experience also induces a refinement of intracortical multisensory connections by pruning of dendritic spines at the end of the critical period. Consequently, stimulus-induced activity is decreased but functional connectivity increased.

Title: Early loss of vision leads to enhanced performance on tactilely mediated behaviors in the short-tailed opossum (monodelphis domestica)

Authors: *M. ENGLUND[1], C. IYER[2], S. FARIDJOO[2], L. KRUBITZER[2]
[1]Psychology, Univ. of California Davis, Auburn, CA; [2]Univ. of California Davis, Davis, CA

Abstract: Early loss of vision has been shown to induce massive cross-modal changes in the size, connectivity, and functional organization of cortical areas devoted to processing inputs from both the lost sense, as well as the spared senses. Specifically, neurons in visual cortex respond to auditory and tactile stimuli, and patterns of thalamocortical and corticocoritcal projections are altered. In addition, connections of somatosensory cortex and the neural response properties of S1 are altered in animals with early loss of vision. However, the behavioral correlates of this neural reorganization have yet to be examined. Using two naturalistic sensorimotor tasks in the Brazilian short-tailed opossum *(Monodelphis domestica),* the *ladder rung walking task* and *skilled reaching task,* this study examined how the early loss of vision leads to enhanced performance on behavioral tasks relying on the spared senses. Early-blind opossums significantly outperformed sighted controls in both tasks in the light and dark, committing less errors on average on the variable ladder task, and increased performance in skilled reaching. Neither crossing time nor top performers were found to drive ladder rung walking error. Additionally,

handedness and angle of approach did not contribute to skilled reaching success. Further, we show the reliance of tactiley mediated discrimination in these tasks was predominantly on the whiskers, since whisker trimming resulted in significantly decreased performance. These results suggest that not only does the early loss of vision alter the organization and connections of both the targeted and the spared sensory systems, but that these changes appear to generate adaptive discriminatory behavior mediated by the spared sensory systems.

Title: Associative interaction among sensory cortices consolidated by the first and second-order conditionings

Authors: G. TASAKA[1], M. YAMASHITA[2], Y. IDE[4], *E. HIDA[3], T. AIHARA[2]
[1]Grad. Sch. of Engin., [2]Tamagawa Univ., Tokyo, Japan; [3]Tamagawa Univ., Machida 194, Japan; [4]Pharmacol. Evaluation Inst. of Japan (PEIJ), Kanagawa, Japan

Abstract: In our previous study, not only the somatosensory cortex but also the auditory cortex was activated by the electrical foot-shock after a fear conditioning with a foot-shock and a tone-stimulation in guinea pigs. Those activations were simultaneously observed in the recording area covering two sensory cortices by using optical imaging method with a voltage sensitive dye. The result suggests that the associative response was represented by the conditioning with sensory stimuli. However, information representation and consolidation mechanisms of inter-cortical associative interactions for various sensory inputs are still unclear.
In the present study, in order to investigate how various sensory information are consolidated in inter-cortical networks, cortical activations in somatosensory, auditory and visual area were simultaneously measured using the optical imaging method after the first- or second-order conditionings with three sensory stimuli (foot-shock, tone, and light) were performed for guinea pigs.
As a result, we found that not only the main sensory area for an applied stimulus but also the other sensory areas for stimuli used the conditioning came to be activated after conditionings. For example, both somatosensory cortex and visual cortex came to be activated by the foot-shock after the second-order conditioning with three sensory stimuli. In addition, those responses were activated by direct electrical stimulation to the other cortical area. It shows that new connections were consolidated among cortical areas by conditionings. While, it has been reported that projections to sensory areas through amygdala and medial geniculate nucleus

relating cholinergic pathway were facilitated and associative responses was observed in cortical areas. Consequently, our results suggest that existing pathways were facilitated and strengthened by conditionings with sensory stimuli, and additional new information pathways were induced.

Title: Connectivity of ferret multisensory cortical LRSS area assessed by tracer (BDA) and by rsfMRI methods

Authors: *M. A. MEREDITH[1], E. H. PRICKETT[2], R. P. GULLAPALLI[3], S. TANG[3], A. E. MEDINA[4]

Abstract: The present study examined the connectivity of an auditory-tactile multisensory area in ferret cortex, the lateral rostral suprasylvian sulcal area (LRSS) using two methods that evaluate neural connections: neuronal tract tracing and resting state functional magnetic resonance imaging (rsfMRI). For tract tracing, anesthetized adult ferrets (n=3; 2 females) received pressure injections of tracer (Biotinylated Dextran Amine-BDA, 3kMW) in the LRSS. Following transport, euthanasia and post-fixation processing, BDA labeled neurons were plotted from serial coronal sections of cortex using Neurolucida. Areal locations were determined using an atlas of ferret cortex (Zhou et al., 2016) and revealed that 39% of ipsilateral projections to LRSS originated from somatosensory cortices (S1, S2, S3; PSSC, MRSS), 37% from auditory areas (A1, AAF, ADF/AVF, PPF/PSF, VP) and where 30% of all connections arose from S2 (16%) and A1 (14%). Resting state functional MRI (rsfMRI) was performed on adult ferrets (n=6, male) using a 7T animal MRI system. Regions of interest (ROIs) were defined using the same ferret atlas (Zhou et al., 2016). Correlation coefficients between the time course of LRSS and other ROIs were transformed to a connectivity z-score using Fisher's transformation. Averaged connectivity with somatosensory areas (S1, S2, S3, PSSC, MRSS) was 0.88, while averaged connectivity with auditory areas (A1, AAF, ADF/AVF, PPF, PSF) was 0.41. Areas with highest LRSS average connectivity scores were the somatosensory MRSS (z = 1.37) and

auditory ADF/AVF (z = 0.52). These results show that both tracer injection and rsfMRI methods demonstrate LRSS connectivity with ipsilateral somatosensory and auditory cortical cortices, consistent with the prevalence (68%) of multisensory somatosensory-auditory neurons in the LRSS. However, regions of highest connectivity varied with methodology: that with the highest rsfMRI correlation scores may be accounted for by possible bidirectional connections with the LRSS, which were not sampled by tracer methodology. Ultimately, both sets of findings support the convergence of connections with somatosensory and auditory cortices as a basis for multisensory processing within the LRSS.

Title: Comparison of visual processing during visual-only and audiovisual contexts in the mouse primary visual cortex

Authors: *J. MCCLURE, JR[1,2], H. KHDOUR[2], P.-O. POLACK[2]
[1]Newark, NJ; [2]Behavioral and Neural Sci., Rutgers Univ., Newark, NJ

Abstract: Classically, multisensory integration was described as occurring in higher-order sensory cortices. This notion was recently challenged in studies demonstrating that the presence of sounds modulates visually evoked activity in the primary visual cortex (V1). However, the net effect of sound modulation on orientation encoding by V1 neurons is still debated. Moreover, the involvement of direct projections from the primary auditory cortex (A1) to V1, during visual processing, remains unclear. The goal of our study is [1] to determine how sound modulation of visually evoked activity in V1 affects orientation encoding and orientation perception, and [2] to test whether sound-induced modulation of visual processing in V1 cannot be attributed, at least in part, to non-specific mechanisms such as an increase in arousal in an audiovisual context.
To address these questions, we performed two-photon calcium imaging in the V1 of mice injected with GCAMP6f, while presenting blocks of audiovisual and visual-only stimuli. At the end of the recording session, we assessed the orientation tuning of the imaged neurons by presenting a series of drifting gratings of 12 evenly spaced orientations. We analyzed the distribution of the preferred orientation of V1 neurons responding to the visual stimulus as well as the orientation encoded by V1 neuronal population activity during the visual stimulus

presentation. We found an improvement of the encoding of visual information during audiovisual blocks compared to visual-only blocks. The improvement of orientation encoding in V1 was due to a potentiation of the response from V1 neurons tuned for the visual stimulus orientation, while the activity of neurons tuned for either the orthogonal orientations or for the opposite direction were decreased. This finding suggested that orientation perception could be facilitated in the audiovisual context, in particular when discriminating visual stimuli that activate overlapping neuronal populations. We tested this hypothesis by training mice to perform a Go/No-Go orientation discrimination task. Once trained to lick for an oriented cue and withhold liking for a cue of orthogonal orientation, the angular distance between the Go and No-Go cues was progressively decreased. We found that at the limit of orientation discriminability, mice performed better during audiovisual blocks than when visual cues were presented in isolation. Finally, we found that during audiovisual blocks, the mouse pupil was more dilated, which suggested that audiovisual cues enhanced arousal and likely participated in the modulation of visual processing in audiovisual contexts.

Title: Multisensory processing of external salinity by larval zebrafish

Authors: *K. J. HERRERA, F. ENGERT
MCB, Harvard Univ., Cambridge, MA

Abstract: Avoiding unfavorable environments is a critical task for all organisms. For larval and adult zebrafish, bodies of water with high salinity represent such environments. However, the mechanisms by which information about external salt content is detected and transformed into an appropriate behavioral response are unknown. Here, we first assay the avoidance response to salinity using various concentrations and ion types. Then, we use volumetric imaging with light-sheet microscopy to identify brain regions that can detect external salt concentrations. We identify a range of chemosensory modalities that can encode salt concentrations, including olfaction as well as, surprisingly the lateral line. Currently, we are using chemogentic approaches to determine how these different modalities contribute to the generation of avoidance responses.

Title: Claustral neurons projecting to the anterior cingulate cortex receive preferential synaptic inputs from higher order and not primary sensory cortical regions

Authors: *Z. CHIA[1,2], G. J. AUGUSTINE[2], G. SILBERBERG[1]
[1]Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden; [2]Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract: We previously characterized the intrinsic electrical properties of claustrum neurons that project to the anterior cingulate cortex (ACC). Here we have determined (1) whether these neurons relay information to the ACC from different cortical regions and (2) where inputs are received in the ACC. The ACC of mice were injected with retrograde beads, to identify claustrum neurons projecting to ACC, while anterograde virus expressing channelrhodopsin-2 (ChR2) was injected into various cortical regions to label neurons projecting to the claustrum. Whole-cell patch clamp recordings were made from bead-labelled claustrum neurons and synaptic responses were evoked by photostimulation of ChR2-expressing cortical axon terminals. Photostimulation of terminals from multiple cortical regions evoked monosynaptic EPSPs in claustrum neurons. Cortical areas exciting the claustrum included the contralateral ACC, orbitofrontal cortex and insular cortex. Connection probability from higher cortical areas (such as the contralateral ACC and insular cortex) to the claustrum was 10-fold higher compared to claustral input from sensory areas, including primary somatosensory, visual, and auditory cortices. To characterize the synaptic inputs to the claustrum, the insula-claustrum pathway was probed in more detail. Claustrum neurons receive synaptic input only from the ipsilateral insula. Additionally, these insula projections arise primarily from Layer 5. Dual recordings showed that both claustrum projection neurons and parvalbumin (PV) expressing interneurons receive insula input. PV interneurons received stronger and faster synaptic inputs from insula, suggesting a feedforward inhibitory pathway within the claustrum microcircuitry. Finally, the site of claustrum projections on the ACC was investigated by recording from neurons in different layers of the ACC. We found that claustrum projections send monosynaptic excitatory projections to all layers of the ACC (Layers 1, 2/3, and 5/6). In summary, multicortical integration takes place in the claustrum at a population level, evident by ACC-projecting claustrum neurons receiving input from multiple cortical areas. These ACC-projecting claustrum neurons synapse on all

layers of the ACC. The insula-claustrum-ACC circuit may underlie the “Salience Network”; this is the first evidence of functional intercortical connectivity mediated via the claustrum.

Title: Toward a unified coding of motion: Multisensory integration of moving visual and somatosensory cues in the associative parietal cortex (APC) of the rat

Authors: *J. CARON-GUYON, J. CORBO, Y. ZENNOU-AZOGUI, C. XERRI, N. CATZ
Sensory and Cognitive Neurosciences Lab., Aix-Marseille Univ., Marseille, France

Abstract: The central nervous system is able to create a stable representation of our own movements in a constantly moving environment. Most frequently, motion information is available concurrently through different sensory channels. Combining multisensory inputs facilitates the elaboration of a motion percept by disambiguating sensory cues, allowing to distinguish object-motion from self-motion. The Middle Temporal area (MT) is dedicated to the processing of visual motion stimuli. For other sensory modalities, however, no specific motion area has been identified. Gathering and processing all sensory information about motion in a unique area could be a parsimonious way to build up a unified percept. Recent investigations suggested a role of MT in multisensory integration of motion. This study aims at characterizing this multisensory integration in the rat’s APC, a potential homolog of MT located at the interface of the primary visual (V1) and somatosensory (S1) cortices. To mimic both exo- and egocentric motions, we presented visual gratings and applied air puffs to the whiskers. To assess whether different sensory inputs reached the APC, we used voltage sensitive dye imaging and found that visual and somatosensory stimuli-evoked activations, respectively in V1 and S1, propagated and converged into that region. To characterize the neuronal responses in this area, we recorded the activity of over 900 single units in the APC and showed that this region contains unimodal (visual or tactile only) neurons (27%). Direction selectivity is a main and defining characteristic of MT neurons, which enables the processing of visual motion. We have been able to comparably reveal this property in APC visual neurons, which fired only to one preferred direction. Remarkably, the somatosensory neurons also showed direction selectivity during whisker displacement, proving APC’s ability to compute motion from several channels. To be considered as a multisensory integration area, the APC must also contain multimodal neurons that extract and combine unimodal motion features. We showed that 61% of the recorded units were multimodal, significantly responding to both sensory stimuli. Visual and somatosensory

direction selectivity was also observed in these bimodal neurons, meeting the requirement for potential multisensory integration of motion. By combining the unisensory stimulations in congruent and incongruent situations, we revealed that the two recorded populations of APC neurons displayed multisensory integrative processes, depending on the stimulation patterns. These results strongly suggest that APC, potential homolog of MT, is a multimodal hub for motion processing.

Title: Parietal inputs convey multisensory visuo-tactile synaptic inputs to nociceptive-sensitive midcingulate circuits and facilitate their premotor output

Authors: *S. PAPAIOANNOU, E. MALININA, A. TRIPATHI, P. MEDINI
Integrative Med. Biol. (IMB), Umeå Univ., Umea, Sweden

Abstract: Parietal areas are multisensory and their output is conveyed to prefrontal, premotor cortical targets in all mammals studied so far. However, how multisensory synaptic inputs conveyed by identified parieto-frontal streams are processed when the prefrontal target is activated by an adequate stimulus, as well as the functional impact of such projection on the premotor output of the target area, remain to be elucidated at synaptic and microcircuit level. To address these questions, we used the prefrontal projection of the multisensory, visuo-tactile parietal area RL to midcingulate cortex as an approachable model system in the mouse, suitable for microcircuit investigation. Intra and extracellular recordings revealed that association parietal area RL drives subthreshold but also suprathreshold visuo-tactile responses in the target, posterior midcingulate (pMC) cortex, and that the target pMC spot showed multisensory enhancement. pMC revealed to be a pain-sensitive circuit as nociceptive stimulation triggered a long-lasting UP-state-like depolarization that were accompanied by an abrupt switch of the ongoing firing rate (decreased if it was tonically active and increase in case of silence) in a layer-specific pattern. In vivo whole-cell recordings in other visual areas (visual cortex) as well as functional neuroanatomy with c-fos activation, showed that this pattern of pain-driven activation was area-specific. Synaptic multisensory responses increased in amplitude in a subset of neurons

and had a shorter duration during nociceptive stimulation. We next investigated the functional impact of the parietal synaptic inputs onto the premotor output of pMC. Electromyography showed that pMC intracortical microstimulation induced bilateral whisker movements whose amplitude and duration were robustly facilitated by parietal RL activation. pMC-evoked movements had partially a premotor character as the pMC spot innervated by RL was reciprocally connected to a division of M1, whose optogenetic inactivation reduced the amplitude of pMC-driven whisker movement. Taken together, our data show the circuit and synaptic basis behind pMC acting as a sensory-motor hub that triggers faster and stronger visual-tactile motor responses during nociceptive stimulation. Our study reveals and elucidates at the microcircuit and synaptic levels the intrinsic susceptibility of cingulate prefrontal circuits to respond to both nociceptive and parietal inputs, we also provide the first evidence and further discuss the impact on the behavioral level.

Title: Sensory projections towards the mouse posterior parietal cortex

Authors: *S. R. GILISSEN[1], K. BUTTIENS[1], K. FARROW[2], V. BONIN[3], L. ARCKENS[1]
[1]KU Leuven, Leuven, Belgium; [2]NERF / Imec, Leuven, Belgium; [3]Imec NERF, Leuven, Belgium

Abstract: The posterior parietal cortex is a brain region responsible for the processing of spatial information and orientation. This involves for example the spatial ratios between objects and the position of our body to ensure proper movement trajectories or visual attention. To carry out its function, the posterior parietal cortex needs to receive information from the different sensory modalities. In humans and primates this brain region is therefore known as a multisensory area, which is not surprising since it is anatomically situated between the somatosensory, visual and auditory cortical regions. At the behavioral level, the posterior parietal cortex thus contributes to spatial navigation, perceptual decision making as well as multisensory integration. All these features make it highly likely that the posterior parietal cortex is involved in cross-modal cortical recovery processes upon sensory loss. Our research group validated the adult monocular

enucleation mouse model to study this type of plasticity. In this model the deprived visual cortex becomes reactivated by whisker inputs from the spared somatosensory modality. Seven weeks post enucleation, maximal whisker-driven reactivation of the visual cortex is reached (Van Brussel et al., 2011). To create knowledge about the intricate cortical network that drives this recovery from late-onset loss of vision we initiated a connectome study to identify posterior parietal cortex in the mouse in order to validate that this plasticity process indeed relies on the posterior parietal cortex as a hub to transfer information from the somatosensory cortex to the visual cortex. We investigated what cortical subregions may entail the posterior parietal cortex in the mouse and what the specific sensory inputs are from the various sensory cortical areas. We predict that mouse PPC exists of the secondary visual regions RL, A and AM. By using a retrograde tracing approach, where modified Herpes Simplex virus was injected in these regions, we revealed that they indeed have different projection patterns originating from somatosensory, auditory and visual cortex typical for multisensory cortical regions encompassing the posterior parietal cortex. In sum we were able to identify an anatomical substrate that may carry somatosensory inputs to mouse visual cortex upon vision loss.

Title: Cross-modal plasticity of inhibitory thalamic gating in adults

Authors: *D. CHAKRABORTY, J. L. WHITT, H.-K. LEE
Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Loss of one sensory modality initiates compensatory changes in the spared senses which are generally referred to as cross-modal plasticity (Bavelier and Neville, 2002). We previously reported that loss of vision causes potentiation of thalamocortical (TC) inputs to promote relay of auditory signals in the primary auditory cortex (A1) (Petrus et al., 2014). We hypothesized that TC plasticity may be due to changes in the inhibitory gating of sensory thalamic nuclei. The primary inhibition onto visual thalamus (lateral geniculate nucleus, LGN) and auditory thalamus (medial geniculate body, MGB) comes from a common source, the thalamic reticular nucleus (TRN). To determine if TRN inputs to these primary sensory thalamic nuclei are altered by sensory deprivation, we stereotactically injected double-floxed ChR2 (DIO-

ChR2) into TRN of parvalbumin-Cre or somatostatin-Cre mice to measure the inhibitory synaptic transmission of reticular-thalamic synapses in LGN and MGB. Measurements were done by performing whole-cell recordings in the LGN, MGB, and TRN of three-month-old normal reared mice and mice deprived of vision for 1 week prior to the recordings. We found that visual deprivation differentially alters the inhibitory synaptic strengths at TRN-LGN and TRN-MGB synapses and changes the efficiency of transmission of high-frequency stimulation at TRN-MGB synapses. These findings show that the adult thalamus undergoes experience-dependent plasticity specifically by regulating the inhibitory gating in reticular-thalamic synapses and thus have functional significance for cross-modal sensory adaptation in adults.

Title: Cross-modal gain control in sensory thalamus

Authors: *M. LOHSE, J. C. DAHMEN, V. M. BAJO-LORENZANA, A. J. KING
Dept. of Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: Considerable attention has been focused on the involvement of cortical areas in multisensory processing. Although visual and somatosensory influences on auditory responses can arise via direct corticocortical pathways, it is likely that some aspects of multisensory cortical processing are inherited from the thalamus. However, we currently know much less about the nature of the multisensory interactions or the circuits involved in sensory thalamus. Using electrophysiology, 2-photon imaging of thalamocortical axons and optogenetics, we investigated multisensory interactions within different divisions of the medial geniculate body (MGB) and the local circuits underlying these effects in mice.
Auditory responses were found to be reliably suppressed (~ 25 % reduction in firing rate across neurons) by somatosensory inputs in both the ventral and dorsal divisions of the MGB. Auditory responses in the more medial structures (medial division of MGB/posterior intralaminar nucleus and suprageniculate nucleus) were facilitated by somatosensory stimulation, with a subgroup of

these medial neurons also being driven by whisker deflection.
Somatosensory suppressive influences were also found in auditory cortex, but absent in the auditory midbrain. In vivo 2-photon calcium imaging of auditory thalamic axons revealed that only the somatosensory inhibitory control of auditory thalamus was relayed to auditory cortex. Optogenetic activation of primary somatosensory cortex (S1) suggests that the pathway from S1 to thalamus is sufficient for mediating this cross-modal gain control. Using a disynaptic circuit tagging approach between sensory thalamic nuclei, we are currently aiming to understand the intra-thalamic circuit contributions to the cross-modal gain control between somatosensory thalamus and auditory thalamus.
Our results suggest that sensory thalamus and surrounding circuits provide an important substrate for cross-modal gain control of auditory inputs.

Title: Effects of congenital blindness on olfactory functions and brain plasticity

Authors: J. THIBAULT, E. LUNA AMIRAULT, G. BRONCHTI, *S. AL AIN
Anat., Univ. Du Québec à Trois-Rivières, Trois-Rivieres, QC, Canada

Abstract: Early blindness clearly results in an enhancement of auditory and tactile performances, associated with dramatic cerebral structural and functional changes. On the other hand, human studies showed contradictory results regarding olfactory abilities in early blind individuals. However, recent studies found that olfactory bulb is larger in blind than in sighted humans and visual cortex is activated by olfactory exposure in blinds only. So far, the impact of congenital blindness on olfactory functions and its underlying neurobiological basis remain poorly understood. The present study aims to determine the effects of blindness on olfactory functions and brain plasticity in mouse model of congenital blindness. We used the ZRDBA mouse strain, a unique mouse model, from which half of newborns are sighted and half are anophthalmic. In this study, a series of behavioral tests were performed on 20 anophthalmic and 20 sighted mice to assess their olfactory performances (i.e., odor sensitivity, discrimination, localization, memory tasks). To investigate olfactory processing in the brain, mice were exposed to a 5-minute odor stimulus. After perfusion, the brains were collected, frozen, and cut to

perform serial sections for immunohistochemistry analysis. Preliminary results indicate that anophtalmic mice exhibit higher olfactory abilities in most of behavioral tasks. Ongoing immunohistochemistry analysis will test whether enhanced olfactory performance in blind mice may correlate with structural changes and functional alterations in olfactory processing areas and in the visual cortex. This research brings a better understanding of the impact of visual deprivation on olfactory functions and the underlying neuronal mechanisms.

Title: Biologically plausible deep learning with segregated dendrites and multiplexing

Authors: *J. GUERGUIEV[1], T. MESNARD[3], B. A. RICHARDS[2]
[1]Univ. of Toronto Scarborough, Toronto, ON, Canada; [2]Biol. Sci., Univ. of Toronto Scarborough, Scarborough, ON, Canada; [3]École Normale Supérieure, Paris, France

Abstract: Deep learning refers to learning in networks of neurons with many layers of synaptic connections. While there is growing evidence that the cortex is able to learn complicated tasks using some form of deep learning, it remains unclear how this occurs. This is called the 'credit assignment' problem. In the machine learning world, techniques for achieving deep learning with artificial neural networks (ANNs) have been wildly successful in learning tasks such as image recognition, natural language processing and navigation, in some cases even surpassing human performance. While deep ANNs were originally inspired by the brain, the state-of-the-art learning rules used to train them are wildly biologically implausible for many reasons. As a result, there has been limited impact of AI advances on neuroscience.
The present work helps to unify deep learning principles from AI with what we know about the physiology of the brain in order to help explain how the cortex enables powerful learning abilities. We demonstrate a biologically plausible form of deep learning with ensembles of neurons. Our model makes use of the unique morphological properties of pyramidal cortical neurons (namely, that they have two groups of dendrites that are electrotonically segregated), as well as the theory that ensembles of neurons can communicate two information streams encoded

separately in their *event rates* and *burst probabilities* (called multiplexing). Our model also makes use of inhibitory interneurons to shape activity at apical dendrites in a way that ensures proper credit assignment. The combination of inhibitory input, multiplexing and segregated dendrites may enable cortical circuits to perform credit assignment through many layers of synaptic connections without needing separate phases of learning.
Our model demonstrates that biologically plausible deep learning can be accomplished using segregated dendrites and multiplexing of bottom-up and top-down signals, therefore providing a unique interpretation for the morphology of cortical neurons. It also generates several experimental predictions about the types of signals that are communicated in bottom-up and top-down information streams, and how top-down feedback at apical dendrites shapes plasticity in the neocortex. This work is important for helping to further our understanding of how deep learning can be implemented by biological networks of neurons to enable the powerful learning capabilities of the brain.

Title: Can machine learning models account for predictive coding-like features observed in sensory cortex?

Authors: *C. J. GILLON, J. GUERGUIEV, B. A. RICHARDS
Biol. Sci., Univ. of Toronto Scarborough, Scarborough, ON, Canada

Abstract: Sensory processing in the brain relies on a hierarchy of regions which respond to increasingly complex stimulus features. Computational neuroscientists have postulated that this structure implements a predictive coding system, whereby each region sends predictions of the inputs it expects to lower-order regions, allowing the lower-order regions to efficiently propagate only prediction errors, i.e. unexpected or novel features of stimuli. This hypothesis has multiple lines of support: (1) predictive coding models trained on natural images develop similar receptive fields to those seen in visual cortex areas like V1, (2) top-down predictive signals and (3) prediction error signals have been found in sensory cortex. However, although these findings are consistent with predictive coding, there are other forms of hierarchical statistical model used

in machine learning that might also show these properties, but which are rarely considered by neuroscientists. Here, we investigate three such models that are effective at solving visual tasks: the bidirectional Helmholtz machine, variational autoencoder, and generative adversarial network. If V1-like receptive fields, and prediction and error signals also emerge in some or all of these models, this would suggest that the predictive coding model should be considered just one possible explanation for existing neuroscience data. We then show preliminary two-photon recording data showing population dynamics in mouse visual cortex in anticipation of expected stimuli (2) and in response to unexpected stimuli (3). By comparing these dynamics to predictions drawn from the models, we can begin to establish which, if any, the brain is most likely implementing during sensory processing.

Title: Neural correlates of sound symbolic crossmodal correspondences

Authors: *S. M. LIST[1,2,3], S. LACEY[5], L. C. NYGAARD[4], K. SATHIAN[5]
[2]Neurol., [3]Grad. Div. of Biol. and Biomed. Sci., [4]Psychology, [1]Emory Univ., Atlanta, GA;
[5]Neurol., Milton S. Hershey Med. Ctr. & Penn State SOM, Hershey, PA

Abstract: Humans share consistent associations, known as crossmodal correspondences (CCs), between seemingly unrelated features in different sensory modalities. While one of the fundamental properties of language is the assumed arbitrariness between sound and meaning, sound symbolism is a notable exception that has been studied empirically using CCs between auditory pseudowords (e.g. ‘loh-moh’ and ‘kee-kay’) and visual shapes (e.g. rounded or pointed). The characteristics of the neural signals that underpin sound symbolic CCs are not well understood. Here, we report the results of a functional magnetic resonance imaging (fMRI) study that examined blood oxygenation level dependent (BOLD) responses to auditory pseudowords and visual shapes. Participants also provided post-scan perceptual ratings of roundedness and pointedness for a range of auditory nonwords and visual shapes. Representational dissimilarity matrices (RDMs) for the perceptual ratings of the auditory and visual stimuli were significantly correlated ($r = 0.93$, $p<0.0001$), indicating a close relationship between ratings in the two modalities. During fMRI scanning, participants attended to pairs of audio-visual stimuli and responded that the pairs either matched (congruent pairs e.g. ‘kee-kay’ and pointed shape or ‘loh-

moh' and rounded shape) or did not match (incongruent pairs e.g. 'kee-kay' and rounded shape or 'loh-moh' and pointed shape). Behaviorally, participants were faster to respond to the congruent pairs than the incongruent pairs, indicating their sensitivity to sound symbolic CCs. For a univariate contrast comparing BOLD activity during the perception of congruent pairings to that during the perception of incongruent pairings, the BOLD signal was stronger for the congruent condition in areas important for multisensory integration, such as the right posterior superior temporal sulcus, as well as areas in auditory and visual cortex, and in areas important for attention, such as the right inferior frontal gyrus. This research provides insights into the fundamental nature of sound symbolic CCs and how they might evoke specific interpretations of physical meaning in natural language at the perceptual and neural levels.

Title: Age-related hearing loss impacts functional connectivity at rest

Authors: *S. ROSEMANN[1,2], C. M. THIEL[1,2]
[1]Univ. of Oldenburg, Oldenburg, Germany; [2]Cluster of Excellence "Hearing4all", Oldenburg, Germany

Abstract: Previous research investigating cortical plasticity in age-related hearing loss provides evidence for cross-modal reorganization in the auditory cortex, additional recruitment of the frontal lobe and increased coupling of visual and auditory cortex for matching audio-visual input. These changes already occur after mild to moderate impairment and not only after severe hearing loss. By using functional magnetic resonance imaging (fMRI), we here investigated the influence of mild to moderate hearing-impairment on functional connectivity during resting state. Nineteen hearing-impaired subjects with a mean age of 63.5 ± 5.3 years and nineteen normal-hearing participants with a mean age of 63.2 ± 5 years participated in the study. The group of hearing-impaired subjects showed a uniformly varying degree of mild to moderate and symmetrical age-related hearing loss. The measurement included a resting state MRI, as well as assessment of listening effort and the McGurk illusion outside the MRI. In this study, our main aim was to relate high-frequency hearing loss to changes in network dynamics during resting state. Additionally, the relation of listening effort and McGurk illusion with resting state connectivity was investigated. Regions of interest included visual and auditory cortex as well as the default

mode network, salience network, dorsal attention network and frontoparietal network. Behaviorally, the hearing-impaired group showed a significantly higher listening effort and significantly stronger McGurk illusion. At the neural level, between-group comparisons showed an increased positive correlation in the salience network for hearing-impaired participants as well as an increased negative correlation in the dorsal attention network in normal-hearing participants. The multiple regression with listening effort demonstrated significant correlations between listening effort and negative connectivity in default mode, dorsal attention and salience networks. Further, listening effort was related to a negative connectivity between auditory cortex and frontal lobe. McGurk illusions were correlated to an increased positive connectivity within the default mode network. We here provide evidence of resting state connectivity changes due to age-related hearing loss. Hearing loss affects both the salience and dorsal attention networks, whereas listening effort is related to changes in default mode, dorsal attention and salience networks as well as to changed auditory cortex connectivity. These results suggest that already mild to moderate hearing impairment leads to disruption of network connectivity during rest.

Title: Effects of ownership sense of the virtual body induced by the full body illusion on the sound localization

Authors: *C. TOI, A. ISHIGUCHI
Ochanomizu Univ., Tokyo, Japan

Abstract: One of critical factors of the body ownership sense, or the body-related sense of self (bodily self-consciousness: BSC) is the multisensory integration. If only this integration is completed, we could gain the sense of body ownership to even fake bodies. This effect is shown by the various experiments of full-body (out-of-body) illusion (Ehrsson, 2007), and suggests that the sense of body ownership can be easily deceived. In the typical full-body (out-of-body) illusion experiment, participants sit on the chair wearing the Virtual Reality Head-Mounted Display (VR-HMD). They see their own backs through VR-HMD on which the video image of their own bodies captured by the camera 2 m behind them is projected in real-time. In this situation, while they see a rod approaching the camera, they are touched by another rod with simultaneous position and timing. This makes them start to feel like they are sitting behind themselves. In our current experiment, applying this method to the sound localization task, we tested whether participants' ability of sound localization was changed while they felt the illusion

of the sense of virtual body ownership. We hypothesized that their sense of sound localization would be deceived by the illusion and the degree of the impairment of the ability of sound localization depends on the extent of the change of the sense of their own bodies' positions. Our results partly confirmed this hypothesis, and it suggests that although our sense of body ownership or BSC is derived from visual-tactile integration in this experiment, it could affect even auditory perception, which is not manipulated directly in the experiment.

Engin. and Neurosci., Univ. of Rochester, Rochester, NY; [5]Pediatrics and Neurosci., Albert Einstein Col. of Med., Bronx, NY; [6]DEC, École Normale Supérieure, Paris, France; [7]UCL Ear Inst., London, United Kingdom

Abstract: Speech is most commonly perceived as multisensory. Indeed, integrating auditory and visual information from a talker's face is known to benefit speech comprehension. However, the neural mechanisms underlying this integrative process are not well understood, especially in the context of natural, continuous speech. Recent work relating EEG to the acoustic speech envelope has shown enhanced neural tracking of congruent audiovisual (AV) speech relative to unisensory (A+V) speech (Crosse et al., 2015), especially under challenging listening conditions (Crosse et al., 2016). This approach of relating EEG activity to the acoustic envelope however, is limited in its ability to deal with more complex representations of the speech signal. This is unfortunate given recent work demonstrating the ability to index auditory speech encoding at different hierarchical levels using EEG (Di Liberto et al., 2015). In order to overcome this limitation we have used canonical correlation analysis (CCA) to relate a multivariate representation of a speech stimulus to the multivariate EEG response. Specifically, CCA applies a linear transformation to both the stimulus and response with the goal of optimizing the correlation between the two. This allows us to examine integration effects at different hierarchical levels

using spectrotemporal and phonetic-feature representations of speech.
Our results show that when we represent the speech in terms of its spectrotemporal information there is a significant multisensory integration effect for speech in noise - suggesting that seeing the speakers face restores tracking of the spectrotemporal information in the speech signal. When we represent the speech in terms of its phonetic content however, we find a significant multisensory effect both for speech in quiet and speech in noise. Thus it appears that having access to the visual articulations of the speaker benefits phonetic encoding of the speech signal above what the acoustic information alone can provide. Further analyses will seek to isolate the unique contributions of spectrotemporal and phonetic processing to the EEG signal. The overarching goal is to provide a framework for testing hypotheses about how the temporal dynamics and articulatory information from a speaker's face help us to understand speech in challenging listening conditions.

Abstract: Over months prior to the weigh-in (24h before the match), professional boxers (Pro-boxers) typically keep training and reduce their body mass (BM) empirically to gain a strength/size advantage over opponents. Few studies have investigated sport elite’s neural plasticity, and none have explored the impact of weight-making effect on neural structure and functional connectivity (FC). To address this issue, using voxel-based morphometry (VBM),

resting-state functional magnetic resonance imaging (rs-fMRI), we included twenty-one male licensed Pro-boxers (26.7 ± 4.0 years) in the time point of one-month before match (T1, mean BM index [BMI]: 21.9 ± 4.0) in comparison to age-sex-BMI matched Controls (27.2 ± 3.8 years, BMI: 21.4 ± 1.6). Then we longitudinally followed the Pro-boxers at the time point of within-one week before the match (T2, BMI: 20.6 ± 1.1) and one-month after the match (T3, BMI: 22.3 ± 1.4). In the time point of T1, Pro-Boxers presented significant higher gray matter density compared to controls, in left anterior insula (AI) ($p<0.001$, cluster level FWE [family wise error] corrected) and the left caudate ($p<0.016$), generally representing sensory integration and motor control respectively. In rs-fMRI analysis seeding these two clusters (left AI and caudate), significantly higher FC were found between left AI and left hippocampus ($p<0.033$), and between left caudate and bilateral insula/post-central gyrus ($p<0.001$) in Pro-boxers. In the time point of T2, the FC seeding the AI and caudate clusters had extended to the network including middle cingulate cortex/orbital gyrus ($p<0.001$) and dorsal anterior cingulate cortex ($p<0.001$) respectively, which is overlapped with the FC area correlated with BMI decrease in Pro-boxers ($p<0.001$). No significant FC were found in T3. These findings suggest the structural and functional plasticity in Pro-boxers and its widely distributed FC were enhanced by BMI decrease, implying the significance of weight-making in pre-match period.

Title: Multisensory processing in the elderly

Authors: *B. M. SEXTON, H. BLOCK
Kinesiology, Indiana Univ. Bloomington, Bloomington, IN

Abstract: With age, degradation of sensory systems leads to poor motor control which may result in earlier placement in a long-term care facility. It is well documented that elderly adults have reduced proprioception and sensorimotor function. However, the effect of age on multisensory processing is unknown. When executing a motor command with the hand, we typically have information from multiple senses: vision from the retina, and proprioception from the muscles and joints. Integrating multiple sensory systems helps reduce variability to provide a more reliable goal directed movement. Here we ask whether elderly adults integrate vision and proprioception in a way that minimizes variance as young adults do, and whether elderly subjects compensate for an imposed visuo-proprioceptive mismatch as young adults do. Five elderly right handed participants with no history of neurological disease or injuries and normal or corrected to normal vision participated. Subjects sat at a custom 2D virtual reality apparatus with a touchscreen. Subjects were instructed to match their right index finger (indicator finger) to visual (V), proprioceptive (P), or combined (VP) targets, with no direct vision of either hand. The V target was a 1 cm white square that appeared in the plane of the touchscreen, the P target was the subject's left index finger (target finger) placed on a tactile marker beneath the reaching surface, and VP targets were a combination of the two. After a veridical baseline block, a misalignment was gradually imposed by shifting the V component forward without the subject's awareness. At the end of the misalignment block, the V component was displaced 70 mm from the P component. Compared to a group of 72 young adults, elderly subjects tended to have higher variance and bias in matching V and P targets. Weight of vision versus proprioception was similar for young and elderly subjects, with both relying slightly more on proprioception. Visual and proprioceptive realignment were similar for both young and elderly subjects in the misalignment block, suggesting elderly subjects are able to realign as much as young subjects. Intact multisensory processing in the elderly needs to be explored as a means of mitigating degradation in individual sensory systems.

Title: The perceptual illusions of dual body ownership and dual self-location

Authors: *A. GUTERSTAM[1,2], J. SZCZOTKA[2], D. LARSSON[2], H. EHRSSON[3]
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [3]Dept. of Neurosci., [2]Karolinska Institutet, Stockholm, Sweden

Abstract: The feeling of being a unitary physical entity-that is, owning one body located in one given location in the external space-is a fundamental subjective experience. Previous research has shown that is it possible to elicit a perceptual illusion of owning two copies of the same limb (e.g. two right arms). However, it remains unclear whether the coherent feeling of owning a full-body may be duplicated in the same manner, and, if so, how it relates to the sense of self-location. To this end, we adapted a full-body illusion (Petkova et al 2008) in which ownership of a mannequin's body is induced through correlated visuo-tactile stimulation. Specifically, participants wearing head-mounted displays were presented two full-bodies lying in parallel being touched by an object while receiving correlated tactile stimulation (Fig1A). In a series of five experiments (n=138; 83 females; 27±7yrs), we systematically manipulated the visuo-tactile congruence and visual perspective (first- vs third-person; 1PP vs 3PP) and quantified the senses of ownership and self-location using questionnaire ratings and threat-evoked skin conductance responses (SCR). The presentation of two bodies viewed from the 1PP and receiving synchronous visuo-tactile stimulation was associated with higher ratings of dual body-ownership questionnaire items ($p<0.001$; Fig1B) and increased threat-evoked SCR ($p<0.05$; Fig1C), suggesting that the two bodies were owned simultaneously. We failed to find support for the hypothesis that splitting the visual field in two and placing each of the bodies in different spatial environments would lead to an illusion of dual self-location, as evident from the subjective ratings on a self-location task ($p>0.05$). However, a strong sense of dual self-location and dual body ownership was induced when the visual perspective repeatedly 'jumped' between two bodies' 1PPs and a common 3PP (Fig1D). In summary, these findings suggest that congruent, ambiguous visuo-tactile stimulation of two bodies can elicit the illusion of owning two separate full-bodies and being in two locations at once.

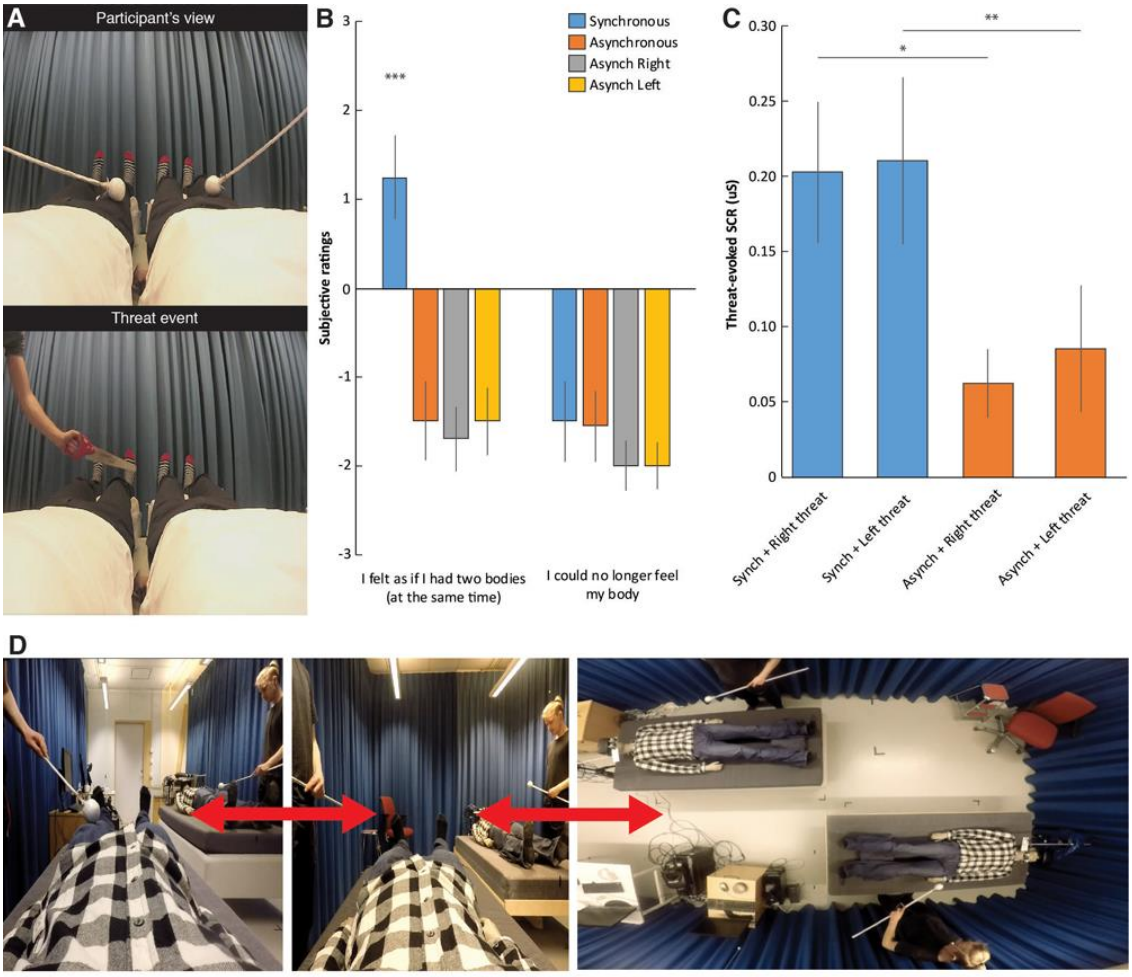

Figure 1. A. Participant's view of visuo-tactile stimulation and threat event. **B.** Questionnaire results. **C.** Threat-evoked SCR. **D.** Visul stimuli in experiment #5, in which the visual perspective changed (here indicated by the red arrows) every 18 s between two 1PPs and one 3PP. *p<0.05. **p<0.01. ***p<0.001.

Title: Rapid modulation of activity in auditory cortex by visual speech information revealed by electrocorticography

Authors: P. J. KARAS[1], *B. METZGER[1], J. F. MAGNOTTI[1], Z. WANG[2], D. YOSHOR[1], M. S. BEAUCHAMP[1]
[1]Dept. of Neurosurg., Baylor Col. of Med., Houston, TX; [2]Dept. of Statistics, Rice Univ., Houston, TX

Abstract: Speech perception is inherently multisensory: observers make use of visual information from the talker's mouth as well as auditory information from the talker's voice. The neural interchange between auditory and visual cortex that allows this is poorly understood. In the present study, we recorded activity from electrodes implanted in epilepsy patients. Patients were presented with auditory-only (A), visual-only (V), and audiovisual (AV) speech consisting of two different types of words: words in which visual mouth movements preceded the onset of auditory speech (visual-leading; *e.g.* 'drive'); and words in which auditory speech preceded the visual mouth movements (auditory-leading; *e.g.* 'known'). We recorded from 111 electrodes implanted on the superior temporal gyrus across 8 patients. Average high-frequency gamma broadband activity (75-150 Hz) in the window from 0 ms to 500 ms after auditory stimulus onset was used as a measure of local neuronal response. From these 111 electrodes, we selected only electrodes that showed significant activity in any of the experimental conditions ($F > 25$, $R2 > 0.18$, $p < 10^{-15}$), resulting in 58 electrodes. The mean percent signal change response to A and AV speech across all words was 121% (+/- 11% standard error) and 120% (+/- 11%), respectively. To compare how the signal changed between A-only and AV words, we first calculated the AV reduction for each word type in each electrode by taking the mean difference between A trials and AV trials. We then compared the AV reduction for visual-leading (mean A-AV = 8% +/- 7%) and auditory-leading words (mean A-AV = -7% +/- 4%). On average, visual-leading words showed a larger difference between A and AV conditions, $t(57) = 2.74$, $p = 0.008$). Across electrodes, 40 of 58 were consistent with the overall finding that visual-leading words have a greater AV reduction than auditory-leading words. We explain this observation with reference to theories of predictive coding in sensory processing. Under this framework, the visual component of AV speech provides a prediction of the incoming auditory component, but only if the visual information precedes auditory speech (visual-leading words). The additional visual information reduces the computational burden on auditory cortex, leading to more efficient word identification and reduced neural activity.

Title: Children with idiopathic toe walking showed differences in areas of tactile and vestibular processing

Authors: *V. W. CHU, J. LEE, B. CHAN
Occup. Therapy, Virginia Commonwealth Univ., Richmond, VA

Abstract: Idiopathic toe walking (ITW) is characterized by the absence of heel contact during gait, without a medical cause for the toe walking. Long term consequences of persistent toe walking include shortened Achilles tendon and ankle equinus. A link between ITW and sensory processing dysfunction has been suggested, but to date, there is limited research examining this relationship. Areas of sensory processing that potentially relate to ITW include: sensory seeking, tactile defensiveness, poor proprioception, vestibular dysfunction and difficulties with sensory modulation. Identifying the specific sensory function that underpin ITW will be invaluable to the development of specific diagnoses and treatments for this gait abnormality. We recruited children with ITW between the ages of 4 to 12 years from VCUHS and local clinics. Age-matched typically walking participants were recruited from the local community. Children completed a set of activities to assess their sensory processing related to walking. Balance-related proprioceptive, vestibular and visual processing was assessed with the Sensory Organization Test (SOT) and perturbation tests using the Neurocom SMART Balance Master®. Vibration perception threshold was measured with a vibrometer and tactile threshold was measured with the Semmes Weinstein filaments. Proprioceptive processing was assessed by testing ankle position sense and ankle force perception without visual feedback. Sensory modulation response to stimuli was examined by measuring skin conductance in response to tactile and vestibular stimuli. Preliminary results showed that children with ITW have difficulty with balance tasks that involved ankle perturbations, and reduced use of effective ankle strategies for balancing. They also have increased latency and larger response magnitude to balance perturbation. Children with ITW also showed abnormally high skin conductance response indicating potential difficulty with sensory modulation. Children with ITW also showed either extremely high or low tactile detection thresholds compared to typically developing children. Children with ITW did not show significant deficits in proprioception discrimination tasks. Further testing in more children with ITW will allow us to examine subtypes of sensory differences in ITW. This research will significantly advance our understanding of ITW by

providing a framework to detect and analyze the underlying sensory differences in children with ITW. Our research strives to better understand the causes of ITW, so that we can develop effective treatments to guide earlier intervention to prevent long-term consequences of persistent toe walking.

Title: Evaluating the effects of english second language status on fixations and first-pass skip rates during a continuous reading task

Authors: *C. Y. DELGADO[1], T. A. DOTY[3], D. L. LARRANAGA[4], D. A. DEL CID[5], C. MCGINNIS[2]
[1]California State Univ. Northridge, Tarzana, CA; [2]California State Univ. Northridge, Northridge, CA; [3]Cal State Northridge, Northridge, CA; [4]Psychology, VISN Lab. at California State University, Northridg, Altadena, CA; [5]Psychology, Vision Sci. Information Lab. @ CSUN, Sherman Oaks, CA

Abstract: Previous literature has indicated that bilinguals are more likely to make errors while reading function words aloud than content words (i.e. word class) in mixed language texts (Gollan, Schotter, Gomez, Murillo, & Rayner, 2014). More specifically, bilinguals are more likely to make intrusion errors (e.g saying *pero* instead of *but*) when fixating in a non-target word in a mixed-language text (Gollan et al., 2014). Studies have shown that eye movements are ahead of the voice, indicating that overt and covert attention are not aligned. This implies an increased vulnerability to intrusions when reading mixed-language text. (Gollan et al., 2014.) There has been a significant difference in overt attention in both fixation and first-pass skip reading (i.e. skipping words) on word length and word class (Chamberland, Saint-Aubin, & Légere, 2013). Previous work implied mechanisms of language control inhibit the dominant language when switching between two languages to reduce intrusions (Gollan et al, 2014). Conflicting studies used fMRI to demonstrate language inhibition is not possible. The bilingual brain cannot inhibit and avoid language conflicts, because both left caudate and anterior cingulate cortex have been observed to be active in the neural networks of language selection of both languages (Abutalebi et al., 2007; van Heuven et al., 2008).
The present work aims to evaluate a possible interaction with English second language (ESL) individuals on word length, word class and gaze durations through fixations and first-pass skip rates of words. Twenty-three participants' gaze and ocular movements were recorded using an

EyeLink 1000 Plus (SR-Research) eye-tracker to investigate this possible interaction. Results confirm previous findings that there are significant differences in both fixation and first-pass skip rates based on word length and word class. However, no significant effects were observed based on ESL status of the reader.

Title: Brain regions involved in sound-to-meaning mapping and its relationship to phoneme perception

Authors: *S. ITAGAKI, S. MURAI, K. I. KOBAYASI
Doshisha Univ., Kyotanabe, Kyoto, Japan

Abstract: In the association between meanings and sounds (i.e., phonemes), a phenomenon termed “sound symbolism” has been confirmed by several studies. This is the idea that a sound makes a certain of impression (e.g., phoneme “p” is associated with small impression) and it could serve as a psychological basis for the word-meaning association. The purpose of this study is to clarify the involvement of a phoneme-perception-related brain region in the sound symbolism. We conducted two experiments. In the Experiment I, we focused on sound symbolism in visual size. Subjects were all Japanese native speakers, and they did not have knowledge about sound symbolism and this experiment. They were required to answer visual size difference between a standard and a target stimulus. Visual stimuli had 1 type of standard and 2 types of target. Target size was either smaller or larger than the standard. Sound stimuli were voice sounds (/bo/, /bi/, /po/ and /pi/), noise and click sound (control). Voice sounds were assumed to have impression of “larger” or “smaller”, according to previous researches. The subject performed the task under functional magnetic resonance imaging (fMRI) scanning. We defined the congruent and incongruent conditions as follows and analyzed the data accordingly. It is congruent condition when the impression from the visual stimulus is consistent with the impression of the sound stimulus. It is incongruent condition when the relationship between stimuli was reversed. As a result, reaction times in incongruent condition were longer than congruent condition suggesting that sound symbolism was observed between visual size and syllables under fMRI, and right superior temporal gyrus was more activated in congruent condition. This region has been reported to relate to vowel perception by previous studies. In the Experiment II, we investigated the brain region related to phoneme perception. Subjects were all

Japanese native speakers and most of them participated in the Experiment I as well. They were required to discriminate phoneme. Sound stimuli were voice sounds (/bo/, /bi/, /po/, /pi/, /a/, /i/ and /o/) and noise. In Experiment II, right superior temporal gyrus and left and right fusiform gyrus were activated when subjects discriminate phoneme. We will discuss relationship between the activation area for sound symbolism and for phoneme perception in individual level.

Title: The pre- and post-stimulus dynamics of the brain's multisensory causal inferences

Authors: *T. ROHE[1], A.-C. EHLIS[1,2], U. NOPPENEY[3]
[1]Dept. of Psychiatry and Psychotherapy, [2]LEAD Grad. Sch. & Res. Network, Univ. of Tuebingen, Tuebingen, Germany; [3]Computat. Neurosci. and Cognitive Robotics Ctr., Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Humans integrate stimuli from multiple modalities to obtain more reliable multisensory representations of their environment. However, given the multitude of multisensory stimuli in any environment, the brain needs to integrate stimuli only if they arouse from a common cause, but has to segregate stimuli from independent causes (Koerding et al., 2007). Humans infer a common cause if they perceive a small temporal, spatial and structural disparity between multisensory stimuli. Current fMRI studies (Rohe & Noppeney, 2015, 2016, 2018) demonstrate that the brain implements such causal inference processes along a cortical hierarchy. However, the temporal dynamics of the brain's causal inference processes remain unknown. In the current EEG study, human participants (N = 23) were presented with one to four synchronous flashes and beeps and they counted either the number of flashes or the number of beeps. As predicted by the Bayesian Causal Inference (BCI) model, participants behaviorally integrated the stimuli if a small numeric disparity (≤ 1) between the number of flashes and beeps suggested a common source, while the stimuli were segregated for a large disparity. Representational similarity analysis demonstrated that the geometry of participants' audiovisual numeric representations was predicted by the BCI model's internal estimates of stimulus number and their likely causal structure. 300 ms up to 100 ms before stimulus onset, the power of alpha and gamma EEG oscillations as well as alpha phase modulated participants' perceptual prior of the

stimuli's likely causal structure. Starting from 150 ms after stimulus onset, a multivariate pattern analysis on EEG recordings decoded the number of presented stimuli with high accuracy. The decoding approach demonstrated that the brain first represented the stimuli's numeric disparity and computed the stimuli's likely causal structure. Next, the brain integrated the stimuli in case of a small numeric disparity, but segregated the stimuli in case of a large disparity. Overall, the brain's neuronal dynamics before and after stimulus onset reflect the hierarchical organization of multisensory causal inference across the cortices.

Title: Use of click-based echolocation may preserve retinotopic-like representation of space in calcarine cortex in early-blind people

Authors: *L. J. NORMAN, L. THALER
Durham Univ., Durham, United Kingdom

Abstract: In sighted people, calcarine cortex (CC) in each hemisphere contains a neural mapping of the contralateral visual field, where more peripheral points in visual space are represented more anteriorly. CC in early-blind people is known to process input from non-visual modalities - e.g. auditory (1) or tactile (2) - and there is some evidence from resting state functional connectivity that the visual cortex of congenitally blind people is functionally connected in a way that resembles retinotopic organisation (3). It is not known, however, whether this organisation can be used for spatial representations of sensory input - a condition that may be essential for successful visual rehabilitation following vision loss (e.g. visual prostheses). Therefore, here we tested if basic principles of retinotopic organisation (contralaterality and eccentricity mapping) are used to map acoustic space in CC of early-blind people, who either had a history of using click-based echolocation (n=5) or not (n=5), as well as in sighted blindfolded controls (n=5). Echolocation is the ability to perceive objects through sound echoes, and is associated with processing in CC (4). During fMRI, each participant listened to individualized binaural recordings of clicks and click echoes reflected from objects located at one of eight positions along the horizontal meridian, or to binaural recordings of source sounds from the same positions. We then used cross-correlation to map representations of these echo- and source- positions in CC. In three out of the five echolocators, we found evidence

of contralateral mapping of acoustic space for both echo- and source- positions. Furthermore, in two of these three echolocators there was evidence of preserved eccentricity mapping, and this was more prominent for echo- than source-acoustic positions. There was no evidence of contralaterality or eccentricity mapping in blind people who did not use echolocation, or in sighted blindfolded people. This suggests that the results found in the early-blind echolocators were driven specifically by expertise in using echolocation, and not by vision loss or by the ability to form mental imagery, for example. Overall, this result provides evidence that the use of click-based echolocation by early-blind individuals may allow some retinotopic-like representation of space to be preserved in CC, and this may have implications for successful visual rehabilitation in individuals with early vision loss (e.g. visual prostheses). 1 Collignon et al (2011). Title: Neural correlates of cross-modal influences in top-down processing of visual speech

Authors: *R. THÉZÉ[1], A.-L. GIRAUD[1], P. MEGEVAND[2,1]
[1]Dept. of Basic Neurosciences, Univ. of Geneva, Geneve, Switzerland; [2]Neurol. Dept., Geneva Univ. Hosp., Geneva, Switzerland

Abstract: Audiovisual speech processing results from a mixture of bottom-up sensory information and top-down predictions, and it is hypothesized that the integration of information from each modality across cortical areas involves cortical oscillations. The aim of this study was to probe the interplay between bottom-up and top-down influences on audiovisual speech processing by dissociating them. We developed a cross-modal “pop-out” task where the same speech stimulus is presented thrice: first (V1), in visual modality only (i.e. no sound), second (AV), with the corresponding sound information and, third (V2), again in the visual modality only. We built a set of 60 stimuli (i.e. sentence long video samples from known movies with a character speaking to the camera) and asked participants (n = 10) to rate the intelligibility on each presentation. On average, the videos were rated as not intelligible on the first presentation, and highly intelligible on the second. On the third presentation they were rated as significantly

more intelligible than the first presentation but less than the second. In other words, a given visual speech stimulus became more intelligible if it immediately followed presentation of the corresponding audiovisual speech stimulus. Two patients with epilepsy agreed to perform the experimental task while we recorded their brain activity with intracranial subdural EEG electrodes while they undertook the task. We identified a subset of electrodes located for the most part in the right superior temporal cortex and precentral gyrus in which high-frequency activity correlated with speech envelope during presentation of audiovisual stimuli (AV). Importantly, we found one electrode in the motor cortex where high-frequency activity did not respond to pure visual stimuli on the first presentation (V1) but tracked speech envelope during the second presentation of visual stimuli (V2), thus mirroring the behavior of subjective intelligibility ratings.These findings support the idea that top-down predictions on the contents of visual speech influence its perception, a process that takes place outside of the auditory speech areas.

Title: Multisensory data-driven modeling of fMRI responses across primate species

Authors: *M. ARMENDARIZ[1], D. MANTINI[2], W. VANDUFFEL[3]
[1]Lab. of Neuro- and Psychophysiology, [2]KU Leuven, Leuven, Belgium; [3]Radiology, Harvard Med. Sch., Charlestown, MA

Abstract: Multi-sensory processing has been studied in both human and non-human primates (Driver and Noesselt, 2008). Recent comparative efforts focused on functional correspondences of sensory brain networks based on comparisons of fMRI timeseries across species (Mantini et al., 2012; Mantini et al., 2013). Yet, comparative multi-sensory processing remains largely unexplored territory. Here, we aimed to activate large portions of monkey and human cortex using multisensory stimulation. Specifically, we collected fMRI responses from both species while identically-ordered sequences of visual, auditory and tactile stimuli where randomly presented in an event-related manner to the awake and fixating subjects. We first calculated

voxel-by-voxel inter-subject correlations within each species to identify voxels showing reliable correlations (Hasson et al., 2004). These voxels were extracted to establish ROIs responding reliably to our multimodal stimuli. Next, these ROIs were used for computing intra-species correlation matrices. We then used a hierarchical clustering analysis, which segregated three groups of ROIs corresponding to the three sensory systems. Then, we averaged ROI responses within each cluster to obtain three independent timecourses (visual, audio, tactile) separately for each species. To account for differences in HRF between species, we convolved these sensory components with a canonical HRF from the other species. Using the resulting sensory signals, we modelled voxel responses throughout the brain across species. Thus, the sensory-driven functional responses from one species are used to model the responses in the other species. This enabled us to identify regions across species involved in sensory processing for the three modalities. Most interestingly, we identified overlap of the three sensory maps based on the inter-species modeling. Evidence for trimodal processing was found in inferior-frontal (IFJ, IFS), somatosensory (1, 3, 4), insular, posterior STS and even early visual (V1) regions of the human cortex. In the monkey, we found trimodal overlap based on intra-species modeling in ventral prefrontal (46v, 12m), insular, posterior STS (Tpt, pTPO), somatosensory (3a-b), and the MT-complex. Virtually no trimodal overlap, however, was detected using the inter-species modelling in monkey, which may suggest a higher capacity for cross-modality integration in human. Overall, we present a purely data-driven approach, whereby the fMRI responses in one primate species (and not the stimulus design per se) are used to reveal large-scale multi-sensory driven brain regions in other species.

Title: The effect of head direction on gait trajectory in human

Authors: *H. JOO[1], S. KIM[2,4], J.-K. RYU[3], K. LEE[2,5]
[1]Interdisciplinary Program in Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Interdisciplinary Program in Cognitive Sci., [3]Inst. for Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [4]Neurosci. Res. Inst., Gachon Univ., Incheon, Korea, Republic of; [5]Neurol., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Background
There have been numerous research findings on neural structures that process spatial orientation such as place cell, grid cell, head direction cell, and etc. These structures, however, are located in the subcortical region which made human-based research has been explored to a limited extent. The purpose of the study was to examine the influence of head direction on straight locomotion task in behavior level in human. As many researches revealed that head direction cells exist in different animal species, this study will base its idea that human also has direction cells and plays an important role in motor control behavior.
Method
To isolate the head direction effect, two conditions were investigated: 0-degree and 30-degree rightward rotation in a horizontal plane. Since vision is the dominant sense in the human sensory system, subjects were examined with and without the eye mask. Eleven subjects(5 female) participated and were asked to walk in a straight line ten times in each condition (four-conditions in total) from the same starting point. To calculate walking orbits, participants wore a cap type motion tracker. A Factorial ANOVA was conducted to compare the main effects of type of head direction and visual sense availability as well as the interaction between the type of head direction and vision on the angular difference at the five-meter point from the baseline. Baseline was derived from the averaging walking path in the 0-degree head direction with vision.
Result
The main effect for vision type yielded an F ratio of $F(1, 109)=30.211$, $p<.001$, indicating a significance difference between using vision condition($M=-2.587$, $SD=.071$) and mask condition($M=-3.878$, $SD=.226$). The main effect for head direction type yielded an F ratio of $F(1, 109)=9.651$, $p<.01$, indicating that the effect for head direction was significant, 0-degree($M=-2.917$, $SD=.163$) and 30-degree($M=-3.549$, $SD=.151$). The interaction effect was significant, $F(1,109)=11.539$, $p<.01$. There was no significant sex difference.
Conclusion
These findings suggest that vision exerts a crucial role in modulating heading direction even though the head's direction doesn't match with the body's direction to walk. The head direction factor also modulates subjects' path to drift in the direction of head rotation as compared to frontward head direction. To further understand the role of head direction, possible input signals to head direction cells such as the vestibular system, proprioception, etc. should be systematically controlled.

Title: Anisotropic decline of ownership illusion intensity in spatial mismatch condition: A guideline to modulating pain signal

Authors: *M. SEO, S. KIM[1,2], J.-K. RYU[1], K. LEE[1]
[1]Interdisciplinary Program in Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of;
[2]Neurosci. Res. Inst., Gachon Univ., Incheon, Korea, Republic of

Abstract: Ownership illusion modulates pain perception by raising pain threshold. Ownership illusion is a phenomenon, which feels ownership of object that do not belong to one's own body. The illusion is induced when the object is similar to one's own body. Similarity can arise from location, movement, texture and visual properties like shape and color. When inducing ownership illusion, synchronous tactile-visual stimulation is usually used. Pain modulation of ownership illusion is still available in virtual reality.
To control the intensity of ownership illusion precisely, quantification of relationship between ownership illusion intensity and spatial mismatch was preceded. Participants were instructed to put on HMD and see the left or right hand made up by using UNITY. The virtual hand and participant's real hand was collocated as much as possible. Then virtual and real hand were stimulated by using Geomagic Touch. Stimulation was given synchronously but location was different. There were 8 conditions of spatial mismatch, which differs in distance and direction. Intensity of ownership illusion was measured by a modified questionnaire originally presented by Botvinick and Cohen(Botvinick and Cohen, 1998).
As a result, ownership illusion intensity declined as size of spatial mismatch increased. Same tendency was discovered in several papers(Samad M, Chung AJ, Shams L, 2015). Meanwhile, the ownership illusion intensity found to be more robust to vertical spatial mismatch than horizontal spatial mismatch.
This anisotropy can be explained by dermatomal distribution. According to dermatomal distribution of hands, vertically different tactile signal can share same afferent fibers while the horizontal cannot. This anatomical difference could be the cause of anisotropy of ownership illusion intensity by influencing multisensory integration. This phenomenon should be considered when studying an analgesic effect of ownership illusion.

Title: Grapheme-color synesthetes and inhibitory differences during an anti-saccade task

Authors: *D. L. LARRANAGA[1], R. ESQUENAZI[2], M. F. AWAD[2], S. A. DREW[2]

Abstract: Research into synesthesia can inform many fields, including cognitive neuroscience, language, emotion, imagery, and attention (Kadosh & Henik, 2007). Grapheme-color synesthetes consistently report the same color being associated with a given letter. One of the primary theories of why this occurs involves an inability to inhibit feedback between neurological areas (Grossenbacher & Lovelace, 2001). The present study examined whether this lack of inhibition extends to other domains of functioning by means of an antisaccade task. Three grapheme-color synesthetes, along with two age- and gender-matched controls for each, were recruited and asked to complete an antisaccade task in the lab. Results indicate a significant difference between synesthetes and non-synesthetes in the latencies for their pro- and antisaccades. These data indicate partial support for the disinhibition-feedback theory of synesthesia as inhibited processing extends to domains other than grapheme processing.

Title: The peripersonal space representation in paraplegic patients depends on the level of lower-limb residual neurological functions

Authors: *S. SHOKUR[1], F. ASNIS[1], S. ALMEIDA[1,2], M. A. NICOLELIS[3,1,4]
[1]Associacao Alberto Santos Dumont para Apoio à Pesq, Sao Paulo, Brazil; [2]Associação de Assistência à Criança Deficiente (AACD), Sao Paulo, Brazil; [3]Neurobio., Duke Univ., Durham, NC; [4]Edmond and Lily Safra Intl. Inst. of Neurosci., Macaiba, Brazil

Abstract: The peripersonal space (PPS) is a multisensory representation of the space immediately surrounding the body encoded in frontoparietal cortical areas. PPS representation is essential in the sensory guidance to generate suitable motor acts and allowing us to interact with objects (Ladavas 2015). Numerous studies have shown that PPS is plastic and changes, for example, when a subject uses an external tool (Canzeroni 2013, Serino 2007) or shrinks for amputee patients around their stump.
Here we study the PPS representation for patients with sensory-motor deficiency due to spinal cord injury (SCI). We recorded the lower-limb PPS representation for a group of 13 paraplegic patients, throughout 16 months of a training protocol developed by our laboratory (Donati 2016), which has previously demonstrated to induce partial neurological recovery in SCI patients.
To measure the PPS limit, we used an audio-tactile discrimination paradigm (Canzeroni 2012). We used the ASIA evaluation (golden standard for neurological assessment, Ditunno 1994) to assess patients' sensory-motor functions.
First, we found that the PPS limit for SCI patients was significantly shorter than for healthy subject (ttest, $P<0.05$). Second, among the SCI patients, we found a significant correlation between patients' lower-limb PPS limit with both their sensory score ($R= 0.69$, $P=0.008$, $N=34$) and their motor score ($R=0.62$, $P = 0.02$). These results suggest that the low-level neurological recovery, which was induced by our training protocol, triggers a reorganization of the patients' body perception and as a result expands their PPS.

Title: Directional visual motion is represented in the auditory and association cortices of early deaf individuals

Authors: *T. L. RETTER[1,2], M. A. WEBSTER[1], F. JIANG[1]
[1]Univ. of Nevada, Reno, Reno, NV; [2]Univ. of Louvain, Louvain-La-Neuve, Belgium

Abstract: Individuals who are deaf since early life may show enhanced performance at some visual tasks, including discrimination of directional motion. The neural substrates of such behavioral enhancements remain difficult to identify in humans, although neural plasticity has been shown for early deaf people in the auditory and association cortices, including the primary auditory cortex (PAC) and superior temporal sulcus (STS) region, respectively. Here, we investigated whether neural responses in auditory and association cortices of early deaf individuals are reorganized to be sensitive to directional visual motion. To capture direction-selective responses, we recorded functional magnetic resonance imaging (fMRI) responses frequency-tagged to the 0.1 Hz presentation of central directional (100% coherent random dot) motion persisting for 2 s contrasted with non-directional (0% coherent) motion for 8 s. We found direction-selective responses in the STS region in both deaf and hearing participants, but the extent of activation in the right STS region was over seven times larger for deaf participants. Minimal but significant direction-selective responses were also found in the PAC of deaf participants, both at the group level and in five out of six individual deaf participants. In response to stimuli presented separately in the right and left visual fields, the pattern of activation across the right and left hemispheres was similar in both the PAC and STS region of deaf participants, and could support a right visual field advantage reported previously in behavioral studies. Taken together, these results show that the reorganized auditory cortices of early deaf individuals are sensitive to directional motion. More speculatively, these response suggest that auditory and association regions can be remapped to support enhanced visual performance.

Title: TMEM240: A novel cerebellar synaptic protein

Authors: *M. L. HOMA, A. LOYENS, D. MAZUR, V. HUIN, L. BUÉE, B. SABLONNIÈRE
UMR-S 1172 Ctr. De Recherches Jean Pierre Aubert, Lille, France

Abstract: Introduction. Dominantly inherited spinocerebellar ataxias (SCAs) are heteregeneous neurodegenerative diseases characterized by cerebellar impairment. To date, 38 different loci and 27 genes have been described for the SCAs. Recently, missense mutations and a stop mutation in transmembrane protein 240 (TMEM240) have been reported in spinocerebellar ataxia 21 (SCA21) among 11 french families. SCA21 stands out by its association with severe cognitive impairment and early age onset. Nowadays, TMEM240 function is still unknown.
Objectives. 1. Establish a general brain mapping of TMEM240 expression in mice 2. Determine TMEM240 specific expression in mice cerebellum 3. Define TMEM240 cellular and subcellular expression.
Methods. Immunohistochemistry analyses are performed on mice brain tissues. To establish cellular and subcellular localization, we realized immunohistochemistry on mice brain sections. Immunostaining is studied by confocal microscopy. TMEM240 synaptic expression is analyzed by electron microscopy.
Results. Immunostaining shows that TMEM240 is mainly expressed in cerebellum and especially in the uvular lobe (IX) and nodulus lobe (X). At a cellular level, TMEM240 is localized in neurons from cerebellar cortex : molecular layer, cerebellar glomeruli in the granular layer and in the soma and dendritic arborization of Purkinje cells. TMEM240 is located among synapses between Purkinje cell and granular cells, and co-localized with synaptic markers as validated by confocal microscopy.
Conclusion. TMEM240 protein is expressed in neurons from cerebellar cortex. TMEM240 expression is mainly observed in synapses. TMEM240 could have a synaptic function in cerebellar cortex neuronal network.
Perspectives. SCA21 model in zebrafish, identification of TMEM240 partners.

Title: Cortex-cerebellum dynamics in the execution and learning of a motor task

Authors: *M. J. WAGNER, T. H. KIM, J. KADMON, N. D. NGUYEN, S. GANGULI, M. J. SCHNITZER, L. LUO
Stanford Univ., Stanford, CA

Abstract: The neocortex and cerebellum have expanded together during mammalian evolution, and the cortex-pons-cerebellum pathway is among the densest long-range connections in the brain. However, little is known about cortico-cerebellar information transmission. Here we show, by simultaneous two-photon Ca^{2+} imaging in premotor layer 5 pyramidal and cerebellar granule cells during a motor planning task, that cortical representations of behavior are communicated to granule cells with high fidelity. Moreover, granule cells represented events more reliably than did their correlated cortical partners. Transiently silencing basal pontine neurons indicated that coherent activity requires cortico-cerebellar transmission. Chronic cortex-cerebellum imaging over weeks of learning revealed that cortex and cerebellar task representations emerged in parallel. Cortico-cerebellar and intra-cortical correlations also rose substantially with learning. These findings support a circuit model in which pons amplifies coherent layer 5 dynamics that emerge with learning before relaying signals to granule cells. Thus, the cerebellum receives detailed representations of cortical dynamics that are substantially enhanced by learning, which likely facilitates cerebellar participation in cortical computation.

Title: The role of the medial cerebellum in modulating synaptic responses in the ventrolateral periaqueductal gray

Authors: *C. E. VAAGA, I. M. RAMAN
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Stimulation of the ventrolateral periaqueductal gray (vlPAG) can elicit freezing, an innate defensive behavior necessary to avoid predation. Other brain regions provide input to the PAG and are therefore likely involved in processing innately threatening stimuli. For example, lesions of the cerebellar vermis selectively impair innate freezing, and cerebellar projections from the medial cerebellar nucleus (mCbN) to the vlPAG have been reported (although primarily attributed to oculomotor function). These results suggest that the cerebellum may modulate vlPAG circuitry via a direct, monosynaptic projection; however, the synaptic contribution of the mCbN to vlPAG circuitry has not been tested. Here, we examined the functional connectivity of cerebellar afferents to vlPAG circuitry using anatomical and slice electrophysiological techniques in mice (both sexes, p17-p56). Stereotaxic injections of CTb-GFP into the vlPAG labeled neurons in the mCbN. Neurons in the mCbN had high spontaneous firing rates (121.5±8.7 Hz), 25-50 Hz higher than in the neighboring interpositus nucleus. To selectively target glutamatergic vlPAG neurons involved in freezing behaviors we used a Chx10-cre mouse, which labels a subset of glutamatergic neurons in the vlPAG thought to drive freezing. Anterograde injections of AAV-DJ-ChR2-eYFP into the mCbN labeled axon terminals in close proximity to Chx10+ neurons in the vlPAG. Chx10+ neurons had small diameters (7-8 μm) and high input resistances (584.1±47.3 MΩ). In current clamp recordings, 70% of Chx10+ neurons were regular firing (5.8±1.2 Hz), whereas the remaining 30% showed prominent bursting. To assay the functional connectivity between the mCbN and the vlPAG, we injected a ChR2-expressing viral vector into the mCbN. Optical stimulation of cerebellar afferents in the vlPAG resulted in glutamatergic EPSCs (4.2 to 110 pA; mean 33.7 pA) in 6 of 32 cells unlabeled small cells, confirming that direct, though small, excitatory cerebello-PAG connections exist. To test whether the cerebellum exerts effects on the PAG through other means, we tested the effects of cerebellar activity on IPSCs. Electrically evoked IPSCs were 322.2±90.3 pA in control conditions. Interestingly, high frequency stimulation (25 Hz) of cerebellar afferents potentiated

electrically evoked IPSCs in 5 of 8 cells by 162.5±8.2%. Because disinhibition is thought to be a primary means of activating freezing responses in the vlPAG, these results suggest that the cerebellum may be well positioned to modulate freezing responses through both direct and modulatory effects on vlPAG circuitry.

Title: Midlateral cerebellar purkinje neurons participate in visuomotor associative learning

Authors: *N. SENDHILNATHAN[1], M. E. GOLDBERG[2]
[1]Columbia Univ. Dept. of Neurosci., New York, NY; [2]Neurosci., Columbia Univ., New York, NY

Abstract: The cerebellum has been primarily considered to have roles in motor learning and coordination. However, Recent clinical, anatomical and electrophysiological evidence suggest that the cerebellum has a role in cognition as well as in motor control. There is a growing consensus that visuomotor associative learning requires a network that includes the cerebellum, the prefrontal cortex, and the basal ganglia. To test this hypothesis at the level of single neuron activity, we trained Rhesus monkeys to associate well-learned left- and right hand movements with arbitrary visual symbols. We first studied the activity of midlateral cerebellar Purkinje cell simple spikes while the monkeys performed the visuomotor association task using familiar, overtrained symbols. 83% of neurons increased their activity during the hand-movement, and 17 % of neurons had no movement-related activity. We then changed the symbols to non vebalizable (by humans) fractal stimuli that the monkeys had never seen. The monkeys had to figurev out, by trial and error, which symbol was associated with which hand, which took them 20-60 trials. The kinematics of the movements did not differ before and after the symbol switch. After the symbol switch, both types of Purkinje neurons showed a global change in firing

activity, and both types of Purkinje neurons began to report the prior trial's outcome: simple spike activity differed between prior correct and prior wrong trials; but only in a particular epoch of the trial for each neuron. Across the population, the epochs tiled the whole trial period. The neurons reported the trial outcome independent of changes in reaction time, hand movement kinematics or laterality, visual symbol novelty and reward expectation. This activity was not merely a report of reward: the neurons did not signal when the monkey failed to receive a reward while performing the overtrained task. Our results suggests that that cerebellum's unique structure for learning is suited for a purely cognitive learning context as well as a motor learning context.

Title: Computations in the cerebellar flocculus - Divide and conquer

Authors: R. A. HENSBROEK, J. MARUTA, B. J. VAN BEUGEN, T. BELTON, *J. I. SIMPSON
PHYSIOLOGY & NEUROSCIENCE, New York Univ. Sch. of Med., New York, NY

Abstract: In the rabbit's cerebellar flocculus both Type 1 and Type 2 mossy fiber responses to horizontal vestibular rotations are present in about equal numbers. Type 3 is present, but to a lesser degree. (Type 1 responses have activity increases for rotations to the recording (ipsilateral) side and/or decreases for rotations to the contralateral side. Type 2 responses have the oppositely directed activity changes, and Type 3 responses have activity increases for both rotation directions.) Curiously, the simple spike responses of horizontal Purkinje cells are virtually only Type 2. To address how this asymmetry may occur, we recorded from various neuron classes in the anesthetized rabbit's flocculus (mossy fibers, granule cells, basket/stellate cells, Purkinje cells, unipolar brush cells (UBCs), and Golgi cells). The rabbits were sinusoidally rotated in the light. Neurons were classified using our previous algorithm (Ruigrok et al., 2011). Of the recorded interneuron classes, UBCs and Golgi cells do not synapse directly on Purkinje cells, but rather their influence is embedded in the activity of those granule cells with which they synapse. We, thus, simplified the computations into two parts: those occurring through inner paths involving cells that do not synapse on Purkinje cells and those occurring through outer paths involving cells that do synapse on Purkinje cells. Granule cells rarely had significant background

activity, so their Type 1 or Type 2 responses consisted largely of only increased activity. Since the excitatory activity of specific granule cells combined with the inhibitory activity of specific molecular layer interneurons (basket/stellate cells) generates Purkinje cell activity, the Type 2 Purkinje cell activity may be most simply explained as dominance of Type 1 molecular layer interneuron activity in combination with Type 2 excitatory granule cell activity. Similarly, with a different subset of granule cells and molecular layer interneurons, Purkinje cell activity could be unmodulated, accounting for the near absence of Type 1 Purkinje cells. Another kind of asymmetry consisting of Purkinje cell responses to only ipsilateral rotations or to only contralateral rotations was unexpectedly present. A way for that behavior to occur can now be understood as a consequence of using only Type 2 granule cell activity or only Type 1 molecular layer interneuron activity. This study suggests that a general way to comprehend cerebellar computations may be, as described above for the flocculus, to divide interneuron activity into two anatomically based inner and outer paths and to focus on the diversity of granule cells and molecular layer interneurons.

Title: Synaptic responses and spiking of cerebellar output neurons in larval zebrafish during fictive swimming

Authors: *T. HARMON[1], D. L. MCLEAN[2], I. M. RAMAN[1]
[1]Neurobio., [2]Northwestern Univ., Evanston, IL

Abstract: Cerebellar output neurons receive excitatory drive related to motor commands, which is integrated with inhibition from Purkinje cells (Pkj). To test how these inputs interact during movements in larval zebrafish, we made whole-cell recordings from olig2+ eurydendroid neurons (ENs, homologous to glutamatergic cerebellar nuclear cells) while monitoring spontaneous and evoked fictive swimming with ventral root (VR) recording. Voltage clamp recordings revealed basal synaptic input in the form of parallel fiber EPSCs and Pkj IPSCs. During swimming, EPSCs and IPSCs both increased in rate and summated. Responses to

spontaneous and sensory-evoked swimming were different, however. For spontaneous swimming, EPSCs preceded the VR response (-25 ± 11 ms) and arrived before IPSCs (-9.2 ± 1 ms). For evoked swimming, both responses lagged the onset of the VR response (EPSC: 6.3 ± 3 ms, IPSC: 27 ± 8 ms). The amount of synaptic drive also differed, with evoked swimming associated with greater charge transfer (EPSC: 3.3 ± 0.6 nC, IPSC: 11.5 ± 2.3 nC) than spontaneous swimming (EPSC: 1.0 ± 0.3 nC, IPSC: 4.7 ± 0.9 nC). Current clamp recordings revealed that firing rates increased to comparable levels during spontaneous and evoked swimming. However, the onset of spiking closely matched the onset of spontaneous swimming and lagged evoked swimming (lag, 1 ± 8 ms, vs. 27 ± 8 ms). A subset of EN cells showed activity related to the motor burst cycle. Also, lateral ENs received greater and earlier Pkj input than medial cells. To further characterize Pkj inhibition of ENs, we analyzed spontaneous IPSCs and IPSCs recorded while optogenetically suppressing Pkj simple but not complex spikes. While the mean control amplitude of IPSCs was 26 ± 2 pA, the distribution was skewed toward larger values (40-60 pA). With simple spikes suppressed, mean amplitudes were similar (23 ± 2 pA), indicating that large IPSCs were not exclusively from presynaptic complex spikes. To estimate the Pkj-EN convergence, we compared the IPSC rates to rates of Pkj spiking. Basal IPSCs occurred at 13 ± 2 IPSCs/s, about twice the mean Pkj firing rate (~7 spk/s). Simple spike suppression led to a rate of 1.4 ± 0.3 IPSCs/s, ~5 times the complex spike rate (~0.3 spk/s). Thus, the Pkj-EN convergence ratio is likely between 2 and 5. These results demonstrate that cerebellar output neurons can receive distinct patterns of synaptic input, and that their responses differ according to whether swimming is sensory-evoked or spontaneous.

Title: Diversity of cellular morphology and physiology of Purkinje cells in the adult zebrafish cerebellum

Authors: *V. Z. HAN
Ctr. for Integrative Brain Res., Seattle Children's, Seattle, WA

Abstract: This study was designed to explore the functional circuitry of the zebrafish cerebellum, with a focus on its Purkinje cells, using whole-cell patch recordings in slice preparations. Following physiological and pharmacological characterizations, the recorded cells

were labeled for morphological identification. It was found that the zebrafish Purkinje cells are surprisingly diverse .Based on their physiology and morphology, they can be classified into at least three subtypes: a *narrow spike cell* (Type 1), which fires only narrow Na^+ spikes (<2 ms in duration), and has a single primary dendrite with an arbor restricted to the distal molecular layer; a *broad spike cell* (Type II), which fires broad Ca^{2+} spikes (5-7 ms in duration) and has a primary dendrite with limited branching in the inner molecular layer and then further radiates throughout the molecular layer ; and a *very broad spike cell* (Type III), which fires very broad Ca^{2+} spikes (≥ 10 ms in duration) and has a dense proximal dendritic arbor that is either restricted to the inner molecular layer (Type IIIa), or radiates throughout the entire molecular layer (Type IIIb). The graded paired-pulse facilitation of these Purkinje cells' responses to parallel fiber activations are largely similar to those reported in mammals. However, two types of CF responses were observed: one a simple waveform and the other a complex-like one, with both all-or-none and paired-pulse depressed. The labeled axon terminals of these Purkinje cells end locally, as reported for other teleosts. The present study, for the first time, provides evidence that zebrafish Purkinje cells are remarkable diverse in their physiology and morphology, suggesting that the corresponding functional circuitry and information processing differ from what has been well-established in the mammalian cerebellum.

Title: Heterogeneous mossy fiber activity patterns and their implications for sensorimotor encoding in the cerebellar cortex

Authors: *H. ROS, S. SADEH, N. CAYCO-GAJIC, R. SILVER
Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: The brain gathers information about the body and the surrounding world, enabling it to build internal representations and to plan and execute movement. The cerebellum is thought to predict the sensory consequences of movements and coordinate movement by learning sensorimotor relationships. Cerebellar mossy fiber (MF) inputs convey a wide range of sensory and motor related information that is integrated by granule cells. But little is known about how populations of MFs encode sensory and motor signals locally within the input layer. To address this we used adeno-associated viruses to express the genetically encoded calcium indicator

GCaMP6f in distinct precerebellar nuclei, implanted a chronic window over Crus I/II and vermis of the cerebellar cortex and performed two-photon (2P) imaging of MFs in awake behaving mice. Since MF synaptic rosettes are sparsely distributed, we used high speed 3D 2P Acousto-Optic Lens (AOL) microscopy to record their activity within a 250 x 250 x 250 μm imaging volume. We observed a wide range of activity patterns across MFs, with individual MFs exhibiting either an increase or a decrease in activity with locomotion. Surprisingly, positively and negatively modulated MFs were often observed within the same local region (i.e. 10 - 100 μm), suggesting that individual GCs could be innervated by functionally opposed inputs that cancel out. Examining the spatio-temporal patterns of MF population activity and relating this to behaviour will allow us to identify how information from specific pathways is encoded.

Title: Sensorimotor processing in the cerebellar corticonuclear circuit amplifies reflexive whisking via well-timed spiking

Authors: *S. BROWN, I. M. RAMAN
Neurobio., Northwestern Univ., Evanston, IL

Abstract: To test how cerebellar crus I/II Purkinje cells and their targets in the lateral cerebellar nuclei (CbN) integrate sensory and motor-related inputs and contribute to reflexive movements, we recorded extracellularly from awake, head-fixed mice during non-contact whisking. Air puffs to the whisker pad elicited changes in population instantaneous firing rates of Purkinje simple spikes, which matched and slightly preceded (~15 ms) the change in whisker position (~1 Hz/1 degree protraction) over the first few hundred milliseconds after the puff. Purkinje spike rates changed similarly whether the location of the air puff was on the ipsilateral or the contralateral side, suggesting little role for these responses in fine sensory discrimination. Responses also remained relatively unaffected when ipsilateral sensory feedback was removed by lidocaine. The later portion of the response was reduced by optogenetically inhibiting the reticular nuclei but not motor cortex, consistent with a motor-command-related signal. Optogenetically silencing cerebellar output suppressed movements by about 30%. CbN cell responses during puff-evoked whisking did not match whisker kinematics but showed only a brief elevation of firing rates in

the first 50 ms following the puff. Examination of spike timing during puff-evoked whisks demonstrated that both Purkinje and CbN cells generated well-timed spikes in sequential 2-4 ms windows at response onset, such that they alternately elevated their firing rates just before protraction. In contrast, with spontaneous whisks, which were smaller than puff-evoked whisks, although Purkinje cell spiking matched whisker kinematics, CbN cells were slightly inhibited (by ~5 spikes/sec), and well-timed spikes were absent from both Purkinje and CbN cells. Thus, sensory input can facilitate millisecond-scale well-timed spiking in Purkinje and CbN cells and permit cerebellar amplification of reflexive whisker movements.

Title: Lugaro cells in the avian cerebellum (?)

Authors: *D. R. WYLIE[1], I. CRACIUN[1], C. G. GUTIERREZ-IBANEZ[1], A. S. M. CHAN[1], H. LUKSCH[2]
[1]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [2]Tech. Univ. of Munich, Freising, Germany

Abstract: Lugaro cells are inhibitory interneurons that reside in the upper granular layer of the cerebellar cortex, just below or within the Purkinje cell layer. They are characterized by: 1) a fusiform cell body oriented in the parasagittal plane; 2) two pairs of dendrites emanating from opposite ends of the cell body; 3) innervation from Purkinje cell axon collaterals; and 4) an axon that projects into the molecular layer and travels parallel to granular cell parallel fibers. Lugaro cells have previously been described in mammals, but not others vertebrate classes, save one report in a teleost fish. Here we propose the existence of Lugaro cells in the avian cerebellum based on the morphological characteristics and connectivity described above. Immunohistochemical staining for the calcium binding protein secretagogin, using an antigen retrieval protocol, revealed Lugaro-like cells in the pigeon cerebellum (see Figure). These cells exhibited fusiform somata and horizontally projecting dendrites when viewed in the parasagittal plane. We also observed long axons projecting deep into the molecular layer and turning sharply to travel alongside parallel fibers in the coronal plane. Immunohistochemisty to other molecular markers was explored, including calretinin, calbindin, and glutamic acid decarboxylase (GAD). While mammalian Lugaro cells are known to express calretinin, the secretagogin-labelled cells

in the pigeon did not. Additionally, secretagogin was not expressed in rat Lugaro cells. GAD was expressed in the pigeon secretagogin-labelled cells, confirming their inhibitory function. Calbindin labelling revealed Purkinje cell terminals surrounding the secretagogin-expressing cells (see Figure). Our results suggest that Lugaro cells are more wide spread among vertebrates than previously thought and may be a characteristic of the cerebellum of all vertebrates.

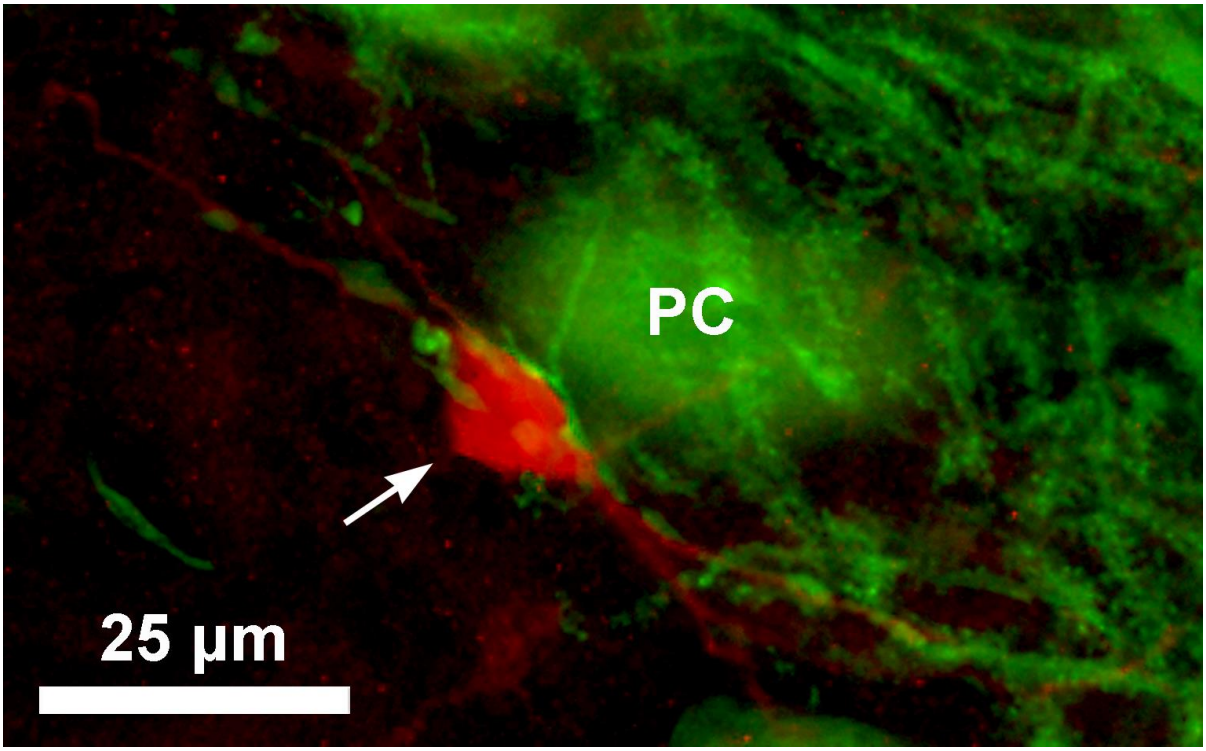

Figure: Secretagogin immunochemistry (red) reveals Lugaro-like cells (arrow) in the granular cell layer. Note the contacts from Calbindin +ve (green) varicosities, presumably from Purkinje cell (PC) collaterals.

Title: Activation of purkinje cells of the cerebellum during the appetitive andconsummatory phase of sexual behavior in the wistar male rat

Authors: *B. A. LARA[1], G. J. SANCHEZ[1], D. HERRERA[2], F. ROJAS[2], G. A. CORIA-AVILA[2], J. MANZO[2], R. TOLEDO-CARDENAS[2]
[1]DOCTORADO EN INVESTIGACIONES CEREBRALES, UV, XALAPA, Mexico; [2]Ctr. de Investigaciones Cererables, Xalapa, Mexico

Abstract: The cerebellum is a structure that has been associated with multiple functions, such as motor skills, learning processes, and sexual behavior, among others. The correlation that exists between cerebellum and sexual behavior has been described by different authors; in experiments performed in rats, it has been shown that there is an activation in the granular layer of the cerebellum during the execution of the behavior. However, the participation of Purkinje cells (Pk) is still unclear. Two behavioral paradigms were used to evaluate the participation of Pk cells during sexual behavior: 1) non-contact stimulation in presence of a receptive female (appetitive phase), and 2) the execution of one, two, three, and four ejaculations in the same session (consummatory phase). Sexually experienced adult male rats (300-350g) were used. For the treatment of cerebellar tissue, the immunohistochemical technique was performed using the c-Fos protein as a marker of cellular activation, and Calbindin (Cb) as a specific marker of Pk cells. Only the cells that showed colocalization were counted. The analysis of Pk cells was made in the apical and basal area of the 10 lobes of the cerebellar vermis. Results showed a significant increase in the number of Pk c-Fos Cb-ir cells during the appetitive phase of sexual behavior (receptive female) compared to the control group (non-receptive female). Regarding the consummatory phase, a significant increase in the number of Pk c-Fos Cb-ir cells was observed in the one ejaculation group compared to the control group. However, in the second and third ejaculation groups a decreased number of Pk c-Fos-Cb-ir cells was observed, that was significant only in the third ejaculation. However, in the fourth ejaculation, the immunoreactivity increased again, until reach the levels by the control group. The activation of the apical region of the lobes was significantly higher compared to the basal region. Based on the results, it is suggested that the activation of Pk cells in the appetitive phase, could indicate the preparation of the system to execute further patterns of sexual behavior when achieving the consummatory phase. The increase during the first ejaculation is maintained, suggesting an optimization in the activity of the cells of Pk so that the behavior can continue. Then, this activation decreases as the behavior is repeated in the next ejaculations of the same session. For the fourth ejaculation, the activation Pk cells increases again, suggesting that is a preparation to start another ejaculatory series.

Title: Cerebellar involvement in controlling the intrinsic variability of the respiratory rhythm in mice

Authors: Y. LIU[1], S. QI[1], R. V. SILLITOE[2], *D. H. HECK[1]
[1]Anat. & Neurobio., Univ. of Tennessee, Memphis, TN; [2]Pathology and Immunol., Baylor Col. of Med., Houston, TX

Abstract: The cerebellum has strong reciprocal connections with the brain stem in both rodents and primates [1, 2]. Investigations into the functional significance of these projections have linked the cerebellum to various brain stem controlled functions such as blood pressure regulation, cardiovascular and respiratory activity. However, those studies were mostly conducted in anesthetized or decerebrate conditions and thus did not provide information about what aspects of these brain-stem controlled behaviors the cerebellum controls in an awake behaving animal. Activity of neurons in the medial cerebellar nucleus has been shown to represent orofacial behaviors controlled by brain-stem pattern generators, including respiration, and neurons from the medial cerebellar nucleus project to brain-stem areas that contain the respiratory pattern generating circuits [3]. These projections provide a potential route for cerebellar modulation of respiratory activity. Here we asked what aspects of respiratory behavior the cerebellum might control by measuring respiratory behavior after genetically targeting the output of Purkinje cells. We used the Cre/LoxP approach to selectively block Purkinje cell GABAergic neurotransmission, thereby functionally disconnecting the cerebellar cortex from the cerebellar nuclei [4]. Respiratory behavior was monitored for 30 min by placing mice in a plethysmograph. Peak pressure changes related to inspiration were marked and the inspiration times were used for further analysis of different aspects of the respiratory rhythm, such as mean interval duration, coefficient of variation (CV), and intrinsic variability (CV2). The CV2 is represents the standard deviation of two adjacent inter-inspiration intervals. Our results show that loss of cerebellar Purkinje cell neurotransmission did not affect the average respiratory frequency or the CV of the respiratory rhythm. However, the mutant mice did show a significant decrease in CV2 of the respiratory rhythm ($p < 0.001$, t-test). A reduced CV2 in mutant mice signifies reduced local interval variability, indicating that influence from the intact cerebellum somehow

increases variability. This is consistent with the assumption that the intact cerebellum is involved in fine temporal control of the respiratory rhythm, which might be related to a proposed cerebellar involvement in the coordination of respiratory with other orofacial behaviors [3,5]. 1. Title: The cellular mechanism of Prrt2-associated paroxysmal dystonia

Authors: *B. LU[1], Z.-Q. XIONG[2]
[1]Lab. of Neurobio. of Diease, Inst. of Neurosci., Shanghai City, China; [2]Inst. of Neurosci., Shanghai, China

Abstract: Paroxysmal dyskinesia is a brain disorder characterized by sudden attacks of involuntary movements. Paroxysmal kinesigenic dyskinesia (PKD), a subtype of paroxysmal dyskinesia, was caused by loss-of-function mutations in PRRT2 gene. In our previous study, genetically engineered animal models of PKD has been generated. However, how does the dysfunction of PRRT2 contribute to stimulus-triggered dystonia is still not fully understood. In this study, we found dystonia was closely accompanied with hyperexcitability in cerebellum of Prrt2-mutant mice. By monitoring the activity of population neurons with electrophysiological recording, we found that optical stimulation induced more extended excitability in cerebellum of Prrt2-mutant mice compared to which in wild type mice. The carbamazepine, an effective medicine for preventing PKD attack in clinical, reduced cerebellar excitability and alleviated dystonia attack in animal model of PKD. Together, our findings provided persuasive evidence for the hypothesis that cerebellar hyperexcitability might be an underlying neuropathological mechanism in Prrt2-associated paroxysmal dyskinesia.

Title: Cerebellar modules in the olivo-cortico-nuclear loop labeled by pcdh10 expression in the adult mouse

Authors: G. A. SARPONG[1], S. VIBULYASECK[1], Y. LUO[1], M. S. BISWAS[1], H. FUJITA[2], S. HIRANO[3], *I. SUGIHARA[1]

Abstract: Topographic connection between corresponding compartments of the cerebellar cortex, cerebellar nuclei and inferior olive forms parallel cerebellar modules, which are essential for the cerebellar function. Compared to the striped cortical compartments which are labeled by molecular markers such as aldolase C or zebrin II, the supposedly-corresponding nuclear of olivary compartmentalization has not been much clarified. Some members of the cadherin family of cell adhesion molecules are expressed in subdivisions of the cerebellar cortex, cerebellar nuclei and inferior olive, implying their involvement in topographic axonal connection. We previously clarified expression of *pcdh10*, which encodes protocadherin 10 protein, in embryonic Purkinje cell subsets by using *pcdh10-lacZ* knock-in mice. Here, we focused on the expression pattern of *pcdh10* in the adult mouse to compare it with aldolase C stripes, the standard marker of molecular compartments of the cerebellar cortex. In the cerebellar cortex *pcdh10* was strongly expressed in (1) aldolase C positive vermal stripes a+//2+ in lobules VI-VII, and (2) paravermal narrow stripes c+, d+, 4b+, 5a+ in crus I and neighboring lobules and (3) paravermal stripes 4+//5+ across all lobules from lobule III to paraflocculus, areas less involved in somatomotor function. In the cerebellar nuclei, *pcdh10* was enriched in the caudal part of the medial and posterior interposed nuclei which project less to the medulla or to the red nucleus than to other metencephalic, mesencephalic and diencephalic areas. In the inferior olive, *pcdh10* was enriched in the rostral and medioventrocaudal parts of the medial accessory olive which have connection with the mesencephalic areas rather than the spinal cord. Axonal labeling experiments confirmed that the three cortical *pcdh10*-positive areas were topographically connected to the nuclear and olivary *pcdh10*-positive areas. This showed that these *pcdh10*-positive areas coincide with modular structures in the olivo-cortico-nuclear loop. We speculate that these modules are

functionally involved in various non-somatomotor functions through their afferent and efferent connections.

Title: Spatial and temporal locomotor learning in mouse cerebellum

Authors: D. M. DARMOHRAY, J. R. JACOBS, *M. R. CAREY
Neurosci., Champalimaud Ctr. For the Unknown, Lisboa, Portugal

Abstract: Stable and efficient locomotion requires precise coordination of movements across the body. Learned changes in locomotor patterns can be induced by exposure to a split-belt treadmill that imposes different speeds on the limbs on each side of body. We developed a transparent split-belt treadmill for mice that provides quantitative readouts of locomotor behavior in order to study the neural circuit mechanisms underlying this form of motor learning. Here we show that mice adapt to split-belt walking in a way that is remarkably similar to humans. Like human learning, mouse locomotor adaptation is specific to measures of interlimb coordination, has spatial and temporal components that adapt at different rates, and is highly context-specific. Further, split-belt adaptation in mice is dependent on an intact cerebellum, but insensitive to large lesions of cerebral cortex. To begin to narrow down the potential sites of plasticity underlying locomotor adaptation, we targeted inhibitory DREADDs to Purkinje cells projecting to each of the three distinct deep cerebellar nuclei. Using this chemogenetic approach, we identified a subregion of the cerebellum that is necessary for this form of locomotor learning. Consistent with predictions from our interlimb coordination analyses, this region shows differential lateralization for spatial and temporal aspects of locomotor adaptation. These findings provide a starting point for a circuit-level model for how movements of four independent limbs are coordinated and maintained during locomotion.

Abstract: Studies in patients with Parkinson's disease (PD) have shown that cerebellar function is modified by an alteration in basal ganglia. This suggests an anatomical and functional relationship and would imply a possible compensatory mechanism for the dysfunction of the cortico-basal circuits. These observations support the idea that both structures function as an integrated system. In the present study, we altered the ventrolateral striatum (VLS) of the basal ganglia with an electrolytic lesion in male Wistar rats (250 and 300 gr). Multiunit activity (MUA) recordings were made in cerebellum. Rats were divided into three groups, a control, a sham which also an electrode descended in the VLS and the lesion group to which an electrolyte lesion was performed (3.5 mV / 30 s) in the VLS. In each of these three groups, three subgroups were formed (Sim b, Crus II lobes, and dentate nucleus) according to the structure where MUA was registered. Thus, all animals were independent between groups and structures. The aim was to analyze and determine the effect of the electrolytic lesion of the VLS on the MUA of the granular neurons of the cerebellum. In all the groups the basal activity and the maximum amplitude reached during the mandibular tremor caused by the lesion were analyzed. The results show differences in the Crus II lobe and in the dentate nucleus during the recording of basal activity. In both the sham and the lesion group decreased the amplitude compare to the control group. The mandibular tremor was observed in the lesion group as expected, surprisingly the rats of the Sham group also showed the behavioral pattern of mandibular tremor and bursts during AMU registration. Our results confirm a role of the cerebellum in the alteration of the

ventrolateral striatum. Further studies are needed in the sham group as this could be proposed as an acute model of parkinsonism in the rat.

Title: The activity of Purkinje cells in the vestibular cerebellum during active versus passive rotational head movements

Authors: *O. ZOBEIRI, K. E. CULLEN
Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: The cerebellum, a structure that is well-conserved across vertebrates, is thought to contain a forward model that predicts the sensory consequences of self-generated movement. Comparing this prediction with the actual sensory feedback, allows the brain to distinguish sensory inputs that are the consequence of active self-generated versus passive externally-generated movements (i.e., sensory reafference versus exafference). Previous studies by our group have shown that neurons in the vestibular nuclei as well as most medial of the deep cerebellar nuclei - the rostral fastigial nucleus (rFN) - are significantly more sensitive to passively-applied than actively generated vestibular stimulation. However, the neural mechanism underlying the cancellation of vestibular reafference is unknown. Accordingly, here, to investigate the neuronal basis of vestibular reafferent suppression, we recorded from Purkinje cells in the Nodulus and Uvula of the vestibular cerebellum. Single unit extracellular recording were made in rhesus monkeys during comparable active and passive head rotational movements, and Purkinje cell simple spikes were detected via a semi-automated clustering algorithm. Our analysis of responses during passive motion first revealed robust simple spike responses to head motion that were either bidirectional or unidirectional. Next, comparison of neuronal responses during passive and active head rotations, demonstrated that simple spike responses were markedly attenuated (~60%) across our population of Purkinje cells during active versus passive rotations. We hypothesized that these neurons might sum a neck motor-derived (e.g., efference copy) signal with the vestibular input to cancel vestibular reafference. To address this possibility,

we measured neuronal responses while monkeys attempted to make gaze shifts between two targets but their heads were restrained. In this condition, monkeys produced large neck torques, signifying the generation of motor commands comparable to those generated during active head movements. Consistent with our hypothesis, we found that cells that were sensitive to rotational head velocity, also responded when the monkey generated a motor command to move the head as measured by a torque sensor. Thus, taken together, these results provide new insights into the computations preformed by Purkinje cells in Nodulus/Uvula that underlie the cancellation of vestibular reafference.

Title: M1 and cerebellar responses to spatial and temporal perturbations during visuomotor tracking

Authors: *W. XU, A. JACKSON
Fac. of Med. Sci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: The cerebellum is essential for controlling coordinated movements. Internal forward models in the cerebellum are thought to enable smooth and accurate movements in the face of slow and noisy feedback signals by predicting the expected outcome of movements and signalling discrepancies with actual consequences. We explored the neural implementation of such internal models by simultaneously recording from the primary motor cortex and the contralateral cerebellar cortex in a macaque performing a visually guided isometric wrist torque tracking task. 52 putative cerebellar Purkinje cells and 37 M1 neurons formed the dataset. Neurons were recorded using custom-made flexible tungsten wire electrodes designed to enable long-term stable single-unit recordings without the need for head fixation. The monkey had to follow a target that moved from a central torque-neutral position to the periphery and then returned to the central position. We found that whereas M1 neuronal firing largely represented the force produced (monophasic response profile with peak firing rates during the increase in wrist torque), cerebellar Purkinje cell simple spike firing better represented the magnitude of the disparity between target and current states (having a peak in firing both when the target moved to the periphery and when it returned to the torque-neutral home position). Moreover, the initial peak in M1 firing preceded that of cerebellar firing by around 20ms - compatible with the

cerebellum receiving an efference copy of the motor command from M1. We also found that both M1 and cerebellar neurons responded similarly (with an increase in firing) to sudden perturbations that required an abrupt increase in wrist torque irrespective of whether the cursor was abruptly moved away from the target or the target was abruptly moved away from the cursor. This reinforces the notion that cerebellar neurons encode the disparity between current state and desired state rather than the state of either the cursor or target position separately. In a second experiment, we introduced time delays (200 to 600ms) between the wrist torque and the cursor position on screen. This introduced delay-specific changes to both M1 and cerebellar firing rate profiles. In particular, elevated firing of Purkinje cells occurred at a time consistent with the maximal discrepancy between expected and actual visual feedback. These results are consistent with the cerebellum acting as a forward model representing that compares expected and actual movement outcomes whilst taking into account delays in sensory feedback.

Inst. for Basic Biol., Okazaki, Japan; [5]Lee Kong Chian Sch. of Med., Singapore, Singapore

Abstract: The cerebellum receives information from the neocortex, which is crucial for execution and learning of skilled movements. Such information is thought to be particularly important for the operation of cerebellar internal models. Although the structure and function of the cerebro-cerebellar communication loop have been extensively studied in various species from rodents to primates, details of functional connectivity between the two brain structures are still largely unknown.
To comprehensively examine the functional inputs from the sensorimotor cortex to the

cerebellum, we performed cell-attached recordings from single Purkinje cells in various cerebellar lobules (lobule VI to VIII in the vermis, and lobule simplex, crus I and II, paramedian lobule, and copula pyramids in the hemisphere) while layer 5 (L5) pyramidal neurons located at various areas of the cerebral cortex were optogenetically stimulated in Thy1-ChR2-EYFP mice. Photostimulation of L5 pyramidal neurons reliably evoked simple and complex spikes in Purkinje cells, which represent mossy and climbing fiber inputs to the cerebellar cortex, respectively. For each recorded Purkinje cell, changes in simple spikes and complex spikes were plotted separately along the location of photostimulation in order to obtain a map of mossy and climbing fiber inputs from the sensorimotor cortex to single Purkinje cells.
Consistent with previous studies, inputs from the cerebral cortex to the cerebellum via mossy and climbing fibers are largely overlapped. However, the simple and complex spike maps show different patterns depending on the lobules such that each lobule receives spatiotemporally distinct inputs from the motor, sensory and association areas of the cerebral cortex. On average, inputs from the primary areas (S1 and M1) are mainly contralateral whereas those from the higher-order area (M2) are bilateral. However, the laterality is variable at single cell level even in the same lobule, and dependent on the medio-lateral position, i. e., zones where PCs are located. These results suggest that different aspects of information transferred from these cortical areas are integrated in specific cerebellar lobules and zones to form output patterns of simple and complex spikes, which may contribute to accurate coordination of movements.

Title: The cerebellar vermis modulates activity in the prefrontal cortex

Authors: *H. FUJITA, T. KODAMA, S. DU LAC
Johns Hopkins Univ., Baltimore, MD

Abstract: Cerebellar involvement in cognitive functions and mental disorders such as autism and schizophrenia is increasingly evident from clinical and imaging studies. In particular, lesions in the posterior part of the cerebellar vermis lead to impaired executive function (planning, set-shifting, abstract reasoning, verbal fluency, working memory), which have been historically

attributed to the medial prefrontal cortex (mPFC). Inspired by reports of anatomical and functional connectivity between the vermis and prefrontal cortex (Kyuho and Kawaguchi, 1985; Steriade, 1995; Kelly and Strick, 2003; Watson et al., 2014), we examined neuronal activities in the mPFC in response to optogenetic stimulation of the posterior vermis in awake behaving mice. We found that brief (10s of msec) inhibition of Purkinje cells in vermal lobule VII can robustly excite or inhibit mPFC neurons with minimal latency of ~25 ms. Despite the polysynaptic nature of the circuits linking the posterior vermis and mPFC, response onset latency to the cerebellar stimulation was well preserved across trials, indicating temporal precision of cerebellar control over the mPFC. To anatomically investigate neural substrates mediating cerebellar activity to the mPFC, we made double tracer injection into the mPFC and the fastigial nucleus, the main vermal output nucleus to retrogradely label mPFC-projecting neurons and to anterogradely label fastigial axons. We found major overlap of signals from the two tracers in the VM and MD thalamic nuclei and sparser overlap in the brainstem reticular formation. These results suggest that brief disinhibition of fastigial neurons can robustly modulate activity in the mPFC in heterogeneous ways to subserve distinct aspects of executive function.

Abstract: Previous studies have shown that cerebellar granule cells carry a predictive signal for motor action and the expectation of reward. However how these cerebellar input neurons respond in the associative learning in self-initiated go no-go odorant discrimination task has not been investigated in awake behaving animals.
To answer this question, we selectively expressed the Ca2+ sensor GCaMP6s in granule cells of cerebellum to enable the neuron activity detection. We performed head-fixed two-photon

imaging to perform large ensemble recordings of Ca2+ during behavioral training. The water-deprived mouse was trained with two odors to perform the go no-go task and neural activity of 100-200 granule cells was recorded simultaneously with two-photon imaging. To explore the possible roles of granule cells in associative learning, we collected data from mice learning to discriminate two odorants (forward training session) and we switched the rewarded odorant (reverse session). We also recorded licking and monitored movements though video. Information content of the neural responses was evaluated through perceptron analysis. Initially, a large fraction of granule cells responded similarly to both the rewarded (S+) and the unrewarded odorant (S-). Ca2+ increased following odorant delivery and decreased before the end of odor application and delivery of reinforcement. As learning progressed, the majority of recorded granule cells developed differential responses to S+ and S- trials. In proficient S+ trials, Ca2+ increased before and reached the peak after odor onset, and was maintained several seconds after delivery of reward. In S- trials, the neurons responded similarly before odor onset, but the response reached peak faster than S+ trials. Perceptron analysis of the activity of all neurons in the field classified the odorants correctly shortly after odorant onset. We then performed reverse training with the same animal and interestingly we found that the granule cells maintain the responses to odor values for the forward training in the first few trials, and the reversed task perceptron analysis differentiated between the odorants only after delivery of the reward. After the animals learned to discriminate the odorants in the reversed session the response to the rewarded and unrewarded odorants was re-established and perceptron analysis was able to discriminate between odorants shortly after odor onset.
Currently we are in the process of analyzing the relationship of the Ca2+ responses to motor actions and ultimately we want to figure out how the information stored at cerebellar granule cells contributes to behavioral responses.

Abstract: The use of liquid chromatography coupled with mass spectrometry (LC-MS/MS) is advantageous in in-vivo receptor occupancy assays at pre-clinical drug developmental stages. Relatively, its application is beneficial in terms of high throughput, data reproducibility, sensitivity, and sample processing. In this perspective, we have evaluated the use of FTC-146 as a non-radiolabelled tracer to determine the sigma-1 receptor occupancy of test drugs in mice brain. Further, the brain and plasma exposures of test drug were determined at their corresponding occupancies. In this occupancy method, primary study conditions like sacrification time after intravenous administration of tracer, dose of tracer, and specific brain regions were optimized during initial evaluation. Mice were pre-treated orally with SA4503, fluspidine, haloperidol, and donepezil followed by tracer treatment. In this occupancy assay, SA4503 was used as positive control for the derivation of relative occupancies. There was a dose-dependent decrease in brain regional FTC-146 binding in pre-treated mice. From the occupancy curves of SA4503, fluspidine, haloperidol, and donepezil the ED_{50} values in specific brain regions were observed to be in the range of 0.74-1.45, 0.09-0.11, 0.11-0.12, and 0.07-0.09 mg/kg, respectively. Brain regional distribution and binding inhibition upon pre-treatment were comparable to data reported with labeled [18F]FTC-146. Brain and plasma exposures of test compound were determined and correlated with corresponding sigma-1 occupancy from the same experiment. Their corresponding brain EC_{50} values are 74.3-132.5, 3.4-3.7, 122.5-139.5, and 8.8-11.0 ng/g and plasma EC_{50} values are 34.3-53.7, 0.08-0.10, 7.8-9.5, and 0.6-0.7ng/mL. With this mass spectrometry based assay, a wide category of drugs can be screened for sigma-1 receptor engagement along with their correlation to exposures can be derived which will aid in selecting suitable clinical doses.

Abstract: Axonal regrowth after lesion to the central nervous system (CNS) usually fails because of the limited capacity of CNS regeneration. In contrast, peripheral nervous system (PNS) axons readily regenerate after injury to form functional synapses with target muscle within a critical time period of 35 days in mice. Our previous work showed that motor function recovery was observed only if regenerating axons arrived at the target muscle within the critical time period. There is no doubt that damages in the PNS alter somatosensory cortex activities; however, the study on cortical reorganization is very limited. Cerebellum functions as a movement coordination centre for voluntary motor control. Purkinje cells are the major output neuron for fine-tuning motor activity in the cerebellar cortex. Here, we showed that motor functional recovery was delayed in a conditional knockout mouse with ablation of a transcription factor specifically in mature PCs after sciatic nerve crush. We established a mouse model to study critical period by performing repeated sciatic nerve crushes to prevent regenerating axons from reaching target muscle at specific period of time. Our preliminary data demonstrated that critical period was shortened significantly in mutant mice in terms of motor function recovery assessed by animal behavioral tests, electrophysiology and histology studies. Mutant mice exhibited reduction of toe spreading reflex, along with a decrease in evoked compound muscle action potential and neuromuscular junction formation in target muscle. We believe that current study will provide new insight into the development of neuroprosthetics and neurorehabilitation strategies for treating traumatic PNS injuries.

Title: Control of skilled reach through modulation of specific forelimb muscles by the IntA nucleus of the cerebellum

Authors: *A. R. THANAWALLA[1], A. I. CHEN[2]
[1]Sch. of Biol. Sci., [2]Nanyang Technological Univ., Singapore, Singapore

Abstract: The final output of the cerebellum, the deep cerebellar nuclei (DCN) have the ability to influence movement through connections with the spinal cord and motor cortex. The recent identification of a mouse line which permits recombination in specific neurons of the DCN provides an opportunity to manipulate these neurons and explore their functional relevance. To investigate the influence of glutamatergic projection neurons of the IntA nucleus on the muscular system, we performed EMG recordings in mice that express ChR2 in a subpopulation of IntA neurons, *Ucn3*::Cre recombined neurons. Through optogenetic manipulation of these neurons during a skilled reaching behavioral paradigm, we found that IntA^{Ucn3}neurons have the ability to change the EMG profile of selective forelimb muscles. Furthermore, we explored the temporal nature of these effects and found that IntA^{Ucn3}neurons exert their influence within a specific time window during the reaching movement. Our results show that IntA^{Ucn3}neurons control discrete movement through specific forelimb muscles in the context of skilled reaching. These results provide additional evidence supporting the functional specificity of neuronal subpopulations in the DCN.

Title: Novel substructure in input layer of cerebellar cortex depending on projection of granule cell

Authors: *T. KIM, Y. YAMAMOTO, K. TANAKA-YAMAMOTO
KIST, Seoul, Korea, Republic of

Abstract: The input layer of cerebellar cortex processes various inputs through the synaptic connections between mossy fibers (MFs) and granule cells (GCs), and relays the refined inputs to Purkinje cell via GC axons, parallel fibers (PF). Thus the MF-GC organization is one of essential factors to fully understand cerebellar network. However due to the massive number of

cells and synapses within small volume of the input layer, the studies have been restricted to local unit network, and global organization have been assumed to be simply the repetition of the units. Furthermore, because no attempts have been performed to classify GCs, variability in basic properties of GCs or synaptic connections was assumed to be originated from simple randomness. On the other hand, our recent development of labeling technique enabled the clear dissection of a group of GCs which stretch their PFs at similar distances from Purkinje cell layer. We applied this technique to label two separate groups of GCs with different fluorescent molecules, and analyzed acquired images of the input layer by custom-built program. We then calculated the ratios of two groups of GC dendrites connecting to individual MF terminals, and tested how the ratios are different according to the distance of two PF bundles. To interpret analyzed results, computational network models of three possible distribution patterns of MF-GC connections were generated. The comparison of experimental results with model results revealed the tendency of biased chance to make MF-GC synapses for the same groups of GCs distinguished by our labeling technique. In addition, network model that could mimic experimental results was utilized to simulate activity transfer from MFs to PFs through the MF-GC connections. The simulation suggested that the organized network formation rather than random formation would have advantage to convey spatially distinct patterned input at molecular layer. Based on the results from the model, in this presentation, we claim that network organization of input layer by GCs and MF terminals needs to be considered to have GC's projection dependent substructure unlike the assumptions so far.

Title: Role of the organized formation of parallel fibers during the cerebellar development

Authors: *H.-Y. PARK[1,2], T. KIM[1], Y. YAMAMOTO[1], K. TANAKA-YAMAMOTO[1,2]
[1]KIST, Seoul, Korea, Republic of; [2]Div. of Bio-Medical Sci. and Technol., Korea Univ. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Neural activity is generally believed to play an essential role in the network formation. During the postnatal development of cerebellar cortex, granule cells migrate and they form their axons, parallel fibers (PFs). Coincidentally, Purkinje cells (PCs) extend their dendrites to the molecular layer (ML) where PFs are being made. Considering that PFs act as a presynaptic input to PCs through temporally and spatially overlapped development, it raises a hypothesis that the PF activity would affect the development of cerebellar network. However, it is not yet clear whether the activity of the sequentially formed PFs functions on the cerebellar development. To address this question, we utilized a new method using the adeno-associated virus (AAV) that allows us to express molecules in only a bundle of developing PFs, instead of all PFs. We injected this AAV expressing tetanus toxin (TeTx) in a lobule 4/5 of mouse cerebellar cortex and investigated the effects of blockade of neurotransmitter release from a bundle of PFs on the development of the cerebellar network. The blockade led to the reduction of PC viability, represented by reduced intensity of calbindin staining, the reduction of PC dendrite complexity, and the decrease in the molecular layer thickness. The abnormal PC properties were accompanied by the motor dysfunctions. We also found a partial increase in the density of molecular interneurons, which are developed around the time when PC dendrites and PFs are extending. In addition, innervation of another inputs onto PCs, climbing fibers (CFs), was impaired, as expected from the studies showing that PF inputs are required for normal CF innervation. Thus, the inputs from sequentially organized PFs seem to be necessary for the network development and functions of the cerebellum. We further found that severity of impairments was varied depending on the location and timing of PF bundles expressing TeTx, suggesting that there would be critical periods of PF inputs for the cerebellar development. Interestingly, the abnormal cerebellar networks and motor dysfunctions were observed even after TeTx was no longer expressed in adulthood, indicating that the impairment during the development is irreversible. Based on these results, we conclude that the spatially and temporally organized formation of PFs and their inputs are crucial for the cerebellar development.

Title: Projection-dependent labeling of cerebellar granule cells

Authors: *Y. YAMAMOTO, T. KIM, K. TANAKA-YAMAMOTO
KIST, Seoul, Korea, Republic of

Abstract: Cerebellar granule cells (GCs) compose approximately half of all neurons in brain, and have unique morphological features. Although the morphology of individual cerebellar GCs have been long known, the network structure of GCs associated with their projection areas through parallel fibers (PFs) have been overlooked, owing to the very large number of GCs that prevent their systematic analysis. One way to address this issue is to dissect specific groups of GCs according to the location of their PFs. Our newly developed adeno-associated viral (AAV) vector triggered sufficient molecular expression in a portion of GCs, which are postmitotic but immature at the time of viral injection. This property of the AAV enabled us to label only a particular group of PFs and their GC somas by the stereotaxic injection at a certain time during postnatal development. The systematic injection at different developmental time points resulted in the labeling of different bundles of PFs, and confirmed that earlier-born GCs have PFs in the deeper layer, whereas later-born GCs have PFs in the more superficial layer. Thus, we established a technique that is capable of achieving projection-dependent dissection of cerebellar GCs. By using this technique, we attempted to examine the three dimensional spatial relationship between the PF locations in the molecular layer and the distribution of their GC somas in the GC layer. When a group of GCs was labeled by the AAV expressing GFP, GFP-positive GC somas were not clustered but were dispersed throughout the GC layer of sagittal slices. It has been demonstrated that Purkinje cells expressing some molecules, such as zebrin, or the innervation patterns of climbing fibers, as well as mossy fibers are localized in certain transverse zones. However, transverse slices did not show any zonal stripes of the GFP-positive GCs in the GC layer, whereas they have the GFP-positive PF bundles in the molecular layer. These results indicate that GC somas are randomly distributed in any axis regardless of their PF projections. Our technique is further applicable for the broad range of investigation, such as comparing structural or functional properties of GCs by performing double or triple labeling of different groups of GCs, or testing the effects of activity modulation in a group of GCs and PFs by expressing modulatory molecules in these GCs.

Title: Transient stimulation of the inhibitory cerebello-olivary pathway generates a negative prediction error and causes extinction of conditioned eyelid responses

Authors: *O. A. KIM, J. F. MEDINA
Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: To suppress a previously learned behavior, the brain is thought to generate negative prediction error signals (NPE) that trigger extinction learning. Although NPE signals are recorded in many brain areas, it is not known if they cause extinction. Here, we use an optogenetic approach to generate an artificial NPE signal in the inferior olive (IO) and to examine whether it causes extinction of a cerebellar-driven behavior. Mice with an implanted optical fiber in the IO were trained to blink in response to a tone that was repeatedly paired with an ocular airpuff. After learning, photostimulation during the airpuff caused gradual extinction of learned blinks in mice expressing channelrhodopsin in inhibitory cerebello-olivary synapses, but not in control mice expressing EYFP. Furthermore, photostimulation immediately before or after the airpuff did not cause extinction. Our results reveal an effective mechanism for generating NPE signals and triggering extinction of previously learned cerebellar-driven behaviors.

Title: Plasticity of ponto-cerebellar circuits generates predictive responses in climbing fibers

Authors: *S. OHMAE, J. F. MEDINA
Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: During eyeblink conditioning climbing fibers learn to fire in response to the conditioned stimulus (CS, e.g. a tone or LED-flash), thus providing the cerebellar cortex with a predictive signal that anticipates the impending delivery of an aversive airpuff to the eye. The sites of plasticity and the underlying neural circuits responsible for generating this Predictive-CS response are unknown. Here we performed two experiments to examine the role of the ponto-cerebellar pathway: (1) To test whether Pons activity is sufficient to drive the Predictive-CS response of climbing fibers, we trained mice in an eyeblink conditioning task that used direct

photostimulation of the Pons as the CS (Pons CS). We found that climbing fibers fire robustly in response to the Pons CS after learning, but not before learning. This finding demonstrates that climbing fibers can learn to generate a predictive-CS response via plasticity in the Pons or in areas downstream. (2) To test whether areas of the cerebellum that are downstream of the Pons may be involved, we stimulated the cerebellar Interpositus nucleus of naïve mice while recording climbing fiber responses in the eyeblink area of cerebellar cortex. We found that climbing fiber responses could be reliably elicited by stimulating a small eyeblink-controlling zone of the cerebellar interpositus, but much less by stimulating other neighboring sites (e.g. jaw-controlling zone). This finding reveals a hardwired excitatory connection that links functionally-related areas of the deep cerebellar nucleus and the source of climbing fibers in the inferior olive. Altogether, our results suggest a model in which the cerebellum drives predictive responses in climbing fibers, by increasing the strength of the CS-related inputs that it receives from the Pons during learning.

Title: Predictive control of a motor synergy by the cerebellum

Authors: *S. A. HEINEY[1], J. F. MEDINA[2]
[1]Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA; [2]Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Aversive stimuli elicit defensive reflexes that require activation of neural circuits specialized for coordinating the movement of multiple body segments. Here, we show that when the aversive stimulus can be predicted, mice learn to make the same defensive motor synergy preemptively. Furthermore, we identify a small area in the rostral anterior interpositus nucleus of the cerebellum that is both sufficient and necessary for performing the entire defensive motor synergy. Neurons recorded within this critical region are activated predictively in anticipation of the aversive stimulus, and display firing rate modulations that are correlated with the vigor of the synergistic movement on a trial-by-trial basis. The same neurons have sensorimotor receptive fields with mixed selectivity for multiple body segments, providing a neural substrate for the synergy. Our results suggest that some regions of the cerebellum may be organized in

ethologically-relevant “action maps” whose neurons can be selectively engaged via predictive mechanisms to reduce dimensionality and simplify motor control.

Title: Cerebellar participation in a cognitive timing task in mice

Authors: *G. J. WOJACZYNSKI, J. F. MEDINA
Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: A growing body of evidence from human studies suggests that the cerebellum plays a significant role in cognitive function. Achieving a full mechanistic understanding of the cerebellar contribution to cognition would be greatly facilitated by developing cerebellar-dependent cognitive tasks for rodents, which offer a wealth of methodological advantages. Here, we introduce a novel subsecond timing task for mice, based on cognitive “omitted oddball” detection tasks previously developed for humans and non-human primates. We used lesions to identify a region of the anterior interpositus nucleus of the cerebellum that is necessary for performing the task. Furthermore, we found that neurons within this critical region of the cerebellum fire strongly in correct trials when the mouse successfully reports the omitted oddball stimulus, and are less active in unsuccessful trials. Collectively, our results establish a cerebellar-dependent cognitive task for mice, paving the way for future research into the underlying neural mechanisms.

Title: Regional differences in the development of the cerebellar cortex

Authors: *M. SCHONEWILLE[1], G. C. BEEKHOF[2], C. OSORIO[2], F. BLOT[2], J. J. WHITE[2]
[1]Erasmus MC, Rotterdam, Netherlands; [2]Neurosci., Erasmus MC Rotterdam, Rotterdam, Netherlands

Abstract: The cerebellar Purkinje cell is one of the largest neurons in the mammalian brain. In mice, as in most other mammals, the inputs to the Purkinje cell as well as its massive dendritic tree are largely configured postnatally. Coincidentally, cerebellar lesions have been link to deficits in cognitive and emotional abilities and cerebellar injury in early life forms a major risk factor for development of autism spectrum disorder. Here we describe physiological, morphological and immunohistochemical changes that occur during Purkinje cell development in normal mice. Our data indicate the presence of early regional variation in the activity of Purkinje cells during development. Deeper analysis of these pre-symptomatic changes will provide the framework needed to study the spatial and temporal profile of pathogenesis and thereby facilitate early identification of disorders and the testing of potential treatments.

Title: The zona incerta modulation of precerebellar nuclei

Authors: *R. BHUVANASUNDARAM, S. WASHBURN, J. E. KRZYSPIAK, K. KHODAKHAH
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The zona incerta (ZI) is one of the least-studied regions of the brain, despite its robust projections throughout the brain. Recently a number of studies have associated a few potential functions with ZI. One study showed that stimulation of GABAergic neurons in ZI drives rapid binge eating in mice. Another study identified a GABAergic sub-population of neurons in the

ventral ZI that promote sleep. Additionally, caudal ZI has been shown to be a potential target for deep brain stimulation (DBS) for treatment of some forms of tremor. Anatomical findings show that ZI sends projections to pontine nuclei (PN) and inferior olive (IO), two of the major precerebllar nuclei that in turn provide the main inputs to the cerebellum known as the mossy (mf) and climbing fibers (cf). In this study, we examined the functional properties of ZI inputs to PN and IO. We performed *in vivo* extracellular single unit recordings in PN in awake head-fixed mice, and optogenetically activated the ZI-PN pathway. Optogenetic stimulation of the ZI axons in the PN elicited rapid responses in more than 75% of recorded cells with a short latency of 2-3 milliseconds. Using trains of stimuli, we found the ZI-PN pathway remained robust at 20 Hz. Next, we used *in vitro* electrophysiology to study synaptic transmission at ZI-IO. Our data suggest that optogenetic activation of channelrhodopsin expressing ZI axonal fibers in IO evoking large synaptic response. Together, our data suggest that ZI sends functional projections to neurons in the pontine nuclei and inferior olive. Future studies will explain the function of these pathways.

Title: Serotonin regulates tonic inhibition at the input stage of cerebellar processing

Authors: *E. FLEMING, C. HULL
Neurobio., Duke Univ., Durham, NC

Abstract: The cerebellum plays a key role in motor learning, in particular by harnessing diverse sensorimotor inputs to form learned associations that refine the dynamics of movement. Recent work indicates that the cerebellum can also form contextual associations in order drive appropriate motor output and learning according to behavioral state (Courtemanche et al., 2009, Kimpo et al., 2014, Brooks et al., 2015, Lawrenson et al., 2016). While such context-dependent representations of sensory input are evident in the granule cell layer (Ozden et al., 2012), it is unknown what circuit mechanisms could modulate granule cell layer synaptic integration in a manner consistent with changes in brain state or behavioral context.
Anatomical evidence suggests that the cerebellum receives significant serotonergic (5-HT) projections from the raphe and reticular nuclei (Bishop & Ho, 1985) that are particularly dense in

the granule cell layer (Takeuchi et al., 1982). Here, we use an acute brain slice preparation from young adult rats to demonstrate that 5-HT depolarizes granule cell layer inhibitory interneurons called Golgi cells through activation of the 5-HT2A receptor without directly affecting either granule cells or mossy fibers. As a result, 5-HT acts to significantly increase spontaneous inhibition onto both granule cells and Golgi cells. While 5-HT produces a net depolarization of Golgi cells that elevates their firing, it does not significantly alter the probability or timing of evoked Golgi cell inhibition onto granule cells. Thus, the increased spontaneous inhibition paired with normal feed-forward evoked inhibition acts to reduce mossy fiber driven spike probability in granule cells without degrading spike timing. Hence, these data provide a circuit mechanism by which 5-HT can regulate the gain of input/output transformations in the granule cell layer by adjusting signal-to-noise ratios in a manner consistent with enhancing pattern separation. Such changes in network integration could underlie the types of context-dependent gating of sensorimotor input that have been observed in the cerebellum in vivo.

Title: Drd1 receptor activation in cerebellar cortex increases granular cell layer activity

Authors: *J. CANTON-JOSH, Y. KOZOROVITSKIY
Neu, Northwestern Univ., Chicago, IL

Abstract: The cerebellum is influenced by a wide range of neuromodulatory circuits. These circuits are likely to mediate significant effects on activity and plasticity within the cerebellum, thereby modulating motor control. Using transgenic Drd1a-Cre mouse line (Dopamine receptor type 1) and fluorescent in situ hybridization, we have discovered and quantified evidence for mRNA expression of Drd1a receptors within the granule layer of the cerebellar cortex. Since Drd1 receptors are Gs-coupled and have been shown in the striatum and mPFC to lead to increases in cellular excitability, we hypothesized that Drd1Rs could have similar effects in cerebellar neurons. Using ex vivo electrophysiological recordings we have found that selective pharmacological activation of Drd1Rs leads to an increase in tonic firing rates ($n=13$, $p<0.05$) and increases in NMDAR ($n=7$, $p<0.05$) mediated excitatory inputs. These changes are blocked by the addition of Drd1a antagonists ($n=13$, $p=0.5$). Our current studies are examining the

presynaptic sources of dopamine in the cerebellum using optogenetic circuit dissection techniques.

Title: Monosynaptic tracing within the cerebellum reveals distinct Purkinje innervation patterns of diverse cell types within the nuclei

Authors: S. M. LEWIS, D. G. HECK, *A. L. PERSON
Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: The cerebellar nuclei sit at the interface between the learning machinery of the cerebellar Purkinje neurons and the rest of the brain. Purkinje cells project to the nuclei with broad parasagittal topography, but the organization of convergent Purkinje cells at the single cell level has, to our knowledge, never been tested, despite having important computational implications. To identify the organization of inputs to premotor output neurons, Ntsr1-Cre (n = 15) or Vglut2-Cre (n=2) mice of either sex were unilaterally injected into the interposed nucleus (IN) with AAV-DIO-mCherry-TVA and AAV-DIO-H2B-GFP-oG to express an engineered EnvA receptor (TVA) and optimized glycoprotein (oG) in Cre-expressing cells. After 6 weeks, the same IN was injected with EnvA-G-deleted-rabies-eGFP, with mice sacrificed one week later and processed for histology. To identify presynaptic partners to inhibitory neurons, we used the same procedure with Gad1-Cre mice (n=8). Our injection parameters limited uptake of rabies helper viruses, restricting monosynaptic rabies jumps to afferents of very few starter neurons. Using this method, we have identified distinct and highly reproducible Purkinje convergence patterns that differed distinctly between premotor output neurons and neighboring inhibitory neurons. Purkinje neurons presynaptic to premotor output neurons in IN occupied extremely circumscribed parasagittal stripes between one and three neurons wide that appeared consistently in disparate zones in posterior Lobule 8, the border between Lobule 6 and Crus I, and the paraflocculus, with counts totaling an average of 110 Purkinje neurons (+/- 70 s.d.; 9.4 +/- 4.1 neurons per stripe; n = 8). In contrast, Purkinje neurons presynaptic to Gad1-Cre IN neurons were much more numerous (average 3010 +/- 2002 s.d.; n = 3) and occupied a broad parasagittal band spanning Lobules simplex, 4/5 and Crus I. Together these data suggest distinct convergence

patterns of Purkinje neurons onto different postsynaptic cell types in the nuclei which could support diverse computations.

Title: Spontaneous activity change of Purkinje cell under direct current stimulation

Authors: *T. YANG[1], M. KC[1], L. LAM[1], H. LU[2]
[1]Philadelphia Col. of Osteo. Med. - Geo, Atlanta, GA; [2]PCOM - Georgia Campus, Suwanee, GA

Abstract: Transcranial direct current stimulation (tDCS) is a noninvasive technique that has been used to potentially correct cerebellar dysfunctions such as ataxia. To understand the mechanism of tDCS to the cerebellar Purkinje cells (PCs), whole cell patch clamp was used to record from these cells. Direct current stimulation (DCS, 200 μA) was delivered at different electrode polarities to mimic the tDCS. The focus of this study is to measure the spontaneous activity of PCs under DCS. Student's t-test was used to study the frequency changes from DCS. The spontaneous activity of PCs every 60 seconds was used to study the effects of DCS. There was no significant increase in firing rate under positive DCS ($p = 0.19$, $n = 7$) and no significant changes in firing rate under negative DCS ($p = 0.82$, $n = 4$). We also tested the firing rate changes with external current injection (+0.2 nA) under DCS, no significant changes were observed with negative stimulation ($p = 0.82$, $n = 13$) or with positive stimulation ($p = 0.07$, $n = 11$). To test our hypothesis that the dendritic tree of individual PC oriented in each folium determines the final output change caused by DCS, more cases will be needed to study the effects with the consideration of this orientation.

Title: Anatomical analysis of afferents to the red nucleus in mice

Authors: *C. S. BEITZEL[1], B. D. HOUCK[2], A. L. PERSON[3]
[1]Neurosci., Univ. of Colorado Denver Sch. of Med., Aurora, CO; [2]Hendrix Col., Conway, AR; [3]Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: The red nucleus (RN) is a major target of cerebellar premotor output neurons and forms a rapid route for cerebellum to influence movement through direct projections to spinal motor pools. Increasing evidence indicates that motor cortex, cerebellum, and basal ganglia work together in service of motor control. The red nucleus is innervated by all three of these motor regions and various brainstem nuclei, setting up the RN as a potential hub of integration linking multiple motor systems. Defining rules for interaction between these systems with in the RN, however, requires identifying afferent overlap and sources of inhibition to the RN which are poorly characterized in any species. We explored the anatomically overlap between the motor cortex and the cerebellum, two major inputs to the red nucleus. We injected anterograde viral tracers expressing either GFP or RFP to the cerebellar interposed nucleus and sensorimotor cortex in wild type mice (n=3). We found limited overlap of terminal fields from the cerebellum and sensorimotor cortex restricted to the most rostral extent of magnocellular RN. Sensorimotor cortex preferentially innervated neighboring parvocellular RN and pararubral areas, which were devoid of cerebellar afferents. To better understand if these areas project into RNm, we examined the sources of inputs to the RN, with particular attention to potential sources of inhibition. Using biotinylated dextran amine injections into either wild type mice or GlyT2.eGFP mice (n=4, n=2, respectively) we identified multiple areas that innervate the RN, including known sources such as the cerebellar nuclei, sensorimotor cortices, and substantia nigra-pars reticulata. We also found retrograde label in multiple brainstem reticular nuclei. Interestingly, we identified two sources of glycinergic inhibition to the RN from pontine reticular nuclei (PNo,PNC, RtTg) and gigantocellular reticular nucleus (Gi). Sparse anterograde label from sensorimotor cortex was seen in some of these areas, including Gi, PNo, as well as mesencephalic reticular nuclei, providing a potential conduit for feed-forward inhibition through known and putative inhibitory afferents to the RN. Together these data support RN as a point of integration between multiple upstream motor centers.

Title: Mechanisms underlying stress-induced motor attacks in a mouse model of episodic ataxia type 2

Authors: *H. D. SNELL, A. VITENZON, E. TARA, K. KHODAKHAH
Albert Einstein Col. of Med., Bronx, NY

Abstract: Episodic ataxia type 2 (EA2) is a channelopathy that arises from mutations in the *CACNA1A* gene encoding for the α1 pore forming subunit of P/Q-type voltage-gated calcium channels. Patients with this disorder exhibit motor attacks in the form of ataxia and dyskinesia, which are brought about by physical or emotional stress, or consumption of caffeine or alcohol. We used a well-established mouse model of EA2, *tottering*, to explore the mechanisms by which stressors trigger attacks. Previously, our lab has shown that a decrease in SK channel activity in Purkinje cells is the underlying mechanism for the baseline ataxia, but the mechanism of the attacks, remained unknown. Because cerebellar Purkinje cells (PCs) are required for the expression of attacks in *tottering* mice, we recorded their activity in awake head-restrained mice when they had attacks. We found that PCs exhibited high frequency burst firing during attacks independent of the stressor used. This finding suggested that the triggers might share a common mechanism to induce attacks. Given that stress is the most ubiquitous trigger among channelopathies, we explored its mechanism of action. Previous work in *tottering* mice showed α1 adrenergic receptors play a role in stress-induced attacks, thus we examined whether the noradrenergic system is required for these attacks. We found that pharmacologically activating α1 adrenergic receptors in the cerebellum was sufficient to induce attacks. We also found that activation of α1 adrenergic receptors in the cerebellum was required for stress-induced attacks. To delineate the mechanism by which stress induces erratic activity of PCs we recorded PC activity in acutely prepared slices. Consistent with our *in vivo* data, we found that bath application of norepinephrine (NE) increased PCs irregularity, and this effect was mediated by activation of α1 adrenergic receptors.
It was previously shown that NE down regulates SK channel activity through activation of α1 adrenergic receptors, and a casein kinase II (CK2) dependent phosphorylation mechanism. We found that knock down of CK2 in the cerebellum of *tottering* mice using shRNAs prevented stress-induced attacks, and prevented burst firing of *tottering* PCs *in vivo*. Consistent with our *in vivo* results, we found that pharmacologically blocking CK2 with 4,5,6,7-Tetrabromobenzotriazole (TBB)
prevented NE induced irregularity in PCs, in slice recordings. Overall, these data suggest the adrenergic pathway may be a potential therapeutic target for patients with EA2.

Title: Intensity dependent effects of cathodal tDCS on cerebellum using an *in vivo* approach

Authors: J. SELZMAN, V. YARABARLA, A. JAMSHAD, C. PICOU, *H. LU
PCOM - Georgia Campus, Suwanee, GA

Abstract: This research aims to examine the physiological activity in the primary motor cortex as the result of transcranial direct current stimulation (tDCS) on the cerebellar cortex. Cerebellar ataxia affects a significant amount of the population and impairs one's quality of life. This form of ataxia can manifest as a result of trauma from stroke, autoimmune attacks, or other various CNS diseases, and tDCS has been shown to have promising results as a form of potential therapeutic treatment. Using normal animal models can give insight into the mechanisms that underlie tDCS therapy and can be used as a precursor for further research involving diseased animal models. Sprague-Dawley rats (n=10) were used to isolate Purkinje cells (n=14) from the cerebellar cortex as well as to record local field potentials in both the cerebellar and cerebral cortices. Cathodal stimulation intensity was set at 100 μA and 200 μA. The mean frequency of firing rate was analyzed to determine the output of individual Purkinje cells. Some Purkinje cells (n=10) had a decrease in overall firing rate following the stimulation whereas other Purkinje cells (n=4) exhibited an increase in firing rate from the same stimulation. A one tailed t-test (p=0.23) indicated there was no significant difference in firing rates based on intensities. A power spectrum analysis was conducted to study the changes in cerebellar cortical activity, and results from this analysis showed an increase in amplitude at approximately 5-10 Hz in (n=7) cells. Other cells (n=2) were observed to have a change in higher frequency around 80 Hz. The remaining cells (n=5) exhibited no significant changes in amplitude. Overall, cathodal tDCS was shown to cause a decrease in the firing rate of Purkinje cells. Power spectrum analysis revealed an increase in amplitude of low frequency activity of local field potential under cathodal stimulation in some of the cells. Further, cross correlation and coherence analyses demonstrate that the activity changes of the motor and cerebellar cortices are interrelated. The correlation level decreases with tDCS. The analysis based on current cases indicates that the correlation level is more depressed at an intensity of 200 μA. All of these analyses suggested that the cerebellar tDCS altered activity in the primary motor cortex due to a change in cerebellar output. Future analysis should focus on comparisons between cathodal and anodal direct-current stimulation, as well as alternating-current stimulation, to determine the most effective form of treatment.

Title: Serotonergic modulation of cerebellar circuitry

Authors: *K. PALARZ, K. KHODAKHAH
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Ataxia (uncoordinated movement) is a debilitating disorder that interferes with patients' ability to perform activities of daily living. Ataxia is often caused by dysfunction of the cerebellum, a brain area involved in motor coordination and maintenance of balance. There are few therapies available for treatment of ataxia, and the ones used, such as serotonergic agents, have limited efficacy often only in a subset of patients. Thus, there is a real need for new and improved therapeutic approaches for the management and treatment of ataxia.
A major cause of cerebellar dysfunction is abnormal Purkinje cell (PC) activity. PCs, the sole output of the cerebellar cortex, are intrinsically active cells that integrate synaptic input from over 150,000 parallel fiber (PF) synapses and one climbing fiber (CF). Various experiments in vivo and in vitro have suggested opposing effects of serotonin in the cerebellum. The mechanisms by which serotonin causes these opposing effects are not understood. Nevertheless, because serotonergic drugs are promising for the treatment of ataxia, it is important to delineate the mechanism by which they modulate cerebellar function.
Serotonergic drugs that have been most efficacious in lessening motor dysfunction were chosen to target the 5-HT1A receptor. However, these drugs can also activate 5-HT7 receptors. Because 5-HT1A and 5-HT7 receptors typically have opposing effects on firing and synaptic transmission, it is plausible that the limited efficacy of serotonergic drugs used to treat ataxia is due to activation of multiple receptors that elicit opposing effects on cerebellar function. In the cerebellar cortex, 5-HT1A and 5-HT7 receptors are only found on PCs and granule cells, and in turn PFs. Thus, PC firing and PF synaptic transmission are likely targets of the serotonergic drugs used to treat ataxia.
As a first step to elucidate the mechanism of serotonergic modulation in the cerebellum, we examined the effect of serotonergic receptor agonists on the firing rate of PCs. We performed extracellular recordings of PCs in acute sagittal cerebellar slices. Serotonergic receptor agonists

were then bath applied at concentrations that preserve selectivity. Our data indicates that 5-HT1A, 5-HT7, and 5-HT2A receptor agonists have no effect on the firing rate of PCs in vitro. Therefore, the beneficial effects of serotonin observed in patients might have occurred via modulation of PF-PC synaptic transmission. Future efforts will delineate the effect of selective 5-HT1A and 5-HT7 receptor activation on PF synaptic transmission and plasticity.

Title: The cerebellar representation of learning in smooth pursuit eye movements across hundreds of trials

Authors: *N. J. HALL[1], Y. YANG[2], S. G. LISBERGER[1]
[1]Dept. of Neurobio., Duke Univ., Durham, NC; [2]Dept. of Neurobio., Inst. of Biophysics, CAS, Beijing City, China

Abstract: We studied the motor learning related changes in neuronal firing of neurons in the cerebellum as monkeys performed smooth pursuit eye movements during hundreds of repetitions of a direction-change task. In each learning trial, a target moved in an initial pursuit direction as the animal followed it with his eyes. After a short, fixed interval of 250 ms, the moving target suddenly, but predictably, changed direction. Over multiple presentations of the learning trials, behavioral learning was measured as a modification of eye velocity just before the target changes direction. As reported by others, we found that neurons in the cerebellum express large changes in firing rate that appear over a few or tens of trials as monkeys perform the direction learning task. However, longer recordings over blocks of hundreds of learning trials revealed that the learned changes are not stable in all neurons. In some neurons, learning changes decreased in amplitude or disappeared entirely as behavioral learning evolved over trials. Our results suggest that motor learning is a dynamic process and might be consolidated outside the cerebellum or only in specific subsets of cerebellar neurons.

Title: Regulation of flexible learning, social interaction, and whole-brain cellular activity by lobule VI of posterior vermis

Authors: *J. VERPEUT[1,2], T. PISANO[1,3], M. KISLIN[1], L. WILLMORE[1], L. TAO[1], D. PACUKU[1], T. D. PEREIRA[1], A. M. BADURA[4], S. S.-H. WANG[1,2]
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Mol. Biol. Princeton Univ., Princeton, NJ; [3]Rutgers-Robert Wood Johnson Med. Sch., New Brunswick, NJ; [4]Netherlands Inst. For Neurosci., Amsterdam Zuidoost, Netherlands

Abstract: The posterior cerebellar vermis is a likely substrate for cognitive and social function: adults with damage to this region show deficits in affect and executive function, and perinatal injury leads to a 36-fold increase in the risk of autism spectrum disorder. We mapped vermal influence over brainwide distal targets, and quantified behavioral consequences of adult and developmental postnatal disruption. To identify distal targets, we performed anterograde transsynaptic tracing using herpes simplex virus (HSV)-H129 injections into lobule VI. After 80 h incubation, we observed GFP-expression in intralaminar thalamic nuclei as well as anterior cingulate, prelimbic, and orbitofrontal cortex. Next, to identify functional targets of lobule VI, we used the light-sensitive proton pump ArchT to inhibit Purkinje cells (PCs; AAV-CAG-FLEX-ArchT-GFP into L7-Cre +/- mice). The resulting brain-wide disinhibition pattern was visualized using quantitative c-Fos mapping and light-sheet microscopy. Compared with L7-Cre -/- littermates receiving the same injection and light stimulation, we found more c-Fos positive neurons in nucleus accumbens (5.3-fold increase; $p<0.05$, Mann-Whitney U, two-tailed), intralaminar nuclei of the thalamus (6.0-fold increase, $p<0.05$), and anterior cingulate cortex (4.1-fold increase, $p<0.05$).
To characterize behavioral consequences of lobule VI perturbation, we reversibly inhibited molecular layer interneurons (MLIs) by expressing hM4Di DREADD (Designer Receptor

Exclusively Activated by Designer Drugs) using AAV-hSyn-hm4Di-mCherry. The DREADD agonist CNO evoked decreases in the rate and modulation of PC simple-spike firing in vivo. To identify consequences of lobule VI disruption during development, we delivered CNO from postnatal days (PND) 30 to 56. Two weeks after CNO, mice (PND >70) showed deficits in reversal learning, social behavior, and novelty-exploration. CNO also acutely impaired reversal learning and novelty-exploration (A. Badura et al., Soc. Neurosci. Abstr. 2017). To test CNO's effects on developing neocortical circuitry, pyramidal neuron dendritic spine morphology of medial prefrontal cortex demonstrated increased mature mushroom spines (26.8%) compared to littermate controls (18.6%; $p<0.05$, t-test, two-tailed). In summary, lobule VI has both developmental and acute effects on flexible behavior, and provides activity sufficient to influence neocortical dendritic refinement. We are now applying automated pose-tracking (see L. Willmore et al. abstract, this meeting) to identify behavioral consequences of lobule VI disruption in freely-behaving mice.

Title: Selective activation of cerebellar granule cells and molecular layer interneurons has distinct impact on performance in watermaze tasks

Authors: *T. SURDIN[1], M. D. MARK[2], S. HERLITZE[3]
[1]Ruhr-Universität Bochum, Bochum, Germany; [2]Ruhr Univ. Bochum, Bochum, Germany; [3]Ruhr-University Bochum, Bochum, Germany

Abstract: The ability to accurately integrate and represent information about environmental features is termed spatial cognition. It comprises declarative and procedural memory components. The procedural component relies on the body-centered reference frame providing knowledge about the sequence of movements, whereas the declarative component integrates information about relationships between landmarks based on allocentric reference frames (i.e. regardless of the animals location). Declarative knowledge of distances and spatial arrangements of objects is supported by active location updating processes creating an accurate spatial map that enables self-localization in the absence of external cues. Without continuous updates, this system is susceptible to accumulating directional errors. Cerebellar structures participate to a great extent in procedural memory, relaying error corrected signals to cortical structures by conveying integrated sensory information, thereby refining movements. Studies using a mouse

model with impaired synaptic long-term depression (LTD) at the parallel fiber-Purkinje cell synapse support the notion that the cerebellar circuit serves to foster the procedural optimization of goal-directed navigation through LTD, whereas the declarative component is not affected by impairment of LTD. Our aim was to dissect the relative contribution of cerebellar granule cells (GCs) and molecular layer interneurons (MLIs) to memory formation for space. We used adeno-associated virus to express channelrhodopsin 2 in respective celltypes of the cerebellar circuitry during two different spatial navigation paradigms: the Morris watermaze (MWM) and the starmaze. The MWM requires both memory components - procedural and declarative. The starmaze, however, relies mainly on declarative capacities. Optogenetic activation of GCs and MLIs resulted in different patterns of performance decrease in the two paradigms indicating their distinctive roles in spatial memory. Whereas optogenetic activation of GCs in C57Bl/6 mice suppressed efficient learning in both mazes, activation of MLIs led to a selective decrease in the late phase of the starmaze navigation performance. Thus, GCs convey information relevant for both components of memory, whereas MLIs may play a distinctive role in the declarative component of spatial navigation.

Title: Probing the functional interactions between distinct elements of the cerebellar cortex and deep nuclei circuitry in awake behaving mice

Authors: *M. BEAU[1], D. KOSTADINOV[2], Y. CHUNG[2], M. HAUSSER[2]
[1]WIBR, UCL, London, United Kingdom; [2]Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: The cerebellum is a structure crucial for motor control and learning. It has been extensively studied in a variety of reductionist motor paradigms, but how it is engaged in complex tasks with more degrees of freedom, and how distinct elements of cerebellar circuitry interact with each other in real time to drive behaviour remain largely unexplored. In particular, the exact interplay between the Purkinje Cells (PCs), the output neurons of the cerebellar cortex, and neurons of the deep cerebellar nuclei (DCN) is an open question in the field, which requires simultaneous recordings of functionally connected cerebellar cortex and DCN neurons.

We are addressing this problem using Neuropixels silicon probes, which allow sampling from 384 densely-spaced channels along a linear recording shank that can span both the cerebellar cortex and DCN. A typical recording session yields >100 well-isolated units across the 4 mm of recording depth. Using a combination of cell-type specific optogenetic tagging, prior knowledge about the firing properties of distinct cerebellar cell types, and post-hoc histological validation of our recording sites, we can cluster these recorded units and putatively identify the major cerebellar cell classes. In the cerebellar cortex, PCs, molecular layer interneurons and granule cells were readily identifiable. Typical recordings yielded 20 ± 4 PCs, 30 ± 10 MLIs and 10 ± 2 GCs (n = 4 mice). Importantly, we can detect PC complex spikes, despite the variability of their waveforms. DCN recordings revealed 15 ± 5 units that were tentatively classified into excitatory and inhibitory neurons based on their firing rates. Correlation analysis of the spike times of these recorded units revealed a variety of functional relationships between nearby cells, as well as neurons spanning the cerebellar cortex and DCN, confirming our ability to record from the entirety of the cerebellar circuitry.
We are now using this system to probe the dynamics of interactions between these cell types during a motor task with several degrees of freedom. In this task, head-fixed mice are trained to use a steering wheel with their forepaws to translate a virtual object presented on monitors. We are now combining this behavioural paradigm with our Neuropixels recordings as well as custom video tracking of limb movements to gain novel insights into how sensorimotor parameters are encoded by distinct cerebellar circuit elements, and guided by interactions between these elements, at single spike resolution. This approach will provide insights into how the cerebellar corticonuclear interactions govern complex sensorimotor behaviours.

Title: Transcriptional role of mef2 in cerebellar granule neurons

Authors: *S. P. MAJIDI[1], N. C. REDDY[1], T. YAMADA[1], L. HU[2], T. CHERRY[3], M. E. GREENBERG[2], A. BONNI[4]
[1]Washington Univ. In St. Louis Sch. of Medic, Saint Louis, MO; [2]Dept. of Neurobio., Harvard Med. Sch., Boston, MA; [3]Seattle Children's Res. Inst., Seattle, WA; [4]Dept. of Neurosci., Washington Univ. in St. Louis, Sch. of Medi, Saint Louis, MO

Abstract: Accurate control of gene expression is critical for the proper development of the diverse cell types that comprise the mammalian brain. Transcription factors (TFs) are an important class of gene regulators distinguished by their ability to bind specific DNA sequences, which gives rise to their ability to regulate complex patterns of gene expression. The myocyte enhancer factor 2 (Mef2) family of TFs has held a longstanding interest in the field of neuroscience due to its strong expression in brain tissue and its critical role in a host of processes in the mammalian nervous system, including activity-dependent regulation of synapse and spine number, dendritic morphogenesis, and learning and memory. Previously, our lab has revealed that a sumoylated form of Mef2a regulates synaptic differentiation of cerebellar granule neurons. In addition to Mef2a, granule neurons also co-express a second Mef2 family member, Mef2d. Despite the high expression of Mef2d in granule neurons, the contribution of Mef2d to granule neuron development has not yet been elucidated. Furthermore, its genome-wide transcriptional role during granule neuron development remains to be studied. To gain insight into the role of Mef2d during granule neuron development, we have performed *in vivo* morphologic assays following conditional knockout of Mef2d in granule neurons. Additionally, in order to shed light on the genome-wide binding and transcriptional activity of Mef2d in the developing cerebellum, we have employed chromatin immunoprecipitation- and RNA-sequencing of granule neurons. Following conditional knockout of Mef2d, RNA-sequencing reveals that gene expression of a substantial portion of Mef2d-bound sites are dysregulated. We are interested in employing strategies in granule neuron culture to further explore the role of Mef2d in regulating transcription at Mef2d-bound sites. These studies should provide further insight on how Mef2 regulates the development of cerebellar granule neurons.

Title: Similarity of execution and observation neuronal population activity in macaque motor and ventral premotor cortex

Authors: *S. J. JERJIAN[1], G. VIGNESWARAN[1], R. N. LEMON[1], M. SAHANI[2], A. KRASKOV[1]
[1]UCL Inst. of Neurol., London, United Kingdom; [2]Gatsby Computat. Neurosci. Unit, Univ. Col. London, London, United Kingdom

Abstract: Motor cortical neurons can modulate their activity during both action execution and observation, yet only the former state is accompanied by overt movement. Single neurons can show very similar activity during the two conditions (classical mirror neurons (MNs)), or opposite patterns of discharge (suppression MNs). Here, we used principal component analysis (PCA) to compare population-level activity during execution and observation and assess the degree of overlap in their cortical representations.
One male rhesus macaque was trained to perform or observe cued reach-to-grasp movements on two objects, affording precision grip and whole-hand grasp. We obtained multi-electrode recordings (Thomas Eckhorn recording drives) of extracellular single-unit responses in contralateral (left) primary (M1) and ventral premotor (F5) cortex during task performance. Pyramidal tract neurons (PTNs) were identified in both areas via antidromic stimulation between two chronically implanted tungsten electrodes in the ipsilateral medullary pyramid.
From clustered single-unit spikes, we compiled trial-averaged peri-event time histograms to form timepoints x units matrices for execution and observation, separately for different task epochs, objects, and neuronal sub-populations. For each matrix, we performed PCA to obtain the top 5 principal components (PCs), representing trajectories through neural space. We then calculated the proportion of explained variance relative to the total variance of each condition's subspace. To quantify shared variance, we projected observation data onto the first 5 execution axes and summed the variance captured. We then quantified overlap between execution and observation as the ratio of this sum to the variance explained by the first 5 observation PCs.
We recorded 51 PTNs (36 M1, 15 F5), and 173 unidentified single units (UIDs) (106 M1, 67 F5), many of which clearly modulated their activity during one or both conditions. During grasp, the first PCs typically captured greater variance in execution than observation in M1, but not F5, suggesting a more precise locking of M1 single units to the execution of grasp. Execution and observation subspaces were generally well aligned during the delay period prior to the go cue, which indicated the upcoming trial type. F5 representations during reach and grasp showed an overall greater overlap between execution and observation than M1, suggesting greater similarity in F5 between the two conditions.

Title: A newly learned controller is inflexible and computationally demanding

Authors: *S. A. HUTTER, J. A. TAYLOR
Psychology, Princeton Univ., Princeton, NJ

Abstract: Over the past two decades, the field of motor learning has primarily focused on the process of adapting a previously learned control model, presumably through the update of an internal forward model. Surprisingly, learning a novel controller (i.e, a mapping between goals and actions) has received relatively little attention. Only a handful of studies have investigated learning new controllers and these have found what appears to be a fundamental difference between learning de novo compared with compensating for a perturbation (Shmuelof et al., 2012; Telgen et al., 2014). Furthermore, a novel controller may be more dependent on decision-making processes (Chen et al., 2017), which have been shown to rely on model-free and model-based learning processes when learning an arbitrary stimulus-response mapping (Haith and Krakauer, 2013). Building on this work, we set out to determine the requirements of learning a controller for a novel motor task. We modified the "grid-sailing task," developed by Fermin and colleagues (2010) to expose how model-free and model-based processes learn to navigate a path with a new stimulus-response mapping (i.e., controller). Here, subjects navigated a cursor across a grid by pressing keys on a keyboard, and we manipulated the mapping between key-presses and movement of the cursor to be either direct and intuitive (i.e. the top button moves the cursor up, the left button moves the cursor left, etc.) or arbitrary and unintuitive. Note, we define intuitive mappings as those that conform with prior expectations based on interactions with spatial navigation. First, we contrast the flexibility and reliability of the established controller (direct key-mapping) with the newly learned controller (arbitrary key-mapping). Flexibility of the controller was assessed with a transfer test, where subjects navigated to novel locations on the grid, while reliability of the controller was assessed on the trained route after experience with the transfer test. Additionally, we hypothesized that reaction time differences between the established and arbitrary controller in the above tasks will elucidate any additional processes required to use the novel controller. This reaction time should depend on complexity for the novel controller, while the established controller should have considerably reduced cost of complexity. We find that the new controller is less flexible, less reliable, and requires greater processing time on transfer trials than the established controller.

Title: Exploring motor repertoires induced by optical stimulation of corticospinal neurons

Authors: *N. SALAH[1,2], Y. LIU[3], Z. HE[4]
[1]Neurobio., Boston Childrens Hospital-Harvard Med. Sch., Boston, MA; [2]Swiss Federal Inst. of Technol., Lausanne, Switzerland; [3]Neurol., Children's Hosp. At Boston, Boston, MA; [4]Children's Hosp Boston, Boston, MA

Abstract: Volitional motor control requires cortical input that is largely mediated via the corticospinal tract, which forms a direct connection between the cortex and the spinal cord. Methods of assessing the involvement of this pathway in motor control have been falling short due to the scarcity of efficient targeting techniques that would enable exclusive manipulation of corticospinal neuron (CSN) activity. Moreover, CSNs have only been studied in animals either in anesthetized or head-fixed states when looking only at a subpopulation of neurons involved in this pathway. Here, a method where exclusive optogenetic manipulation of the entire CSN population in awake, freely behaving mice has been established. A patterned illumination system developed by Mightex has been modified by enlarging the field of view to target the entire forelimb area of the motor cortex. Moreover, the system incorporated the flexibility to target a wide range of CSN population sizes spanning tens of micrometers all the way to the entire CSN population. It also provided high flexibility in designing stimulation patterns where populations could be activated simultaneously or sequentially. Hence, a craniotomy was done to expose the motor forelimb area and a cranial window was implanted on top of which the system was fixed. In doing so, a spatially organized map of motor repertoires resembling ethologically-relevant behavior has been revealed. These were coordinated movements that were exhibited by single-point opto-stimulation at both the mesoscale and microscale levels. Furthermore, the hypothesis that the CSNs possess a modular organization has been explored by sequentially activating regions eliciting certain motor repertoires, and some evidence has been shown here supporting this in some CSN populations, but not all. Therefore, exploiting the full capacity of the system which enables simultaneous imaging and stimulation in the future would lay down the framework of dissecting motor circuits and further studying the mechanisms underlying such variability in the motor outcome across the CSN population.

Title: Cortico-striatal contribution to the execution of a chain of sequences

Authors: *A. SANCHEZ-FUENTES, K. RAMÍREZ-ARMENTA, J. RAMÍREZ-JARQUÍN, F. TECUAPETLA
Inst. of Cell. Physiol., Natl. Autonomous Univ. of Mexico, México CDMX, Mexico

Abstract: It's has been suggested that the basal ganglia receives an internal signal from different cortices in order to start/stop an action sequences, e.g. from the supplementary motor area (in rodent M2) and prefrontal cortices. To date, it's not fully understood how the different cortices may guide the striatal activity to start/stop and switch between actions sequences. In this work we ask how the corticostriatal projections contribute to execute a chain two actions sequences.
Methods: A task in which animals do a chain of two sequences of lever press, presenting in blocks, stimulus-response trials (S-R; where animals are guided to switch between two levers) and self-paced trials (S-P; where animals switch between sequences without any guide) was developed. The neuronal activity of antidrormic corticostriatal neurons was identified [primary (M1), secondary motor cortex (M2) and prelimbic cortex (PL)] while animals execute this chain of sequences. To test whether the cortico-striatal synapses are contributing to initiate/execute the chain of sequences we implemented the optogenetic inhibition of cortico-striatal terminals once the chain of sequences has been learn.
Our preliminary results, from electrophysiology extracellular recordings in cortex show that cells in M1 decrease its activity during the performance of the chain of sequences. PL cortex increased its activity at the boundary of the chain of sequences. The M2 cortex activity increases at the beginning of the first and second sequence. Our preliminary results from the optogenetic inhibition of the cortico-striatal terminals show that the inhibition of the terminals from M2, during the initiation of the chain of sequences, accelerated the performance and the transition to the second sequence in the chain (interestingly it only happened for S-R trials). The optogenetic inhibition of corticostriatal M1 terminals only showed effects when we inhibit during the performance.
These results support the idea that the different corticostriatal synapses have specific contributions for the execution of a chain of sequences.

Abstract: One of the major goals of behavioral neuroscience is to uncover constantly-changing relationships between the animal's behavior, neural activity and the context of behavior. The advent of virtual reality and optogenetic techniques enabled one to easily manipulate behavioral context and neural activity. One element that has been largely absent from these approaches is the ability to rapidly manipulate neural activity based on the context or on sequence of behaviors emitted by the animal. Here we use a neuromorphic chip-based event-driven camera system to implement real-time tracking of whisking behavior in mice trained to move their whiskers to touch a piezo element for reward. Our system tracks the position of single whiskers that are painted with UV paint to enhance tracking. The motion of the whisker is converted into series of thresholded events on the neuromorphic chip, which are used to rapidly estimate the position of the whisker. The system can trigger a TTL output within a short (~2 ms) latency when the whisker reaches the "target region" that we can interactively specify online. Using this system, we can detect each protraction or retraction of a whisker, and can deliver a reward or generate optogenetic stimuli for activating or inactivating cortex. Our methods are fast, flexible and sensitive enough to be used on single slender whiskers of the mouse that can move at frequencies up to 25 Hz, and can therefore be used for tracking whiskers or, in principle, any other part of the animal's body (i.e. the forepaw, hindlimb etc). Closed-loop, fast-feedback and flexible methods such as ours comprise a valuable tool set for manipulating behavior, and for understanding how

activity of neural circuits adapt to changing value of behavior and to a rapidly reconfigured environment.

Title: Perturbation of ipsilateral motor cortex is detrimental to healthy human motor learning

Authors: *A. JOHNSTONE[1], M. NOWAK[1], H. JOHANSEN-BERG[1], C. J. STAGG[2]
[1]Nuffield Dept. of Clin. Neurosci., [2]OHBA, Wellcome Ctr. for Integrative Neuroimaging, Univ. Dept. of Psychiatry, Univ. of Oxford, Oxford, United Kingdom

Abstract: The role of the ipsilateral hemisphere in motor learning has long been debated. One hypothesis is that activity in the ipsilateral motor cortex (M1) makes positive contributions to motor learning (Waters et al., 2017; Berlot et al., 2018), and so increasing this activity should be beneficial. However it has also been shown that the M1s are mutually inhibitory(Ferbert et al., 1992; Chen, 2004), and high levels of activity in the ipsilateral, contralesional hemisphere post-stroke - resulting in higher levels of inter-hemispheric inhibition (Murase et al., 2004)- correlate with worse functional impairments (Ward et al., 2003) in at least some cases. In line with this, interventions to reduce ipsilateral activity have been shown successful in improving post-stroke recovery (e.g. Fregni et al., 2005).
In this within subjects study we investigated how modulating activation of ipsilateral M1 in healthy participants influenced motor learning, consolidation and physiology within the contralateral M1. Participants (n=20, 9 female, mean age = 25.5, age range = 20-32) underwent excitatory anodal, inhibitory cathodal or sham transcranial direct current stimulation (tDCS) to right M1 during learning of a serial reaction time task (SRTT) with the right hand. Transcranial magnetic stimulation (TMS) measures of cortical excitability, $GABA_A$receptor activation (SICI 2.5ms) and glutamatergic activation (ICF) in the left M1 were taken at baseline and three time points after stimulation.
We found that both real stimulation conditions resulted in significant worsening of online

learning compared to sham, but had no effect on offline performance or consolidation of skill. These results indicate that perturbing activation in the ipsilateral M1 of healthy participants, whether in an excitatory or inhibitory manner, is detrimental to motor learning. In line with previous work, we observed that anodal ipsilateral tDCS also caused a significant, but transient, decrease in $GABA_A$receptor activation (Bachtiar, Johnstone et al., *in review*), and increase in glutamatergic receptor activity relative to sham.
Ipsilateral anodal tDCS-induced increase in SICI 2.5ms correlated with stimulation-induced change in skill, such that greater decreases in contralateral M1 GABA were associated with better learning (Stagg et al., 2011). A parsimonious explanation for these results would be that modulating ipsilateral excitability leads to behavioural worsening, but that this can be offset, at least in part, by changes in contralateral GABA activity during learning. These results offer the beginning of a mechanistic explanation for the complex role of the ipsilateral M1 in motor learning.

Title: Motor cortex descending projections drive orofacial behaviors through specific brainstem premotor networks

Authors: *N. MERCER LINDSAY[1], P. M. KNUTSEN[4], H. J. KARTEN[2], D. KLEINFELD[3]
[2]Neurosci., [3]Physics, [1]Univ. of California San Diego, La Jolla, CA; [4]Dept. of Physiol., Univ. of Oslo, Oslo, Norway

Abstract: Focal activation of motor cortex has been shown to enact behaviorally meaningful motor output including defensive behaviors, ethological limb movements, and chewing (Graziano et al., *Neuron*, 2002). However, the details of how the cortical circuitry interfaces with the brainstem premotor circuits is unknown. We studied the hierarchical nature of this control with respect to motor acts that involve vibrissa, jaw, and forelimb muscles.
The spinal trigeminal nuclei pars oralis (SpVO) and rostral interpolaris (SpVIr) contain premotor neurons known to directly synapse on vibrissa, jaw, and forelimb motor neurons (Takatoh et al., *Neuron*, 2013; Stanek et al., *eLife*, 2014; Soledad Esposito et al., *Nature*, 2014). This positions

SpVO and SpVIr as ideal candidates to understand the specificity of cortex-to-brainstem-to-muscle feed forward networks.
We use the transsynaptic tracer pseudorabies to confirm the presence of premotor neurons of the intrinsic vibrissae, digastric, and biceps brachii muscles in the spinal trigeminal nuclei. We show a dense population of premotor neurons for all three muscles in dorsal SpVO and a distinct population of mostly intrinsic vibrissae and biceps brachii premotor neurons in ventral SpVIr. Using a combination of modern viral techniques, we show that 1) motor cortex projections collateralize to both SpVO and SpVIr and 2) the density of motor cortex synaptic inputs shifts with respect to location of labeled neurons in motor cortex. We then virally labeled either SpVO- or SpVIr-projecting motor cortex neurons with a red-shifted channelrhodopsin (ReaChR; Lin et al., *Nat Neurosci*, 2013). We observe that long, i.e., ~ 10 s, trains of light evoked sustained, coordinated activity in a combination of vibrissa, jaw, and forelimb muscles (SpVO-projecting) or vibrissa and forelimb muscles (SpVIr-projecing), consistent with the types of premotor neurons found in each location. Last, we use Thy1-ChR2 mice to show that focal activation of all layer 5 motor cortex outputs results in broad muscle synergies that are specific to a motor act, e.g., forelimb to mouth or chewing.
All together our data illustrates the functional specificity of motor circuits beginning in the cortex and continuing into the premotor populations. We conclude that neurons in motor cortex broadly control muscles through many collateral pathways but with a specialized interface that results in behavioral specificity.

Title: Multimodal signal processing for grasp planning in the primate brain

Authors: *D. BUCHWALD[1,2], B. DANN[1], H. SCHERBERGER[1,2]
[1]German Primate Ctr., Goettingen, Germany; [2]Fac. of Biol. and Psychology, Univ. of Goettingen, Goettingen, Germany

Abstract: Correctly interpreting the environment is essential for all animals in order to perform meaningful actions. Information perceived with different senses greatly facilitates the interaction

with objects or other animals, especially for manipulative actions.
Many brain areas are involved in the sensorimotor transformation process in control of hand grasping, ranging from object recognition to grasp preparation and grasp execution. However, the interaction between these different cortical areas and whether grasp planning activity depends on which sense has been used to perceive an object has not been studied in detail.
In order to shed new light on this topic, we trained two male rhesus macaques (7-8 years old, *macaca mulatta*) to perform a delayed-grasping task, in which they had to lift objects of different size and shape that have been perceived before either by vision or touch. During this task, we recorded spiking activity simultaneously from four relevant cortical areas: the anterior intraparietal area AIP, premotor area F5, primary motor area M1, and the primary somatosensory area S1.
Preliminary analysis from one animal revealed differences in spiking activity between visual and tactile trials. These differences were most prevalent during the preparatory period of the task, after the object was seen or touched but before the animal was instructed to grasp and lift it. Neurons in the grasp-related areas (F5 and M1) showed strong, object selective preparatory activity during the visual trials, as expected. However, this effect was much weaker during tactile trials and disappeared almost completely shortly before grasp execution, hinting towards a sensory modality-specific representation of objects or action intentions in these areas. In AIP, we found a weak memory effect during visual trials and close to no memory effect during tactile tasks. In somatosensory cortex, we observed no significant memory effect during visual trials and only a weak one during tactile trials.
Furthermore, behavioral analysis revealed that the animal was capable of preforming the correct grasp for each object without problems, making the assumption that the animal simply does not memorize the objects or grasps unlikely. Therefore, preparatory object information is either stored elsewhere in the brain (in areas we did not record from, such as prefrontal or temporal areas) or is encoded within these areas in a less straight-forward fashion, which both will require further investigation to resolve.

Title: Sex-related differences in the relationship between dementia risk and cognitive-motor integration performance

Authors: *A. ROGOJIN[1], D. J. GORBET[2], K. M. HAWKINS[3], L. E. SERGIO[2]
[1]Kinesiology and Hlth. Sci., York Univ., Thornhill, ON, Canada; [2]Sch. of Kinesiology and Hlth. Sci., [3]York Univ., Toronto, ON, Canada

Abstract: Cognitive-motor integration (CMI) involves concurrent thought and action which requires the interaction of large networks in the brain. The objectives of our research are to 1) investigate the effect that dementia risk has on the ability to integrate rules into action, and 2) to examine the neural basis of CMI impairment in individuals with dementia risk. Given evidence that early-stage dementia involves neural network dysfunction, we propose that problems with CMI can be used to detect dementia in its early stages. To this end, we previously tested females that are at high- and low-dementia risk (based on family history) on four increasingly visually-dissociated visuomotor tasks using two linked touchscreens (a standard condition requiring direct interaction and three dissociated non-standard conditions of visual feedback reversal, plane-change, and plane-change + feedback reversal). We observed that women at high risk for dementia compared to low-dementia risk showed deficits in movement accuracy and precision (error scores) for non-standard CMI tasks, and that poorer rule-based movement performance was correlated with neural network alterations typically seen in individuals with AD.[1, 2] To extend findings to the entire population and to test for sex-related differences in the relationship between dementia risk and cognitive-motor integration, the current study tested age-matched males at low- and high-risk for dementia on the standard and non-standard CMI tasks. Preliminary findings reveal no significant behavioural differences between high-risk (n=13) and low-risk (n=12) males. Analyses of sex-related differences revealed that low-risk males and females do not differ in their timing or error scores. Interestingly however, there is a significant difference in error scores in two of the cognitively demanding tasks (plane-change and plane-change + feedback reversal), where high-risk females performed worse than high-risk males. These data suggest that the underlying brain networks that control thinking and moving at the same time are different between men and women[3], and that dementia risk may affect female CMI performance to a greater extent. Future work will examine the exact nature of these task-related brain networks and their relationship to individual genetics using collected imaging and genetic data. 1. Hawkins KM, Sergio LE. 2014. Title: Sequence learning improves horizon and speed of motor planning

Authors: *G. ARIANI, N. KORDJAZI, J. DIEDRICHSEN
Departments of Statistics and Computer Sci., The Brain and Mind Institute, Western Univ., London, ON, Canada

Abstract: The ability to plan sequential movements prior to or while executing is an essential feature of skill development. While much of the motor learning literature has focused on planning mechanisms for single discrete movements (e.g. arm reaching), the interplay between planning and execution in the context of motor sequences has remained largely under-investigated. We sought to characterize two mechanisms underlying performance improvements in sequence production: 1) how the possibility of planning sequential movements in advance affects performance, and 2) how this planning ability evolves with sequence learning.
We designed two experiments where participants had to produce sequences of finger presses quickly and accurately in response to numerical stimuli (e.g., 1 = thumb, 5 = little). Experiment 1 manipulated the viewing window (i.e., the number of visible digits ahead of the current finger press) in 14-digit sequences to examine a spatial aspect of planning: how the availability of information about upcoming actions affects performance. Experiment 2 varied preparation time (i.e., the delay before making the first press) for 5-digit sequences using a forced reaction time task to examine a temporal aspect of planning: how the availability of time to plan affects performance. Moreover, to investigate how sequence learning interacts with motor planning and execution processes, both experiments had a period of training over a few days in which participants practiced producing reoccurring as well as random sequences.
Experiment 1 shows that performance improves significantly with the availability of viewing up to 2 digits ahead on the first day of training, and up to 4 digits ahead on the last day of training. Experiment 2 shows that performance in both single finger selection and sequence execution improves with longer preparation times: provided enough time, participants plan up to 3 digits ahead in the sequence, and sequence-specific planning improves as a result of learning. We take these results as evidence that the motor system takes advantage of time and visual information to plan sequential upcoming actions in parallel, and that both planning speed and horizon increase with learning.
We conclude that performance benefits in sequence production as a function of training can be explained by a combination of increased planning horizon, faster single finger selection, and improved parallel motor planning. Finally, we propose a computational model with multiple drift-diffusion processes that captures our behavioral results and sheds light on the interactions between planning, execution, and learning in sequence production tasks.

Title: Sex, age, and strain differences result in different behavioral responses to ritalin (methylphenidate) exposure

Authors: A. KABANI, P. B. YANG, *P. DASH, N. DAFNY
Univ. of Texas Med. Sch. at Houston, Houston, TX

Abstract: Both appropriate and inappropriate use of methylphenidate (MPD) has spiked in the last three decades by both sexes and all ages throughout the world. This study was conducted in order to determine if there is sex, age, and genetic strain differences in response to MPD exposure. The effect of variable MPD doses on the behavior of male and female adolescent (post-natal day 39-49) and adult (post-natal day >60) rats of three different genetic strains: Sprague-Dawley (SD) rats, Wistor-Kyoto (WKY) rats, and spontaneously hyperactive rats (SHR) were studies. Twenty-four male and twenty-four female groups were used. The 48 groups each had an N=8. The results show that adult male and females express more significant ($p<0.05$) hyperactivity as compared to adolescent rats. This difference may be due to ongoing brain development in male and female adolescents. Significant ($p<0.05$) differences in response to MPD were observed among the three genetic strains. There were also significant differences to MPD exposure between males and female rats. Female young and adult rats of all three strains responded with significantly more excitation in their behavior activity when exposed to MPD than their male counterparts. The difference between the adolescent female and male rats suggests that the difference between the sexes is only partially related to the gonadal system. In other words, factors aside from a mature reproductive system (not seen in adolescents) are implicated in the differential response to MPD exposure between sexes. All of these factors reinforce the importance of further studies to characterize differential individual responses to MPD, as this may play a role in potential misuse and dependency.

Title: Dorsal premotor contributions to auditory timing: Causal transcranial magnetic stimulation studies of interval, tempo, and phase

Authors: *J. M. ROSS[1], J. R. IVERSEN[3], R. BALASUBRAMANIAM[2]
[1]Cognitive and Information Sciences, SSHA, [2]Cognitive and Information Sci., Univ. of California, Merced, Merced, CA; [3]Inst. for Neural Computation, UC San Diego, La Jolla, CA

Abstract: It has been suggested that networks involved with movement planning play an essential role in timing perception, but specific contributions of premotor cortex are unknown. The Action Simulation for Auditory Prediction (ASAP) hypothesis proposes that the dorsal auditory stream is involved in predictive beat-based timing through bidirectional interchange between auditory perception and dorsal premotor (dPMC) prediction. Although dPMC involvement in beat-based timing is supported by brain imaging, a causal role of dPMC has not yet been tested. We used a transcranial magnetic stimulation (TMS) protocol that down-regulates cortical activity, continuous theta burst stimulation (cTBS), to test for causal contributions of left dPMC to time perception in three experiments. These experiments observed interval timing perception, musical tempo perception, and musical phase perception. Perceptual acuity was assessed pre- and post-cTBS using a test of sub-second interval discrimination and the tempo and phase subtests of the Adaptive Beat Alignment Test (A-BAT), which tests the ability to detect mismatches between the beat of musical stimuli and a superimposed click track. We show ($N = 30$) that cTBS down-regulation of left dPMC interferes with interval timing ($t(29) = -2.083$, $p = .046$, Cohen's $d = 0.38$) and the ability to detect mismatches in musical tempo ($t(29) = -2.318$, $p = .028$, Cohen's $d = .42$). We did not find disruption of musical phase timing in this study ($t(29) = -1.265$, $p = .216$, Cohen's $d = .23$). Our data support causal involvement of premotor networks in timing, specifically of the left dPMC to accurate interval and musical tempo perception.

Title: Neurobehavioural imaging of natural motor learning in a complex human skill

Authors: *S. HAAR, C. M. VAN ASSEL, A. A. FAISAL
Imperial Col. London, London, United Kingdom

Abstract: Motor skill learning is a key feature of our development and our daily lives, from a baby learning to roll, to an adult learning a new sport, or undergoing rehabilitation after a stroke. Human motor abilities are highly diverse, and as we keep learning new motor skills in all those skills we see tremendous diversity between individuals. While most of us can learn any skill, only some of us have the potential to excel in it. The process of real-world skill learning is long, complex, and difficult to quantify. As a result, it is rarely studied and very little is known about the behavioral and neural process of motor skill learning that makes some of us better learners. Such knowledge can change the way we teach kids, train athletes, or do rehabilitation. Here we use state of the arts methods to do holistic behavioral and brain recordings in order to study the longitudinal learning processes of real-world motor skill. The skill which we work on is playing pool table billiard, and we track the subjects over a period of 3 months, using inertial measurement units to record full body movements, eye-tracking glasses to record eye movements, and EEG to record brain activity. Using this rich data, recorded while naive subjects train in a novel task, we aim to unravel the key behavioral and neural processes that drive motor skill learning. Our results from the early phase of learning, while subjects are practicing repeated trials of the same shot, show a gradual change in the variability structure of arm and hand movement. We see a decrease in the variability of the right wrist rotation in parallel with a gradual increase the covariance between the rotation and the extension of the right wrist. We also see a gradual decrease in the covariance between the joint velocities of the right shoulder and the right elbow, which is in line with improvement in performance. These gradients suggest a biomarker of initial learning. While those are in line with the motor adaptation literature, which shows a gradual decrease in variability throughout adaptation processes, the covariance increase suggests far more complex changes in variability structure. Since skill learning is a longer and more complex process than adaptation, the continuation of this curve and how it changes across different shots is not clear and the accumulating data of this longitudinal experiment would give us insight to such principles of motor learning in complex human skill. This evaluation of changes in the complexity of behavior and its neural correlates (measured directly with EEG and

indirectly by eye movements), enable a systematic and integrative understanding of real-world motor skill learning and its neuronal requirements and constraints.

Title: Transcranial static magnetic stimulation over human primary motor cortex can modulate implicit motor learning

Authors: *I. NOJIMA[1], T. WATANABE[1], M. HIRAYAMA[2], H. SUGATA[3], T. IKEDA[4], T. MIMA[5]

Sch. of Core Ethics and Frontier Sci., Ritsumeikan Univ., Kyoto City, Japan

Abstract: Transcranial static magnetic stimulation (tSMS) is a recently introduced noninvasive brain stimulation technique that can modulate brain function, as well as transcranial magnetic and DC stimulations. However, it is not known whether tSMS can alter robust human behavior or not. Here, we investigated the hypothesis that motor learning might be interfered by tSMS applied over the primary motor cortex (M1), which was reported to temporarily suppress cortical excitability. For motor task, we chose a serial reaction time task including the pre-fixed sequences in the random series to evaluate an implicit motor learning, which M1 has been identified as a key structure for the acquisition and early consolidation. Forty-four healthy right-handed volunteers participated in the study. tSMS was placed over the right M1 (C4 of the 10-20 electroencephalography system) or dorsolateral prefrontal cortex (DLPFC: F4) which is associated strongly with conscious recall of the sequence (explicit learning). The control group received a sham stimulation. We tested their performance before (Pre) and after (Post) practice. The performance was also evaluated 24 hours later (Day2) to examine offline learning. Two participants recalled 8 items out of the twelve-item sequence during the free-recall test and thus

were excluded from analysis. A two-way ANOVA revealed main effects of stimulations and times; however, there was no statistically significant interaction. Although motor performance significantly improved with all groups in Post session, offline learning effect in Day2 session revealed in only M1 group. Offline learning was evident only in the group with M1 stimulation. These findings suggested that modulation of M1 using tSMS, which is reported to suppress cortical excitability, may actually enhance offline motor learning in an implicit task.

Title: Improving motor learning via phase-amplitude coupled theta-gamma tACS

Authors: *H. AKKAD[1], J. DUPONT-HADWEN[2], S. BESTMANN[2], C. J. STAGG[1]
[1]Wellcome Ctr. for Integrative Neuroimaging, FMRIB, Nuffield Dept of Clin. N, Univ. of Oxford, Oxford, United Kingdom; [2]Inst. of Neurol., London, United Kingdom

Abstract: Theta (θ) oscillations are thought to underlie at least some aspects of long-range network functional connectivity, and within a given brain region interact with local gamma (γ) frequency oscillations in a specific type of cross frequency coupling known as phase-amplitude coupling (PAC). PAC is thought to be an important mechanism by which the brain is able to modulate local activity, and has been postulated to have behavioural importance. Recent work suggests that transcranial alternating current stimulation (tACS) can engage endogenous oscillatory circuits in a behaviourly relevant manner.
We investigated the effect of θ-γ PAC on motor learning using tACS over the right primary motor cortex (M1) in a randomized, single-blind, sham-controlled study. When applied exogenously using tACS, θ-γ coupling should exert its excitatory effects during the positive part of the waveform (peak), thus increasing neural firing. Therefore, we hypothesized that applying peak-coupled θ-γ tACS over M1 might enhance learning compared to trough-coupled theta-gamma or sham stimulation. We used a ballistic thumb abduction training task requiring abduction of the left (non-dominant) thumb with maximal acceleration. We used two θ-γ waveforms: a 6Hz θ rhythm modulated the amplitude in the γ-band either at the peak (phase 0°-180°) or trough (phase 180°- 360°) of the θ wave; we will refer to these as θ-γ-peak (TGP) and θ-γ-trough (TGT), respectively. Both real stimulation conditions had a 2mA peak-to-peak

amplitude and a stimulation duration of 20 minutes. 60 subjects were equally randomized to receive TGP, TGT or sham stimulation in a between-subject design during training on the thumb abduction task.
All groups significantly improved their motor performance over the course of the experiment. These improvements were larger in TGP tACS compared to both sham and TGT stimulation, though the latter did not reach significance, whereas TGT and sham showed no significant difference. TGP-tACS resulted in a mean maximal acceleration gain that was ~26% larger than in the TGT or sham groups. Additionally, towards the end of stimulation, the TGP group improved their mean acceleration from baseline by an effect size of Cohen's d= 0.98 compared to sham.
Our findings suggest that θ-γ PAC is important for motor learning and that tACS has the capacity to modulate it. Additionally, our intervention appears to facilitate a substantial gain on motor learning. We are currently replicating our findings in an independent sample, now using a double-blind design and blinded analysis approach. The replication study is pre-registered in full on the Open Science Framework (https://osf.io/452f8/registrations/).

Title: Non-invasive EEG based assessment of laparoscopic clinical simulation based training with first time users

Authors: F. UCRAK[1,2], *M. B. BAYRAM[3], I. A. OZCAN[3], M. E. AKSOY[4], B. ERKMEN[2]
[1]Biomed. Engin., Bogazici Univ., Istanbul, Turkey; [2]Electronics, Yildiz Tech. Univ., Istanbul, Turkey; [3]Dept. of Med. Engin., [4]CASE: Ctr. for Advanced Simulation and Educ., Acibadem Mehmet Ali Aydinlar Univ., Istanbul, Turkey

Abstract: INTRODUCTION: Laparoscopic surgery requires superior and more distinct psycho-motor skills compared to the open surgical procedures. While quantitative determination of the skill level is difficult, the use of electroencephalography (EEG) to measure competency gains has potential to create an unbiased criterion for determining the permanent performance of laparoscopic surgical simulation training. Measurement of brain waves by EEG can

quantitatively indicate how much of the brain capacity is used. There is no precise and complete work in this area, especially in laparoscopic simulations, using two hands in coordinated fashion, tasks that must be completed in a limited amount of time. For this purpose, EEG data collected during laparoscopic surgical simulation training was quantified spectrally and evaluated statistically.
METHODS: In the framework of the protocol approved by the ethics committee, 10 male (right dominant, 22±2.43 years, mean±SD) university students who had no previous experience in laparoscopic surgical simulator participated in the experiment with written consent. The peg transfer test, which is a laparoscopic surgical simulation training module, was performed on two separate dates, exactly one week apart. Each day, the test was performed consecutively for 3 times. EEG was recorded through 32 channels simultaneously. Spectral analysis of EEG data was performed using the NPXLab™ Suite (written by Luigi Bianchi). The results were statistically evaluated with IBM SPSS™ software.
RESULTS: When two time points of relative power were observed in anatomically, significant increases were found in the alpha and theta bands in the T3-T5 channel; alpha bands in the T5-O1 and P4-O2 channels. The increase in the alpha band showed the relaxation and the increase in the theta band might mean that creativity, emotional connection, intuition and relaxation taking place. The change in the T3-T5 region indicated that the subjects remembered the previous experiment and were calmer and the change in the T5-O1 region allowed subjects to understand the process more easily, while the change in the P4-O2 region showed that they used the non-dominant side and spatial memories more actively. It is observed that when the subjects came for the second day, they had higher concentration, performed the tests more calmly and remembered the operation, based on their successful test runs, compared to their first day.
CONCLUSION: EEG rhythms have a direct relationship with physical motor activities and motor planning. Our preliminary findings may be used as a marker for a quantitative formation of laparoscopic surgical simulation training criterion.

Title: Low-frequency modulation of discrete goal-directed force contractions

Authors: *S. L. BRACKSIECK[1], E. SAJJADI[2], A. CASAMENTO MORAN[1], B. YACOUBI KEYHANI[1], E. CHRISTOU[1,2]
[1]Applied Physiol. and Kinesiology, [2]Physical Therapy, Univ. of Florida, Gainesville, FL

Abstract: Fluctuations in force during steady force tasks are mainly explained by low frequency oscillations (<0.5 Hz). Although this low-frequency modulation of the force output is a strong predictor of the within-contraction variability, it remains unknown whether it predicts the variability of repeating discrete dynamic force contractions. Thus, our purpose was to characterize the modulation of the force output across discrete dynamic goal-directed force contractions. Nine young adults (23.6±4 years) performed a 50-s dynamic task with the dominant ankle. Within this time, participants repeated force contractions at a frequency of 0.8 Hz aiming at a force amplitude of 10% and 40% maximum in separate trials. This manipulation of force increases the voluntary drive to the motor neuron pool. We quantified the modulation of the force output by quantifying the power spectrum density of the peak force. To be able to examine the power spectrum density of discrete data points, we transformed the discrete peak forces across trials into a continuous signal. We examined the power spectrum at a 0.05 Hz resolution. All of the subjects exhibited a clear peak in the modulation of peak force at ~0.1 Hz for both the 10% (0.09±0.01 Hz) and 40% (0.1±0.01 Hz) amplitude. The low-frequency modulation of peak force was related to the variability of peak force across contractions for 10% (R^2=0.71, P<0.01) and 40% (R^2=0.69, P<0.01). As expected, the peak force variability increased from 10% to 40% maximum (0.03±0.005 N^2) and related to an increase in low-frequency oscillations from 0-0.2 Hz (R^2=0.56, P<0.01). Thus, similar to steady contractions, the force output variability of discrete contractions is influenced by a low-frequency modulation. Given that these low-frequency oscillations are present during steady contractions and fast discrete dynamic contractions, it likely suggests a central origin.

Title: Conflict and suppression during action preparation: Suppression of task set, not responses

Authors: *J. XU, L. ELPHAGE, A. M. HAITH
Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: In our daily activities, we often need to withhold an automatic, habitual response in order to carry out the desired action. Prevailing theories suggest that such selection is achieved through a combination of *conflict monitoring* (detecting whether there are conflicting candidate responses) and *response suppression* (inhibiting specific actions) to allow the correct, deliberate response to be generated (Botvinick et al., 2001; Ridderrinkof, 2002; Wiecki & Frank, 2013). Here, we present evidence against this framework, suggesting instead that conflict is detected and resolved at the level of stimulus-response *mappings*, rather than at the level of individual *responses*.
In our task, an arbitrary symbolic cue (Phoenician letter, or colored 'X') instructed participants which of four potential directions to aim a reaching movement (e.g. blue = left). We created a conflict by presenting this cue in a spatial location that was sometimes incongruent with the instructed direction. In order to track the evolution of participants' response preparation, we had participants perform this task under timed-response conditions - forcing them to emit responses at a range of preparation times (PTs) ranging from 0 to 600ms. In incongruent trials, when participants were forced to respond at very low PTs (200-400ms), participants reliably (and erroneously) moved towards the spatial location of the stimulus. At higher PTs (>500ms), however, they were able to consistently select the correct response. At intermediate PTs (300-400ms), however, participants transiently increased their probability of responding to one of the two locations that did not follow either map. This pattern is consistent with the idea that the prepotent response was suppressed before the deliberate response was selected. However, this signature of suppression was apparent even in congruent trials, in which there was no conflict between candidate responses. Our results challenge the view that response preparation is influenced by monitoring of conflict between candidate responses and selective suppression of prepotent responses. We suggest that response preparation and response initiation may be sensitive to different forms of conflict, with response preparation influenced primarily by conflict between task sets (SR mappings), and response initiation influenced by conflict between candidate responses.

Title: Individuals with an ACL reconstruction have altered neuromotor function

Authors: *C. N. ARMITANO, S. MORRISON, D. M. RUSSELL
Physical Therapy and Athletic Training, Old Dominion Univ., Norfolk, VA

Abstract: The anterior cruciate ligament (ACL) is a key structural component in stabilizing the knee joint during purposeful movement. However, damage and subsequent ACL reconstruction does not always often result in a return to normal function. Indeed, wide spread motor problems can emerge as a result of the absence of a natural ACL. For example, individuals with a reconstructed ACL often exhibit increased variability and irregularity coupled with changes in coordination during gait. What has not been assessed to date is whether ACL damage also leads to slowing of responses under postural conditions. The current study was designed to compare differences in reaction time under both seated and postural (i.e. standing) conditions. It was also of interest to examine how ACL reconstructed individuals responded under the more challenging postural task. Fifteen adults with unilateral ACL reconstruction and 15 age-matched healthy controls participated in this study. Baseline assessment of neuromotor function including measures of proprioception, balance, strength, and walking ability were performed. Simple and choice reaction time response were assessed under seated (i.e. control) conditions and during a postural stepping task. The results revealed similarities between both groups with regards to the baseline measures of proprioception, balance, strength, and gait as well as the seated reaction time tasks. However, during the postural stepping task, individuals with ACL reconstruction had significantly slower reaction times compared to the healthy controls. This finding indicates that these persons had a reduced ability to respond quickly under more challenging postural conditions. This finding of slower responses when stepping for the ACL reconstructed adults may be a compensatory response to the previous injury and/or residual symptoms post-ACL reconstruction. Overall, these findings indicate that reconstruction of the ACL ligament impacts neural mechanisms, altering individuals' ability to respond under challenging balance tasks.

Title: Eye movements in real baseball batting by elite players

Authors: *Y. KISHITA[1], M. KASHINO[2,1]
[1]Tokyo Inst. of Technol., Tokyo, Japan; [2]NTT communication science laboratories, Atsugi, Japan

Abstract: In baseball, it takes only about half a second for pitched balls to reach home plate. In such a short amount of time, baseball batters judge whether to hit or not and then swing the bat at the right time and place. A previous study (McLeod, 1987) suggests that it takes about 200 ms to adjust their swing to novel visual information. The swing itself takes about 200 ms as well. For

these reasons, baseball batters predict the ball's trajectory and start their swing when the ball is still far from home plate. Moreover, ball velocity in visual angle reaches more than 500 deg/s around home plate. For this reason, it is considered that batters cannot keep their eye on the ball through its full fright. Our question is: How do good batters hit the ball in such tough conditions, What is a reasonable visual-motor strategy? We examined eye movements of baseball batters hitting random pitches of two types: a fast ball (about 130 km/h) and a curve ball (about 110 km/h) in order to elicit eye movements that would take place in real baseball games. Batters were required to judge the pitch a fast ball or curve ball before swinging the bat. Participants included professional players, skilled non-professional players, and a former college league player. Batters hit a series of pitches wearing a helmet equipped with an eye tracker (500 fps). In most cases, batters kept their gaze with fixational-like eye movements on the ball in the early stages, and then started predictive saccades toward the ball. The saccadic eye movements landed 0 - 200 ms before bat-ball contact in most cases, and the relationships between the ball and predictive saccades in terms of time and space differed according to batting results. In successful trials, predictive saccades led the gaze to where ball be or would be. However, in false trials (swing away or miss), the gaze reached the wrong place. In some cases, misjudgments of the types of pitch (fast ball or curve ball) led the gaze to the batter's predicted trajectory of the pitch. These results suggest that predictive eye movements reflect the prediction of ball trajectories and types of pitches.

Title: Cognition-action behavior of top athletes in experimental batting explains their performance in real games

Authors: *D. NASU, A. KOBAYASHI, M. YAMAGUCHI, N. SAIJO, M. KASHINO, T. KIMURA
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: Human action often involves cognitive processes, i.e., sensory processing, prediction and decision making. Sports provide a case in point, and top athletes should possess high abilities in both cognition and action. In sports, such a cognition-action process frequently occurs within a split second. For example, in baseball/softball, a batter has to predict the trajectory of a

pitched ball, decide whether to swing and hit it within about 500 ms from the time the pitcher's releases. Previous studies have shown the importance of cognitive and motor processes in baseball/softball. However, they examined each process separately, which leaves the overall picture veiled. In particular, the relationship between the two processes and how much each contributes to the batting performance in real games are still unclear.
Here, we paired a cognitive task and a real batting task to investigate the cognition-action structure in softball batting. Elite women softball players, some of whom had been members of the national team, participated in the experiments. Balls were thrown by real pitchers at two speeds, one relatively higher than the other. Batters responded by pressing a button in the first task (cognitive task). Then they tried to hit a ball in the next task (batting task). In both tasks, batters did not know how fast the ball would be thrown. Since different ball speeds change the time to contact (TTC), participants had to predict the ball speed/TTC by discriminating ball speed and to swing according to their prediction. To clarify the cognition-action structure, we introduced a path analysis using structure equation modeling. Our model consisted of six variables, obtained from the two tasks and the season batting average.
Our model showed good fitting (χ^2 test, $p = 0.58$; CFI = 1.00; TLI = 1.07; RMSEA = 0.00) and produced three findings. First, the discrimination accuracy (false alarm rate) and speed (reaction time) obtained from the cognitive task were significantly related to the time shift of swing onset in the batting task, indicating that batters who showed accurate and early discrimination shifted their swing onset according to ball speed/TTC. Second, batters who shifted their swing onset showed superior batting performance (i.e., high exit velocity and low miss ratio) in the batting task. Third, the experimental performance was significantly related to batting average in the 2017 season. Overall, we described the cognition-action structure for top athletes quantitatively and showed that the relationship between these two processes could explain a batter's performance in real games.

Title: Availability of pitching motion information in batting timing control revealed by virtual reality

Authors: *T. KIMURA, D. NASU, M. YAMAGUCHI, M. KASHINO
NTT Communication Sci. Labs., Atsugi-Shi, Japan

Abstract: Recently, we found that skillful softball batters adjust the timing of their trunk motion in bat swings according to ball speed when the pitcher randomly throws slow or fast balls. The timing adjustment starts about 300 ms after the pitcher releases the ball, suggesting that expert batters make very early decisions about swing timing based on information related to the pitching motion. In this study, we manipulated the pitching motion using a virtual reality (VR) batting system to assess its effect on batting timing control in female expert batters, including national team players. We used a head-mounted display-based VR system for application to softball batting. With this system, batters can experience highly realistic virtual hitting of a pitched ball: pitched balls are depicted based on previously recorded ball trajectories, thrown in time with the motion of a pitcher avatar based on simultaneously recorded motion capture data, and launched depending on their interaction with the bat. In this virtual batting measurement, we found that the trunk rotation timing in some players started earlier for mismatched combinations (slow balls thrown with fast ball pitching motion) compared with matched combinations (fast ball motion and a fast ball). In a separate measurement, where they were asked to push a button as soon as they had judged the ball to be a fast ball, they showed increased uncorrect responses in the mismatched combination. Interestingly, none of the participants were conscious of such mismatched combinations. These results empirically indicate one cognitive feature in the implicit (unconscious) brain processing of skillful bat control; namely, some batters unconsciously utilize information related to the pitching motion when deciding whether or not to swing (go/no go). Our VR system will provide novel insights into athletic performance and its neural mechanisms in a batting scenario, which had been hard to obtain in conventional measurements.

Title: Increased gain in online correction of a reaching task in ball game athletes

Authors: *T. IJIRI[1], H. KOBAYASHI[2], K. NAKAZAWA[1]
[1]Dept. of Life Sci., [2]Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Introduction Catching or hitting a flying ball requires us to adjust the trajectory of hand or bat within an very short time to minimize spatiotemporal error. During arm reaching movement, the movement can be adjusted to sudden target displacement in a much shorter latency than that of conventional button-press choice reaction task (Kadota and Gomi 2010). The

initial component of the correction is known to be implicit and unconscious (Prablanc and Martin 1992). Although the fast and implicit visuomotor processing could be crucial for athletes' high performance, there is no research that examined the characteristics of the motor response of athletes at short latency described above. Here, we investigated the latency and gain of unconscious movement correction athletes and non-athletes.Methods: Ten male subjects (mean age of 24.0 years old; range of 21-35; 5 ball-game athletes and 5 non-athletes; all right handed) participated in this study. Subjects were asked to move their right index finger to a visual target shown at the center of PC monitor. In one-third of the trials, the target jumped leftward or rightward 60 ms after the finger movement initiation (TJ trial). The task was performed under two conditions: subjects were instructed to adjust their movement to the new target location (pro-task) and in the opposite direction to the new target location (anti-task). The subjects performed 90 trials for each condition (180 trials in total). A reflective marker was attached on the tip of index finger and the marker position was measured with a motion capture system (oqus300, Qualisys) at 500 Hz. Latency of movement correction was defined as the time from the target displacement to moment when the lateral/medial acceleration of the index finger became different from that of control trial (no target jump). Gain of unconscious movement correction in anti-task was defined as the difference of peak acceleration amplitude between left and right TJ trials.Results: The mean latency of movement correction in pro-task was 103.0 ± 15.0 ms in athletes and 110.5 ± 3.6 ms in non-athletes. In anti-task condition, The mean gain of movement correction was 5.90 ± 1.1 m/s^2 in athletes and 2.3 ± 0.9 m/s^2 in non-athletes.Discussion: Our results suggest that the latency of movement correction was not different between athletes and non-athletes, on the other hand, the gain of movement correction was highly increased in ball game athletes. We also acquired diffusion weighted MRI for each subject to further analyze a neural mechanism underlying the fast corrective response. The structural connection between V5/MT+ and lateral geniculate nucleus or superior colliculus will be examined in the future study.

Title: Efficient cortical coding of 3D posture in freely behaving rats

Authors: *B. MIMICA, B. A. DUNN, T. TOMBAZ, S. BOJJA, J. R. WHITLOCK
Kavli Inst. for Systems Neurosci., NTNU, Trondheim, Norway

Abstract: In order to meet physical or behavioural demands of their environments, animals constantly update their body posture, but little is known about the neural signals this ability is dependent on. To better understand the role of cortex in relation to natural pose and movement, we tracked heads and backs of eleven freely foraging rats in 3D while recording from posterior parietal cortex (PPC) and frontal motor cortex (M2), areas reliably shown to encode orienting movements or movements of individual effectors, such as the eye, arm and hand. This enabled us to determine arena-centered (i.e. allocentric) relevant variables, namely the animals' spatial locations, but also to disambiguate head-direction from movement-direction. In addition, we estimated head rotations around three axes (azimuth, pitch and roll) relative to the body (i.e. in egocentric coordinates) together with postural states of the back alone. Our analysis of coding properties of individual neurons revealed remarkable specificity in tuning, mainly to the combination of different head angle positions relative to the body, but sometimes also to azimuthal flexion and the pitch of the back independently. These coding properties were shown to persist even in complete darkness. Importantly, detailed GLM analyses revealed single units in both regions were predominantly tuned to postural features of the head, back and neck, but only to a lesser degree to their movements. Likewise, the observed coding scheme was distributed in an efficient manner, where more cells were likely to be tuned to features which were less likely to occur during unrestrained movement, thereby not over-representing the default-state posture. Representations of the head and back were organized topographically, and the analysis of signal correlations across areas suggest that, on average, PPC preceded M2 activity by ~50ms. Tuning in both areas was sufficiently robust to allow reconstruction of ongoing pose with ~90% accuracy. Together, these data provide a first-time view of PPC and frontal motor areas' activity related to body pose in unrestrained individuals.

Title: Task-dependence of movement coding in mouse parietal cell populations

Authors: *T. TOMBAZ[1], B. A. DUNN[1], R. J. A. CUBERO[1], P. MAMIDANNA[2], K. HOVDE[1], B. MIMICA[1], J. R. WHITLOCK[1]

Abstract: A fundamental question in neuroscience is the elucidation of neural mechanisms underlying natural behaviors, which emerge when freely moving animals interact with the environment. To ensure survival, the brain must be able to rapidly generate flexible behaviors to meet the demands of different contexts. However, the extent to which movement coding in cortex depends on an animal's given context is not well understood. To investigate the specificity or generality of behavioral coding at the single-cell and network levels, we recorded neural population activity in posterior parietal cortex (PPC) while freely behaving mice performed different tasks. We chose this area because it interfaces with sensory and motor processing streams in cortex, and because it has well-established functions in the spatial coordination of motor behavior. Specifically, we performed *in vivo* calcium imaging in layer 2/3 and layer 5 of PPC while animals engaged in goal-oriented behaviors in a pellet-reaching task, and during spontaneous foraging in an open field with a running wheel. Single cell analyses showed that 40-50% of PPC neurons stably represented various behaviors in each task, such as grasping food or rearing. While a large fraction of the population was active in both tasks, this was not informative of the extent to which the network state discretized behavioral contexts. To address this, we applied the t-student stochastic neighbor embedding (t-SNE) dimensionality reduction method, which embedded deconvolved spike trains of the imaged ensemble in a two-dimensional manifold. This revealed clusters of neural activity states that could be easily visualized and used to indicate discrete behaviors. Moreover, the activity clouds between different tasks were completely non-overlapping, despite the similarity of individual behaviors across tasks (e.g. turning). Our results demonstrate that individual PPC neurons are tuned to multiple actions in different tasks, but the way in which cell populations represent these actions differs fundamentally depending on the context in which they were embedded.

Title: Neural representations of discrete, sequential behaviors in the rodent posterior parietal and frontal motor cortices

Authors: *B. DUNN[1], T. TOMBAZ[2], B. MIMICA[2], K. HOVDE[1], J. R. WHITLOCK[3]
[1]The Fac. of Med., Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]Kavli Inst. for Systems Neurosci., NTNU, Trondheim, Norway; [3]Neurosci., Kavli Inst. for Systems Neurosci., Trondheim, Norway

Abstract: There is an emerging view that posterior parietal (PPC) and secondary motor (M2) cortices represent behaviors at different scales: from elemental poses that comprise behavior, to the choice of the behavior itself. It is not clear, however, how these areas encode the different sequences of dynamic posture underlying the rich diversity of naturally-occurring behaviors. To address this, we observed freely-behaving rats while recording from neurons in PPC and M2 using silicon probes, or while performing calcium imaging using miniscopes in freely-running mice. We tracked the head and body of the animals in 3D and, using machine learning methods, segmented the animals' movement data into sequences that capture the common movement patterns found across animals. We identified a combination of neurons whose tuning was independent of the behavioral sequence in which a movement was embedded, while others responded preferentially to specific sequences. In light of these findings, we propose that PPC and M2 not only encode basic features of behavior, but string postural sequences together to form meaningful sequences of actions.

Title: Uncorrelated low-dimensional population response and noise correlation network structure in the macaque fronto-parietal grasping network

Authors: *B. DANN[1], H. SCHERBERGER[1,2]
[1]German Primate Ctr., Goettingen, Germany; [2]Dept. of Biol. and Psychology, Univ. of Göttingen, Goettingen, Germany

Abstract: Recently developed multi-electrode arrays and corresponding recording systems enabled analyses of how neuronal populations perform cognitive and behaviorally relevant

computations. Several studies on monkeys and mice performing perceptual choice and delayed movement tasks revealed that neuronal population activity in prefrontal, parietal, and temporal cortex could be well understood as a dynamical process in a low-dimensional space with far less dimensions than neurons. It has been hypothesized that the low-dimensional population structure is tied to the underlying network connectivity, but since it is impossible to measure the structural connectivity of the corresponding neuronal population, this relationship has not been studied directly. However, noise correlations capturing the trial-to-trial co-fluctuations estimated for the same specific task conditions and with high temporal precision can be assumed to reflect structural connectivity as an approximation. This allows a direct comparison of the noise correlation network structure with the low-dimensional population response to provide a first glimpse of their relationship.We used parallel recordings from about 48-90 neurons in the fronto-parietal grasping network while two monkeys performed a free-choice or instructed delayed grasping task. The low-dimensional single trial population structure was extracted using a customized dimensionality reduction method based on linear discriminate analysis. We found that seven dimensions captured more than 80 percent of all task-related single trial population activity. The fine-scale noise correlations network structure was extracted using pairwise cross-correlations that were corrected for correlations induced by task-related activity. For this cross-correlated surrogate activity with the same low-dimensional population structure was simulated and subsequently subtracted.Intriguingly, the contributions to the seven dimensions of population activity and the number of significant noise correlations per neuron were heavy-tailed distributed showing a high degree of heterogeneity of neuronal contributions. However, the number of significant noise correlations per neuron was uncorrelated with the contributions to any of the population activity dimensions (mean $R^2 <$ 10E-2). Based on these results we hypothesize a continuum in the population, in which some neurons strongly encode task relevant information but contribute little to the network communication (‘information hubs’), whereas other neurons hardly encode task-related information but are crucial for network coordination (‘coordinator hubs’).

Title: Modulation of corticomotor excitability in response to localized cooling

Authors: Y. ANSARI[1], A. REMAUD[2], *F. TREMBLAY[1]
[1]Sch. of Rehabil. Sci., Univ. of Ottawa, Ottawa, ON, Canada; [2]Clin. Neurosci. Lab., Bruyere Res. Inst., Ottawa, ON, Canada

Abstract: Thermal stimulation (TS) has been proposed as a method to facilitate motor recovery after stroke, but its neural basis remains poorly defined. Recently, we showed (Ansari et al., 2018) that distal focal cooling or warming stimulation targeting a single digit produced a variable modulation in corticomotor excitability, as reflected in motor evoked potentials (MEPs). These results raised the question as to whether extending the area of TS could produce more consistent effects. Here, we report our observations regarding the impact of a ~3X increase in cooling area, going for single- to multi-digit application. Participants (n=22, young and senior, 12 females) consisted of a subset of the pool who participated in our original study with single digit cooling (Ansari et al., 2018). The protocol was identical and consisted in measuring skin temperature and MEPs (target muscle, FDI) at baseline (BL), during cooling at 1-min (C1) and, then, post-cooling at 5-min (PC5) and 10-min (PC10). The cooling stimulation was produced using a large Torex® gel pack sleeve that covered the four digits up to the metacarpal bones, sparing the thumb finger. For BL measurements, a neutral gel pack at 24° covered the fingers, whereas, for those with cooling, a gel pack at 10° was applied. Increasing the area of cooling produced comparable changes in skin temperature with a peak decline at C1 of -11.1 and -10.4 °, respectively. No main effect or interaction was detected on MEPs ($F<1.0$, $p>0.49$), indicating that extending the cooling area did not influence variations in amplitude. However, a trend was noted for MEP latency, which tended to be prolonged with multi-digit when compared to single-digit cooling. Much like in our first study, individual responses were variable with ~half the participants showing MEP depression (9/22) at C1 and one-third showing facilitation (7/22). The rest showed no modulation (6/22). These proportions were comparable to those previously reported for single-digit cooling. Interestingly, variations in MEP amplitude measured at C1 for single-digit were correlated ($r=0.50$, $p=0.02$) with those measured for multi-digit cooling at the individual level. These results indicate that extending the area of cooling stimulation in the distal hand did not produce more consistent effects on corticomotor excitability. Also, our results confirm that modulation in response to distal focal cooling are variable from one person to another but seems fairly consistent for a given individual with repeated applications, regardless of the area of stimulation.

Title: The inhibition of voluntary muscle relaxations depends on similar mechanisms to the inhibition of muscle contractions

Authors: *J. DE HAVAS[1,2], S. ITO[1], H. GOMI[1]
[1]Human & Information Sci. Lab., NTT Communication Sci. Labs., Atsugi, Kanagawa, Japan; [2]JSPS Intl. Res. Fellow, Tokyo, Japan

Abstract: Successful control of the body depends on both our ability to execute planned movements, and on our ability to rapidly cancel movements that are no longer required. Most movements are executed via muscle contractions. However, voluntary movements are also often the result of a combination of gravity and a voluntary muscle relaxation. Such voluntary relaxations have been found to be preceded by increased activity in prefrontal and motor regions of the brain, suggesting they result from a motor plan. Determining whether voluntary muscle relaxation can be inhibited once initiated, and if so, what time-course and muscle activity is associated with this inhibition, will be informative with regards to establishing how voluntary relaxations are planned and executed by the brain. To this end, we employed a modified version of the Stop Signal Task to compare inhibition of muscle relaxations and contractions in humans. Participants sat in front of a screen with their elbow on a padded table, supinated and bent at an angle of ~40° from the horizontal. They were instructed to move their arm downwards as rapidly as possible whenever a green circle appeared on the screen (Go trials), and remain stationary whenever a green square appeared (No-go trials). During 'relaxation blocks' they moved the arm downwards by relaxing the biceps muscle, but during 'contraction blocks' the movement was achieved by contracting the triceps muscle. Participants were instructed that if they heard a tone (Stop trials) they should cancel the movement and maintain the current arm position. Tone onset time in relation to the go signal varied between 0 and 500ms (stop signal delay). Electromyography was recorded from right biceps brachii and triceps brachii (lateral head). Results from n = 5 (4 female, mean age = 32.6, SD = 9.34 yrs) participants indicated that there was no significant difference in RT for the go trials across contraction and relaxation conditions (500 vs. 537ms; $t(4) = 1.56$, $p = 0.19$). Both voluntary contraction and relaxation commands could be inhibited ~50% of the time. The probability of successfully inhibiting a response increased reliably as stop signal delay decreased. By plotting probability of moving against stop signal delay it was possible to calculate stop signal reaction time (SSRT). We found no significant difference in SSRT across contraction and relaxation conditions (237 vs. 220ms; $t(4) = 0.9$, $p = 0.42$). In both conditions cancelling movement was associated with transient increases in muscle activity, time-locked to the stop signal. The results suggest there may be similar mechanisms underlying how voluntary muscle relaxations and contractions are initiated and controlled.

Title: Cerebellar-motor cortex connectivity: One or two different networks?

Authors: *D. SPAMPINATO[1], P. A. CELNIK[3], J. ROTHWELL[2]
[1]Biomed. Engin., [2]Univ. Col. of London, London, United Kingdom; [3]Physical Med. & Rehab, Neurol, Johns Hopkins Univ., Baltimore, MD

Abstract: Recently it has been argued that two distinct interneuron networks in the primary motor cortex (M1) contribute distinctly to two varieties of physiological plasticity and motor behaviors (Hamada et al., 2014). Although one of the interneuron groups is thought to be dependent on cerebellar (CB) activity, direct physiological distinction regarding CB-M1 interactions (CBI) to these subpopulations remains poorly understood. In a series of experiments, we assessed whether M1 coil orientation, thought to test different neuronal populations, is differentially influenced by cerebellar stimulation. In experiment 1 (n = 10), we tested the effect of coil orientation (posterior-anterior, PA; anterior-posterior, AP) and inter-stimulus intervals (ISI: 3, 5 and 7 ms) on CBI; assessed with a conditioned TMS pulse over the cerebellum prior to TMS over the contralateral M1. We found there was a significant ISI x coil orientation interaction, specifically PA-CBI was most prominent at 5ms ISI (p = 0.02), whereas AP-CBI at 7ms ISI (p = 0.01). In a follow-up experiment, we sought to determine whether this result reflects distinct processing of cerebellar inputs within M1. To do this, we measured AP- vs. PA-CBI at their preferential ISI, prior to and following standard paired associative stimulation (PAS). Importantly, we administered the repeated pairs of electrical stimuli to the median nerve and PA-TMS at an interval of 21.5 (i.e. PAS at 21.5) since this technique is capable of modulating the plasticity of PA-M1 excitability without affecting cerebellar activity. We found that PA-CBI changed following PAS 21.5 (p = 0.04), but did not modulate AP-CBI (p = 0.47), indicating that CB-M1 interactions are different for the two M1 neural networks. In a final experiment (n = 12), we assessed whether M1 coil orientation affects CBI in the context of two motor behaviors that weight differently cerebellar vs. M1 contributions. Here, we tested how learning two distinct motor learning tasks (weighting sensorimotor calibration vs. a sequencing task) affected AP- vs. PA-CBI measured at their preferential ISI. To determine how learning affects AP- vs. PA-CBI, we compared CBI before, during and after training. We found that learning a sensorimotor calibration modulated PA-CBI specifically early during learning (p = 0.02), whereas AP-CBI changed only late (p = 0.01). Additionally, during sequence learning, PA-CBI also changed only early (p = 0.01), whereas AP-CBI was not modulated. Together, these

results suggest that there are two independent CB-M1 pathways that contribute distinctly to different forms of motor learning.

Title: Do the facial primary motor cortices communicate directly with each other?

Authors: F. GINATEMPO[1], N. G. MANZO[2], *J. C. ROTHWELL[3], F. DERIU[1]
[1]Biomed. Sci., Univ. of Sassari, University of Sassari, Italy; [2]Human Neurosciences, Sapienza Univ. of Rome, University of Rome, Italy; [3]Inst. Neurol, London, United Kingdom

Abstract: The crucial role of the corpus callosum in the execution of movements involving both body sides, particularly the hands, is well known[1], whereas proximal muscles are more likely to involve cortico-reticulospinal pathways[2]. Studies investigating the function of the primary motor cortex innervating lower facial muscles (fM1) showed that cortical projections to the facial motor nucleus are bilateral. However, how and at which level bilateral movements of facial muscles are coordinated is still unknown. Aim of this study was to probe the function of interhemispheric connections between fM1s, using TMS protocols. In 9 healthy subjects, interhemispheric inhibition (IHI) and facilitation of fM1 were investigated bilaterally using a paired pulse, twin coil, TMS protocol, in the depressor anguli oris (DAO), upper trapezius (UT) and first dorsal interosseous (FDI) muscles. Test motor evoked potentials (MEP) were conditioned using conditioning stimuli (CS) between 90% and 130% of the resting motor threshold (RMT) at 7 different interstimulus intervals (ISI) ranging 4-12ms. To exclude a possible stimulation of the contralateral DAO, the effect of the CS alone and of paired pulse TMS at 1 and 2ms ISIs were investigated (CS intensities of 110% -130% RMT). Latency and amplitude of conditioned MEPs were analysed. IHI was observed in the UT and FDI using a CS of 120% RMT at ISIs of 8ms (-23% p=0.02) and a CS of 120% and 130% RMT at 8-12ms ISIs,(-29% p=0.004), respectively. By contrast IHI was not detectable in the DAO, where a facilitated conditioned MEP with larger amplitude (+55%; p=0.009) and shorter latency (2.1, 1.4 and 1ms for 4, 2, 1ms ISIs; p=0.001) than the test MEP was detected at ISIs of 1, 2 and 4ms and pulse intensities from 110% to 130% RMT. No significant differences were found between the test DAO MEP and those obtained with the CS alone or with paired pulse TMS at 1,2 and 4 ms ISIs. While this study confirms that IHI occurs in both the hand and axial muscles, with lesser effect in the proximal muscles, it shows for the first time no evidence of a clear control exerted by the corpus callosum on fM1. It is likely that the coordination of lower facial muscles mainly

involves brainstems circuits rather than interhemispheric connections. This hypothesis is supported by studies showing that facial muscles are not able to contract asymmetrically[3] and are not affected by lesions of the corpus callosum[4]. Title: Brain preparation to self-paced movements using TMS-EEG: New insights into the role of preparatory cortical inhibition

Authors: *J. IBANEZ PEREDA[1], A. REKA[2], R. HANNAH[3], L. ROCCHI[1], J. C. ROTHWELL[4]
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London, London, United Kingdom; [2]UCL, London, United Kingdom; [3]UCL Inst. of Neurol., London, United Kingdom; [4]Inst. Neurol, London, United Kingdom

Abstract: Motor cortical processes in preparation for movements can be studied probing changes in cortical excitability with transcranial magnetic stimulation (TMS). Many studies have focused on analyzing how the brain reacts to TMS at times right before muscles activate. For practical reasons, such studies have typically been done using simple reaction time paradigms or variations thereof. Paradoxically, while non-invasive recordings of brain electrical activity in preparation for movements indicate that cortical circuits involved in the generation of forthcoming actions are increasingly more active in the last hundreds of ms before an action is released, Motor Evoked Potentials (MEPs) resulting from single-pulse TMS appear to show something different: an inhibitory period is observed at around the time when the imperative command to move is given. Classically, such inhibition has been suggested to prevent premature responses. However, this and other proposed interpretations of the observed changes in MEPs in preparation for movements may be a mere result of assessing these neurophysiological changes using only highly time-constrained conditions to probe evolutions in cortical excitability.

Here we present results from an experiment in which subjects perform self-paced bilateral button presses while TMS pulses are delivered over the motor cortex. We show MEP changes in task-relevant/-irrelevant muscles together with changes in EEG-derived TMS-evoked potentials (TEPS). Also, we present results regarding the timings of movements relative to the TMS events to study possible influences that stimuli have on the self-chosen movement times. We observe a significant ($p<0.01$) reduction of MEPs ~200ms before the times of button presses in both task-specific and task-irrelevant muscles. At the same time, late TEP components (P60/N100) show a significant ($p<0.05$) reduction in amplitude, while early components remain unchanged. Additionally, we observe a shift of movement times towards the TMS time points when stimuli are delivered around 350-200ms before movements are recorded. Our results reflect unexpectedly tight resemblances with physiological and behavioural recordings obtained in simple reaction time paradigms, thus questioning interpretations of the influence of external cues in driving cortical activities, and in the way we estimate the brain generates voluntary movements in a self-paced way

Title: Effects of behavioral tasks on neural activity relevant to motor preparation

Authors: T. KUBO, Y. MATSUMOTO, *T. URAKAWA, O. ARAKI
Tokyo Univ. of Sci., Dept. of Applied Physics, Katsushika-ku, Japan

Abstract: Cortical networks relevant to specific behavioral tasks have been reported in a number of previous studies [e.g., 1], in which motor preparation (MP) has been less focused on. Meanwhile, previous MP studies have exclusively investigated neural activities relevant to MP, in which differences in the behavioral task were not taken into account [e.g., 2]. The present electroencephalographic (EEG) study attempted to clarify whether neural activities relevant to MP itself would depend on the behavioral task. In experiments, two behavioral tasks were employed: 1) POSITION TASK, in which a motor action (a movement of the finger) was required based on the spatial position of a target number on a visual image and 2) PARITY TASK, in which the motor action was required based on parity of the target number. In each task, two conditions (the movement condition, MC; the no-movement condition, NMC) were set to capture neural activity relevant to the MP itself (MC vs. NMC). Under this experimental paradigm, we tried to determine whether and how a difference in the behavioral task would

affect the MP itself. In analyses, phase synchronization analysis between EEG electrodes was performed using the phase lag index (PLI). Results obtained showed that the PLI significantly increased between the central and parietal electrodes at the frequency of the delta to theta range in the POSITION TASK. This synchronization persistently occurred during the MP. As for the PARITY TASK, the PLI was significantly higher among the frontal, parietal, and occipital electrodes at the frequency of the alpha to beta range. This synchronization occurred exclusively during an early phase of MP. Our findings suggest that neural activity relevant to the MP itself differs based on the behavioral task. The frequency-dependent functional connectivity and occurrence timings during the MP period were all specifically modulated in a task-dependent manner.

Title: Beta-band intramuscular coherence in the tibialis anterior predicts temporal gait adaptation on a split-belt treadmill

Authors: *S. SATO[1], J. T. CHOI[2]
[1]Neurosci. and Behavior Program, Univ. of Massachusetts, Amherst, Amherst, MA; [2]Dept. of Kinesiology, Univ. of Massachusetts Amherst, Amherst, MA

Abstract: INTRODUCTION: Synchronization of motor unit firing from the same muscle is thought to indicate the presence of common synaptic inputs. Specifically, coherence between motor unit firing in the beta frequency band (13-30 Hz) has been shown to be dependent on intact supraspinal control. The functional role of common drive to leg muscles in gait adaptation is unclear. The objective of this study was to (1) examine changes in tibialis anterior (TA) intramuscular coherence during split-belt treadmill adaptation and re-adaptation, and (2) determine if TA intramuscular coherence measure predict adaptive kinematic changes. METHODS: 18 healthy young adults walked on a split-belt treadmill. Each session consisted of a pre-adaptation, adaptation, post-adaptation, and 2 re-exposure periods. During the pre-adaptation period, subjects walked symmetrically at a slow (0.5 m/s) and a fast (1.0 m/s) speed

for 5 mins each. During the adaptation period, walking was challenged by altering the speed of each leg at a 1:2 speed ratio (0.5 m/s for the slow belt, 1.0 m/s for the fast belt) for 15 mins. During the post-adaptation period, subjects walked with both legs at 0.5 m/s for 10 mins. Each re-exposure paradigm consisted of a 10-min adaptation at the split-speed condition and a 10-min washout period (0.5 m/s). Kinematics were recorded with reflective markers on the lower extremity, and EMG was collected using two pairs of surface electrodes placed at the proximal and distal ends of TA. RESULTS: Beta frequency coherence was significantly greater early in adaptation compared to late adaptation period (early swing, $p < 0.001$; late swing, $p = 0.011$). This difference in coherence was less during the 2nd split-belt adaptation (early swing, $p = 0.023$; late swing, $p = 0.192$), and insignificant during the 3rd exposure (early swing, $p = 0.106$; late swing, $p = 0.460$). Higher amount of beta band coherence early in adaptation in early swing phase was associated with smaller double-support (DS) asymmetry ($p = 0.006$, $r = -0.619$, $r^2 = 0.383$), but not with step-length symmetry values ($p = 0.064$). Early adaptation DS symmetry was positively associated with difference in DS symmetry between early and late adaptation ($p < 0.001$, $r = 0.870$, $r^2 = 0.758$). CONCLUSION: Association between higher beta coherence during early swing in the TA with smaller DS asymmetry may reflect a functional role of the common drive to the TA. Individuals with higher common drive adjust their temporal parameters faster on the split-speed condition.

Title: Neural correlates of impaired speech and hand motor timing processing in Parkinson's disease

Authors: *K. JOHARI[1], R. BEHROOZMAND[2]
[1]Univ. of South Carolina, Columbia, SC; [2]Communication Sci. and Disorders, Univ. of South Carolina, Irmo, SC

Abstract: Parkinson's disease (PD) is a neurological disorder associated with the degeneration of dopaminergic neurons in the basal ganglia primarily affecting the motor system. Studies have shown that patients with PD exhibit slower responses during a wide range of motor reaction time tasks, which is accounted for by their abnormal temporal processing during the planning phase of movement compared to neurologically intact control subjects. In addition, PD patients show deficits in tasks involving temporal judgment and generate shorter timing intervals in self-paced tapping tasks. These findings support the notion that temporal processing mechanisms of

movement are compromised in PD due to dysfunctional fronto-striatal circuits. Electrophysiological studies have found Beta band desynchronization as a neural signature of impaired temporal processing in PD during the planning phase of limb movement. However, our understanding about how PD may affect motor timing processing during speech is not clear. The present study examined the neural and behavioral mechanisms of motor timing deficits during speech production and hand movement in PD patients. Event-related potentials (ERPs) were recorded in 15 PD patients and 15 age-matched control subjects while they were visually-cued to prepare to produce a steady vocalization of a vowel sound or press a button, and to initiate the cued movement following the onset of a go signal on the screen. Experiment was conducted in two counterbalanced blocks in which the timing interval between the visual cue and go signal was temporally-predictable or unpredictable. Findings showed PD Patients were slower than control subjects for both speech and hand movement regardless of stimulus timing. ERP findings showed attenuation of pre-movement ERP activities over the frontal and parietal regions for PD vs. control subjects regardless of stimulus timing and response modality. These findings suggest that the attenuation of pre-movement ERP activities is a neural correlate of motor timing deficits during the planning phase of speech production and hand movement in PD.

Title: Visual stimulation facilitates cervical interneuron systems mediating corticospinal excitation to motoneurons in arm muscles

Authors: *T. NAKAJIMA[1], H. OHTSUKA[1], S. IRIE[1], R. ARIYASU[1], S. SUZUKI[2], T. KOMIYAMA[3], Y. OHKI[4]
[1]Kyorin Unversity Sch. of Med., Mitaka City/Tokyo, Japan; [2]Kyorin Univ. Sch. of Med., Tokyo, Japan; [3]Chiba Univ., Chiba City, Japan; [4]Kyorin Univ. Sch. Med., Tokyo, Japan

Abstract: Modulatory actions of visual inputs to cervical interneurons (IN) are poorly understood in humans. In the present study, we examined whether photic stimulation (PS)

modulates corticospinal excitations to arm muscles, which would be mediated by cervical IN systems. Healthy subjects, who all gave informed consents, were seated with recording of electromyograms from the right biceps brachii (BB) muscle. Flash stimulator for PS [white light, 50 μs duration, 2 J (relative energy)] was placed 60 cm in front of the subject's eye. Transcranial magnetic stimulation (TMS) over the contralateral primary motor cortex and electrical stimulation of the ipsilateral ulnar nerve at wrist (NERVE) were delivered separately or in combination. A 10 ms inter-stimulus interval (ISI) for the combined stimulation (TMS behind) was used to give converging inputs on the upper cervical segments. PS was sometime delivered 60 ms before TMS. Combination of TMS and NERVE gave rise to facilitation of motor evoked potentials (MEPs) in the BB. When the combined stimulation was delivered with PS, the NERVE-induced facilitation of the MEP significantly increased in comparison to the control condition without PS. Furthermore, with recording of single motor units and constructing post-stimulus time histograms, it was observed that a short-latency excitatory peak (i.e., di- or oligosynaptic effects), but not the shortest one, following the combined stimulation was significantly facilitated by PS. PS facilitates short-latency cortico-spinal excitations in an arm muscle, which was facilitated by peripheral nerve stimulation under a short ISI. The present findings therefore suggest that PS facilitates cervical IN systems, which receive converging inputs from pyramidal tract and peripheral nerve, and project to arm motoneurons.

Title: Motor planning muscle activation patterns and reaction time

Authors: *S. DELMAS, A. CASAMENTO-MORAN, S. H. PARK, B. YACOUBI, E. A. CHRISTOU
Univ. of Florida, Gainesville, FL

Abstract: Reaction time (RT) is the short time interval between the appearance of a stimulus and initiation of a motor response. Within reaction time (RT), two processes occur, selection of motor goals and motor planning. An important but unresolved question is whether perturbation to the motor planning component of RT slows the response and alters the neural drive to the

muscle. The purpose of this study was to determine how the modulation of muscle activity, an index of the neural drive to the muscle, during a RT response changes with motor plan perturbation. Twenty-four young adults (20.5 ± 1.1 years, 13 women) participated in this study. Participants performed 15 trials of an isometric reaction time task with ankle dorsiflexion using an oscillating anticipatory strategy (oscillating force from 10-20% MVC). We compared RT and modulation of muscle activity when the stimulus appeared at the trough or at the peak of the sinusoidal task. When the stimulus appears at the trough, it is compatible with the response requirements in that the anticipation motor plan and response require a force increase. In contrast, when the stimulus occurs at the peak, the anticipation motor plan and response are incompatible in that the anticipation motor plan is to decrease force whereas the response requires an increase in force. We recorded the electromyographic (EMG) activity of the primary agonist muscle (tibialis anterior; TA). We quantified RT as the delay between the onset of stimulus and agonist EMG. We found that RT ($P = 0.003$) was longer when the stimulus occurred at the peak compared with the trough. During the time of the reaction, the EMG power from 10-35 Hz was less at the peak than the trough ($P = 0.019$), whereas the EMG power from 35-60 Hz was similar between the peak and trough ($P = 0.92$). These results suggest that a perturbation to motor planning lengthens RT and alters the neural drive to the muscle by decreasing the relative amount of power from 10-35 Hz.

Title: Neurophysiological biomarkers of the psychological flow in realworld tightrope walking

Authors: *G. CHERON[1], A. LEROY[2]
[1]Fsm-Université Libre De Bruxelles, Brussels 1070, Belgium; [2]LNMB, Univ. Libre de Bruxelles, Brussels, Belgium

Abstract: The experimental search of psychological “flow” can be accomplished by the combined recording of the electromyographic (EMG), electroencephalographic (EEG) and electrocardiographic (ECG) signals during highly skilled motor performance. This singular brain state emerges from an action requiring clear goal and a perfect match between specifics skills and challenge (Csikszentmihalyi, 1975; Mao et al., 2016; Cheron, 2016). Amongst different

sports, the tightrope walker activity appeared as particularly attractive because the highly restrictive field of action requiring optimal balance control permanently exerted at the edges of the fatal fall. As the high density EEG recording represents the dynamics of the brain states resulting from synchronous neuronal activity of local field potentials distributed into temporal and spatial coordinated networks of neurons, we have here quantify in the dynamic EEG signals (ERS, ERD and phase locking) the part of this activity devoted to its downstream impact on motor behaviour and the part of neuronal modulation involved in the constant monitoring of the vital internal organs (e.g. heart and gut) which are permanently regulated by the central nervous system and also implicated in the emergence of the flow. For this the EMGs of lower limb muscles and the ECG signals served as trigger for evoked related potentials (ERP), evoked related spectral perturbation (ERSP) and intertrials coherency (ITC). This analysis was firstly accomplished on Oliver Zimmerman's brain before and during walking on a long cable (100 m) placed at an altitude of 15 meters. In the second time, slack-line performers were analysed with the same methodology in laboratory. The effects of virtual reality stimulation representing tightrope visual sensation were also studied. The neuronal generators of the different EEG oscillations were studied by means of inverse modelling (swLORETA) showing along these performances the respective contribution of different cortical areas, the basal ganglia and the cerebellum.

Title: Corticospinal excitability changes during a complex locomotor task in humans

Authors: *C. DAMBREVILLE, C. NEIGE, C. MERCIER, A. BLANCHETTE, L. BOUYER
Univ. Laval, Quebec, QC, Canada

Abstract: INTRODUCTION. In animal models, the primary motor cortex (M1) is known to be involved during complex locomotor tasks such as ladder walking and obstacle avoidance. In humans, while M1 has been shown to contribute to normal walking, only one study looked at additional contribution of the corticospinal system to more complex walking (stepping onto lateral targets) and the reported effects were small. As this task only required small adjustments in the locomotor pattern, it may not have unravelled the full ability of the corticospinal system to adapt ongoing gait movements. The aim of the current study was therefore to measure if a more

complex walking task (requiring step length adjustments) would lead to a larger modulation of corticospinal excitability in humans.
METHODS. Sixteen young healthy participants walked on a treadmill at a speed of 1.0 m/s while facing a large screen during 2 tasks (counterbalanced order): regular walking (the 'simple' condition) and stepping onto virtual targets projected on the screen (the 'complex' condition). During the complex condition, 3 target distances were presented in random order (80, 100 and 120% of individual step length). Real time foot position was also projected onto the screen in the form of small spheres and participants had to adjust their step length to hit the targets. To assess corticospinal excitability, motor evoked potentials (MEPs; n=25 per condition) were induced by single pulse TMS during early swing (Tibialis Anterior hotspot). MEP size (area under the rectified MEP) was compared across conditions.
RESULTS. MEP size increased in all participants during the complex task (mean increase of 100+/-65%, $p<0.0001$; Glass' Δ effect size: 2.27). A learning effect was also observed: target hits raised from 82% to 93% ($P< 0.01$) over the task. Also, the first 10 MEPs were larger than the last 10 ($p<0.02$), but remained larger than during simple walking ($p<0.01$), suggesting possibly a greater need for corticospinal drive during initial learning. There was no correlation between the increase in MEP size and success score ($r= 0.16$; $p=0.27$). To control for the difference in visual inputs between the simple and complex condition, four participants performed a 3rd condition where they were instructed to walk normally while a single, very long target was presented on the screen. There was no statistical difference in MEPs size between this condition and simple walking ($p=0.625$).
CONCLUSION. As hypothesized, M1 was more recruited during the complex gait task. Interestingly, a learning effect was also measured, supporting an additional contribution of the corticospinal system to the early phase of complex motor learning during gait.

Title: Predicting corticospinal excitability from oscillatory activity over motor cortex

Authors: *C. K. TISCHLER[1], L. LABRUNA[2], A. BRESKA[2], R. IVRY[3]
[1]Psychology, Univ. of California Berkeley, Berkeley, CA; [2]Psychology, Univ. of California, Berkeley, Berkeley, CA; [3]Univ. California, Berkeley, CA

Abstract: Transcranial Magnetic Stimulation (TMS) over primary motor cortex can probe changes in corticospinal excitability by allowing us to record the changes in the amplitude of the electromyographic response to the stimulation, known as the motor-evoked potential (MEP). One of the problems with using MEPs to monitor corticospinal excitability is the trial-wise variability in the size of the MEP under the same experimental conditions. Moreover, the differentiation between cortical and spinal sources of this variability has still not been disentangled. In this study, we seek to identify cortical sources of MEP variability by combining TMS with electroencephalography (EEG). We will explore correlations between EEG activity in various oscillatory bands and corticospinal excitability while participants are at rest and while they are preparing a movement in a delayed response task. We will focus particularly on Beta power, given that both MEP size and EEG beta band power decrease preceding a movement. Using single-pulse and paired-pulse TMS paradigms we will test whether the beta oscillatory activity reflects the same intracortical inhibitory mechanisms for motor preparation that alters the size of the MEP or if the inhibition and variability of the MEP preceding movements is dominated by a separate process from cortical oscillations.

Ctr., San Francisco, CA; [7]Neurosurg., UCSF, San Francisco, CA; [8]UC Berkeley, Berkeley, CA; [9]Univ. California, Berkeley, CA

Abstract: The decoding success of unilateral movement from ECoG or single unit activity is similar for contralateral and ipsilateral motor cortex (Ganguly, 2009). While this observation offers a promising neuroprosthetic alternative for patients with hemiparesis from cortical stroke,

the functional relevance of ipsilateral motor representations in the healthy brain remains unclear. One hypothesis is that, during motor planning of unilateral movements, the activation of an action goal results in the parallel preparation of independent control signals for each limb, with subsequent processes determining which limb is used. In this manner, some degree of preparation for motor execution would have taken place prior to movement selection. From this perspective, ipsilateral representations need not be related to the actual movement, but rather the planned, but not initiated movement of the contralateral limb. We refer to this as the "inferred motor plan."

This hypothesis was tested in two individuals (male, aged 22; 25 years) undergoing intracranial monitoring for the localization of an epileptogenic focus. The patients performed an instructed-delay reaching task using the arm ipsilateral to the subdural grid. The critical manipulation was the position of the non-moving, contralateral hand. In one configuration, it was placed near the midline, adjacent to the ipsilateral limb (Near). In the other condition, the contralateral hand was moved to an eccentric position (Far). In this manner, the movements performed by the ipsilateral hand were essentially identical in the two conditions. However, the inferred motor plan for the contralateral hand would differ for the Near and Far conditions.

Similar to prior work, target location could be classified above chance using the ipsilateral hemisphere. We then built a finite impulse response (FIR) model to predict the activity in the ECoG electrodes based on task features (e.g., target onset, movement onset). If ipsilateral activity represents the inferred motor plan of the stationary hand, we would expect activity to change in a target dependent fashion and, most important, to be modulated by the stationary hand position (e.g., the plan to a given target will differ in the Near and Far conditions). Indeed, model comparison using the mean R^2 across ten validation sets revealed that the best model for a subset of electrodes in both patients included a multiplicative interaction term (i.e., position of contralateral hand X target location). This suggests, in line with the parallel planning hypothesis, there may be information about the inferred motor plan of the stationary contralateral hand in the ipsilateral hemisphere.

Title: Putative propriospinal modulation of premotor and motor cortical output during grasping

Authors: *K. L. BUNDAY[1,2], Z. POH[2], S. AZZOPARDI[2], M. DAVARE[3]
[1]Univ. of Westminster, London, United Kingdom; [2]UCL, London, United Kingdom; [3]Inst. of Neurol., London, United Kingdom

Abstract: The primary motor cortex (M1) and ventral premotor cortex (PMv) play a major role in the control of grasping. Anatomical studies have revealed that these regions project to the spinal cord, directly and indirectly, and likely interact with the propriospinal network (PN). The PN is a pre-motoneuronal network located at mid-cervical levels (C3-C4), which transmits and alters descending cortical commands for targeted reaching and grasping. How the PN interacts with motor output from M1 and PMv during different grasps in humans is not well understood. The PN can be studied indirectly by conditioning motor evoked potentials (MEPs), elicited by transcranial magnetic stimulation (TMS), and H-reflexes, elicited by peripheral nerve stimulation (PNS), with sub-threshold PNS. In experiment #1, sub-threshold PNS was applied to the ulnar nerve at the wrist to condition Flexor Carpi Radialis (FCR) MEPs, elicited by M1 TMS, during an isolated FCR contraction (iFCR) or FCR contraction with precision grip (PG) or whole hand grasp (WHG). Central and peripheral conduction times were used to time the arrival of descending and ascending volleys at the spinal cord at 5 different inter-stimulation intervals (ISIs), namely 0, -3, -4, -5 and -6 ms. Negative ISIs indicate that PNS is delivered prior to TMS, allowing time for PNS volleys to travel to higher cervical segments (e.g. C3-C4), and 0 ms indicating that PNS and TMS-evoked volleys converge monosynaptically at spinal motoneurons (C6-C8). In experiment #2, TMS was applied over PMv to condition PN modulated H-reflexes, elicited by PNS to the median nerve applied at the elbow, during iFCR, PG and WHG. Here, TMS and sub-threshold PNS ulnar nerve volleys were timed to arrive at PN levels (C3-C4) at 5 different ISIs, namely 0, 2, 4, 6 and 8 ms. H-reflexes were either elicited alone (baseline), or conditioned by ulnar nerve PNS (ISI: 4ms), or by ulnar PNS and PMv TMS. In experiment #1, we found a significant interaction between ISI and grasp. Specifically, at 0 ms ISI, MEPs were significantly larger during PG than WHG and, at -4 ms ISI, MEPs were significantly larger during WHG compared to PG. In Experiment #2, we found that PMv TMS differentially modulated H-reflexes during iFCR and PG, but only for late ISIs. This contrasts with our previous findings that, at rest, PMv interacted with PN at early ISIs. Our results suggest that while monosynaptic corticospinal pathways contribute to precisions grip, motor cortical output during whole hand grasp can be modulated by the PN. Interestingly, PMv appears to modulate the PN directly or indirectly (e.g. via M1) depending on whether these interactions are tested at rest or during contraction, respectively.

Title: ERNing performance improvements: Error related negativity (ERN) is associated with errors in lifting performance during an object manipulation task

Authors: *K. A. FERCHO[1], G. R. LYNCH[2], L. A. BAUGH[1]
[1]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD; [2]Billings Senior High Sch., Billings, MT

Abstract: In order to successfully interact with objects, our brain must predict the outcome of motor acts based on a copy of the motor command - often termed an efference copy. One of the ways these predictive models are updated is through reactive adjustments based on sensory feedback during movement. In this circumstance, to adjust an ongoing movement and recover from deviations in prediction, the motor system requires an error signal of a very short latency. The presented analysis was conducted to examine whether error related negativity (ERN) corresponds with errors in an object manipulation task; the ERN component was selected as it is associated with a brain system for detecting errors and engaging in corrective behavior. To accomplish this, we examined electroencephalograms (EEG) and kinematic data from participants (N = 12) during two lifting conditions. In the first condition, object weight was expected, heavier than expected, or lighter than expected, based on the previous lift. In the second series of lifts, the object's surface friction at the point of finger contact changed between trials. The object friction was expected, greater than expected, or less than expected, based on the previous object lift. The epoch of interest (EOI) when examining the EEG data was 0-300ms from timepoint zero (T=0). For the weight series trials, T=0 was defined as the start of load phase, defined as the period between digit placement and lift-off. For the friction series, T=0 was defined as first contact with the object. ERN was defined as the largest negative peak within the EOI at electrode sites Fz and Cz. ERN peak amplitude was significantly larger when the participant lifted an unusually heavy object or an unusually light object, compared to an object of expected weight. Similarly, ERN peak amplitude was larger for trials in which the friction-weight relationship greater or less than expected. Behavioral data verified those trials associated with increased ERN had significant errors in prediction. Specifically, changes in load phase duration, maximum grip force (maximum GF applied by the thumb and finger), and/or maximum load force (summed maximum lifting forces of the thumb and index finger) were observed when compared to those trials in which an expected weight/surface were encountered. In summary, we

provide initial evidence that ERN may be present during trials in which errors are experienced in a natural motor task, possibly serving as the source of error signal used by the motor system to make online adjustments to movement in response to sensory feedback.

Title: Interactions between intracortical and interhemispheric inhibition in chronic stroke

Authors: *C. PATTEN[1,2], Q. DING[3], W. J. TRIGGS[4,5]
[1]Physical Med. & Rehabil., Univ. of California Davis, Sch. of Med., Sacramento, CA; [2]Northern California VA Hlth. Care Syst., Martinez, CA; [3]Physical Med. and Rehabil., Univ. of California Davis, Sacramento, CA; [4]Neurol., Univ. of Florida, Gainesville, FL; [5]Brain Rehabil. Res. Ctr., Malcom Randall VA Med. Ctr., Gainesville, FL

Abstract: The interhemispheric competition hypothesis (IHC) posits a causal relationship between imbalanced interhemispheric inhibition (IHI) and motor function following stroke where contralesional (CH) IHI exceeds ipsilesional hemisphere (IH) IHI. The IHC model is not strongly supported by evidence. It remains unclear whether imbalanced IHI following stroke reflects excessive CH-to-IH or deficient IH-to-CH inhibition. Moreover, the interaction between GABA-mediated intracortical inhibition and IHI is under appreciated. Here we investigated functioning of intra-cortical and inter-hemispheric circuits using ipsilateral silent period inhibition (iSP), to measure IHI, and short-intracortical inhibition (SICI) in both hemispheres of 19 individuals with chronic stroke (age: 62±7 years; chronicity: 4.7±4.4 years; upper-extremity Fugl-Meyer Motor Assessment (UEFMA): 51.5±14/66 (range: 20-66), 15 males) to better understand interhemispheric interactions and their relationship to motor recovery. We assessed motor impairment, correlating UEFMA with grip MVC difference (Non-paretic MVC - Paretic MVC, r = -.689, p =.0003) to produce a continuous measure of motor impairment and associated motor asymmetry. CH SICI revealed a strong association with MVC difference (r = .627, p = .004), indicating systematic CH disinhibition with more severe motor impairment. A laterality index of iSP inhibition [(iSP CH - iSP IH)/(iSP CH + iSP IH)], where positive values indicate greater CH-to-IH IHI, revealed a significant quadratic relationship (r^2 = 448) with MVC

difference indicating lower motor impairment is associated with relative IHI balance, but greater motor impairment with IHI imbalance either CH > IH or IH > CH. Finally, the iSP laterality ratio was significantly associated with IH SICI ($r = -.492$, $p = .038$) indicating the presence of IH inhibition in individuals with stronger CH-to-IH IHI but IH disinhibition in individuals with stronger IH-to-CH IHI. Concurrent evaluation of SICI in both hemispheres, IHI, and motor impairment helps characterize the heterogeneity among individuals post-stroke revealing only a subset of chronic individuals represented by the IHC model. Importantly, our data reveal imbalanced IHI results from overactivity in either hemisphere which likely contributes to inconsistencies in the current literature including why IHC-based interventions (i.e., rTMS, NIBS) have not demonstrated broad efficacy. Finally, our data identify a group of individuals with dysfunction of IH SICI in the presence of balanced IHI highlighting the importance of GABAa-mediated intracortical circuits to motor recovery.

Title: Differences in motor unit discharge characteristics between ankle plantarflexors and dorsiflexors during steady contractions

Authors: L. M. MCPHERSON[1], *C. KIM[1], N. RENDOS[3], A. CHU[2], A. ESPINAL[1], S. ZAVERI[1], J. CARRENO[1], P. VEGA[1], R. VARGHESE[1]
[1]Physical Therapy, [2]Florida Intl. Univ., Miami, FL; [3]Andrews Res. and Educ. Fndn., Gulf Breeze, FL

Abstract: The three primary ankle muscles for sagittal plane control - the tibialis anterior (TA; a dorsiflexor (DF)), the soleus (SOL; a plantarflexor (PF)) and the gastrocnemius (GA; a plantarflexor (PF) and knee flexor) - each provide different biomechanical functions during standing, locomotion, and transitional tasks such as sit-to-stand. For example, during standing, SOL provides primarily sustained postural support whereas TA and GA primarily provide fast responses to maintain balance. In addition, the three muscles differ in their composition of muscle fiber types in a manner that is consistent with the biomechanical functions. SOL contains primarily low threshold slow type muscle fibers in the human, whereas TA and GA have a higher percentage of fast type muscle fibers.
Differences in neural control of the TA, SOL, and GA likely exist to support their functional roles. These muscles are differentially affected after central nervous system injury, and previous work using transcranial magnetic stimulation has shown differences in corticospinal efficacy.

Various analyses of motor unit discharge from proximal and distal arm muscles during voluntary contractions have revealed differences in neural control that are consistent with their biomechanical functions. The purpose of this study was to characterize motor unit discharge from the TA, SOL, and GA during voluntary PF and DF torque generation during sitting and standing, in order to compare neural control among the muscles and tasks.
Six participants without neurologic injury participated in the study. For sitting tasks, the tested ankle was secured to the Biodex System 4 Pro for measurement of PF and DF joint torque during isometric torque generation. One 64-channel EMG grid was placed over the TA, 2 grids were placed on the medial and lateral surfaces of the SOL and 2 grids were placed over the medial and lateral GA. Separate steady isometric contractions of DF and PF were performed at efforts ranging from 10 - 50% of maximum voluntary torque and were held for 20 - 45 sec. For standing tasks, participants performed static standing with eyes closed, with each leg on a separate force plate, as well as anterior and posterior leans, to preferentially engage the plantarflexors and dorsiflexors, respectively. Multi-channel surface EMG data were decomposed into motor unit spike trains using an automated algorithm (Negro et al, 2016).
Differences were seen among the three muscles in terms of motor unit coherence, discharge rates, discharge variability, and properties of the motor unit action potentials. These preliminary findings provide information with which to infer differences in neural control of these muscles.

Title: Cortical, callosal and thalamic inputs to the neck and jaw motor representations in rats

Authors: *H. MOHAMMED[1,2], N. JAIN[2]
[1]Hollis Lab., Burke Med. Res. Inst., White Plains, NY; [2]Div. of Systems Neurosci., Natl. Brain Res. Ctr., Manesar, India

Abstract: In the rodent primary motor cortex, the regions where microstimulation evokes movements of different body parts are organized in a topographic manner. Although the rat whisker and forepaw motor representations have been studied in detail, information about the sources of inputs to the neck and jaw motor representations is sparse. Here we describe cortical,

callosal and thalamic inputs to the neck and jaw representations in the motor cortex of rats. Intracortical microstimulation was performed to delineate these motor representations in adult Long Evans rats, and small injections of the retrograde fluorescent tracers were made. Following appropriate survival period, rats were perfused, the cortex was flattened, and sectioned in a tangential plane. The thalamus was sectioned in a coronal plane. The sections of the brain were processed for fluorescence microscopy and other architectonic markers. Locations of fluorescently labeled neurons in the cortex and thalamus were plotted, and precisely aligned with the help of the motor map, the somatosensory isomorph and the architectonic borders that were drawn using sections stained for Nissl substance and acetylcholinesterase. The results show that both neck and jaw motor representations receive ipsilateral cortical inputs from the motor cortex, the primary somatosensory cortex and the higher somatosensory areas, although the locations of the labeled neurons showed only partial overlap. The neck representation received relatively more inputs from the posterior parietal cortex, retrosplenial, orbital and piriform cortices. Callosal inputs to both the neck and the jaw representations were from the homotopic motor cortex and the surrounding regions. There were also sparse inputs from the contralateral somatosensory cortex. Only the neck motor cortex received strong inputs from the contralateral orbital cortex. Thalamic inputs to the neck and jaw motor representations were from the ventroanterior and ventrolateral nuclei, ventormedial nucleus, posterior nucleus, and the centrolateral and paracentral nuclei. The neck motor cortex received relatively more thalamic inputs from mediodorsal nucleus, whereas the jaw motor cortex received more inputs from the ventroposterior medial nucleus. Results suggest that the neck primary motor cortex has more of an integrative role in motor control as compared to the jaw motor cortex.

Title: Macaque premotor cortex activity and behavior support embodied choice model of decision-making

Authors: *M. WANG[1], C. CHANDRASEKARAN[2], K. V. SHENOY[3]
[1]Neurosciences Program, [2]Electrical Engin., Stanford Univ., Stanford, CA; [3]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: Decision-making is often described as a serial process in which sensory information is evaluated to arrive at a choice, followed by a motor report of that choice. In contrast to this 'serial model', Cisek and Pastor-Bernier (2014) and Lepora and Pezzulo (2015) argue that action dynamics are taken into consideration during the sensory decision-making process - the 'embodied choice model'. Here, we investigated whether monkeys' behaviors were consistent with either model, and which model was represented neurally in premotor cortex (PM). We trained two monkeys to discriminate the dominant color of a red-green checkerboard by reaching to a corresponding colored target. Targets appeared on the left and right, and we manipulated action cost by presenting them at two distances, randomly assigned for each target on each trial. After a variable delay, the checkerboard appeared and the subject could make a reach report. The serial model predicts that a subject would determine the dominant color (red or green) before executing a reach (left or right), and performance would be unaffected by the target distances. In contrast, the embodied choice model predicts that performance would be biased towards the choice with a lower action cost, especially for difficult decisions. We found that monkeys were more likely to reach to the closer target when the checkerboard was more difficult (effect of distance on performance, logistic regression, $p < 0.001$). This behavior is consistent with the embodied choice model and with previous findings in humans (Marcos et al., 2015). Next, we looked for neural correlates of these action costs. We recorded single and multi-units in PM (266 for monkey T, 104 for monkey O). If action costs were reflected by changes in the starting points of population firing rate dynamics, we should be able to find differential activity for the distance configurations. After target onset, when action cost information was first available, neural activity was identical regardless of target configuration (linear regression of target distance on firing rates, $p > 0.01$). On the other hand, firing rates of PM neurons covaried with reach direction, checkerboard difficulty, reaction time, and target distance, suggesting that action cost information may be integrated with perceptual information during the same epoch. Future work will further investigate how these action costs are incorporated into the dynamics. In summary, these results show that monkey behavior and neural activity in PM support the embodied choice model of decision-making, rather than the serial model.

Title: Reward-dependent modulation of correlated neural variability mediates trial-by-trial motor learning

Authors: *J. WANG[1,2], E. HOSSEINI[3], M. JAZAYERI[1,3]
[1]MIT McGovern Inst. For Brain Res., Cambridge, MA; [2]Univ. of Missouri, Columbia, MO; [3]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Recent studies have suggested that neural systems may be able to use reinforcement to regulate variability associated with execution of movements on a trial-by-trial basis. This raises an intriguing possibility that the brain might also be able to use reward to regulate variability associated with motor planning. To test this idea, we analyzed neural activity in cortical circuits of monkeys during a motor timing task in which behavioral variability is largely due to noise in motor planning. Animals performed a 2x2 context-dependent time interval production task in which they were instructed to proactively produce either an 800 or 1500 ms time interval using either a saccade or a ballistic button press.
Produced intervals were variable and significantly correlated across trials (up to 20 trials). As expected from the so-called scalar property of interval timing, the magnitude of variability scaled with the target interval for both effectors. Surprisingly, long-term correlations were effector-specific, and variability within each context reduced systematically when the previous trial was rewarded. In other words, scalar variability, which reflects noise in the nervous system, was subject to reward-dependent modulation.
To investigate the neural mechanisms through which reward impacts behavioral variability, we recorded from neurons in the dorsomedial frontal cortex(DMFC) where neural activity predicts animal's timing behavior. Since correlated neural variability is a key determinant of variance across a population of neurons, we hypothesized that reward might regulate behavioral variability by acting upon correlated neural variability. Therefore, we compared the variance across a population of simultaneously recorded neurons following rewarded and unrewarded trials within and across different effectors. We quantified the trial-by-trial correlated variability

by removing long-term correlations in neural activity and measuring the projection of the residuals on the dimensions of maximum variance (i.e., principal components). Consistent with our hypothesis, rewarded trials led to a reduction of correlated neural variability in a context-specific manner. This finding suggests that noise correlations in cortex are modulated by reward and may play a role in regulating behavioral variability in motor planning. More broadly, our results suggest that correlated neural activity in cortex might provide a substrate for trial-by-trial reinforcement learning.

Title: The role of anterior corpus callosum in bimanual coordination in head-fixed rats

Authors: *M. IGARASHI, Y. AKAMINE, J. R. WICKENS
Okinawa Inst. of Sci. and Technol., Onna-son, Japan

Abstract: Rodents demonstrate dexterous coordination of forelimbs when feeding. Manipulation of food objects involves repertoires of paw usage including symmetric and asymmetric bimanual movements. Recently, we developed a high-resolution kinematic tracking system for studying bimanual coordination in rats. The system recorded forelimb position during spontaneous food handling and consumption in head-fixed conditions. Here, we demonstrate the use of this system in automatic movement classification, and its application to investigating cortical crosstalk in bimanual movements. Five male Long Evans (LE) rats were trained to bimanually handle donut-shaped food rewards. Forelimb movements were recorded by high-speed cameras (200 frames/sec), and stored as 3-D kinematic datasets. An automatic segmentation and classification algorithm was applied to identify three categories of movements: unimanual, symmetric bimanual, and asymmetric bimanual. Quantification of the classified movements revealed that feeding behavior is dominated by symmetric bimanual movements (56.55%) with less prevalent asymmetric bimanual movements (32.18%) and unimanual movements (11.27%). We further investigated the role of cortical crosstalk in bimanual coordination. Forelimb movements were recorded in nine male LE rats during food handling. To block the cortical crosstalk, 500 nL of 2% Lidocaine was injected into the anterior corpus callosum (aCC) through which pass commissures from cortical forelimb motor areas. Test sessions consisted of three repeated daily cycles of baseline (Saline), and aCC inhibition (Lidocaine) conditions. The kinematic tracking

system and classification method revealed that the frequency of occurrence of symmetric bimanual movements was reduced by aCC inhibition. In contrast, asymmetric bimanual movements were increased. Other parameters related to the global scale of motor skills, such as mean food drop rate and consumption times, remained unchanged. Collectively, these results suggest that the symmetric dominance in bimanual movements in rodents is modulated by cortico-cortical crosstalk via the anterior corpus callosum.

Title: Mirror neuron populations lead non-mirror neuron populations during execution of a reach, grasp, and manipulate task

Authors: *K. A. MAZUREK[1], M. H. SCHIEBER[2]
[1]Dept. of Neurol., [2]Neurol. and Neurosci., Univ. of Rochester, Rochester, NY

Abstract: Mirror neurons discharge both when an individual executes a particular action and when the same individual observes another individual perform the action. In populations of mirror neurons (MNs) and non-mirror neurons (non-MNs) recorded during a reach-grasp-manipulate (RGM) task, hidden Markov models (HMMs) have detected sequences of four hidden states corresponding in time approximately to four sequential behavioral epochs in each trial: the initial, reaction, movement, and final hold epochs. Here, we compared the timing of these hidden state transitions in simultaneously recorded populations of MNs versus non-MNs during execution trials of the RGM task.
Two male Rhesus monkeys each executed the RGM task and then observed an experimenter performing the same task. Neural activity was recorded from floating microelectrode arrays implanted in premotor cortex (PM) and primary motor cortex (M1). MNs were identified as single- or multi-units that modulated significantly during both execution and observation trials, whereas non-MNs were identified as units that modulated during execution but not observation trials. Units recorded in each of 3 sessions from each monkey were separated into four subpopulations: PM MNs, PM non-MNs, M1 MNs, and M1 non-MNs. HMMs were trained to detect hidden states separately using each subpopulation without temporal information about the task events separating the four behavioral epochs in each trial.

We then selected those execution trials in which HMMs had detected all four hidden states in both MN and non-MN populations and performed pairwise comparisons of state transition times in the MN versus non-MN populations. Pooling such trials across monkeys and sessions, we found that hidden state transitions in MN populations occurred before the corresponding transitions in non-MN populations. The same was true whether PM and M1 populations were considered together or separately. Our findings challenge the notion that MNs simply monitor actions and suggest instead that during action execution MN populations represent behavioral states before non-MN populations.

Title: Cortical activity during a motor task in behaving mice

Authors: *N. C. GIORDANO[1], C. ALIA[2], A. CATTANEO[3], M. CALEO[2]
[1]Neurosci., CNR - IN / Scuola Normale Superiore, Pisa, Italy; [2]Neurosci. Institute, Natl. Res. Council, Pisa, Italy; [3]Scuola Normale Superiore, Pisa, Italy

Abstract: How the motor cortex controls planning and execution of voluntary movements is not completely understood. This basic knowledge is crucial to understand reorganization and plasticity of cortical outputs after a damage, such as ischemia. After a lesion, the destruction of neural networks indeed stimulates a reorganization of the connections in response to anatomical or functional deficit. However, to assess the brain mechanisms supporting behavior, both in physiological conditions and after a lesion, monitoring the activity of single neurons *in vivo* is needed. This requires the analysis of the coordinated activity of different cell types during a motor act in behaving animals.
Here we used head-restrained mice trained to lick a reward delivered at random intervals. The neuronal signals were acquired through a 16-channel silicon probe. During the task, we performed *in vivo* electrophysiological recordings in two distinct areas known to be involved in the control of licking, the anterior lateral motor cortex (ALM), a potential premotor area, and the posterior-medial motor cortex (PMM), that is part of the primary motor cortex. However, there is a paucity of information on how, across layers, the single units in the ALM and PMM behave in the neural circuitry for the control of voluntary licking.
Licking events were divided in single isolated events or multiple repetitions.
We found that, during single isolated licking events, in ALM many neurons show modulation coinciding with the licking event itself. Moreover, most neurons' activity, especially in the

deeper cortical layers, anticipates the specific action long before the movement onset (100-200 msec). This is consistent with the ALM involvement in planning directed licking. We defined these neurons perimovement and preparatory neurons, respectively. We further showed that during the multiple licking events the perimovement neurons always discharged when the action occurred, while the preparatory neurons showed activity only before the first event and not before every single licking event in the sequence. The analyses on how the information is represented in the PMM are still ongoing.
These preliminary results reveal cell type specific processes within ALM for globally representing the movement; there is a precise transformation of preparatory activity into movement commands. These findings might be relevant for further study on the synaptic reorganization after damage of the premotor cortices.

Title: Distribution of layer 5 sensorimotor cortex neurons projecting to mesencephalic nuclei

Authors: *V. LOPEZ-VIRGEN, R. OLIVARES-MORENO, G. ROJAS-PILONI
Univ. Nacional Autónoma De México, Santiago de Querétaro, Mexico

Abstract: Layer 5 pyramidal tract neurons (PTN) are canonical elements of the cerebral cortex. PTN are the main excitatory output to subcortical structures like striatum, superior culliculus, pons, red nucleus and spinal cord. Nevertheless, little is known about the organization of PTN that may encode different cortical outputs to subcortical structures. The aim of the present work is to characterize the distribution of the thick-tufted layer 5 pyramidal neurons of the sensorimotor cortex (M2, M1, S2 and S1) projecting to tectum, red nucleus (RN) and pons. Eight wild-type C57BL/6 mice adults were simultaneously injected using retrograde tracers in tectum, RN and pons (Cholera toxin conjugated with Alexa-488, Biotinylated dextran amine and Fluoro-Gold). Five days after, the animals were perfused and 50-µm coronal sections were obtained from sensorimotor cortex (2.46 mm to -0.80 mm relative to bregma) and from the injection sites (-3.4 mm to -4.04 mm relative to bregma). Large scale fluorescence images with cellular resolution were obtained to quantify the number of retrogradely labeled cells.No differences in the size of injection size between tectum, red nucleus and pons were observed. All projecting

neurons were distributed broadly in the sensorimotor cortex (M1, M2, S1 and S2) and no significant differences in the density were found in the different areas. However, the density profiles in M2 shown that red nucleus projecting are located more superficial than pons projecting neurons. In S1 and S2 the results indicated that the projection neurons to the pons are located more superficial than RN projecting neurons. Despite the layer 5 cortical neurons projecting to tectum, RN and pons are intermingled in the sensorimoror cortex double and triple retrogradely labeled neurons represents less than 5% of the total projecting neurons. The anatomical segregation of PTN suggests that subcortically projecting sensorimotor cortex layer 5 neurons are also functionally segregated.

Title: Representation of multiple grip types in the primary motor cortex of capuchin monkeys

Authors: *A. MAYER[1], M. K. BALDWIN[2], D. F. COOKE[3], B. R. LIMA[4], J. J. PADBERG[6], G. LEWENFUS[5], J. G. FRANCA[7], L. A. KRUBITZER[8]
[1]Dept. Of Physiological Sci., Federal Univ. Of Santa Catarina, Florianopolis, Brazil; [2]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [3]Dept. of Biomed. Physiol. and Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada; [4]Inst. de Biofisica, Federal Univ. of Rio de Janeiro, Rio De Janeiro, Brazil; [5]Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil; [6]Dept. of Biol., Univ. of Central Arkansas, Conway, AR; [7]Univ. Federal do Rio de Janeiro, Rio De Janeiro, Brazil; [8]UC Davis, Davis, CA

Abstract: Capuchin monkeys are New World primates that are distinguished by their manual abilities and tool use behavior. They can execute 16 different types of precision grips, as well as manufacture, select, and spontaneously use tools in the wild. Despite being an ideal model for studying complex manual behaviors, very little is known about the functional organization of the primary motor cortex (M1) of these primates. In the present study, we investigated M1 using long-train intracortical microstimulation (LT-ICMS) in four adult capuchin monkeys, which

consisted of 500 ms trains of 0.4 ms biphasic square wave pulses (a negative 0.2 ms phase followed by a positive 0.2 ms phase) delivered at 200 Hz. All evoked movements were recorded on digital video and analyzed offline, and all stimulation sites were correlated with architectonically defined cortical borders.
Our results reveal movement representations of the entire body within M1, including foot and tail movements. Around 22% of all evoked movements involved finger movements. The majority consisted of finger flexions (67% of all finger movements) and their stimulation sites were clustered within M1. No clear spatial arrangement between these and finger extension movements could be observed.
Using the criteria described by Spinozzi et al. (2004), 14% of evoked finger flexions could be categorized as "power grip", where all fingers move towards the palm, and 31% could be categorized as "precision grip", in which the thumb moves towards one or more other fingers. Among these, different subtypes of precision grip could be identified. The most common was the opposition between D1 and D2 (75% of all "precision grips"). Interestingly, the execution pattern of movement of these digits varied between animals. In one case, the precision grip was achieved mostly by the adduction of D1 towards D2 such that the medial surface of the first touched the lateral surface of the second. In another case, D2 was mostly touched by the tip of D1. The other variations of precision grips we observed consisted in the opposition between D1 and D2+D3 (19%), and between the tips of D1 and all other fingers (6%). Thus, the complex manual behavioral repertoire of the capuchin monkey is well represented within M1, where specific types of hand grips can be revealed using LT-ICMS.

Title: Normal and perturbed neural dynamics in motor cortex during a reach-to-grab task

Authors: *B. SAUERBREI, J.-Z. GUO, J. ZHENG, W. GUO, M. KABRA, N. VERMA, M. MISCHIATI, K. BRANSON, A. HANTMAN
Janelia Res. Campus, Ashburn, VA

Abstract: Reaching, grasping, and object manipulation play a central role in the lives of mammals with prehensile forelimbs. The musculoskeletal complexity of the limb poses a

challenging control problem for the central nervous system, which must orchestrate precisely-timed patterns of activity in many muscles to perform a wide diversity of tasks. The motor cortex is thought to be critical for producing these patterns, and single-unit recording studies have demonstrated that the activity of cortical neurons is correlated with muscle tension and limb kinematics. Direct experimental control over cortical circuits for reaching, however, has proven challenging. Here, we achieve rapid, reversible, and bidirectional control over reaching behavior in head-fixed mice using optogenetics in conjunction with electrophysiology. In order to isolate the cortical commands for movement, we compare neural dynamics during normal, voluntary reaching with dynamics during optogenetically-induced, involuntary reaches. Involuntary reaches are executed with much shorter reaction times than voluntary reaches, suggesting that motor cortex is downstream of brain regions involved in the decision to reach. Neural dynamics during involuntary reaches recapitulate the dynamics during voluntary reaching. Briefly silencing motor cortex during movement execution perturbs limb kinematics, but the cortical network rapidly recovers from this perturbation, driving successful completion of the task. Furthermore, the cortical network and behavior are robust to cell-type-specific perturbation of excitatory populations. These results suggest that ongoing neural dynamics in motor cortex are both necessary and sufficient to orchestrate reach-to-grasp movements.

Title: Does the medial reach-to-grasp network host mirror neurons?

Authors: *R. BREVEGLIERI, F. E. VACCARI, A. BOSCO, M. GAMBERINI, P. FATTORI, C. GALLETTI
Biomed. and Neuromotor Sci., Univ. di Bologna, Bologna, Italy

Abstract: Mirror neurons are a particular type of cells that discharge both during action execution and during observation of the same action performed by other agents (Rizzolatti et al. 1996, Cogn Brain Res). So far, they have been found in several nodes of the lateral grasping network, a circuit that includes the ventral premotor cortex and the inferior parietal lobule. In the present work, we looked for mirror neurons in the superior parietal lobule, a node of the medial

reach-to-grasp network (Galletti and Fattori, 2018 Cortex) never explored in this regard. We recorded the neural activity of 100 neurons in the medial posterior parietal area V6A of two male *Macaca fascicularis* during grasping movements and during observation of the same action performed by the experimenter. In all tested neurons we also checked the neural response to the passive object observation, when grasping was not required to the animal. The overhealming majority of V6A neurons (86/100) were modulated only when the monkey executed the action, suggesting that these cells were able to discriminate between own and other's actions. A minority (14%) of neurons showed mirror features, discharging also during observation of actions performed by the experimenter. However, differently from the classic mirror neurons, V6A mirror neurons responded also to the passive object observation, like the 'canonical-mirror' neurons of the lateral grasping network, recently described in literature (Bonini et al. 2014, J Neurosci). V6A mirror neurons showed dissimilar responses when the monkey performed the action and when it observed the same action performed by the experimenter, so they seem not to be involved in action understanding, differently from the classic mirror neurons found in the lateral grasping circuit. In addition, because the neural responses of V6A mirror neurons to object observation were different according to the contexts (object observation before own action, before action performed by the experimenter, and when no grasping was required), we suggest that these neurons encode the relevance of the object in the action to be performed. In conclusion, area V6A is well equipped to monitor own actions but is not able to build an internal representation of observed actions.

Title: Single neuron defined cortico-subcortical mesoscale networks are associated with specific motor actions in awake chronic mice

Authors: *D. XIAO, J. M. LEDUE,, M. P. VANNI, T. H. MURPHY
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: How information processing in motor pathways drives a specific action is still largely unknown. Difficulty comes from recording neural activity over large spatial scales while

monitoring motor output and single neuron responses. We provide a chronic recording system which integrates with wide-field calcium functional imaging, multi-site sub-cortical cellular electrophysiology and peripheral nerve recording in head-fixed mice which undergo self-initiated bouts of running and or facial movements. Facial motor nerve impulses were measured by paired fine wire recording. Mesoscale GCaMP imaging was used to assess regional cortical activity. Nerve or single neuron spike-triggered averaging allowed the identification of cortical regions that are preferentially related to specific actions. Multiple tetrodes were then implanted in regions of interest to record extracellular spike activity. Spontaneous firing of facial motor neurons is linked to specific patterns of cortical mesoscopic activity, and unexpectedly was found to be associated with unique patterns of cortical activation which extended to higher-order associative cortical areas, including RS, PTA, ACC and mPFC. These higher-order associative cortical areas along with subcortical areas in striatum and brainstem were linked with spontaneous facial movement that occurred during the self-initiated movement bouts. Preliminary results also indicated cortico-hippocampal networks associated with rhythmic nose movement and a cortico-VTA network was associated with spontaneous running. We suggest that these large scale brain networks coordinate spontaneous running and whisking associated movements. Our chronic recordings remained stable for weeks, demonstrating that this method can be employed to investigate the dynamic and distributed neuronal ensemble interactions that underlie processes of motor control and sensorimotor learning in behaving mice. Our findings are consistent with specific behavioral actions involving large scale brain networks.

Title: Encoding of contralateral and ipsilateral hand movements by neurons and local field potentials in the primary motor cortex in monkeys

Authors: *Y. NAKAYAMA, O. YOKOYAMA, E. HOSHI
Neural Prosthesis Project, Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: The primary motor cortex (M1) of primates is considered to play a crucial role in executing contralateral hand movements. However, the input-output organization of the M1 involved in controlling hand movement still remains elusive. In the present study, we recorded

neuronal activity and local field potentials (LFPs) from the M1 while monkeys (*Macaca fuscata*) performed a button-press movement with either the right or left hand. Three types of movement-related neuronal activity were observed: (1) with only the contralateral hand (contralateral neuron), (2) with only the ipsilateral hand (ipsilateral neuron), and (3) with either hand (bilateral neuron). The proportion of contralateral neurons was much larger than that of ipsilateral neurons, and quantitative analyses also revealed that neuronal selectivity was biased toward contralateral hand movement. We also found a movement-related power increase in the high-gamma (80-120 Hz) and theta (3-8 Hz) bands of LFPs. These power increases were classified into the following three types: (1) a greater modulation during contralateral hand movement than during ipsilateral one (contralateral LFP), (2) a greater modulation during ipsilateral hand movement than during contralateral one (ipsilateral LFP), and (3) a comparable modulation during contralateral and ipsilateral hand movement (bilateral LFP). The proportion of contralateral LFPs was much larger than that of ipsilateral LFPs in both high-gamma and theta bands. These results suggest that in the M1 both input signals from other cortical areas and output commands to the spinal cord have contralateral biases. Taking together with our previous findings that the caudal cingulate motor area (CMAc) and supplementary motor area (SMA) are involved in selecting which hand to use (Yokoyama et al., 2016; Nakayama et al., 2015), the M1 may play a role as a cortical center that receives inputs about contralateral hand movement pre-selected in other cortical areas such as the CMAc and SMA, and sends motor commands to the spinal cord to execute contralateral hand movements.

Title: Stability and independence of the ipsilateral representation of reaching movements in motor cortex

Authors: *T. C. DIXON[1], C. M. MERRICK[2], R. T. KNIGHT[2], R. B. IVRY[2], J. M. CARMENA[3]

Abstract: The canonical understanding of motor control is that each side of the body is primarily controlled by the contralateral hemisphere of the brain. However, multiple streams of evidence suggest an additional role for the ipsilateral motor cortex. The level of dissociation between these contralateral and ipsilateral signals and their roles in control remain open topics. Here we investigate one candidate explanation for the ipsilateral representation of reaching movements. Built on past findings that the cortex can simultaneously represent multiple alternative motor plans, we test the hypothesis that plans for accomplishing a common reaching goal are prepared in parallel for both limbs contralaterally. In this framework, correlations between the non-selected and selected reach plans would thus provide a spurious representation of the reaching movement in ipsilateral cortex despite being truly related to the contralateral limb. We tested this hypothesis using ensemble spiking activity from bilateral primary motor (M1) and dorsal premotor (PMd) cortices in one macaque monkey performing a simple reaching task. Spiking data were recorded using multi-channel acute recording probes (V-probe: Plexon, Inc). Kinematics of both upper limbs were monitored (PhaseSpace, Inc) while the subject received feedback in a 3D virtual reality environment. Using an instructed-delay reaching task, the subject was required to obtain specific starting configurations of the hands before reaching with a single limb to one of six targets. In this manner, we explicitly dissociated the selected movement from ostensible non-selected plans for the stationary limb. We analyzed the data using a population decoder approach, predicting motor behavior from neural activity, to test 2 key predictions of this hypothesis: 1. Ipsilateral decoders will generalize poorly to trials where the non-selected (stationary) hand is placed in a different position. 2. Modulation of neural activity during ipsilateral reaching will be similar during contralateral reaching. Consistent with the first prediction, our results show that ipsilateral decoders were more sensitive to changes in the starting position of the non-selected hand than contralateral decoders. However, no substantive similarity between activation profiles during ipsilateral and contralateral reaching was observed. These results suggest that parallel preparation of reaching plans with either limb does not account for a significant portion of the ipsilateral modulation in motor cortex during movement. Rather, the ipsilateral activation may simply be an independent signal that is more sensitive to changes in body posture.

Title: Cholinergic modulation enhances the performance of skilled motor behaviors

Authors: *X. PENG, D. C. DONEGAN, J. L. HICKMAN, C. G. WELLE
Neurosurg., Univ. of Colorado Denver, Aurora, CO

Abstract: Cortex receives widespread cholinergic modulation which desynchronize neural activity in cortex, increase arousal and improve sensory discrimination. Despite the well-documented ascending cholinergic projections to motor cortex, little is known about the role of cholinergic inputs on the performance of skilled motor behaviors. This work aims to determine the influence of cholinergic inputs during the performance of dexterous forelimb reach in the adult mouse, and to identify corresponding changes in neural dynamics of motor cortex. In mice trained to perform a dexterous forelimb reach task, temporally-precise stimulation was delivered to basal forebrain (BF) immediately following a successful reach. Stimulation was delivered by optical activation (20 Hz, 10 ms pulse) of channelrhodopsin (ChR2) driven by the ChAT promoter in cholinergic neurons, or in all neuronal subtypes of BF through AAV2-driven expression. Paired cholinergic activation enhanced the success rates above baseline performance. Interestingly, optical stimulation of all neuronal subtypes in BF enhanced motor performance more effectively than stimulation of cholinergic neurons alone, suggesting that multiple BF ascending projection systems may be relevant for modulating skilled motor behaviors. These results suggest that the BF projection system may modulate the motor cortex and can be exploited to enhance the performance of dexterous motor behaviors. In order to further investigate the effects of BF inputs on motor cortical circuits, population neural dynamics were monitored in freely moving animals using a miniscope to image neural calcium activity (GCaMP6) in M1. Preliminary data shows that individual neurons from layer II~III forelimb motor regions respond selectively to components of the reach movement. Future experiments pairing BF stimulation with successful reach will provide insights in the influence of BF inputs on motor cortical neural ensembles in the dexterous reach task.

Abstract: Cognition depends on the brain's ability to integrate past and current information and manipulate information internally in the absence of external stimuli. A fundamental challenge is to understand how the structure and dynamics of neural circuits support such internal states. Measurements of activity have been mostly limited to a handful of neurons in one brain region. However, even simple cognitive tasks engage multiple interacting brain regions and we currently lack a comprehensive picture of neural activity across the brain for any behavior. Recent advances in electrophysiology (e.g. Neuropixels probes) provide the opportunity for simultaneous recordings of neural activity across multiple brain regions. We use one or two neuropixels probes for recordings from up to a dozen brain areas at the same time. Our goal is to produce comprehensive, whole brain 'activity maps' for mice during decision-making and motor planning.
We present data from a delayed response behavioral task, in which mice make a sensory discrimination, followed by a delay epoch during which they plan a directional movement, and then followed by a response epoch during which they execute the movement. We have previously identified the anterior-lateral motor cortex (ALM) as an area critical for motor planning and movement initiation. Using an anatomy-based scheme based on the Allen Mouse Brain Connectivity Atlas (and our own data) we target brain areas that form multi-regional networks with ALM. Each electrode track is recovered in three dimensions and mapped into a standardized brain atlas. We are developing pipelines for processing, analyzing, and sharing large-scale neurophysiology data. In this preliminary report, we show data from ALM, thalamus, basal ganglia, superior colliculus, brainstem, and cerebellum. This work will advance our understanding of modular, multi-regional neural dynamics underlying cognition.

Title: The effects of sensory loss on the neurobiomechanics of sensorimotor behavior

Authors: *F. I. ARCE-MCSHANE[1], N. G. HATSOPOULOS[1,2,3], C. F. ROSS[1], B. J. SESSLE[4]

Abstract: Oral somatosensation plays a key role in breathing, feeding, and speech such that altered sensation in pain disorders and sensory loss following neurological injuries have devastating effects on the quality of life. However, how neurons in the primary orofacial sensorimotor cortex use afferent information from the tongue, jaw, and facial muscles to effect functionally critical, coordinated movements is still largely unknown. To address this question, we examined the effects of sensory loss on the performance of a tongue-protrusion task and on the activity of neurons in the primary motor (MIo) and primary somatosensory (SIo) areas of the orofacial sensorimotor cortex in monkeys (*Macaca mulatta*). Temporary sensory loss to the anterior two-thirds of the tongue was induced by using a bilateral lingual nerve block while recording the spiking activity from microelectrode arrays implanted chronically in MIo and SIo. A monkey performed two blocks of 100 trials of the tongue-protrusion task prior to the nerve block application and a block of 100 tongue-protrusion trials every half-hour following anesthesia. Immediately after the nerve block, the monkey's success rates dropped transiently to 30% but returned to pre-nerve block success rate within the hour. However, the decrease in peak force and the increase in the time to reach the required force after injection of the nerve block persisted for over three hours. In pre-nerve block trials, the monkey generated greater forces than required. In the nerve block condition, the monkey was able to generate the required force though at a slower pace. Spiking activity of MIo and SIo neurons also differed between pre-nerve block and post-nerve block as seen in changes in the mutual information carried by single units and the coherent activity between pairs of neurons. Our results demonstrate that while sensory loss to the anterior two-thirds of the tongue transiently impaired the gross performance of the sensorimotor task, the finer details of task performance rely heavily on the availability of relevant sensory inputs.

Title: Sensory-motor sequence generation and learning of tongue movements

Authors: *D. XU[1], Y. CHEN[2], A. M. DELGADO[2], D. H. O'CONNOR[1]
[1]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Behaviors are generally composed of basic motor outputs coordinated in sequences. Learning new motor sequences and tuning them requires an animal to voluntarily output actions and alter future actions based on sensory feedback. The pinnacle of sensory-motor sequence learning is embodied by human language, where the control and modulation of tongue motion is essential. Rodents also show rich and complex motor sequences using the mouth and tongue. To study the neural basis of sensory-motor sequence learning, we developed a novel behavior in head-fixed mice where they learned to perform sequences of licks to a set of defined target locations. Tongue motions were captured by high-speed video and kinematics quantified by artificial deep neural nets. Contact forces between tongue and lick port were recorded by custom made sensors. Mice learned this task within a week and could perform a sequence of licks to 7 directions within ~1 second. During behavior, we recorded single-unit activity (n >= 250) from various brain regions (S1, M1, M2, striatum, thalamus) using silicon probe electrode arrays. Units across and within regions showed diverse task-related activities, many of which were tuned to aspects of motor sequences beyond the directions of individual licks. To examine any causal role of various brain areas, we performed closed-loop optogenetic silencing experiments, focusing on preparation, initiation and continuation of motor sequences. By combining rich behavioral quantifications, high-density electrophysiology and loss-of-function screening, we aim to characterize how an ongoing sensory-motor loop is evolved and tuned, and the underlying mechanisms of learning.

Title: Cortical dynamics associated with multiple timescales of sensorimotor adaptation

Authors: *N. MEIRHAEGHE[1], H. SOHN[2], M. JAZAYERI[3]
[1]Div. of Hlth. Sci. & Technol., Harvard-MIT, Cambridge, MA; [2]McGovern Inst. for Brain Research,Center for Sensorimotor Neural Engin., MIT, Cambridge, MA; [3]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: Humans can efficiently adapt to changes in their environment. To do so, the brain must flexibly adjust its neural dynamics to meet the ever-changing behavioral demands. In the framework of dynamical systems, such adaptive dynamics can be achieved in two ways. First, controlling external inputs enables the system to visit unexplored neural states. Alternatively, changes in synaptic couplings within the system modify its latent dynamics, effectively creating new activity patterns in state space. Because synaptic modifications occur on relatively slow timescales, we hypothesize that fast behavioral adaptation relies on input-control strategies, while slow adaptation relies on adjustments of latent dynamics.To test these hypotheses, we build on a time reproduction task in which monkeys measure a sample time interval between the first two beats of a rhythm and produce a saccadic eye movement on the third omitted beat. In this task, animals' responses are biased toward the mean of the previously encountered intervals. This bias can be quantitatively captured by a Bayesian model that integrates a noisy measured interval with the animals' knowledge about the prior distribution of sample intervals. Moreover, our previous work has shown that prior knowledge exerts its influence on behavior through an adjustment of both inputs to and latent dynamics of premotor cortical areas. Leveraging these observations, we sought to test the role of inputs and latent dynamics in two modified versions of the time reproduction task that elicit fast and slow adaptation. For fast adaptation, we covertly changed the distribution of sample intervals from a narrow prior to a single-interval. Animals adapted rapidly over a few hundred trials within a single behavioral session. For slow adaptation, we covertly switched a wide prior to a narrow prior. In this case, behavior adapted slowly across 5-6 sessions over the course of thousands of trials. We speculate that fast adaptation is achieved via adjusting the inputs to premotor areas without changing the latent dynamics, while slow adaptation depends on gradual reshaping of latent dynamics within premotor cortex. Our ongoing work seeks to test these hypotheses by comparing cortical dynamics in premotor areas during fast and slow adaptation.

Title: Directional selectivity across macaque motor cortical layers during reach planning and execution

Authors: *B. E. KILAVIK
INT, CNRS - Aix-Marseille Univ., Marseille, France

Abstract: Neurons in motor cortex are selective to different parameters during movement planning and execution, such as the direction of arm reaches. While this directional selectivity has been extensively studied, we still know very little about how it is distributed and dynamically modulated across different cortical depths.
In this study, directional selectivity was explored in a macaque monkey performing a pre-cued center-out reaching task. The target location was cued visually, several seconds before the directionally non-informative go-signal. During the delay, the monkey had to memorize the target location and could prepare the movement. Recordings were made simultaneously from superficial and deep cortical layers with multi-contact linear array (laminar) probes, in arm regions of dorsal premotor cortex (PMd) and the transition zone between PMd and primary motor cortex (M1).
Directional selectivity was explored in two task periods: following the visual cues and around movement execution. Following the cues, the neuronal population in superficial layers had an earlier phasic response than that in deep layers. However, directional selectivity developed stronger in the deep neuronal population, following the earlier, but less directionally selective superficial response. Just before the movement onset and during its dynamic phase, selectivity was stronger in superficial layers. The neurons in deep layers became equally directionally selective as the superficial population only as the hand arrived in the target, towards movement end.
These different dynamics of directional selectivity might be related to the different predominance of cortico-cortical vs. sub-cortical projections of superficial vs. deep cortical layers, respectively. Cue information seems present in superficial motor cortical layers before the directionally specific planning commences, predominantly involving deeper layers. This suggests that motor cortex participates in the decision process linking visual cues and motor preparation. Eye movements demonstrated a strong reliance on visual feedback before and during the dynamic phase of the reach, possibly causing the increased selectivity of superficial neurons in these movement epochs. The increased selectivity of neurons in deep layers towards movement end might reflect final motor command adjustments to successfully enter the peripheral target.

Title: A robust brain-spinal interface using local field potentials and epidural stimulation

Authors: *M. AMBROISE, A. JACKSON
Newcastle Univ., Newcastle-upon-Tyne, United Kingdom

Abstract: Previously we have demonstrated a brain-spinal interface (BSI) to restore volitional grasping movements to monkeys after temporary pharmacological paralysis (Zimmerman and Jackson, Front Neurosci 2014). We have since made several modifications in order to improve long-term reliability and facilitate implementation in a low-power, implantable neuroprosthesis. First, we derive control signals from local field potentials (LFPs) as they provide better long-term stability and require lower sampling rates than action potential recordings, and use unsupervised areal velocity decoding (Jackson and Hall, IEEE TNSRE 2017) to detect intended movement from low-frequency cycles in the multichannel LFP. Second, we deliver epidural instead of intraspinal stimulation, using a multi-contact electrode positioned around the ventral and dorsal surface of the cervical enlargement. Here we report results of testing this improved BSI in a macaque monkey.

The monkey was trained to perform a movement task that required grasping a lever and pulling downwards by extending the elbow, prior to surgical implantation with electromyogram (EMG) electrodes in six hand and forearm muscles, two 32-channel floating microelectrode arrays in dorsal and ventral premotor cortex, a chamber over primary motor cortex and an 8-channel cuff electrode around the C7 segment of the spinal cord. Areal velocity was calculated in real-time by projecting the multichannel premotor LFP onto a plane using Principal Component Analysis. During normal task performance, this areal velocity signal increased at the onset of volitional movement.

Over 7 testing sessions, we located hand area of primary motor cortex (by intracortical microstimulation) and injected muscimol to induce reversible paralysis lasting several hours. When the BSI was enabled, areal velocity exceeding a threshold triggered spinal stimulation (50 Hz trains of biphasic stimuli delivered between dorsal and ventral sites, 100-200 μA, 0.2 ms per phase) that elicited robust EMG responses and strong muscle contractions. With the BSI enabled, the monkey performed an average (±SD) of 6.0 ± 3.1 successful trials per minute. By contrast, with the BSI disabled the monkey could perform only 0.5 ± 0.6 successful trials per minute, despite an areal velocity signal that indicated the animal's continued attempts to move.

These results demonstrate the potential for our BSI to restore simple voluntary upper-limb movements. Moreover, our use of LFP decoding and epidural stimulation offers the possibility of implementing this approach in a robust and reliable implanted neuroprosthesis suitable for clinical application.

Title: Epidural and transcutaneous spinal cord stimulation facilitates descending inputs to upper-limb motoneurons

Authors: *T. GUIHO, J. KERSEY, S. N. BAKER, A. JACKSON
Med. Sch., Univ. of Newcastle, Newcastle Upon Tyne, United Kingdom

Abstract: Renewed interest in spinal cord stimulation (SCS) has emerged in recent years following reports of significant gains of voluntary motor function in spinal cord injured patients after SCS-assisted rehabilitation. Although not fully elucidated, the mechanism behind this effect is believed to be a potentiation of spinal network excitability that unmasks spared but weakened descending pathways from the brain. We performed a series of experiments in anaesthetized, neurologically intact monkeys in order to better characterize SCS and elucidate its impact on corticospinal excitability. Spatial selectivity of SCS was investigated using an 8-contact ring electrode placed epidurally or subdurally around the cervical spinal cord while electromyogram (EMG) signals were recorded from upper limb muscles. In separate experiments we delivered transcutaneous stimulation using a high carrier frequency through electrodes on the skin. Trains of suprathreshold SCS at different frequencies were used to characterize temporal facilitation and suppression after ventral or dorsal stimulation. Ventral electrodes elicited more robust movements than the dorsal side, with spinal motor evoked potentials reliably following even high-frequency trains. For dorsal electrodes, short-term facilitation was observed for the first few pulses followed by subsequent suppression for the rest of the train. This effect was most pronounced at high frequencies.
Next, we assessed the interaction between cortical inputs and subthreshold SCS by delivering intracortical microstimulation to the hand area of primary motor cortex during trains of epidural or transcutaneous SCS (at frequencies of 10, 20, 50 and 100 Hz). Cortical-evoked motor

potentials were reliably facilitated by dorsal stimulation, although the effect was more pronounced for epidural versus transcutaneous SCS. Facilitation was maximal for the stimulus frequency of 50 Hz. Interestingly, no suppression of the cortical motor evoked potential was observed, even for the highest SCS frequency.
These results can be explained by a simple model whereby dorsal stimulation activates afferent inputs to motoneurons, raising their excitability, but also presynaptically inhibits subsequent afferent input. SCS at high frequencies thus suppresses subsequent spinal-evoked responses but does not suppress the cortical-evoked response. We further suggest that the facilitation of cortical-evoked responses could be used to optimise patient-specific stimulation parameters prior to SCS-assisted rehabilitation.

Title: Parietal and premotor planning signals for walk-and-reach movements towards far-located goals in unrestrained rhesus macaques

Authors: *M. BERGER[1,2], A. GAIL[1,2,3]
[1]Cognitive Neurosci. Laboratory, Sensorimotor Group, German Primate Ctr., Göttingen, Germany; [2]Fac. of Biol. and Psychology, Univ. of Goettingen, Goettingen, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany

Abstract: In sensorimotor neuroscience with non-human primates reaching movements are usually studied in isolation or in combination with tightly constrained hand, eye or head movements. We know little about how goal-directed reaching movements are planned and controlled when whole body movements are involved. In our recently developed Reach Cage (Berger and Gail, 2018 bioRxiv), we now studied how the fronto-parietal reach network encodes walk-and-reach movement goals.
We trained two rhesus macaques to a delayed walk-and-reach task. Movement targets were at four horizontally distributed directions near to the animal (reach) and four further away so that the animal needed to walk towards the targets before reaching (walk-and-reach). The monkeys performed movements towards one of eight targets with variable instructed delay (planning period) after visual cueing of the target. We recorded wirelessly single and multi-unit activity

from the parietal reach region (PRR), dorsal premotor cortex (PMd) and arm area of the primary motor cortex (M1). We analyzed motor-goal encoding during the instructed delay prior to the movement.
Individual units were modulated for both, reach movements and walk-and-reach movements, with an overall lower fraction of walk-and-reach modulated units. To characterize the population activity, we used demixed principle component analysis (dPCA) to identify how much variance is captured by the target distance (reach vs. walk-and-reach) and horizontal position. Distance explains most variance of planning activity (>50% for PMd and PRR and approx. 30% for M1). In all areas we found distance related dPCA components that show significant modulation starting less than 200ms after target onset. This was expected due to the clear differences in movement behavior between reach and walk-and-reach movements. We wanted to know whether the fronto-parietal network encodes distance-invariant target position. If horizontal target position is encoded for near and far-located movement targets, we expect to find components that contain an isolated representation of horizontal position. If encoding would be specific for near-located targets, the full horizontal position variance would be dependent on distance and dPCA would characterize this as an interaction term. Indeed, dPCA could isolate significantly modulated components in all three brain areas that represent only horizontal position. The variance explained by horizontal position is around 10%-20%. The significant modulation for position independent of distance suggests that the fronto-parietal network is co-encoding far-located walk-and-reach targets with near-located reach targets.

Title: Encoding of licking direction in a shared space of neuronal ensemble activities in anterior lateral motor cortex in rodents

Authors: *S. CHAE[1], S.-P. KIM[2]
[1]Design and Human Engin., Ulsan Natl. Inst. of Sci. and Technol., Ulsan / Ulsan Metropolitan City, Korea, Republic of; [2]Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

Abstract: Anterior lateral motor cortex (ALM) in rodents have been known as a cortical area commanding directional licking. Neurons in ALM also retain the directional information before movement execution. A number of studies have revealed the neural mechanisms of a conditional

licking strategy associated with sensory information within ALM as well as between ALM and other brain areas. However, how neurons in ALM neurons transform licking direction information in working memory into licking movements within the ALM still remains unknown. To address this, we analyzed the publicly available datasets in the CRCNS data repository. In the experiment, multi-channel neural spikes from left ALM were recorded in 11 adult mice during a tactile decision task. A pole touched the whisker of the mice for 1.3 s, cueing the direction of reward. After the pole was off, mice waited for 1.3 s (delay period) and licked to the right or left after 0.1-s beep sound (response period). The behavioral results were classified into four cases: Hit right (HR), Hit left (HL), Error right (ER) and Error left (EL), where the error trials occurred when the mice licked in the direction opposite to cued direction. We hypothesized that ALM neurons shared the information of licking direction in the delay period to transform it to movement execution after an action cue (i.e. beep), rather than processing information independently. To estimate shared information among neurons, we used the factor analysis to decompose ensemble activity in every 200-ms of the delay period into the shared signal, which was modulated by low-dimensional latent variables, and private signals with no covariance between neurons. We approximated shared space alignment which was defined as the projection of the shared space in the response period onto the shared space in the delay period. The resulting alignment ranged between 0 and 1 where 1 denoted perfect alignment between two shared spaces and 0 denoted orthogonality between the spaces. A projection matrix was estimated using the data in the Hit trials. We found that the shared space alignment in the Hit trials was significantly higher than a chance level ($p<0.01$). However, when we aligned the shared space of the Hit trials with the Error trials based on the cuing direction (e.g. ER onto HR), the shared space alignment was not significantly different from the chance level. In contrast, when we aligned the shared space of the opposite Hit trials with the Error trials (e.g. EL onto HR), the shared space alignment became significant ($p<0.01$). This result indicates that neurons in ALM may collectively form a specific pattern to encode future licking direction, which is kept aligned during licking.

Title: The organization of motor cortex in the Egyptian fruit bat (rousettus aegyptiacus): Specializations of the tongue representation associated with echolocation

Authors: *A. C. HALLEY[1], M. M. YARTSEV[2], L. A. KRUBITZER[1]
[1]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; [2]Bioengineering, Univ. of California Berkeley, Berkeley, CA

Abstract: The Egyptian fruit bat *Rousettus aegyptiacus* and other members of its genus are the only megachiropteran bats that echolocate, and the only known bats to use tongue clicks rather than laryngeal vocalization to produce active sonar. Very little is known about the organization of motor neocortex in bats generally, or in *Rousettus* specifically, as no previous study has attempted to map the motor cortex in any species of *Chiroptera* using intracortical microstimulation techniques. Here we present the first movement maps in motor cortex made in any bat species. We utilized both short- (50ms) and long-train (500ms) intracortical micro-stimulation (ICMS) techniques applied to a large region of neocortex spanning primary motor cortex, somatosensory cortex, and posterior parietal cortex. Movements were elicited from stimulation of both somatosensory and motor cortices, with hindlimb representations located caudomedially, representations of the face and jaw located rostrolaterally, and wing representations in an intermediate position. Most notably, stimulation of the head and face areas revealed extensive motor representation of the tongue that is topographically organized, such that proximal and distal tongue movements are elicited from stimulating adjacent but distinct areas of the neocortex. While there are no motor stimulation studies on non-echolocating bats to allow for a direct comparison, studies of somatosensory cortex in non-echolocating megabats (Krubitzer & Calford 1992) show no evidence of magnified tongue representation. This suggests a unique evolutionary adaptation in *Rousettus* to allow for finer motor control of tongue movements in the generation of active sonar clicks.

Title: Long-term stability of single channel neural activity during execution of gross and fine reaching in rats

Authors: *D. T. BUNDY[1], D. J. GUGGENMOS[1], M. D. MURPHY[4], M. SAMI[2], R. J. NUDO[3]

Abstract: Following a lesion to motor cortex, reorganization occurs throughout the remaining brain regions and is thought to underlie motor recovery. Unfortunately, the standard neurophysiological and neuroanatomical measures of post-lesion plasticity can only be indirectly related to changes in motor execution. Assessing alterations in task-related neural activity during motor recovery will lead to an increased understanding of how these neuroplastic measures directly contribute to motor execution following recovery. This study examined the long-term stability of neural activity associated with execution of reaching movements in healthy rodents. Male Long-Evans rats (*Rattus norvegicus*, n=5) were trained to perform a reaching task consisting of a 'gross' lever press that allows access to perform a 'fine' pellet retrieval. In each animal, two chronic, 16-channel microelectrode arrays were implanted in motor cortex contralateral to the reaching forelimb, with one array implanted in the caudal forelimb area (rodent primary motor cortex) and a second implanted in the rostral forelimb area (rodent premotor cortex). We recorded multiunit spiking and LFP activity 2-3 times per week from 10 days to 8 weeks post implant and analyzed the consistency of channel-specific task-aligned multiunit firing rate changes. Channels with statistically significant task-aligned firing rate changes were included for further analysis. For each channel, we calculated the multiunit firing rate in a 4s window aligned to either the lever press or pellet retrieval, and calculated the correlation (Pearson's r) of the average firing rate from each recording with the average firing rate from all recordings. Across days, channels, and rats, the average correlation between the daily and overall firing rate was 0.66 for the pellet retrieval and 0.60 for the lever press. We observed decreased correlations in early (days 10-20) and late (>6 weeks) days as rats regained proficiency following the implant procedure and electrodes were encapsulated, and individual units were lost from multiunit recordings, respectively. These results demonstrate that task-related multiunit firing rates are generally consistent with maintained cortical involvement in movement execution; therefore, multiunit firing rate changes can be used for future evaluation during recovery from a cortical injury, particularly in the subacute to chronic periods in which injury-related neuroplasticity is known to occur. Future work will seek to compare the consistency of task-related LFP activity to multiunit spiking activity, particularly for early and late recording sessions.

Title: Sensorimotor cortical population responses across natural behaviors

Authors: *J. WALKER[1], F. PIRSCHEL[2], J. N. MACLEAN[4], N. G. HATSOPOULOS[3]
[1]Committee on Computat. Neurosci., [2]Organismal Biol., [3]Organismal Biology, Committee on Computat. Neurosci., Univ. of Chicago, Chicago, IL; [4]Neurobio., The Univ. of Chicago, Chicago, IL

Abstract: Theoretical and ethological perspectives suggest investigating cortical population responses during complex, natural behaviors will be key to understanding the cortical population code. Multiple groups have found surprisingly low dimensional structure in population responses while studying several cortical areas during highly trained and constrained behaviors. Evidence for low dimensional structure of neural population activity in macaque motor cortex across different tasks has recently been reported, but it remains unclear if such structure persists across naturalistic behaviors. Here we measured structure in sensorimotor cortical population responses during unconstrained natural behavior in the Common marmoset using wireless multielectrode array recordings. We summarized the marmoset's behavioral repertoire and found that more than 90 percent of a waking hour is spent sitting, vertically clinging, engaging in locomotion, leaping, foraging or food manipulation behaviors. Our initial characterizations of sensorimotor cortical population responses during natural behaviors suggest that more dimensions are required to account for the variance in neuronal activity than would be predicted from more constrained behaviors.

Abstract: Activity in motor cortex predicts specific movements, seconds before they are initiated. This preparatory activity has been observed in L5 descending 'pyramidal tract' (PT) neurons. A key question is how preparatory activity can be maintained without causing movement, and how preparatory activity is eventually converted to a motor command to trigger appropriate movements. We used single cell transcriptional profiling and axonal reconstructions to identify two types of PT neuron. Both types share projections to multiple targets in the basal ganglia and brainstem. One type projects to thalamic regions that connect back to motor cortex. In a delayed-response task, these neurons produced early preparatory activity that persisted until the movement. The second type projects to motor centers in the medulla and produced late preparatory activity and motor commands. These results indicate that two motor cortex output neurons are specialized for distinct roles in motor control.

Title: Grip affordances are encoded in conjunction with grasping movements in M1

Authors: *R. N. TIEN, A. B. SCHWARTZ
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Spiking activity in primary motor cortex (M1) correlates with aspects of reaching and grasping movements. The extent to which this movement encoding remains stable over time and

across contexts is largely unknown. Moreover, the possibility that M1 may encode contextual information in addition to ongoing movements has remained mostly unexplored.
Here, we present evidence that in a reach-to-grasp task, M1 neurons encode both the grasping movement and contextual information related to the affordances of the grasped object.
We trained two rhesus macaques to grasp and hold two simple objects and a compound object. The first simple object afforded only a power grip, the second only a precision grip, and the compound object afforded both grips. The goal of the study was to elicit the same grasping movement in different contexts. We recorded M1 spiking activity, the subjects' arm and hand kinematics and muscle activity throughout the behavior.
This paradigm allowed us to compare conditions in which the executed grasping movements were the same while the identities of the grasped object differed (e.g. power grip on the simple object vs. power grip on the compound object). We found that the majority of M1 neurons displayed significantly different firing patterns when different objects were grasped, even when the movements had nearly identical kinematics. In terms of single unit firing rates, the magnitude of firing rate modulation due to object encoding was comparable to or greater than that due to movement encoding, especially around movement onset.
Object identity did not appear to be encoded simply or directly, as most single units displayed complex interactions between object identity and executed movement encoding. This interactive (rather than additive) coding also evolved in time, such that different neurons encoded objects at different times. The net effect was that objects were consistently classifiable from the neural population at well above chance levels from before movement onset through object contact. This contrasts with movement encoding, where classification accuracy for movements increased as the hand approached the object.
Further experiments and classification analyses revealed that object identity representations based on both learned and perceived grasp affordances could be extracted from M1. The results from these experiments will be important to consider in the design of future neuroprosthetic decoders for cortical control of a robotic arm and hand.

Title: Multimodal measurement of swallowing using human electrocorticograms, Kinect v2, an electroglottography and a throat microphone in order to reveal swallowing-related neural activities

Authors: *H. HASHIMOTO[1,2], M. HIRATA[1,2], K. TAKAHASHI[3], S. KAMEDA[1], F. YOSHIDA[4,1], T. YANAGISAWA[1,2], S. OSHINO[2], T. YOSHIMINE[1], H. KISHIMA[2]
[1]Clin. Neuroengineering, [2]Neurosurg., Osaka Univ., Suita-Shi, Japan; [3]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [4]Neurosurg., Kyushu Univ., Fukuoka-Shi, Japan

Abstract: Research for swallowing-related neural activities in human has been done mainly by a non-invasive manner, PET, TMS, NIRS, fMRI and MEG. These results showed some cortical areas are activated during swallowing, but the spatiotemporal resolution of these results is not high. Therefore, we have used human electrocorticograms (ECoGs) to the analysis of swallowing-related neural activities with high spatiotemporal resolution. For measurement of ECoGs during swallowing, we developed a novel multimodal measurement system.For non-invasive swallowing detection, we used an electroglottograph (EGG), a throat microphone and a simple swallow tracking system (SSTS). Swallowing-related neck impedance changes recorded by EGG and bolus sound recorded by a throat microphone helped us to detect the onset time of swallowing. The SSTS is newly developed by us in order to quantify swallowing-related motion using the Kinect v2 (Microsoft,Redmond, Washington, USA). We defined three mouth-related parameters and two larynx-related parameters. We measured five parameters during water swallowing in ten health participants. Simultaneously, we captured the motion of participants using an RGB camera of the Kinect v2. Changes in mouth-related parameters were observed before swallowing and reached peak values at the time of swallowing. In contrast, larynx-related parameters showed little change before swallowing and reached peak values immediately after swallowing. The SSTS successfully quantified the swallowing process from the oral phase to the laryngeal phase. The SSTS is non-invasive, wireless, easy to set up, and simultaneously measures the dynamics of swallowing from the mouth to the larynx.An electro stimulator supplied digital signals to an EGG, a throat microphone and a 128-channel digital EEG system. The signals made an LED light flash, which was captured by the RGB camera of Kinect v2. The digital triggers and LED light flash enabled us to synchronize multimodal data of an EGG, a throat microphone, SSTS and an EEG. The simultaneous recording of an EGG, a microphone and SSTS enabled us to non-invasively and accurately identify the timing of the swallowing movement. Therefore, we could insert triggers into ECoGs data corresponding to the timing of swallowing. We newly constructed multimodal measurement system during swallowing and analyzed the oscillatory changes related to swallowing using ECoGs data. Time-frequency plots of the subcentral area (Brodmann area 43) demonstrated that high gamma band activity appeared specific to swallowing. This high gamma activities may be the key phenomenon of cortical activities involved in swallowing.

Title: Differential modulation of neural activity in the ventral lateral nucleus of the thalamus during speech production

Authors: *D. WANG[1], W. J. LIPSKI[1], A. BUSH[1], C. DASTOLFO-HROMACK[2], A. CHRABASZCZ[3], D. J. CRAMMOND[1], S. SHAIMAN[2], R. S. TURNER[4], J. A. FIEZ[3], M. RICHARDSON[1]
[1]Dept. of Neurolog. Surgery, [2]Dept. of Communication Sci. & Disorders, [3]Dept. of Psychology, [4]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Both basal ganglia-thalamo-cortical and cerebello-thalamo-cortical circuits contribute to speech motor control and language processing. The thalamus functions as a relay center in both circuits, yet its involvement in speech production rarely has been studied directly. The posterior part of the ventral lateral nucleus (VLp) mainly receives inputs from the cerebellum and sends outputs to the motor cortex, while the anterior part of the ventral lateral nucleus (VLa) primarily relays information between the globus pallidus and the premotor cortex; both regions are encountered during implantation of deep brain stimulation (DBS) leads into the Vim nucleus. We recorded spoken acoustics and simultaneous local field potentials (LFPs) in the ventral lateral nucleus of the thalamus (VL) in 12 essential tremor subjects while they performed an intra-operative speech task during DBS surgery. On each trial, subjects were asked to name a consonant-vowel-consonant syllable when it appeared on the screen. LFP signals were spectrally decomposed and power values were normalized relative to the baseline period. Recording locations were determined using the Lead-DBS toolbox, and contact locations were categorized to VLa and VLp. High Gamma (70-150 Hz) activation and beta (13-30 Hz) desynchronization were observed during speech, indicating active participation of thalamus in speech production. The increase in high gamma power was locked to speech onset (30/47 contacts, Pearson correlation, $p < 0.01$, FDR corrected), while beta desynchronization was locked to presentation of the visual cue (35/39 contacts, Pearson correlation, $p < 0.01$, FDR corrected), suggesting that oscillations within these frequency bands encode different aspects of the speech task. Furthermore, we observed that the strength of power changes during speech were dependent on

recording location within the nucleus. High Gamma activation during speech was greater in electrode contacts localized to the VLp compared to those localized to the VLa ($p < 0.01$), indicating functional heterogeneity of VL in speech control. These results provide support for the involvement of VL in speech motor control and establish a novel methodological framework to test neurophysiological models of speech production.

Title: Peripheral constraints on motor learning: Maximal speed of adult vocal muscles is not available during song learning

Authors: *I. ADAM, M. VELLEMA, C. P. ELEMANS
Univ. of Southern Denmark, Odense, Denmark

Abstract: Like human babies, songbirds learn their vocalizations from a social tutor through auditory guided motor learning. To imitate the song of their tutor, they first memorize a template by listening to a social tutor (auditory learning) followed by motor practice (sensorimotor learning). Over the latter period, temporal precision and song complexity increases and finally achieves sub-millisecond timing precision of sound elements. These extraordinary demands on vocal motor skills are met by superfast muscles (SFMs) in the syrinx. Superfast muscles are the fastest known synchronous muscles capable of contraction rates <250 Hz, enabling precise motor execution at the millisecond time scale. We recently showed that the heavy myosin chain linked to this superfast behavior is encoded by the MYH13 gene, which makes up most of the heavy myosin chains in the syringeal muscle of adult songbirds. So far, it is not known how the expression of MYH13 in syringeal muscles is regulated. Moreover, very little is known about the postnatal development of the syrinx, which coincides with vocal learning. Here, we demonstrate that over the course of song learning: (I) MYH13 was upregulated, (II) the duration of syringeal muscle contractions decreased, and (III) the composition of heavy myosin chains changed towards faster myosin forms. Furthermore, we investigated to what extent delayed song learning affected muscle speed and MYH13 expression. Taken together, we show that muscle speed - crucial to achieve precise timing of sound production- increases significantly during vocal motor

learning and that the maximal speed achieved in adult animals is not available during song learning. Our results suggest that increasing vocal performance during song learning may not only reflect neural circuitry maturation but also superfast muscle performance increase. The observed speed increase may result from training by use as consistent with other muscles expressing MYH13. Consequently, postnatal changes in the vocal muscles of songbirds may set constraints on the performance and development of learned vocal motor skills.

Title: Fundamental frequency control by dynamic actuation of the songbird syrinx

Authors: *C. P. ELEMANS[1], A. MAXWELL[2], C. LAUGESEN[2], B. J. KNÖRLEIN[3], D. N. DÜRING[4]
[2]Biol., [1]Univ. of Southern Denmark, Odense M, Denmark; [3]Ctr. for Computation and Visualization, Brown Univ., Providence, RI; [4]Inst. of Neuroinformatics, Univ. of Zurich, Zürich, Switzerland

Abstract: Juvenile songbirds navigate the motor space of their vocal organ - the syrinx - and respiratory system through trial-and-error leaning to generate precise vocal targets and sequences. Studying stereotyped in vivo motor behavior provides limited insight into the biomechanical system because only the final individual solutions are observed, which may not be unique. Understanding how the brain controls song requires therefore systematic quantification of the system's behavior across its multi-dimensional parameter space.
Using novel experimental paradigms, we here combine marker-based 3D motion capture of syringeal elements with simultaneous servomotor actuation of two muscle insertion sites, force measurements and precise pressure control to systematically map the partial syrinx motor space during sound production in vitro. We focused on the control of a biologically important acoustic parameter - fundamental frequency (f_o) - of the produced sounds. Earlier work showed that two muscles (Musculus syringealis ventralis (VS) and Musculus syringealis dorsalis medialis (MDS) directly modulate the length of the vibrating tissue - thought to set f_o Additionally, air pressure and VS activity during song and VS stimulation in vivo and ex vivo affected f_o.
We used individual and combinatory sweeps of VS/MDS shortening and air pressures to map the motor space. Our data shows positive linear relations between pressure and fo and VS shortening

and f_0 Interestingly, co-activating syringeal muscles shifted or increased the fo range in half of the subjects. Additionally we quantified 3D motion of syringeal elements induced by muscle microstimulation ex vivo. These data validate the imposed muscle shortening trajectories using in vitro, and also provide novel insights into biomechanical function of syringeal muscles. Furthermore, our results confirm that the peripheral motor space is redundant in the control of the key vocal parameter fo.
The presented methodology breaks ground towards quantifying the acoustic effects of muscle recruitment, motor output and the calibration and testing of sound production models in bird. As such, we aim to enable experimental access to the entire neuromechanical control loop of vocal motor control.

Title: Stability in postural tongue control: Response to transient mechanical perturbations

Authors: *T. ITO, J.-L. CAILLET, P. PERRIER
Gipsa Lab, CNRS, St Martin D Heres Cedex, France

Abstract: Tongue has properties as a muscular hydrostat that are unique in the human body. It is also a fundamental organ in a variety of basic biological functions for humans, such as breathing, swallowing and speaking. However, the neurophysiological mechanisms enabling its fine motor control have not been yet thoroughly investigated. While the involvement of reflex mechanisms has been largely documented for quick compensations in postural control of limbs and body as a low-level of control function, the functional role or even the existence of autogenous reflex has not been yet clearly established for the tongue. This study aimed to examine responses to transient mechanical perturbations in postural tongue control. Eight native speakers of French were asked to sustain three vowel utterances (/i/, /e/, and /ɛ/) silently, while whispering and while voicing. Articulatory movements were recorded using an electromagnetic-articulometer, together with the acoustic speech signal. Seven sensors were glued to the tongue (tip, blade and dorsum), the upper and lower lip, and the lower incisor (jaw) in the sagittal plane. Transient mechanical perturbations (1N during 1s) were provided to the tongue during the task using a robotic device, via a thin string glued to the blade. We observed an immediate compensatory response against

the mechanical perturbation. The position of each sensor on the tongue did not return to their original position, but the response tends to enable recovering the original shape of the tongue contour. During vowel production the spectral characteristics of the sounds were also modified, but were recovered quickly in synchronization with the compensatory response in motion, which suggests that tongue control was organized so as to maintain the acoustic output. We observed over time two phases in the compensatory response. The amplitude in the earlier phase was strongly related to the amplitude of the initial displacement induced by the perturbation, suggesting the involvement of a purely passive mechanism. The amplitude in the later phase varied according to the task and the location on the tongue, suggesting the involvement of a reflex mechanism which gain was systematically controlled to maintain the tongue shape according to the requirement of the task. The current finding is the first evidence for the existence of tunable reflex-based compensatory mechanisms in postural tongue control. The tongue posture for vowel production can be regulated based not on the specific position, but on the global shape of the tongue contour, which determines vocal tract geometry and, then, speech acoustics.

Title: Oral cavity numbing reduces sensorimotor adaptation to altered auditory feedback

Authors: *I. RAHARJO, H. KOTHARE, J. F. HOUDE, S. S. NAGARAJAN
UC San Francisco, San Francisco, CA

Abstract: Sensorimotor adaptation experiments in speech have shown that the speech motor control system learns to compensate for consistent alterations of the auditory feedback. However, these compensatory changes are incomplete, i.e. subjects do not fully oppose the applied alteration. This constraint in adaptation has long been postulated to be caused by the modulatory role of somatosensory feedback. Here, we examined this role by assessing the effect of orosensory numbing on adaptation to altered formant feedback.
We conducted formant adaptation experiments with real-time alteration of formant frequencies. Forty subjects were prompted to produce the word ‘head’ (vowel /ɛ/) 90 times. The repetitions

were split into 20 trials of unaltered feedback (baseline block), 50 trials of +200 Hz shifted feedback in the first formant (F1) (hold block), and lastly followed by 20 trials of unaltered feedback (washout block).
Subjects then swished for a minute depending on their assigned experimental groups (20 subjects each). The lidocaine group swished with a numbing solution (5 ml of 4% lidocaine with 5 ml flavored water), whereas the placebo group swished with a non-numbing solution (5 ml bitter lemon water with 5 ml flavored water). Effectiveness of numbing by lidocaine was verified using nylon monofilament sutures that mapped the tactile threshold of the tip of the tongue at various time points in the experiment. After swishing, the same formant adaptation experiment was then repeated.
Pre-swish and post-swish adaptive responses were calculated in both groups, and were normalised to individual average baseline F1 frequency. A generalised linear model (GLM) revealed that adaptation values were significantly reduced in the post-swish hold block for the lidocaine group ($p<0.0001$), and remained significant in the washout block ($p<0.01$). Reduced adaptive response was not seen in the placebo group. To verify that somatosensory feedback was indeed altered by the lidocaine solution, buckling force data for the filaments was run through a similar GLM model. Tactile sensitivity of the tip of the tongue was reduced significantly for the lidocaine group ($p<0.05$) and remained unaltered for the placebo group.
We observed a reduction in adaptation to altered auditory feedback resulting from oral numbing. This runs counter to the enhancing effects of numbing on immediate compensation for transient auditory perturbations. Nevertheless, our results so far are consistent with our State Feedback Control model of speech motor control.

Title: Sound naturalness of wideband speech affects articulatory compensation for altered formant feedback

Authors: *Y. UEZU, S. HIROYA, T. MOCHIDA
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: In order to investigate the importance of auditory feedback during speech production, transformed auditory feedback (TAF) experiments have been conducted, where articulatory compensation while giving perturbation to formant frequency has attracted a lot of attention. Most previous TAF studies have used a formant conversion system with a sampling rate of 8

kHz (or sometimes 10 or 12 kHz). Although a sampling rate of 8 kHz is common for telephone speech, as most linguistic information in speech is conveyed within the narrow-bandwidth of 4 kHz, a wider band speech, e.g. a sampling rate of 16 kHz, is needed to convey nonlinguistic information such as speaker individuality. Our previous studies have shown that compensatory responses to formant perturbation could be significantly larger by improving speech sound naturalness even at a sampling rate of 8 kHz. However, few studies have reported that the improvement of sound naturalness by increasing the sampling rate of feedback speech further affects articulatory compensatory response. In this study, we examine whether the sound naturalness of wideband transformed speech improves articulatory compensation compared to that of narrowband speech. A formant conversion system which we used estimates formant frequencies robustly against a fundamental frequency using our phase equalization-based autoregressive exogenous (PEAR) model. A sampling rate of input speech was set to 16 kHz. We examined a compensatory response to formant perturbation when a sampling rate of output signals was either 8 kHz or 16 kHz by low-pass filter switching. Speech stimuli used a Japanese /he/ syllable. Formants were transformed so that vowel /e/ gradually shifted to sound like /a/ by changing both the first and second formant frequencies (F1 and F2). Results showed that articulatory compensatory responses to F1 were not significantly different between sampling rates, but the aftereffects of 16 kHz for F1 were larger than that of 8 kHz. Moreover, compensatory responses to F2 were significantly larger for 16 kHz than 8 kHz. This indicated that wideband speech naturalness affected the adaptation pattern in F1 and increased compensation magnitude in F2. This result may be related to the sense of agency, but this will be an issue to be addressed in the future.

Title: Adaptive song modification is impaired following FoxP2 overexpression in adult zebra finches

Authors: *N. F. DAY, S. N. FREDA, S. A. WHITE
Integrative Biol. & Physiol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: The acquisition and maintenance of complex sensorimotor skills require sensory feedback to optimize motor output. In songbirds such as male zebra finches, an essential animal

model for human speech, sensorimotor learning is required throughout the lifespan to control song behavior. Juveniles imitate a tutor song during initial song acquisition whereas adults correct vocal errors during daily song maintenance. Similar to sensorimotor learning in mammals, vocal plasticity in songbirds is controlled by a basal ganglia thalamo-cortical loop. Speech impairments arising from mutations in the *FOXP2* transcription factor underscore the importance of understanding how individual or suites of genes may influence or impede vocal learning. Within the song-dedicated region of the avian basal ganglia, Area X, *FoxP2* is dynamically regulated based on the the type and quantity of song. In juvenile zebra finches, dysregulation of *FoxP2* disrupts vocal learning. Additionally, overexpression of Area X *FoxP2* in deafened adult birds hastens song degradation, which links *FoxP2* and auditory feedback processing. To further establish a connection between *FoxP2* and sensorimotor error correction, we used disruptive auditory feedback to evoke learning in adult finches. Briefly, a bird received a short burst of white noise when he performed a specific syllable in his song above (or below) a specified pitch threshold. All birds were able to learn to modify their song to avoid punishment. Following three days of incremental learning and one day of rapid learning, a subset of birds was injected with a herpes simplex virus (HSV) to drive overexpression of *FoxP2* in Area X. We compared learning before and after HSV injection to test whether *FoxP2* overexpression interferes with sensory-guided vocal output. Data from five birds suggests that adaptive song modification is impaired following *FoxP2* overexpression, which prevented them from effectively avoiding negative reinforcement. Our results implicate *FoxP2* in song evaluation, establishing a molecular basis for auditory processing that guides reinforcement-based learning.

Title: A songbird model system for understanding the biological evolution of human language

Authors: *M. FARIAS-VIRGENS[1], P. INGLE[1], T. DEACON[2], K. OKANOYA[3,4], S. A. WHITE[1], E. HUERTA-SANCHEZ[5]
[1]Univ. of California Los Angeles, Los Angeles, CA; [2]Univ. of California Berkeley, Berkeley, CA; [3]RIKEN-Brain Sci. Intitute, Wako, Japan; [4]Univ. of Tokyo, Tokyo, Japan; [5]Univ. of California Merced, Merced, CA

Abstract: Recent discoveries demonstrate striking analogies between birdsong and human speech. These comprise similarities at several levels, including structural (concerning the rule-dependent sequencing of vocal units), developmental (the social and asocial aspects of vocal production learning), neural (the overall architecture of engaged brain areas), and molecular (the underlying genetic regulatory networks). These striking parallels motivate the additional search for evolutionary analogies (parallel evolutionary trajectories) between vocal production learning in humans and songbirds. Our research empirically identifies evolutionary processes leading to increased complexity of vocal production learning in a songbird model system that has long been proposed to parallel key aspects of human speech evolution. Among songbird model species, the Bengalese finch (BF) (*Lonchura striata domestica*) draws special attention, due to its remarkably complex song, in which transitions between vocal units (i.e., syllables) are not firmly fixed, introducing variability in song sequencing. This vocal complexity evolved during BF's domestication from the white-backed munia (WBM) (*Lonchura striata*), and it is greater than that exhibited by more popular songbird model species, such as the zebra finch (*Taeniopygia guttata*). Moreover, BFs have evolved the ability to learn multiple tutor's songs, thus generating a composite song. Different hypotheses have been proposed to explain how BF evolved a more complex vocal behavior than its wild ancestor. One such hypothesis argues for the major role of positive selection (e.g. female choice for more complex songs), while an alternative hypothesis argues for a major role for relaxation of evolutionary constraints due to domestication. Sources of evolutionary constraints commonly found in the wild, but absent in the domesticated setting, would include pressures to avoid confusion with other cohabitating finch species and female attraction. Our study investigates the genetic signatures left by the evolutionary forces that led to BF's increased song complexity relative to WBM. For this, we have sequenced whole genomes of individuals within the two bird strains (12 BFs and 11 WBMs), which we are scanning for signatures of positive selection or relaxation of evolutionary constraints, thus allowing us to identify candidate genes modified in this evolutionary transition. Preliminary analysis of this data signals several genomic areas with high differentiation between the BFs and WBMs, as evidenced by the Fixation Index, and relatively reduced levels of genetic variability in BF, as evidenced by measures of heterozygosity.

Title: Bengalese finches can use learned sensory cues to flexibly shift between opposing song modifications

Authors: *L. VEIT[1], L. Y. TIAN[1], C. J. M. HERNANDEZ[2], M. S. BRAINARD[1]
[1]Dept. of Physiol., UCSF, San Francisco, CA; [2]Univ. of New Orleans, New Orleans, LA

Abstract: Bengalese finch (*Lonchura striata*) song is a complex learned motor skill with variable sequencing of discrete song elements, or syllables. In addition to initial song learning during development, adult Bengalese finches can be trained to modify the pitch or sequencing of individual song elements through reinforcement learning. These modifications typically occur over the timescale of hours or days, presumably reflecting the gradual updating of song control parameters in response to the recent history of performance-related feedback (Tumer & Brainard 2007, Warren et.al. 2012). However, a key feature of motor sequencing in humans is its flexible control by cognitive or sensory contextual variables, such as internal goals or task demands. It is unknown whether birdsong can be flexibly modified by contextual cues, and how sensory information may guide the flexible deployment of different actions by the song motor circuit. Here, we show that adult Bengalese finches have the capacity to flexibly and rapidly switch between learned changes to their song if they are provided with contextual cues indicating that different song modifications are adaptive in different contexts. In a pitch learning experiment, we paired opposite directions of pitch reinforcement for the same song syllable with different colors of cage illumination, e.g., reinforcing upward pitch shifts in orange light and downward pitch shifts in green light. In a sequence learning experiment, different light colors were paired with aversive feedback delivered to either of two alternate syllable sequences at a point in the song with naturally variable syllable sequencing, e.g. punishing syllable sequence a-b-c in orange light and a-b-d in green light. After training birds on these protocols, light switches elicited immediate adaptive changes to the song that minimized the aversive feedback in each context. These changes were apparent in the first song bout after light switches, as well as in probe contexts without reinforcing feedback. Therefore, the light cue alone had become sufficient for eliciting the song changes after training. These results indicate that Bengalese finches can learn to associate arbitrary contextual cues with specific changes to both the pitch of individual syllables

and to syllable sequencing. This suggests that the song system could be an excellent model for investigating how neural circuits enable flexible and adaptive reconfiguration of motor output in response to different contextual demands.

Title: Testing whether LMAN acoustically biases juvenile zebra finch song

Authors: *S. N. BRUDNER[1], R. MOONEY[2]
[1]Durham, NC; [2]Neurobio., Duke Univ., Durham, NC

Abstract: Juveniles acquire certain crucial motor skills by imitating the behavior of highly skilled adults. An influential idea is that to imitate an adult target, juveniles must: (1) produce sufficiently variable behavior to sample both target-similar and target-dissimilar actions, and (2) bias the distribution of their behavior towards increasingly target-similar actions. We do not understand how the juvenile brain implements and coordinates these processes. Zebra finch song learning, a primary model for studying juvenile imitative learning, requires a song-dedicated, premotor cortical region called LMAN that increases the acoustic variability of juvenile song. Although LMAN-dependent song variability may be essential for learning, adult conditioning experiments also reveal that LMAN can alter song acoustic distributions to avoid pitch-contingent punishment. Repeated, transient LMAN inactivations over multiple days of conditioning show that large song alterations can arise from the downstream integration of small, daily LMAN-dependent biases. Here, we test the hypothesis that LMAN biases juvenile song acoustic distributions towards more target-similar acoustics. We repeatedly, transiently inactivate LMAN in juveniles learning to copy an adult while recording acoustic parameters of their song output across multiple days. By modeling the acute contribution of LMAN to song and changes in juvenile song acoustics over time, we assess whether LMAN induces an acute bias in modal song characteristics, and whether such a bias predicts the trajectory the juvenile will take towards his target song. Because LMAN activity is the exclusive premotor output of a song-dedicated cortico-basal ganglia circuit in zebra finches, this experiment may have implications for the premotor function of cortico-basal ganglia circuits in juvenile imitative learning more generally.

Title: Motor contributions to vocal sequence learning biases

Authors: *L. S. JAMES[1,4], R. DAVIES, Jr[2], C. MORI[5], K. WADA[5], J. T. SAKATA[3,4,6]
[2]Computer Sci., [3]Biol., [1]McGill Univ., Montreal, QC, Canada; [4]Ctr. for Res. in Brain, Language, and Music, Montreal, QC, Canada; [5]Biol., Hokkaido Univ., Sapporo, Japan; [6]Integrated Program in Neurosci., Montreal, QC, Canada

Abstract: Vocal learning is sculpted by biological predispositions. Revealing the nature of these predispositions requires controlled experiments and computational approaches. We recently discovered biological predispositions in vocal sequence learning in the zebra finch (James and Sakata, Current Biology, 2017). In particular, following tutoring with random sequences of species-typical syllables, zebra finches consistently produced specific types of syllables at particular positions in their song motif. Zebra finches also differentially produced syllables with particular acoustic features (duration, pitch, amplitude, and measures of entropy) at different positions within the motif; for example, they tended to produce longer syllables at the end of the motif. To further understand the importance of each acoustic feature to syllable sequencing, we employed machine learning algorithms to reveal which features best differentiated syllables across motif positions. Using random forest algorithms, we found that syllable duration provided the most predictive information about position in song, with pitch, amplitude and various measures of entropy providing secondary information about motif position.
We then used this computational framework to assess how motor biases contribute to vocal learning biases. We investigated acoustic patterning within the songs of zebra finches developmentally deprived of auditory experience and the extent to which acoustic information similarly predicted syllable position within the songs of these birds. We specifically analyzed the songs of birds that were not exposed to song throughout the sensitive period for song learning ("isolate birds") and of birds that were deafened prior to the sensitive period for song learning ("deafened birds"). Isolate and deafened birds produced songs with acoustic patterns that resembled those observed in experimentally tutored birds; for example, they also produced

longer syllables at the end of their motifs. Random forests revealed that duration similarly provided the most predictive information about motif position. Because these birds were not able to hear either a tutor song or themselves sing, these data suggest that motor biases contribute to some of the acoustic patterning observed in tutored birds and, thus, to vocal learning biases. In addition, these data suggest that the vocal motor system could be predisposed to organize sequences of sounds based on syllable durations.

Title: Visual reinforcement of vocal pitch in deaf songbirds

Authors: *A. T. ZAI[1], S. CAVÉ-LOPEZ[1], N. GIRET[2], R. H. HAHNLOSER[1]
[1]Inst. of Neuroinformatics, ETH Zurich / Univ. of Zurich, Zuerich, Switzerland; [2]Neurosci. Paris Saclay Institute, UMR CNRS 9197, Orsay, France

Abstract: Auditory feedback is important for vocal learning and maintenance in both songbirds and humans. Lacking auditory feedback in young subjects leads to vocal learning deficits (Goldin-Meadow 1989, Konishi 1965) and in adults it leads to vocal degradation (Waldstein 1990, Nordeen and Nordeen 1992). However, is auditory feedback also necessary for trial-and-error processes of vocal learning and to what extent can auditory feedback be replaced by feedback from another sensory modality?
We test an alter-modal approach to vocal learning using visual feedback as a substitute for auditory feedback. We adapted a widely used reinforcement learning paradigm. Instead of delivering auditory reinforcement in form of a loud white-noise burst or a song syllable, we briefly switched off the light in the sound-isolation chamber whenever the pitch of a particular song syllable was below (or above) a manually set threshold. We find that deaf zebra finches reliably adapt pitch in response to the visual feedback. Our results show that auditory feedback is not necessary for adaptive changes of song.
Furthermore, we tested the involvement of the basal ganglia in visual reinforcement of pitch. Bilateral lesion of Area X, homologous to the mammalian basal ganglia, prevented visual reinforcement learning of pitch in deaf birds, showing that the basal ganglia do not require vocal performance signals to mediate reinforcement learning.
Hearing birds can also adapt their pitch in response to visual feedback, suggesting that birds are born with the ability to use reinforcement signals from various sensory modalities for vocal

learning. However, deaf birds not only adapted pitch faster than hearing birds, they also adapted pitch to increase the rate of light-off events, whereas hearing birds adapted pitch to decrease that rate. This demonstrates that the presence or absence of one sensory modality can change the reinforcement valence of another sensory modality. Thus, songbirds are flexible learners that are not limited by their ability to evaluate motor performance; they can take advantage of multimodal correlations between their singing and their sensory surrounding.

Title: Is there synergy between song learning and vocal stimuli discrimination?

Authors: *K. WATANABE[1], K. TOKAREV[2], O. TCHERNICHOVSKI[3]
[1]Dept. of Psychology, City Univ. of New York, Hunter Col., New York, NY; [2]Hunter College, CUNY, New York, NY; [3]Dept. of Psychology, Hunter Col., New York, NY

Abstract: Song recognition and production are intimately linked in songbirds. The principal motor song nuclei are connected to auditory pathways and to reinforcement stimuli from the brainstem (Gadagkar et al, 2016). Auditory input and reinforcement via auditory feedback then shape vocal changes, driven by the anterior forebrain pathway (Sober & Brainard, 2009). There is, however, no direct behavioral evidence that specific auditory discrimination abilities are mechanistically coupled with vocal changes during song learning. Are juvenile birds with better auditory discrimination capacity more likely to imitate song accurately? Can the acquisition of auditory discrimination skills affect the outcome of specific song learning? In this exploratory study, we investigated these questions in juvenile zebra finch (*Taeniopygia guttata*) males. Birds were trained to imitate operant song playbacks (Tchernichovski, et al 2001). We tested if the accuracy of vocal imitation of specific song syllables relates to auditory discrimination between tutor's song syllables. Birds were trained to discriminate between syllables during early stages of song learning using a social reward (Tokarev & Tchernichovki, 2014, Tokarev et al, 2017); the tested bird was allowed to interact with an adult female via a small window. Song syllables were played sparsely, only during social interactions. Playbacks of one syllable type were followed by an aversive air puff, unless the bird escaped within 2 seconds (aversive syllable). Playbacks of the other syllable type allowed social interactions to continue (social syllable). We found that juvenile birds quickly learned to escape while hearing the aversive syllable, but not after

playbacks of the social syllable. This allowed us to rapidly assess auditory discrimination between any pairs of song syllables during vocal learning. Preliminary results suggest that birds that were trained with auditory discrimination show faster song learning than we usually observe. Follow-up experiments now test if this effect is replicable, and if the putative facilitation of vocal learning is associated with specific auditory discrimination tasks presented to the birds.

Title: Performance error computation in zebra finch song at sub-syllabic time scales

Authors: *D. LIPKIND[1], O. TCHERNICHOVSKI[1], R. H. R. HAHNLOSER[2]
[1]Dept Psychology, Hunter Col., New York, NY; [2]Inst. of Neuroinformatics, Univ. of Zurich/ETH Zurich, Zuerich, Switzerland

Abstract: When learning a complex motor skill with many constituent parts, such as a song, a dance, a language, or a sports game, it is too daunting to treat the desired target behavior as a single goal. Rather, it may be more efficient to divide the learning task into sub-goals and use distinct subroutines to attain each. For example, young Zebra finches (*Taeniopygia guttata*) simplify the problem of imitating the complex song of an adult "tutor" by learning the syllable repertoire of the target song independently of the syllable order. Birds initially make the minimal adjustments necessary to match the acoustic structure of the syllables of the target song, even if this results in sequencing errors, which they correct later. Such a "greedy" strategy requires the ability to rearrange syllable positions within the song to correct sequencing errors. We therefore hypothesized that if smaller sub-syllabic units cannot be rearranged with respect to each other, a different error-correction algorithm would be employed to learn sub-syllabic structure. We tested strategies of sub-syllabic error correction in zebra finches using artificial tutoring with synthetic songs. We trained juvenile zebra finches to perform a song, in which one of the syllables was composed of two distinct sub-syllabic notes (N_1N_2). Once the birds learned the song, we introduced a second song, in which the order of the two notes within the syllable was reversed, and the pitch of one of the notes slightly shifted ($N_{2+}N_1$). We then tracked the vocal adjustments that birds made to match the altered target syllable. We found that most birds successfully matched the altered syllable by employing non-greedy strategies: they either shifted the pitch of both sub-syllabic notes within the context of the entire syllable ($N_1 \rightarrow N_{2+}$; and $N_2 \rightarrow N_1$), or generated a new syllable $N_{2+}N_1$ from scratch. In contrast, using a greedy strategy ($N_2 \rightarrow N_{2+}$, leading to the incorrect syllable N_1N_{2+}) occurred rarely, and lead to a developmental dead end

due to inability to correct the ordering of sub-syllabic notes. Our results indicate that zebra finches employ error evaluation strategies specific to the level of their song hierarchy: while the syllable repertoire of the song is learned independently of syllable ordering, the structure of sub-syllabic notes is learned with respect to neighboring notes within a syllable. This combination of strategies may be an adaptation to efficient learning of a complex motor skill within a relatively short developmental time window.

Title: Understanding the origin of introductory vocalizations in a song bird, the zebra finch

Authors: *S. KALRA[1], V. YAWATKAR[1], L. S. JAMES[2], J. T. SAKATA[3], R. RAJAN[1]
[1]Indian Inst. of Sci. Educ. and Res., Pune City, India; [3]Biol., [2]McGill Univ., Montreal, QC, Canada

Abstract: Many passerine birds initiate their song sequence with a repeated number of simple introductory vocalizations (Richards DG, Behavior, 1981). These vocalizations have been hypothesized to function as motor preparation for song sequence initiation (Rajan R, Doupe AJ, Current Biology, 2013) or as an alerting component for song (Richards DG, Behavior, 1981). It is widely known that the acoustic structure and sequencing of song elements ('syllables') are generally learned from a tutor, though some components of song are unlearned. However, the extent to which introductory vocalizations are learned or unlearned remains largely unknown.Here, we address this question using the zebra finch, a songbird that learns its vocalizations during development.Song bouts of adult male zebra finches begin with a variable number of introductory notes (INs). To determine the extent to which the number and acoustic structure of INs is learned, we first compared INs produced by sons ('pupils') and their fathers, who serve as their tutors. Number of INs produced by pupils was positively correlated with the number of INs produced by their fathers (n=54 birds; 16 nests). Further, INs of pupils showed high acoustic similarity with INs of their fathers. Next, we isolated juvenile zebra finches from

their father (starting at day 10 post-hatching) and experimentally tutored them using one of two different methods: (1) social tutoring with a male that produced a different number of INs from their father (n=5 birds; 3 nests) or (2) artificial tutoring with playbacks of their father's song without INs (n=8 birds; 3 nests). Our preliminary results demonstrate that the number and acoustic structure of INs of socially tutored birds were similar to those of their social tutor. Interestingly, birds tutored with playbacks of their father's song without INs still produced variable number of INs at the beginning of song bouts. IN numbers were similar to their father but the acoustic structure of INs was variable across birds and not similar to their father. Together, these data suggest that, like song, INs also appear to have innate and learned components.

Title: Analysing the role of sensory feedback in the initiation of zebra finch song

Authors: *D. RAO[1], A. KUMAR[1], S. KOJIMA[2], R. RAJAN[1]
[1]Indian Inst. of Sci. Educ. and Res., Pune City, India; [2]Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: The song of the adult male zebra finch is a widely established model to study naturally learned motor sequences. However, how such movements are initiated by the brain remains poorly understood. Song bouts begin with a variable number of short introductory notes (INs). Sequences of such INs speed up and reach a consistent acoustic “ready” state just before the start of each song, suggesting a role for INs in motor preparation (Rajan and Doupe 2013). Here, we test a related hypothesis that INs represent a calibration process that uses peripheral sensory feedback to get the brain “ready” to produce song.
To analyse the role of feedback, we first characterised baseline changes in IN properties in adult male birds by recording the same bird multiple times within a 3 year period. We found that the mean number of INs showed very little day-to-day fluctuations (-0.0152 +/- 0.0032; mean +/- SEM; n=21 birds recorded twice within 5 days). Mean IN number increased by 0.3493 +/-

0.1105 (mean +/- SEM) after the first year and then remained mostly unchanged (-0.05 +/- 0.0151; mean +/- SEM). The timing and progression of INs remained consistent across all ages. At all ages, we found that the number of INs at the start of a bout was significantly lower if the first IN of the bout was preceded by non-song vocalizations (calls). This reduction in number of INs was strongest when calls preceded the first IN by < 250ms.
Next, we examined the influence of feedback by removing either (1) peripheral proprioceptive feedback by bilaterally severing the tracheosyringeal (ts) nerve or (2) peripheral auditory feedback through bilateral removal of cochlea. Mean IN number reduced immediately post ts nerve cut, but remained largely unchanged immediately post-deafening. Timing and acoustic progression of INs remained unaffected by both these manipulations. Interestingly, in both sets of birds, mean IN number still reduced when the first IN of a bout was preceded by calls. Together, these data hint at a role for sensory feedback and vocalisation history in determining the mean number of INs at the start of each song bout.

Title: Sensorimotor learning in children and adults who stutter

Authors: *K. S. KIM[1], L. MAX[2]
[1]Speech and Hearing Sci., Univ. of Washington, Seattle, WA; [2]Univ. Washington, Seattle, WA

Abstract: Stuttering is a neurodevelopmental speech disorder in which speech fluency is disrupted by repetitions and prolongations of articulatory and/or laryngeal movements. Studies have demonstrated evidence for sensorimotor deficits in stuttering individuals (e.g., slow movements even during fluent speech, fluency enhancement under altered auditory feedback). We also have shown that adults who stutter lack the pre-speech auditory modulation that is observed in fluent control subjects but that this difference disappears when speaking with delayed auditory feedback. In addition to the above evidence, other work suggests that stuttering may be associated with sensorimotor learning deficits. However, it remains unknown whether sensorimotor learning limitations (a) are already present in childhood, and (b) affect only speech or both speech and nonspeech effector systems. Here, we integrate the final data from a series of four experiments investigating not only speech auditory-motor learning but also limb visuo-

motor learning in both children and adults who stutter versus matched nonstuttering individuals. The speech experiments (one for children, one for adults) made use of an auditory-motor adaptation paradigm in which subjects produced monosyllabic words with real-time formant-shifted feedback. In separate conditions, the formant frequencies were shifted up or down, and this shift was implemented suddenly or gradually. We measured formant frequencies across trials to quantify auditory-motor adaptation. The nonspeech experiments (one for children, one for adults) made use of a visuo-motor rotation paradigm in which subjects made reaching movements toward targets while visual feedback was rotated counterclockwise around the center of the workspace. We measured the hand's initial reach direction across trials to quantify visuo-motor adaptation. Speech auditory-motor adaptation results indicate that both stuttering children and stuttering adults show absent or reduced speech sensorimotor learning relative to nonstuttering peers. Reach visuo-motor adaptation results from adults suggest a subtle difference between stuttering and nonstuttering subjects in the rate (but not extent) of limb sensorimotor learning. Reach visuo-motor adaptation from children are ambiguous: a between-group difference emerged only in the oldest age group where control subjects increased adaptation extent but stuttering subjects decreased adaptation extent (relative to the younger groups). Overall, findings suggest that stuttering is associated with substantial difficulties in auditory-motor learning and more subtle limitations in visuo-motor learning.

Title: Song preference predicts vocal development in juvenile zebra finches

Authors: *C. A. RODRÍGUEZ-SALTOS[1], G. RAMSAY[3], T. J. LIBECAP[2], D. MANEY[1]
[1]Psychology, [2]Emory Univ., Atlanta, GA; [3]Marcus Autism Ctr., Atlanta, GA

Abstract: In many species of vocal learners, strong social bonds develop between learners and their tutors. The zebra finch is a great model in which to study this phenomenon. In this species, juveniles learn to sing by imitating their male caregivers, which under natural conditions are their fathers. The quality of interactions between caregivers and juveniles has been shown to affect the quality of imitation of caregiver song. We hypothesize that early social interactions cause the juvenile to ascribe incentive salience to caregiver song. In this study, we tested whether

the incentive salience of a song predicts how well juvenile finches learn to sing it. We studied 10 male finches who were isolated throughout the sensorimotor phase of song learning (35-90 post-hatch day). Each day, we quantified the extent to which each juvenile preferred to hear one of two songs, one produced by the caregiver and the other by an adult neighbor that was present when the juvenile was reared. To quantify preference, we presented the juveniles with two keys that, upon being pressed, elicited playback of one of the two songs. The juveniles were trained to associate playback of each song with a particular key, allowing us to quantify preference for each song. At the same time, our operant schedule allowed us to balance the number times the bird heard each song. Despite equal exposure to each of the two songs, the juveniles ultimately learned to sing caregiver song only. We calculated the degree of similarity between the final songs of the juveniles and their respective caregivers, in other words a "similarity score", using the software Sound Analysis Pro. These similarity scores were positively correlated with the strength of the preference to hear caregiver song early during the sensorimotor phase, but not after the birds were 60 days old. Thus, the correlations were found before the age by which zebra finch song typically becomes stable. Our results suggest that being attracted to a song early in song learning may facilitate accurate imitation of that song. The fact that the birds in our study preferred to learn caregiver song further suggests that social interactions with an adult male before the sensorimotor phase are important to establish a preference to learn a given song.

Title: The role of new neurons in the emergence of precisely timed bursts in songbird HVC

Authors: *Y. TUPIKOV, D. Z. JIN
Dept. of Physics, The Pennsylvania State Univ., University Park, PA

Abstract: The premotor nucleus HVC (proper name) is critical for song learning and production in songbirds. New neurons that project to the motor pathway are continuously added to HVC in juveniles, mostly before and during song learning [1]. The functional role of this addition is poorly understood. Here we propose that new neurons facilitate the emergence of temporal sequence in HVC that controls the song structure. With a computational model, we show that high spontaneous activity of new neurons makes them the prime targets for assembling a feed-forward network through a self-organized process via synaptic plasticity. High spontaneous activity of new neurons originates from their increased excitability, which is observed

universally in many brain regions [2-5]. Once recruited, the new neurons fire readily at precise times, and they become mature. The network is assembled neuron-by-neuron and such gradual formation is supported by experimental observations [6]. Our model incorporates spatial structure of HVC with realistic axonal delays between HVC neurons. The emergent forward network of the projection neurons has a characteristic that the burst timing is uniform and there are no silent gaps. This property arises due to the substantial axonal delays. This is in contrast to the synfire chain model of HVC, in which groups of projection neurons burst synchronously. In this case, synchronous bursting combined with axonal delays create gaps in burst timings between adjacent groups. Electrophysiological [7] and calcium fluorescent imaging [8] recordings support continuous time representation of song in HVC, which is inconsistent with the synfire chain model. The network emerged in our model, "polychronous chain", has no distinctive groups. The spatial distributions of the synapses between the projection neurons agree with recent experimental data [9]. Our model suggests that projection neurons in HVC are wired into a polychronous chain with continuous and uniform time coverage, and the addition of new neurons in juveniles is a critical component in this self-organized process.

Title: Cortical adaptations to enable enhanced vocalization

Authors: *C. M. CERKEVICH[1,2,3], P. L. STRICK[1,2,4,3]
[1]Systems Neurosci. Ctr., [2]Neurobio. Dept., [3]Ctr. for the Neural Basis of Cognition, [4]Univ. of Pittsburgh Brain Inst., Univ. Pittsburgh Sch. Med., Pittsburgh, PA

Abstract: Marmoset monkeys vocalize more often and exhibit more complex vocal motor behavior than macaque monkeys. To gain insight into the central control of vocalization, we used retrograde transneuronal transport of rabies virus from the cricothyroid (CT) muscle to identify cortical areas that influence this muscle in the two species.
This comparative approach revealed that five cortical motor areas in the frontal lobe of both species are involved in the descending control of this laryngeal muscle. Three of these areas are on the medial wall and near the midline of the hemisphere: the rostral cingulate motor area (CMAr), the ventral cingulate motor area (CMAv), and the supplementary motor area (SMA). Another two cortical areas are on the lateral surface of the hemisphere: the primary motor cortex (M1) and ventral area 6 (6V). All of these areas displayed patterns of labeling indicative of disynaptic projections to CT motoneurons.
Although the same five cortical areas influenced the CT muscle in both monkeys, two cortical areas in the marmoset contained many more output neurons than in the macaque. Area 6V of marmosets contained ~3.5 times more output neurons than area 6V of macaques. Similarly, the SMA of marmosets contained ~2.5 more output neurons than the SMA of macaques. These results suggest that the enhanced vocal skills of marmosets are the result of increases in output from both a lateral motor area, area 6V, and a medial motor area, the SMA.

Title: Cortical control of vocal interactions in a neotropical singing mouse

Authors: *A. BANERJEE[1,2], D. E. OKOBI, Jr[2], G. A. CASTELLUCCI[3], S. M. PHELPS[4], M. A. LONG[2]

Abstract: How the brain enables flexible sensorimotor transformations is a central question in neuroscience. During conversation, for instance, we listen to the words of another person, interpret them and modify our speech accordingly. Carefully designed behavioral tasks with experimental control over both the stimuli and motor responses have advanced our understanding of neural mechanisms that support sensorimotor transformations. We hope to extend these paradigms to study neural mechanisms that govern more flexible and natural sensorimotor behaviors such as vocal interactions. Seeking a rodent model to fill this niche, we have begun to investigate the neural mechanisms of vocal communication in Alston's singing mouse

(*Scotinomys teguina*) - a highly vocal neotropical rodent native to the cloud forests of Central America. Acoustically isolated S. teguina males produce advertisement calls, and each individual vocalization is composed of a series of human audible syllables of increasing duration, that are highly stereotyped across renditions. We find that this vocal stereotypy is broken and songs become significantly more variable when exposed to other males in a social context. In fact, two or more males temporally coordinate their advertisement songs in a phenomenon known as countersinging. To test if motor cortical circuits underlie song execution and coordination, we used intracortical micro-stimulation (ICMS) to localize an anterolateral motor cortical hotspot that activated laryngeal muscles with short latency. Subsequently, bilateral electrical stimulation of motor cortex during singing temporarily paused song progression while focal cooling of motor cortex slowed down song progression without stretching individual syllables. These results are consistent with a hierarchical control of song timing, with motor cortex being functionally upstream of a song-generating circuit, and they suggest a potential role for motor cortex in mediating this vocal social interaction. We tested this idea by inactivating motor cortex with muscimol (GABAA agonist) and found that countersinging was severely compromised, highlighting the utility of motor cortex for integrating sensory information and generating a socially appropriate behavioral response. Going beyond these specific results, we believe that S. teguina is an excellent rodent model to investigate neural dynamics underlying an experimentally tractable, naturally occurring, vocal sensorimotor behavior.

Title: Stable sequential activity underlying the maintenance of a precisely executed skilled behavior

Authors: *K. KATLOWITZ[1], M. A. PICARDO[2], M. A. LONG[3]
[1]Neurosci., New York Univ., New York, NY; [2]NYU Neurosci. Inst., New York Univ. Sch. of Med., New York, NY; [3]NYU Sch. of Med., New York, NY

Abstract: A vast array of motor skills can be maintained throughout life. Do these behaviors require stability of individual neuron tuning or can the output of a given circuit remain constant despite fluctuations in single cells? This question is difficult to address due to the variability inherent in most motor actions studied in the laboratory. A notable exception, however, is the courtship song of the adult zebra finch, which is a learned, highly precise motor act mediated by orderly dynamics within premotor neurons of the forebrain. By longitudinally tracking the activity of excitatory projection neurons during singing using two-photon calcium imaging, we find that both the number and precise timing of song-related spiking events remain nearly identical over the span of several weeks to months. These findings demonstrate that learned, complex behaviors can be stabilized by maintaining precise and invariant tuning at the level of single neurons.

Title: Local network mechanisms for sequence generation underlying a complex learned behavior

Authors: *R. EGGER[1], Y. TUPIKOV[2], K. KATLOWITZ[1], S. E. BENEZRA[1], M. A. PICARDO[1], F. MOLL[1], J. KORNFELD[3], D. Z. JIN[2], M. A. LONG[1]
[1]Neurosci. Inst., NYU Sch. of Med., New York, NY; [2]Dept. of Physics, Pennsylvania State Univ., University Pk, PA; [3]Electrons Photons Neurons, Max Planck Inst. of Neurobio., Planegg, Germany

Abstract: Sequential neuronal activity patterns form the network basis for a diverse range of neural processes across various brain regions. For instance, such sequences have been observed in the hippocampus during spatial exploration and mental replay, in the striatum during movement planning, and in the parietal cortex during decision-making. However, the cellular and network mechanisms underlying sequence generation in forebrain circuits are at present not

well understood.
The zebra finch has emerged as an excellent model system for studying sequential network dynamics underlying a complex learned behavior. During song production, HVC premotor neurons produce a sequence of bursting activity, with each individual premotor neuron active at only one point throughout the sequence. Previous perturbation studies are consistent with the notion that these dynamics are likely due to circuitry intrinsic to HVC and have prompted a range of network models capable of driving sequential activity. However, due to lack of information about the organization of premotor neuron circuits, the validity of these models has not been rigorously tested.
Here we describe our efforts to use newly collected functional and anatomical data to constrain hypotheses concerning the network architecture of HVC. To determine the spatiotemporal organization of HVC neurons, we used 2-photon calcium imaging during singing. Using single-cell labeling and reconstructions, we investigated the spatial organization of local premotor neuron axons. We found a structural basis for the observed spatiotemporal organization during singing, consistent with the hypothesis that local circuits in HVC drive sequential activity. At the subcellular level, we used *in vivo* electrophysiology and anatomical measurements to determine the precise conduction delays of premotor neuron axons. These experimental constraints were then used to construct several network models, with a range of network connectivity schemes, and we tested the validity of these models by comparing the output of each with experimental observations. Our simulations and observations support a *polychronous* network organization, which takes advantage of a variety of axonal conduction delays to generate a feedforward network capable of generating continuous neural sequences throughout song performance. These efforts provide a framework for formalizing the network structures of other neural circuits associated with the generation of sequential activity.

Title: Improving usability of silicone-based neural electrodes by introducing color labels

Authors: M. ULLOA, *M. SCHUETTLER, R. PFEIFER, C. BIERBRAUER, S. BENSCH, C. HENLE
Cortec Gmbh, Freiburg Im Breisgau, Germany

Abstract: Background:
In the past years, we developed a method for semi-automated laser-based microfabrication of neural electrode arrays that allows fast prototype realization as well as series production. Devices built using this method have been extensively used acutely and chronically in animal research as well as acutely and sub-chronically in man.
Materials and Methods:
The electrodes typically consist of implantable grade silicone rubber as substrate material with embedded metal contacts, conduction lines and weld pads, typically made from platinum-iridium alloy.
Silicone was chosen as a substrate material since it has proven excellent bio-acceptance and biostability over the last decades it is used as implant material. The silicone we use is very soft (Young's Modulus in the same order of magnitude like that of neural tissue) minimizing trauma during implantation, and is optically transparent, which helps to e.g. spot air bubbles accidentally trapped underneath the electrode but also to be able to visually inspect the neural tissue underneath the electrode. In many application, such as brain mapping, direct association of electrode contact number to the corresponding biological tissues is desired. Consequently, visible labels are required to improve the usability of the electrode arrays.
Such labels shall not compromise the bio-compatibility of the device and should be of high optical contrast to the tissue and electrode contact material. In case of micro electrode labelling, the labelling process should allow very small feature sizes (range: 1mm font height) and need to be integrated in the existing microfabrication process.
Results:
We developed a process that meets these requirements by blending implantable grade pigments (blue, black, green, or white) into silicone adhesive resulting in a high-contrast ink. During our layer-by-layer build-up production process, electrodes are labelled by depositing this ink in an intermediate process step. Labels can use letters as small as 0.8 mm in height before blurring. Samples produced this way include micro-ECoG arrays with contact numbering on the back for easy identification, high-channel peripheral nerve cuff electrodes with contact numbers and spinal cord stimulation paddles with contact numbering and branding.

Title: Stability of siloxane sensors *in vivo* for real-time, spatiotemporal mapping of oxygen in brain tissue

Authors: *L. DE MESQUITA TEIXEIRA, A. SRIDHARAN, B. MOGHADAS,, V. KODIBAGKAR,, J. MUTHUSWAMY
Sch. of Biol. and Hlth. Syst. Engin., Arizona State Univ., Tempe, AZ

Abstract: Measuring oxygenation levels with high spatiotemporal resolution can serve as a biomarker for interfacial tissue health for neural implants. Brain cells typically rely on aerobic respiration to obtain energy and consequently, proper oxygen tension (pO_2) is needed to maintain neuronal function. The main objective is to develop a PDMS (poly-dimethyl siloxane) based carrier for liquid siloxane contrast agent capable of sensing pO_2 around microelectrodes using a novel magnetic resonance MR-PISTOL (proton imaging of siloxane to map tissue oxygenation levels) imaging technique. Previous work demonstrating MR-PISTOL on cells and muscle tissue *in vivo* demonstrated that T1 relaxation rates of the siloxanes have a linear dependence to pO_2 levels. In this study, carbon fiber probes (50-100 microns width) were insulated with epoxylite™ and coated with either hard (elastic modulus, E~1-3 MPa) or soft (elastic modulus, E~3-5 kPa) silicone using an injection molding process. Subsequently, the coated fibers were loaded with siloxane (PDMSO - 410 g/mol) contrast agent by absorption. Nile red (100 µM) fluorescent dye that was solubilized in PDMSO was used as a marker for testing retention under simulated blood-brain-barrier (BBB) breach conditions in in vitro tests. Untreated or surface-passivated siloxane loaded probes were tested under accelerated conditions using 50 mg/ml albumin in artificial cerebrospinal fluid (aCSF) at 37°C for 3 days. Both ‘hard’- and ‘soft’-coated probes that were surface passivated were able to retain 65-78% of the fluorescent signal intensity. Without surface passivation, ‘hard’ coated probes lost >56% of signal intensity, while ‘soft’ coated probes lost >95% of signal intensity, suggesting surface passivation protects against biofouling. Probes placed in control solutions with no albumin had no change in signal intensity. For validation in vivo, ‘hard’ and ‘soft’ probes with siloxane sensors were implanted in the mouse brain and T1 relaxation values corresponding to pO_2 levels in brain tissue around the probes were measured over 4 weeks to create spatio-temporal maps of oxygen concentration. PO_2 values were more stable in brain tissue around ‘soft’ compared to ‘hard’ coated probes in vivo. Histology around the probes after 8 weeks of implantation showed significantly increased IgG (biomarker for BBB breakdown) for ‘hard’ compared to ‘soft’ probe. Future studies will correlate tissue response of the interface with electrophysiology and quantitative, high resolution spatial maps of pO_2 levels *in vivo* under chronic conditions.

[1]Dept Bioengineering, [2]Arizona State Univ., Tempe, AZ

Abstract: The detection of neurotransmitters (i.e dopamine) and other biochemical activity in specific neural circuits *in viv*o is vital for elucidating neurodegenerative mechanisms and pathways involved in many diseases (i.e Parkinson's, Schizophrenia , Alzheimer's etc.). Electrochemical sensors utilizing amperometry and voltage-based methods such as fast cyclic voltammetry have made significant strides in real-time characterization of synaptic function in deep brain neural circuits *in vivo* with fast response times and high sensitivity. However, these electrochemical methods have significant limitations for use *in vivo* due to challenges with selectivity, interference, biofouling, sensor degradation and instability under long-term implantation conditions. Our group previously developed a soft, brain-like, conductive silicone that has stable electrochemical impedances and is capable of recording single units over one year in a rodent model. In this work, we embed tyrosinase (a dopamine-sensitive enzyme) within the novel, soft silicone based scaffold to demonstrate enzyme-based amperometric detection capability and stability in benchtop experiments. Tyrosinase is physically adsorbed onto multi-walled carbon nanotubes and embedded in the conductive, silicone scaffold using a fast heat curing process onto bundled carbon fibers (~100 µm final thickness). Amperograms are obtained with L-tyrosine methyl ester as a substrate with concentrations of 0 - 20 mM (corresponding to physiological concentrations) in (a) artificial cerebrospinal fluid (aCSF) (b) aCSF with 0.2-50 mg/ml albumin (to simulate blood-brain-barrier breach), and (c) aCSF with 10 µm-10 mM hydrogen peroxide (to simulate oxidative stress). The sensitivities of the enzyme embedded electrodes in PBS, aCSF, aCSF-albumin (50 mg/ml), and aCSF-H_2O_2 mediums were 6.08, 18.58, 39.17, and 0.29 nA/mM, respectively. Subsequent cyclic voltammetry show that the functionality of the enzyme is preserved upon removal of the hydrogen peroxide from the medium. Cyclic voltammetry (CV) of tyrosinase embedded electrodes show characteristic reduction potentials between 0.4-0.6 V. Storage stability tests suggest that the enzyme remains functional in the silicone scaffold for at least 6 weeks. Operational stability tests using a 100 continuous cycles of CV (-1V to +1V at 100 mV/s scan rate) show significantly improved stability with enzyme

embedded silicone scaffolds experiencing only a 5.75% decrease in peak currents compared to controls with no scaffold (>25% decrease). Currently, sensor validation and performance *in vivo* are in progress.

Title: Single unit recordings from central and peripheral nervous system using metallized graphene electrodes

Authors: *M. GONZÁLEZ-GONZÁLEZ[1], A. KANNEGANTI[1], C. L. FREWIN[1], J. J. PANCRAZIO[1], R. A. JALILI[2], G. G. WALLACE[3], M. I. ROMERO-ORTEGA[1]

Abstract: Interfacing the nervous system is an effective approach to decode the neuronal functions and modulate its activity. The emerging use of therapies based on electrical stimulation and the design of prosthesis requires of low impedance electrodes with high signal-to-noise ratio (SNR) that allow for sensitive recording of single unit activity, and high charge storage capacity (CSC) for effectively and safe neural stimulation. Microelectrodes are commonly fabricated in silicon with platinum (Pt), Pt/Iridium and Iridium oxide electrodes. However, the micromotion of the silicone shafts implanted into the soft nervous tissue exacerbates the foreign body response and contributes to the eventual failure of these devices. The alternative use of carbon nanotube coated microelectrodes has been promising due to their biocompatibility and high CSC (~372 mC/cm^2) and low impedance (~20 MΩ), however the stiffness of the metal shafts and delamination of the carbon nanotube coating limits the chronic use of these electrodes. We have recently advanced the production of graphene fibers form liquid crystalline dispersions of graphene oxide that demonstrated excellent electrochemical and mechanical characteristics. Here, we report the improvement of the electrochemical performance of these fibers by the incorporation of a metallic coating that drastically improved the electrochemical characteristics of 40 µm diameter graphene fibers (CSC ~947 mC/cm^2 and impedance of ~11 MΩ). Adult rats were used to characterize these electrodes in vivo both for cortical recordings and for peripheral neural interfacing. The electrodes recorded a lower baseline, ~40µV compared to conventional Pt electrodes (~60-65 µV) and effectively recorded single unit recordings, with a SNR of 9.2 in the motor cortex. We also recorded spontaneous neural activity in the sciatic and vagus nerves at a SNR of 4.3. We demonstrated that these metallized graphene electrodes are effective in

stimulating evoking a localized motor response from the sciatic nerve. Together, the data supports the use of metallized graphene fibers as intraneural electrodes for the neural interfacing of brain and nerve activity.

Title: Implantable amplifiers for chronic *in vivo* research

Authors: *D. MCDONNALL[1], I. MYERS[1], B. CROFTS[3], A. M. WILDER[2], S. HIATT[1]
[1]Ripple, Salt Lake City, UT; [2]Ripple, Salt Lake Cty, UT; [3]Ripple LLC, Salt Lake City, UT

Abstract: Percutaneous connections in long-term chronic experiments are commonly the site of failure of these experiments. Infection and bone degradation can be major limitations of these technologies which complicate chronic experiments. We have developed an implantable system to record biopotentials and transmit signals to an external transceiver. In this presentation, we report design considerations for system integration and results from *in vitro* performance of the system and an *in vivo* trial to validate device function in an animal model. The implants are constructed on a ceramic circuit board with a bioamplifier ASICs and additional discrete components. Theses implants are inductively powered by an external transceiver, and digitized signal data are sent from the implants by infrared data transmission. Recording implants have 32 single-reference channels that can be implanted independently from the hermetic electronics/telemetry module. The recording implant has been validated in a GLP study in canine subjects in a six-month trial. The 32-channel implant was surgically inserted in the forelimb with intramuscular electrodes implanted in deltoideous and lateral head of triceps. Following implantation, each animal was fitted with a backpack carrying an external transceiver coil and a battery-powered data acquisition system, and the dogs were allowed to freely walk down a hallway. EMG recorded from each animal as it walked down a hallway had very low noise and, in conjunction with recorded video, clearly indicated swing/stance phases of gait. Devices have also been implanted in non-human primates for chronic recording experiments. This technology will support clinical trials at multiple institutions for year-long take-home trials as part of the DARPA HAPTIX program. We will also provide implantable and wearable technologies to other

neuroscience investigators to provide a research platform for other large animal and human subject studies. This work was supported by the DARPA HAPTIX project and SBIR grants from DARPA and NIH.

Title: The biocompatibility of diamond ultramicroelectrode materials for neural sensing applications

Authors: M. B. SETIEN[1], S. DANIELS[1], C. RUSINEK[2], Y. GUO[1], R. RECHENBERG[2], M. BECKER[2], W. LI[1], *E. K. PURCELL[1]

Abstract: The drive to better understand normal brain function and pathological states has intensified demand for new technologies which can interrogate the nervous system with enhanced spatiotemporal resolution. Our team is developing all-diamond implantable ultramicroelectrode arrays to deliver long-term, stable recordings of extracellular bipotentials and neurochemical signals via cellular-scale site sizes (<50 μm^2). Here, we report the results of an initial characterization of the biocompatibility of the novel diamond-based materials used in the array, including conductive boron-doped polycrystalline diamond (BDD) and insulating polycrystalline diamond (PCD). BDD is an attractive electrode material based on its high corrosion resistance, minimal background current, and long-term stability for neurotransmitter detection. Indium tin oxide (ITO), which is an electrically conductive material previously shown to enhance the electrophysiological responses and network formation of attached neurons, is included as a reference control material in addition to cell culture-treated plastic. Primary cultures of rat embryonic cortical neurons (E18) are seeded onto the different materials and maintained for 21 days, where patch-clamp electrophysiology and immunohistochemistry is performed at 7, 14, and 21-day time points. Our ongoing analysis compares the substrate materials on the basis of four criteria: (1) the degree of neuronal attachment and viability (as assessed by caspase-staining), (2) the excitability of neurons on each material assessed with patch clamp electrophysiology (based on the maximum number of action potentials in response to injected current, the action potential amplitude, and the maturity of passive membrane

characteristics), (3) the associated expression of markers of excitability identified with immunohistochemistry (synaptic transporters and ion channels), and (4) the degree of neurite outgrowth from neurons on each material as assessed with Sholl analysis. The results presented will inform the transfer of the novel diamond substrate materials to sensing applications in the *in vivo* environment, where we expect to leverage the positive performance characteristics of the diamond materials displayed *in vitro*.

Abstract: Developments in microelectrode technology has enabled deeper understanding of brain and nervous system function. The small size and low capacitance allow microelectrodes to sense neurotransmitters (NTs) at rapid rates on the sub-second time scale. These measurements have traditionally been executed using fast scan cyclic voltammetry (FSCV) with carbon-fiber microelectrodes (CFMs). While CFMs have exhibited the properties needed for *in vivo* neurochemical sensing, the need for a stable, batch-fabricated, and up-scalable microelectrode remains. Diamond is a material which exhibits excellent fabrication flexibility in conjunction with many other advantageous electrochemical properties such as good biocompatibility, low background current, and wide potential window. In this work we demonstrate the analytical capability of a novel, all-diamond microfiber (υ-fiber) electrode for neurochemical sensing. The diamond υ-fibers consist of a conductive boron-doped diamond (BDD) core encapsulated by insulating layers of un-doped polycrystalline diamond (PCD). Analysis by scanning electron microscopy (SEM) revealed overall dimensions of 6 υm high x 25 υm wide and ~2 mm in length with an electroactive surface area of roughly 70 υm^2. The diamond υ-fibers were electrochemically characterized using model redox analytes such as ferri/ferrocyanide ($Fe(CN)_6^{3-/4-}$), ruthenium hexaamine ($Ru(NH_3)_6^{2+/3+}$), and hydroquinone; excellent steady state response

was observed for each analyte using cyclic voltammetry (CV). The diamond υ-fibers were then assessed for their ability to several detect NTs- dopamine (DA), serotonin (SA), epinephrine (EPI), nor-epinephrine (NE), and 3,4 dihydroxyphenylacetic acid (DOPAC) using FSCV. Several FSCV parameters were investigated such as waveform, scan rate, and potential range. These were completed using the High Definition Cyclic Voltammetry (HDCV) interface developed at the University of North Carolina Chapel Hill. For further characterization and assessment, the FSCV performance diamond υ-fibers were thoroughly compared with commercially available CFMs. These novel all-diamond υ-fiber electrodes have commercial-scale potential, generating a powerful tool for neurochemical analysis.

Abstract: One of the greatest scientific challenges nowadays is to unveil the brain circuitry, and sensing for electrical and chemical signals of single neurons is a critical step to achieve this grand goal. Microelectrode implantation, as a practical approach, has shown promising feasibility for neuronal recording. In the effort of our group, a microfiber electrode, constructed with microcrystalline diamond (MCD) as an encapsulation and boron-doped polycrystalline diamond (BDD) as a conducting core, has been successfully developed. To fabricate such microfiber electrodes, a thin BDD layer was grown on top of an MCD layer on a silicon wafer; both layers were grown using microwave plasma assisted chemical vapor deposition and plasma etched using a Cu mask. A sealing layer of MCD was selectively grown on the patterned fiber, except for the contact pads where a Ti/Cu mask was applied to inhibit diamond growth. After being released from the Si substrate, the fiber was cleaved off from an anchor, exposing pristine

BDD at the tip for neural sensing. Then the fiber was mounted onto a custom-made PCB for subsequent mechanical testing. In this work, the mechanical flexibility and bulking force of the microfiber were studied using analytical calculation, finite element analysis, and experimental measurements. Analytically, the Euler's equation was used to estimate the buckling force of the microfibers with different dimensions. Furthermore, the devices were simulated using Solid Mechanics Module in COMSOL to investigate the stress distribution on the fiber shank and critical buckling load during perpendicular insertion. To measure the buckling force experimentally, the fiber was pushed against a solid substrate at a constant speed, and the corresponding force was monitored as a function of the tip displacement. The maximum force measured immediately before a reduction was seen as the critical force required for fiber failure due to buckling and compared with the theoretical value. For further development of device implantation strategy, experiments were conducted by pushing the fiber into a tissue-mimicking gelatin phantom to test the feasibility of fiber insertion into the brain tissue.

Title: Multi-neuromodulator measurements in the behaving macaque cortex and basal ganglia using solid-phase micro-extraction fibres

Authors: *S.-A. HASSANI[1,2], S. LENDOR[3], E. BOYACI[3], V. SINGH[3], J. PAWLISZYN[3], T. WOMELSDORF[1,2]

Abstract: Different neuromodulators rarely act independent from each other to modify neural processes, but are co-released, gated, or modulated in yet unknown ways. To better understand this interdependence of neuromodulators and their collective influence on local circuits during different behaviors, it is necessary to reliably extract the local concentrations of multiple neuromodulators in vivo.

Here we describe the results from a versatile extraction method, Solid Phase Micro-Extraction (SPME), and illustrate sensitive, multi-neuromodulator measurements from micro-fibres. These biocompatible micro-fibres can be made with wires of arbitrary length and are coated with a matrix compatible polymer containing sorbent particles capable of retaining neurochemicals of small molecular size by chemical interactions after they diffuse into the coating. Given the small size, arbitrary length and ease of handling of the SPME fibres, multiple samples were taken from two cortical and one subcortical brain regions simultaneously: prefrontal cortex, premotor cortex and the head of the caudate nucleus. Data was taken from two adult male rhesus macaques while performing goal directed behavior in order to acquire liquid reward.
We obtained reliable measurements of Glutamate, Dopamine and Acetylcholine simultaneously within sampled brain regions in both macaque monkeys during goal-directed behavior. We find glutamate concentrations several orders of magnitude higher than acetylcholine and dopamine in all brain regions. Dopamine was reliably detected in the striatum at tenfold higher concentrations than Acetylcholine. Acetylcholine concentrations were detected with high consistency within monkeys, between monkeys, and across brain areas.
To our knowledge no prior dataset exists with simultaneous measurements of multiple neuromodulators across the fronto-striatal network in the behaving macaque. We demonstrate that glutamate, dopamine and acetylcholine exist in different concentrations within sampled brain regions, different animals have comparable concentrations of each neuromodulator in the same brain regions, and that dopamine is present at much higher concentrations in the caudate than in either cortical region sampled. These findings provide an important starting point for characterizing the neurochemical profiles of brain circuits underlying cognition during goal – directed behavior.

Title: CMOS technology for three dimensional neural recording using microwire arrays

Authors: *N. MELOSH, A. OBAID
Materials Sci., Stanford Univ., Stanford, CA

Abstract: Mammalian brains consist of billions of neurons operating at millisecond time scales, which current recording techniques only capture a tiny fraction. Recent advances in CMOS device design have led to high-recording quality planar probes, with diminishing sizes to ameliorate the extent of tissue damage. Matching these powerful silicon electronics to the inherently three dimensional architecture of the brain has remained challenging however, as devices are constrained to the planar two dimensional surfaces required for silicon processing. Here we show a new strategy to take advantage of the scalability and electronic processing power of CMOS-based devices with a low-tissue damage, three dimensional neural interface. The core concept is using a bundle of insulated microwires mated to a large-scale CMOS microelectrode array, such as found in modern camera chips or displays. Microwires are known to have low insertion damage and good electrical recording performance, yet required individual mounting and connectorization. Arranging them into bundles controls of the spatial arrangement and three dimensional structure of the distal (neuronal) end, while providing a robust parallel contact plane on the proximal side which is interfaced to a planar pixel array. The modular nature of the design enables a wide array of microwire types and size to be mated to a variety of different CMOS chips, making the same fundamental platform scalable from a few hundred electrodes to tens of thousands. We thus link the rapid progress and power of commercial multiplexing, digitisation and data acquisition hardware together with a bio-compatible, flexible and sensitive neural interface array. We present recent massively parallel recording using mouse and rat models, showing both spiking activity from single neurons and local field potentials. Immunohistology of microwire bundles was also done, demonstrating minimal to no observable damage post implantation.

Title: High-density microwires array for neurochemical monitoring

Authors: *N. HEMED[1], A. OBAID[2], P. WANG[2], N. MELOSH[2]
[1]Materials Sci. & Engin., Stanford university, Stanford, CA; [2]Materials Sci. and Engin., Stanford Univ., Stanford, CA

Abstract: Various debilitating neuropsychiatric and neurodegenerative disorders are characterized by abnormal levels of neurotransmission in the brain. Detecting subsecond neurotransmission variation accurately and for extended, clinically relevant timescales is a critical unmet need. Chronic measurements of neurotransmission would enable the identification of specific neurotransmitors that contribute to complex behaviors being degraded as a result of disorders, and aid in testing the clinical feasibility of treatments. Fast scan cyclic voltammetry (FSCV) has been used over the last 20 years to study neurotransmission in brain tissue *in vivo* and *ex vivo* at the single cell level. This technique exhibits the best overall performance for measuring neurotransmission at the required timescales, chemical selectivity, and sensitivity. This well-established method, however, has only utilized for accurate monitoring of neurotransmitters in primates with acutely (few hours) implanted sensors. Despite recent advances in material science and engineering, this technique has not yet been integrated with microfabricated microelectrode arrays (MEAs) due to materials limitation. Progress towards a highly scalable, dense electrode arrays, will also enable observation of how different neurotransmitters and neuroanatomical areas function together and provide quantitative insight into the complicate nature of the brain. Currently, most studied are using implantable carbon-fiber microelectrodes (CFMs) with small diameter fused-silica. These electrodes can be affixed in the brain with minimal tissue response, enabling neurotransmission sensing in single recording locations during behavior. In contrast, those electrodes have been restricted to measurements at a single electrode. This research will focus on a new methodology whereby we perform heterogeneous integration of a bundle of microwires (BMWs): tens of thousands of functionalized (using PEDOT:PSS) metal-in-glass wires of less than 30µm in diameter, to a CMOS microchip. This architecture allows each wire to be independently addressable for sensing purposes, enabling different spatial and temporal sensing patterns, ameliorating issues of scalability. In addition, such large high-density microelectrode arrays could be integrated with stimulation and recordings, providing a broad neuroscience impact.

Title: Neuroroots, an ultra-low damage scalable neural interface

Authors: *M. D. FERRO[1], A. GONZALEZ[2], E. ZHAO[1], L. M. GIOCOMO[2], N. MELOSH[1]
[1]Materials Sci., [2]Neurobio., Stanford Univ., Stanford, CA

Abstract: Communication between living brain tissue and engineered devices is the key link to understand the brain fundamental function and to clinically restore neurological deficits.
The tools that are currently broadly available for this interface exhibit some limitations such as invasiveness, low channel count, complicated implantation strategies and bulky connectorization, which hinder these devices from optimal performance and widely accepted clinical solutions.
Enabled by new materials and device designs, a new generation of brain interface technologies is replacing bulkier, non-compliant systems with the aim of seamless electronic-biological interfaces with lower tissue damage, reduced immunogenicity, high-density, tunable spatial distribution, and long-term stability. Recent successful examples leveraging mechanically compliant materials have demonstrated major breakthrough in brain research using ultra-flexible systems for ECoGs recordings, and for depth electrodes. Yet, surgical implantation damage, scalable channel count and the number of devices implanted simultaneously are still significant challenges.
Neuroroots is a new platform enabling facile implantation of ultra-low damage and scalable channel-count penetrating electrodes for chronical brain recording and stimulation. The platform consists of dangling 'root' electrodes only 5 um wide by 1µm thick, matching both cell-size dimensions and tissue mechanical properties, yet without interconnectivity between electrodes that can lead to tissue damage and block nutrient diffusion. We have developed a surgical apparatus based on the commonly used NeuraLynx Halo Microdrives to easily and precisely insert these ultraflexible arrays into the tissue target of interest. The microwires are too flexible to insert on their own, thus we developed an ultra slim, 35µm diameter microwire as a temporarily shuttle onto which numerous individual electrodes self-align. Once inserted, these wires delaminate, and the shuttle is removed.
This strategy enables implantation of a number of electrodes into various brain regions at once. Initial chronic implantation of an array of 32 electrodes into the hippocampus of freely moving trained rats exhibit recordings of single unit potentials a few minutes after electrode implantation, as well as a minimal damage both acute and chronically. The open structure of the mesh is believed to minimally perturb the ecosystem and nutriment diffusion. Subsequent implantation into the medial entorhinal cortex of trained rats has demonstrate the ability of this platform be implanted into region which are difficult to access for traditional probes.

Title: Simultaneous detection of dopamine and 5-hydroxytryptamine through fast scan cyclic voltammetry using glassy carbon microelectrode arrays

Authors: *E. CASTAGNOLA[1,2], S. NIMBALKAR[1,2], B. CARIAPPA[1,2], C. CEA[1,2], A. GAUTAM[1,2], S. KASSEGNE[1,2]
[1]San Diego State Univ., San Diego, CA; [2]Ctr. for Sensorimotor Neural Engin., Seattle, WA

Abstract: Dopamine (DA) and 5-hydroxytryptamine (5-HT) are the two most important neurotransmitters in the brain that play a pivotal role in a large variety of neurophysiological functions. They often interact in their effect. Therefore, the simultaneous detection of DA and 5-HT concentrations represents a challenging neuroscience goal. A variety of electrochemical techniques have been mainly used to monitor neurotransmitter levels in *vivo*. Among these, Fast Scan Cyclic Voltammetry (FSCV) is preferred, ensuring a temporal resolution on the sub-second scale, compatible with the measurement of chemical fluctuations in the brain. One of the main concern in the optimization of FSCV co-detection of DA and 5-HT is the selectivity of the oxidation peaks of the two neurotransmitters, that are usually close to each other (in a range between 0.6 V to 0.75 V). Furthermore, in a physiological environment, ascorbic acid (AA) typically occurs in much higher concentration than that of DA and 5-HT (100-1000 times), interfering with their detection selectivity and sensitivity. In the present study, we use glassy carbon (GC) penetrating microelectrodes arrays (4 microelectrodes with 220µm vertical space and 2000 μm^2 area) to optimize a FSCV waveform capable of co-detecting 5-HT and DA *in vitro* in 0.01M phosphate-buffered saline solution (PBS). The sensing capability, in term of sensitivity and lower detection limits, is first evaluated separately for DA and 5-HT and, subsequently, in presence of 1mM of AA. GC microelectrodes detect 10 nM as lowest detection limit for both DA and 5-HT with a sensitivity of respectively 68±7 $pA/\mu m^2$ and 46±8 $pA/\mu m^2$ at 500nM concentration. In presence of 1mM AA, the lowest detection limit for both DA and 5-HT is 50 nM with a reduction of the selectivity of the 27% with respect to the one in PBS solution. In all the cases, we measured a linear range of neurotransmitter concentration from 10 nM to 1 µM. Finally, GC microelectrodes can simultaneously discriminate the reduction and oxidation peak of low concentration (10-50nM) of DA (-0,2; 0.62V) and 5-HT (0; 0.75V) in PBS solution. In conclusion, we demonstrated that our GC microelectrodes present promising neurotransmitters detection ability in term of sensitivity and selectivity. These results represent an important step towards the optimization of a sensor that will allow the understanding of the basic neurotransmission mechanisms in the brain.

Abstract: Many neurodegenerative diseases involve the alteration of key neurotransmitters in the brain, including Parkinson's Disease, Huntington's Disease, and Alzheimer's Disease. Real-time assessment of these neurotransmitters and their metabolites will undoubtedly become a necessary part of treatment monitoring in neurodegenerative patients. In Parkinson's Disease, dopamine-signaling neurons in the substantia-nigra and striatum are the first to degenerate, lowering physiological dopamine levels. This degeneration is thought to preclude clinical symptoms. Monitoring changes in dopamine levels over time could facilitate more precise treatment. In this study, we assess the longevity and stability of four types of electrodes: stainless steel wire, multi-walled carbon nanotubes (MW-CNTs), screen-printed electrodes, and gold coupons. Screen-printed electrodes were obtained commercially, and are coated with carbon-black (counter and working electrodes) and silver/silver-chloride (reference electrode) and an electrically insulating polymeric film. MW-CNT electrodes were fabricated by our team. These electrodes are stainless steel wire stripped for 3 mm at the tip and coated with research-grade MW-CNTs (2.55 mm^2 area). Gold coupons are glass substrates coated with a Chromium adherence layer and 1000 A Gold in a cleanroom environment (area of 5 mm^2). Stainless steel wires were used as control electrodes, with an area matched to the MW-CNT electrodes. All electrodes were examined for longevity in phosphate buffered saline for 0 hours (baseline), 24 hours, 48 hours, and 72 hours at room temperature. Before these longevity tests, the electrodes were tested in dopamine solution then subsequently tested following each 24-hour cycle to evaluate potential degradation of the analyte signal over time. Electrochemical characterization was performed using a 16-channel multiplexer attached to a CHI660D potentiostat. Cyclic voltammetry was performed, as well as electrochemical impedance spectroscopy. Based on preliminary data, the gold-coupon electrodes and the MW-CNT electrodes detected dopamine the most reliably at lower concentrations (50 to 100nM). Additionally, MW-CNT electrodes demonstrated greater longevity and stability compared to the other electrode types.

Abstract: Current technology does not allow measurement of neurotransmitters within the spinal cord with sufficient temporal and spatial resolution to understand the time-course of injury and recovery. Therefore we are developing a neurotransmitter sensing device that can be implanted in a rat model of spinal cord injury. Our goal is to develop microfabricated glassy carbon (GC) electrode (Fig. 1a) for neurotransmitter recording using Fast Scan Cyclic Voltammetry (FSCV) in vitro and in vivo. Our results show that GC electrodes can be successfully fabricated with high flexibility and with sensitivity to 10 nM serotonin (Fig. 1b) and dopamine detection in-vitro. The fabrication method consists of a modular transfer lithographic process that allows electrical and voltammetry microelectrodes in a common polymeric substrate. We focus on detecting serotonin since it is known to be dysregulated following injury. Based on both previous studies and our work, FSCV with N-shape waveform and Nafion electrode coating were used to increase serotonin selectivity. Our results confirm that greater selectivity of serotonin was obtained in vitro with N-shape applied voltage and Nafion coating electrodes compared to bare carbon-fiber electrodes. Finally, acute in-vivo FSCV recording were obtained from Long-Evan rat model

recording in lamina 8 of spinal segment C4-C5 in the cervical spinal cord. Our results demonstrate a promising neurotransmitter recording ability of glassy-carbon electrodes in-vivo.

Abstract: Background: Today's advanced prosthesis hold great potential for restoring function and improving quality of life for amputees. The patient's ability to control these devices with ease and precision is constantly improving; however, seamless control with sensory feedback

remain futuristic goals. We have previously demonstrated proof of principal for interfacing with nerves transposed to the medullary canal of long bones to create an Osseointegrated Neural Interface (ONI). This method builds on the clinical translocation of nerves into bone to treat symptomatic amputation neuromas. **The objective** of our current research is to create a novel ONI, complete with percutaneous osseointegrated abutment for chronic bi-directional electrophysiology in rabbits. **Methods:** Above knee amputation was performed in male and female New Zealand white rabbits. Briefly, the sciatic nerve was isolated and severed above the point of trifurcation. The femur was amputated at the midpoint and the nerve passed through a corticotomy. The terminal end of the nerve was sutured into a bipolar cuff electrode, and pressed back into the medullary canal. A second bi-polar cuff electrode was secured proximal to the corticotomy in order to stimulate and record efferent and afferent signals between the proximal and distal electrodes respectively. Both electrodes were connected to independent printed circuit boards (PCBs), which were intern secured to a stainless steel screw. The stainless steel screw served as both the osseointegrated and percutaneous portion of the ONI device. The muscle and skin were closed over the femur. Animals underwent electrophysiological recordings of compound nerve action potentials (CNAPs) at weeks 3, 5, 8 and 12 weeks under anesthesia, as well as terminal recordings of somatosensory evoked potentials (SSEPs) at week 12. **Results:** Efferent signals can be generated from the proximal electrode and recorded from by the distal electrode from week 3 through to week 12. Moreover, efferent signals improve over the 12 week period, indicated by higher peak amplitudes achieved from lower stimulation over time. Afferent signals generated within the bone and recorded proximal to the corticotomy are not achieved prior to week 8, and improve at week 12. The writing of sensory information via an ONI is demonstrated by the ability to record SSEPs. **Conclusions:** Chronic implantation of an ONI is entirely achievable and repeatable. Furthermore, physiological function of nerves transposed into bone improve over a 12 week period, including the ability to generate sensory signals to the cortex via an ONI.

Abstract: Intraneural electrodes showed in amputees to be able to successfully restore sensory feedback. Unfortunately, the implantation of such devices is very time consuming, increasing the physical exhaustion of the patient, and the risk of complications during the surgery. Furthermore, surgeons need to be trained well for the execution of the implantation making the process more complicated.
Here we developed a novel system, consisting of a 3D printed insertion device and a multifunctional peripheral neural interface, which can drastically reduce the surgery time, whilst maintaining a high spatial stimulation selectivity of nerve fascicles.
The electrode has a total of four epineural and eighteen intraneural active stimulation sites (ASs) which are manually implanted into the nerve using a purposely designed insertion device as a guidance. The epineural portion is placed around the nerve, while in a second step, nine needles are inserted into the nerve, leaving behind eighteen microwires, being in contact with the nerve fascicles.
Over a period of at least one month, the left posterior leg sciatic nerves of six farm pigs were implanted with two electrodes each. In addition, eight muscles innervated by the sciatic nerve, were implanted with monopolar, intramuscular EMG wire electrodes to verify the spatial selectivity of the implants.
Using a custom made graphical user interface, a neurostimulator and a recording unit were weekly used to provide bi-phasic, cathodic first, trains of current pulses amplitude modulated while recording the EMG response of the muscles being innervated by the sciatic nerve. Impedances, EMG recruitment curves and selectivity index were obtained to verify the spatial selectivity of the electrodes.The electrodes were successfully implanted in less than 20 minutes each. Furthermore, we could show that the implant had chronical mechanical and electrical stability, and can provide spatial selectivity over at least five months. Histological analysis showed no damage to the nerve. No infections occurred over the implantation period.

Abstract: Achieving a high-bandwidth recording and stimulation interface with the PNS has become increasingly important for potential therapeutic benefit as the significance of neural innervation of peripheral systems becomes better understood. Achieving a higher information resolution with the peripheral nervous system would allow for isolated nerve fiber interaction and a finer control over the communication taking place. In the case of prosthetic limbs for amputees, high-bandwidth PNS implants would be necessary to more ideally support sophisticated, modern prosthetics with multiple degrees of freedom for both sensory information and motor control. PNS implants require chronic compatibility with the tissue and the robustness to survive local environmental stresses. Our approach to a PNS interface takes advantage of the regenerative ability of the PNS and the common treatment of neuromas that can occur in amputees. Doctors excise neuromas from the nerve and approximate the nerve to a nearby muscle where it can innervate, leading to reduced recurrence of neuroma formation. In our device, a peripheral nerve of an amputee that no longer innervates the original targets would be cut and sutured to the device ends. The nerve then regenerates into the device via an engineered hydrogel where it would be in proximity with a high-density polyimide electrode array. Our implant, referred to as a Tissue Engineered Electrical Nerve Interface (TEENI), is an attempt to develop a reliable, chronic PNS interface with a sufficient input-output bandwidth to support next-generation prosthetic devices. This study demonstrates the functional and histological evaluation of TEENIs in regenerated rat sciatic nerves using a multimodal analysis approach including: electrochemical impedance spectroscopy (EIS), electrophysiological recordings, and immunohistological techniques. Lewis rats were anesthetized and a segment of the right hind-limb sciatic nerve was removed. TEENIs were then implanted into the gap by suturing the

proximal and distal nerve stumps into the respective ends of the device. A connection to the device was then run sub-dermally up to the head where it was secured using bone screws and dental cement. Impedance and electrophysiology were recorded daily and histology was conducted on the implant after 6 weeks of regeneration. The results presented here represent a preliminary analysis of a cohort of implanted rats. Abstract: Neural interfaces have the potential to impact aspects of the human experience ranging from medical treatment to leisure activities. A limiting factor to reliable, chronic implants involves both biotic and abiotic failure mechanisms. While significant work has been accomplished characterizing abiotic failure mechanisms, work is still necessary to understand the biotic tissue response to implanted devices. Characterizing the mechanisms of the foreign body response (FBR) to implanted devices in the central nervous system (CNS) has proven to be a difficult task with electrodes in the same implanted array showing different responses. The variation in the response has made the task of investigating the exact biological mechanisms of FBR to implanted recording and stimulating devices difficult. In this study, we investigate the peripheral nervous system (PNS) as a potential model system to investigate biotic failure mechanisms to implanted neural devices. The device used for this investigation is a Tissue-

Engineered Electronic Neural Interface (TEENI) which allows for high bandwidth bidirectional communication. The purpose of this device is to provide dense sensory and motor communication for cognitive control of and sensory feedback from prosthetic limbs. The device consists of flexible polyimide threads surrounded by a hydrogel and encased in a small intestine submucosa (SIS) wrap. A segment of a rat sciatic nerve is removed and as the nerve regenerates, the hydrogel degrades, and the regenerating axons come into proximity of recording and stimulating sites on the TEENI. Over time, the regeneration matures and encapsulating tissue forms around the device which is remarkably uniform in its appearance compared to tissue encapsulation seen in the CNS. Fourteen male Lewis Rats were implanted with TEENIs by transecting the sciatic nerve in the right hind legs and grafting the device onto the proximal and distal stump. After 6 weeks the rats were euthanized, and the device was explanted. The samples were cryosectioned at 20μm and labeled with primary and secondary antibodies. Using ImageJ eight measurements were taken along each side (left, right, top, bottom) of each thread (1-9) to the edge of the FBR. Statistical analysis was performed on the collected data to compare. The preliminary results of our image analysis support the hypothesis that the FBR to the device is not statistically different in magnitude across threads. Qualitative observation support that the FBR is very similar in shape, but further analysis will be done to verify uniformity of shape and magnitude across the remainder of the threaded samples.

Abstract: Neural interfaces for amputees should reliably capture the activity of motor neurons and stimulate activity in sensory neurons. Targeting peripheral nerves instead of the brain can minimize risk while still providing good prosthesis performance. The primary signal sources and stimulation targets in nerves are the Nodes of Ranvier, which are not spatially correlated between the thousands of neighboring fibers. As a result, the nodes are arranged in an approximately repeating 3-D "cloud" of targets for recording movement intent and stimulating sensory feedback. To comprehensively engage with the nerve and maximize the number of independent motor and sensory channels, neural interfaces for nerves should also be 3-D in nature and scalable.

To date, nerve interfaces have been 1-D (LIFE: longitudinal inter-fascicular electrode, TIME: transverse intrafascicular multichannel electrode, etc.) or 2-D (USEA: Utah slant electrode array, sieve electrodes, etc.) in nature, which means that they tremendously under sample the nerve fibers. Another challenge is the mismatch between the elastic properties of native peripheral-nerve tissue and the mechanical stiffness of interfaces. A significant mismatch is hypothesized to trigger an exaggerated foreign-body response that can negatively affect the functional longevity of neural interfaces.

Our novel multidisciplinary approach is to overcome these barriers by creating mechanically compliant, scalable, and high-performance nerve interfaces through the combination of microfabricated neural-electronic interfaces with tissue engineering and nerve regeneration. Specifically, we developed a hybrid tissue-engineered electronic nerve interface (TEENI), which consists of multi-electrode polyimide-based "threads" embedded into a biodegradable hydrogel composite scaffold that is wrapped in a bioresorbable small intestinal submucosa and sutured to the ends of a transected nerve. Multiple thread sets can be stacked and incorporated in the hydrogel to enable the TEENI device to be scaled up and functionally engage with the 3-D nerve target. Aggressive reactive-accelerated-aging (RAA) soak tests were used to facilitate rapid fabrication process improvements that ultimately have yielded TEENI that can survive RAA equivalent to a 6-month implant with less than 15% change in impedance and charge-storage capacity.

Title: An experimental model for assessing long-term safety and efficacy of vagus nerve stimulation

Authors: *F. YAGHOUBY[1], B. SHAFER[2], S. ASGARI[2], S. VASUDEVAN[3]
[1]CDRH, FDA, Silver Spring, MD; [2]Food and Drug Addministration, Silver Spring, MD;
[3]CDRH/OSEL/Division of Biomed. Physics, U.S. Food and Drug Admin., Silver Spring, MD

Abstract: Therapeutic findings of Vagus Nerve Stimulation (VNS) in several clinical disorders have benefited from investigations on experimental models. However, majority of research on VNS has been limited to acute timelines in such models and long-term effects have been overlooked. In this study, we propose a rat model for longitudinal assessment of safety and efficacy of VNS and validate the feasibility of the model by exploring VNS effects on cardiovascular and immune systems. Under approval by Institutional Animal Care and Use Committee (IACUC) at the U.S. Food and Drug Administration, female Lewis rats (n = 4) were surgically implanted with a telemetry device (EMKA Technologies) for continuous recording of Electrocardiogram (EKG), temperature and activity. Four weeks post-implantation, a custom nerve cuff electrode (Microprobes for Life Science) was surgically implanted around the left cervical vagus nerve in each rat. Cuff electrode leads were enclosed inside a connector mount secured to the rat's lumbar fascia. The transcutaneous mount interfaces with a magnetic connector and provides seamless plug and play connection for applying stimulation or measuring impedance in awake behaving rats. Physiological variables were continuously monitored for another 2-3 weeks post-implantation. After complete recovery, an isolated pulse stimulator was used to deliver a 30s biphasic pulse train of electrical stimulation to rats twice a week. VNS parameters used as 1 mA charge-balanced pulses with 100 μs pulse width at 30 Hz. The stimulation protocol continued for three months and physiological variables and electrode impedance were continuously monitored and analyzed. The robustness of the VNS implant for the proposed model was validated using electrode impedance measurements from a pilot cohort of three rats. Results showed relatively low impedance values (<15kΩ) indicating durability of the implanted electrodes. Physiological variables and particularly EKG were used to assess VNS target engagement in this rat model. Instantaneous bradycardia was observed during VNS in some rats and heart rate variability analysis was performed to investigate detailed changes in cardiovascular autoregulation. Preliminary results from the proposed model demonstrated easy-

to-use electrical stimulation as well as long-term monitoring of electrode impedance and physiological variables in awake behaving rats. In addition to impedance measurements and heart rate variability analysis, ongoing experiments involve cytokine analysis of blood samples for immune system response. This will supplement the preliminary results and validate the model in a long term experimental setup.

Title: Deep learning for neural data: Speech classification and cross-frequency coupling in human cortex

Authors: *J. LIVEZEY, K. E. BOUCHARD[1], E. F. CHANG[2]
[1]Biol. Systems and Engin., E O Lawrence Berkeley Natl. Lab., Berkeley, CA; [2]Neurosurg., UCSF, San Francisco, CA

Abstract: A fundamental challenge in neuroscience is to understand what structure in the world is represented in spatially distributed patterns of neural activity from multiple single-trial measurements. This is often accomplished by learning linear transformations between neural features and features of the sensory stimuli or motor task. While successful in some early sensory processing areas, linear mappings are unlikely to be ideal tools for elucidating nonlinear, hierarchical representations of higher-order brain areas during complex tasks, such as the production of speech by humans. Here, we apply deep networks (DNs) to predict produced speech syllables from cortical surface electric potentials (CSEPs) recorded from human sensorimotor cortex in 4 subjects and then analyze the DNs to understand what structure they are learning from the neural data.First, we show that DNs achieve superior classification accuracy compared to linear models, with increased gains for increasing task complexity, and improved efficiency as a function of dataset size. We then 'opened the black box' and used the DN confusions to reveal the latent structure learned from single trials, which revealed a rich,

hierarchical organization of linguistic features that recapitulated vocal tract configurations.Since DNs classified speech production from high gamma (HG) activity with higher accuracy that other methods, they are also candidates for comparing the relative information content across neural signals. We explored the cross-frequency amplitude-amplitude structure in the CSEPs and discovered a novel signature of motor coordination in beta-HG coupling. Using deep networks, we then show that although there is information relevant to speech production in the lower frequency bands, it is small compared to the amount in HG. Furthermore, the amplitude-amplitude correlations are not clearly related to overall information content and improvements in accuracy.Together, these results demonstrate the utilization of deep networks not only as an optimal black-box predictor with application to brain-computer interfaces, but as a powerful data analytics tool to reveal the latent structure of neural representations, and understanding the information content of different neural signals.

Title: Synthesizing speech from the human sensorimotor cortex

Authors: *G. K. ANUMANCHIPALLI[1,2], J. CHARTIER[3], E. F. CHANG[2]
[1]UCSF, Walnut Creek, CA; [2]Neurosurg., UCSF, San Francisco, CA; [3]Bioengineering, UC Berkeley, Berkeley, CA

Abstract: The ventral sensorimotor cortex (vSMC) encodes coordinated, multi-articulator kinematic movements of the vocal tract that accomplish specific articulatory goals needed to produce natural continuous speech. Our goal here was to decode audible speech only from the associated neural activity during speaking. Two approaches include direct decoding of speech spectrum or decoding articulatory kinematics followed by articulatory synthesis. Between these, kinematics is the closest representational correlate to vSMC neural activity, has less latency, and generalizes well to arbitrary word sequences. Despite these advantages, modeling articulatory kinematics for neural-to-speech decoding has not been demonstrated given methodological constraints on estimating articulatory movements. Here, we developed a model-based approach with two components, i) a neural decoder that converts neural activity into articulator kinematics, and ii) an articulatory synthesizer, that converts articulatory trajectories into audible speech. Both

components were computationally implemented using deep recurrent neural networks with LSTM units. Neural data were collected from five human participants (patients with medically refractory epilepsy), implanted with high-density subdural ECoG arrays, as they spoke fluent sentences. An optimal set of 460 sentences (MOCHA-TIMIT) was used as the speaking material. A previously developed statistical approach was employed for acoustic-to-articulatory inversion to estimate vocal tract kinematics from produced speech acoustics. Articulators were represented as 12 dimensional vectors coding displacements in x and y directions of three points on the tongue, jaw, upper and lower lips and the fundamental frequency coding the laryngeal function. Using this approach, we were able to successfully decode neural activity to synthesize intelligible speech. We found high degree of correlation between synthesized and original spectrograms of subjects' produced speech making this a viable path for future speech based brain-computer interfaces.

Title: Using single unit bursts to decode audible and silent speech recorded chronically from a speaking human

Authors: *P. R. KENNEDY
Neural Prosthetics, Neural Signals Inc, Duluth, GA

Abstract: A major issue with recording from a locked in subject (mute and paralyzed, but intelligent and awake) is that the investigator cannot be certain if the subject is actually speaking *silently*. The *timing* of speech onset as well as the *correctnes*s of the requested speech are also uncertain. For those reasons the articulatory motor area of a speaking human (PRK) was implanted with four Neurotrophic Electrodes on June 21st 2014. Amplifiers and transmitters, powered by inductive coils, were added in October 2014 and all were removed in January 2015 after several weeks of good quality recordings of 65 single units. Audible and silent speech epochs (plus silent control epochs) were analyzed during production of 39 phonemes, some of 290 short words and six phrases (containing all 39 phonemes). The pattern of single unit bursts was analyzed. During recording, an event marker (button push by subject) was used to determine the approximate onset of audible and silent speech. Actual speech, when available, was recorded on a separate channel. As previously reported (SFN abstracts 2015), the patterns of firing of single units were used to detect phonemes with an 80% detection rate using four phonemes that were associated with the most active single unit modulations. However, further analyses did not extend these results to many other phonemes. An alternative method was adopted that used patterns of single unit bursts to decode the speech using a Neural Net Fitting app from Matlab. This app requires a *target* set of values for each phoneme, word or phrase (e.g. Hello World) which target was then compared with an incoming set of values for each time the phrase is spoken audibly or silently.The example below using the phrase ‘Hello World’ *spoken silently*. Note that some of the regression values (R) are close to 0.9.
Conclusion: The present NN Fitting app has the disadvantage of requiring targets to which the incoming data streams are compared. However, deep learning computer paradigms will likely not have this restriction and will decode silent speech when hundreds of units are available.

Title: Real-time decoding of question-and-answer speech dialogue using human cortical activity

Authors: *D. A. MOSES[1], M. K. LEONARD[2], J. G. MAKIN[4], E. F. CHANG[3]
[1]Bioengineering, UC Berkeley - UC San Francisco, San Francisco, CA; [2]Neurolog. Surgery, [3]Neurosurg., UCSF, San Francisco, CA; [4]Ctr. for Integrative Neurosci., Univ. of California, San Francisco, San Francisco, CA

Abstract: The development of an advanced speech prosthesis relies on real-time decoding of speech from high-resolution neural signals. Previous work has demonstrated that it is possible to decode perceived or produced speech with some success in relatively constrained contexts. However, to our knowledge, no work has utilized a naturalistic task where perceived and produced speech are integrated, which could have practical applications for patients who are unable to communicate. Here, we demonstrate real-time decoding of perceived and produced

speech from high-density electrocorticography (ECoG) activity in humans using a real-time neural speech recognition (rtNSR) software package that we developed (Moses *et al*., 2018). In our task, three human epilepsy patients implanted with ECoG arrays listened to questions (e.g., "When would you like me to check back on you?") and verbally produced answers (e.g., "Tomorrow"). The rtNSR system used the ECoG activity to reliably detect when subjects were listening or speaking and then performed phone-level Viterbi decoding to predict the identity of each speech utterance. We leveraged the fact that certain answers were only plausible responses to certain questions to dynamically update the prior probabilities of each answer using the preceding question likelihoods predicted from ECoG activity. Our system was able to reliably decode speech utterances for each subject, with accuracy rates as high as 75% for perceived questions and 61% for produced answers (chance rates were approximately 20% and 7%, respectively). Furthermore, using the decoded questions as context significantly improved answer decoding. We also demonstrated that high accuracy rates are achievable using only 15-20 minutes of training data, suggesting that this paradigm can be used practically in limited data settings. These results demonstrate that neural activity in speech perception and production regions can be used for real-time decoding of speech in natural, conversational settings.

Title: LFP based classification of vocalizations in free-behaving zebra finch

Authors: *D. E. BROWN, JR[1], E. M. ARNEODO[5], S. CHEN[2], T. GENTNER[3], V. GILJA[4]
[1]Electrical Engin., [2]Bioengineering, [3]Psycholgy, [4]Electrical and Computer Engin., UCSD, La Jolla, CA; [5]Biocircuits Inst., La Jolla, CA

Abstract: Songbirds, like humans, are one of the few species capable of learned vocal behavior, making them an attractive animal model for studying vocal learning. Understanding the neurobiological principles and mechanism that support vocal learning in songbirds, can yield useful insight into understanding human speech perception and production, and aid in the longstanding goal to develop a human speech prosthesis. With this goal in mind, we present a discrete neural decoder that predicts the vocalizations produced by an awake freely-behaving zebra finch, a species of songbird, based on local field potentials recorded in the sensorimotor telencephalic region HVC (used as a proper noun), shown in previous research to be involved

with the production and timing of song.
Using band power within multiple frequency bins of the local field potential (LFP) as a feature, and a linear discriminant analysis (LDA) classifier, we identified a separability in neural space for four distinct syllables and the introductory notes in a birds-own-song, and contemporaneous silence, recorded during free vocal activity. We computed syllable classification performance, using 4-fold cross-validation and a grid search over parameters of the LFP bins namely window length and window offset, achieving a peak syllable classification accuracy of 33±2% (mean +/- s.e.m; chance level is 16.7%). In general, classification performance increases as with window length shrinks. As we expected, better classification performance was observed when window onset close to the stimulus onset. We tested the classifier further in a series manner using a 4.5-second snippet of free vocal behavior.
Our results demonstrate that the syllables of a zebra finch's song can be "decoded" from local field potentials sampled in HVC. Notebaly, the model described here does not utilize the temporal structure present in either the bird's vocal behavior or the recorded neural activity. Future work will explore how consistent these dynamics are across subjects and how they correspond to volitional motor control.

Title: A brain-machine-interface to generate vocal communications

Authors: *S. CHEN[1], E. M. ARNEODO[2], D. E. BROWN, II[3], V. GILJA[3], T. Q. GENTNER[4]
[1]Bioengineering, [3]Electrical and Computer Engin., [4]Psychology, [2]UCSD, La Jolla, CA

Abstract: Brain Machine Interfaces (BMIs) can restore impaired motor function and have been employed to understand the mapping between neural activity and motor control. State-of-the-art BMIs fall short, however, when it comes to decoding complex behaviors with high dimensionality, such as vocal communication. Using birdsong as a model for complex behavior similar to human speech, we previously created a BMI for birdsong in which spiking activity in the sensorimotor region HVC (used as a proper noun) can be fit to the parameters of a low-dimensional model of zebra finch syringeal dynamics that generates natural song, using a simple

feedforward neural network. The dimensionality reduction provided by the syringeal model is crucial to the performance of the feedforward network. Here we propose an innovative method that incorporates advances in machine learning, specifically a Long Short-Term Memory (LSTM) network, capable of temporal sequence mapping, to produce a BMI that directly translates HVC spiking activity into the frequency domain representation (mel spectrogram) of a bird's own song. The LSTM-based BMI yields synthetic bird's own songs that sound similar to natural songs using as little as 20% of a 70-song repertoire for training. Acoustic variability in the BMI synthesized songs (computed as the RMSE of the spectrograms) falls within the range of natural variation in the bird's own songs, and is significantly lower than the variability between songs from different conspecific birds. The LSTM-based BMI can also reconstruct novel vocalizations, not presented to the machine during training. For birdsong researchers, these results provide a platform where song output (and thus auditory feedback) can now be directly modulated in much more precise ways compared to previous methods. The BMI also provides a framework for a deeper quantitative investigation of the general intuition that transformation of HVC spiking patterns into a high-dimensional vocal motor behavior involves substantial non-linearities that are captured by the recurrent architecture of an LSTM. Comparing the capacities of various network architectures to generate song from the neural activity of RA and other well-studied song system nuclei can be used to isolate the source of different non-linear mappings and more specifically define processing functions throughout the song system. We suggest that once fully optimized, such a system will substantially advance our understanding of the physiological mechanism behind vocal communication, and benefit fully automated assistive technologies to regain a much wider range of lost motor function than currently available.

Title: Tracking longitudinal changes in sleep features in an intracortical brain-computer interface user with tetraplegia

Authors: *D. J. THENGONE[1,2,3,4], T. HOSMAN[1,2], J. SAAB[1,2,4], J. D. SIMERAL[1,2,3,4], L. R. HOCHBERG[1,2,3,4,5]

Abstract: A primary goal of intracortical brain-computer interfaces (iBCI) is to enable long-term neural control of assistive devices for individuals with severe motor disabilities. While continuous training and decoder calibration are known to influence the stability of iBCI control over time, relatively less is known about the neural circuit mechanisms and effective connectivity across cortical regions during extended iBCI usage in humans. We performed retrospective analyses to track the longitudinal changes in two canonical oscillations typical of NREM sleep: slow-wave activity (SWA) (0.5 - 2 Hz) and spindle frequency activity (SFA) (9 - 16 Hz oscillation lasting 0.5 - 2 sec). In both animal and human neurophysiological studies, SWA and SFA have not only been known to reflect the dynamics of cortical connectivity, but also have been directly linked to motor skill acquisition. Here we present data collected from research sessions carried out with a participant enrolled in the BrainGate2 clinical trial spanning 1 year of iBCI usage and track the sleep oscillations along the similar timecourse as the iBCI user performs neuroprosthetic control. Neural signals were collected using two 96-channels microelectrode arrays (BlackRock Microsystems) implanted in the precentral and middle-frontal gyri. Signals from each electrode were amplified and filtered to attain spike power and thresholded to yield spike rates. Prior to the identification of SWA and SFA, local field potentials (LFP) were low-pass filtered and downsampled to 1000 Hz. Retrospective identification of the NREM sleep epochs were performed using standard criteria: 1) eyes-closed state and 2) LFP periods dominated by high-amplitude, low-frequency oscillations. Using this methodology, a total of 3.8 hours (6 minute segment x 38 sessions) of sleep were selected from the relevant research sessions over the 1-year period. Multitaper power spectral analyses of the LFP revealed significant changes in the SWA and SFA across majority of the channels in both cortical regions over time. Specifically, increased power in the SFA was often accompanied by slight increases in the peak frequency of spindling activity as well. This was consistent across the recordings in both cortical arrays. Coherence analyses across the two regions during sleep revealed changes in local and long-range coherence in the SFA during the same timecourse. These initial observations support the use of iBCI to investigate dynamics of cortical oscillations and effective connectivity in humans.

Abstract: Intracortical brain computer interfaces (iBCIs) use neural activity to directly control external devices, bypassing damaged neural pathways with the aim of restoring communication and independence for people with impaired mobility due to stroke, spinal cord injury, or neurodegenerative disorders. Premotor cortex is a promising candidate for iBCI applications given its combination of prominent corticospinal projections coupled with strong links to frontal and parietal areas involved in sensory-motor transformations. Here, we compare single unit activity between the middle frontal gyrus (MFG) and precentral gyrus (PCG) in a person performing an instructed delay movement imagery game with both auditory and visual cues. Data was collected from participant T10, a 35 year-old right handed man with a spinal cord injury (C4 AIS-A), in the BrainGate2 pilot clinical trial*. T10 had two 96 microelectrode arrays (Blackrock Microsystem, Inc) implanted—one in the left MFG and one in the left PCG. T10 played a 2-part instructed delay game, in which four targets located at cardinal points of a monitor were cued using auditory and visual instructions. Auditory instructions indicated the color of the target (red or blue), while the visual instructions indicated the shape (circle or

square). Both types of information were required in order to identify the target unambiguously. We examined the effect of varying cue order (V-A vs. A-V) or presenting both cues simultaneously (A + V). We found that information related to target direction in MFG was highly dependent on the sensory modality used to instruct the movement. MFG, unlike PCG, was strongly biased towards encoding information presented as goal-relevant auditory cues, rather than visual cues. Information related to target position was evident in PCG only after both auditory and visual cues were presented (i.e. once the precise target location was known). By contrast, target-related information in MFG transiently peaked shortly after auditory cues were presented. Interestingly, MFG did not respond selectively for auditory information when the same auditory cues were presented outside the context of the task (i.e. passive listening). Our results suggest that MFG may be specifically involved in interpreting auditory cues for the purpose of movement guidance.

Title: The effect of default mode network disruption on reaction-timing and cortical activity in a modified Stroop task

Authors: *N. R. WILSON[1], K. WEAVER[2,5], J. WU[1,5], J. G. OJEMANN[3,5], R. P. N. RAO[4,5]
[1]Bioengineering, [2]Radiology, [3]Neurosurg., [4]Sch. of Computer Sci. & Engin., Univ. of Washington, Seattle, WA; [5]Ctr. for Sensorimotor Neural Engin., Seattle, WA

Abstract: Default mode network (DMN) activity increases with lowered attention and mind wandering during task performance. User performance with Brain-Computer Interfaces (BCI) tends to worsen with decreased attention. The monitored signals are typically modulated by attention and are likely influenced by DMN activity. Tracking DMN activity in real-time may

serve as a surrogate for attentional brain state, suggesting a strategy of disrupting the DMN in order to return users to their more alert state, thereby improving BCI performance. Here, we explore the effects of conscious and subconscious disruption of the DMN in humans via an audio beep or electrical stimulation of the cortex over DMN areas. Patients undergoing clinical seizure monitoring and implanted with subdural electrodes consented and volunteered to perform a modified Stroop reaction timing (RT) task. In each trial, subjects were presented with a color word, either congruent or incongruent in meaning and font color, and pressed one of two keys as quickly as possible to label the word as congruent or not. Between trials, a fixation dot was displayed during a variable interstimulus interval (ISI) randomly ranging from 1-10 seconds. In DMN disruption trials, conscious or subconscious disruption occurred 1 second prior to word presentation. Preliminary results suggest auditory disruption of the DMN may improve RT in trials with relatively long ISIs (Fig 1). In agreement with established DMN literature, longer ISIs increase the likelihood that subjects begin to lose focus and engage in mind wandering, leading to increased DMN activity. With cued disruption, subjects are reoriented to the task at hand. Ongoing efforts are implementing high-frequency direct cortical stimulation (DCS) to electrodes positioned over the DMN. Previous DCS research revealed electrical stimulation of the posterior parietal hub of the DMN does not yield a subjective conscious experience. Future analyses will compare the effects of conscious (cued auditory disruption) and subconscious (DCS) DMN disruption on task performance RT.

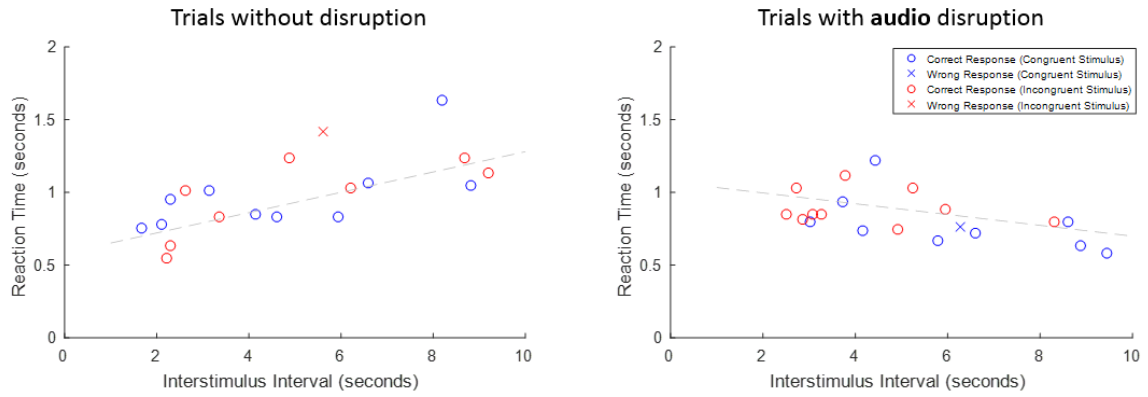

Figure 1. In at least one subject, reaction time appears to be positively correlated with interstimulus interval length in trials without any form of Default Mode Network disruption. This effect is eliminated when an audio beep is sounded one second prior to word presentation.

Title: A novel ischemic stroke model for non-human primate: Quantitative estimate of the scale of photochemically induced infarction in primate cortex

Authors: *Z. YAO, E. P. BURUNOVA[1], W. Y. HAN[1], W. K. S. OJEMANN[1], A. YAZDAN-SHAHMORAD[2,3]
[2]Bioengineering, [3]Electrical Engin., [1]Univ. of Washington, Seattle, WA

Abstract: Stroke is one of the global leading causes of disability. It has been challenging to translate rodent study-derived stroke therapies. On the other hand, non-human primate models are critical for preclinical stroke studies that may prelude effective medical translation. In light of scarce reports of such studies, we propose the use of photothrombosis in developing macaque stroke models.
Photothrombosis produces focal cerebral infarcts via the photodynamic effect of anionic xanthene dyes, e.g. Rose Bengal. Injected to the blood stream, it binds to the vascular endothelium, the platelets and other cells. Upon light exposure at interested cortical locations, the dye's photochemical reaction generates local oxidative stress, causing vascular endothelial damage and platelet aggregation, and resulting in ischemia and neuronal death.
Here, we present a computational model to predict the scale of photothrombotic lesions in the cortex. Based upon McLean's (1998) beam spread function method – assumeing photons reach locations in the media via various-lengthed paths, thus, resulting in time dispersion of intensity – we modeled the relative light intensity distribution in the cortical tissue of a collimated beam. We first calculated the time-resolved impulse response of a single photon energy packet using the beam spread function. It was then temporally integrated to generate the scattering profile of a continuous pencil beam. Such distribution was subsequently convolved in the transverse plain with the geometry of the beam to acquire the intensity distribution of a realistic beam.
We simulated the penetration and scattering profile of the 532 nm light – one of Rose Bengal's characteristic absorption wavelengths. Our model could predict the spatial extent of the radiation's effective region according to the width of the beam. It could also resolve the penetration depth as a function of beam intensity, which would be applicable in titrating the beam's power used to generate infarcts of ideal depth.
Our simulation demonstrated how the scale of photothrombotic infarction quantitatively depends on the intensity and the diameter of the beam. In addition to a multilayer model being developed to account for cortical tissue-optics heterogeneity, future effort will focus on the integration of computational results for in-vivo testing of the stroke model in macaques. We will then modify our computational model based on pathology/histology examinations.

Abstract: Brain-machine interfaces (BMIs) for reach control have enjoyed continued performance improvements, allowing remarkable 2D cursor control. Yet there remains significant clinical need for locomotor (e.g., wheelchair control) BMIs. Proof-of-concept locomotor BMIs were recently demonstrated, using decode methods derived from reaching BMI's. Here we adopt a different approach, and examine the viability of locomotor BMI's guided by rhythmic neural activity.

We exploit a behavioral task in which monkeys cycle a hand-held pedal, forward or backward, to advance along a virtual track and pause on targets to collect juice reward. This task does not involve natural locomotion - the patterns of muscle activity differ and the contribution of spinal pattern generators is likely very different. Instead, the task provides a view of the patterns of cortical activity during a learned, voluntary, rhythmic movement. Those patterns are robust and have been recently characterized, affording the opportunity to develop appropriate decode algorithms and test them in an online setting.

Neural activity was recorded from 96 electrodes acutely implanted in primary motor cortex. Based on data during hand-control, we estimated key parameters of the model, including the subspaces in which neural activity evolved during forward and backward cycling. Our decoder estimated the neural state of the neural population, the velocity of which used to control the direction and speed of virtual motion. A Hidden Markov Model estimated whether the monkey intended to move or remain stationary, and gated output accordingly. The decoder was almost

always successful in driving motion in the appropriate direction, forward or backward, yielding progress toward the juice target. A more challenging aspect of the task involved stopping on that target, which delivered maximal reward. Stopping successfully required a precision, relative to the traveled distance, of 14% - 50% (depending on target distance). In 5 online experiments over the course of two weeks, the monkey stopped successfully on 70.9±20.8% of targets. Performance increased with experience: on the 5th day the success rate was 94%, only slightly worse the native arm performance (98%). The target size was held constant over these experiments, resulting in an average Fitts' law throughput of 1.1±0.1 bits/s, compared with 1.6 bits/s in arm control, when using six distance conditions. Higher throughputs are possible using more distances, pending improvements in stopping precision. These data demonstrate the viability of decoding locomotor signals from rhythmic cortical activity.

Title: Development of cortically controlled FES following spinal cord injury in the rat

Authors: F. BARROSO[1], B. YODER[1], J. WALLNER[1], D. TENTLER[1], P. TOSTADO[3], L. E. MILLER[1], *M. C. TRESCH[2]
[1]Physiol., [2]Biomed. Eng, Physical Med. and Rehab, Physiol., Northwestern Univ., Chicago, IL; [3]UCSD, LA Jolla, CA

Abstract: Cortically controlled functional electrical stimulation (FES) is a promising approach for restoring motor function following spinal cord injury (SCI). In cortically controlled FES, intended movements (or patterns of muscle activity) of a paralyzed limb are estimated from cortical activity and those movements are produced by electrical muscle stimulation. In addition to its potential for restoring function, there is evidence that cortically controlled FES improves rehabilitation. In this application, repeated pairing of cortical activity with evoked movements is thought to strengthen residual descending connections through activity-dependent plasticity, thereby improving overall function.
To evaluate this application, we are developing cortically controlled FES in rats with SCI. We have previously shown that we are able to obtain good predictions of muscle activations and limb kinematics from cortical recordings in intact animals. In the experiments reported here, we

describe the use of cortical recordings to predict and restore function following SCI. We implanted electrode arrays in motor cortex and EMG electrodes in hindlimb muscles. We recorded cortical activity, EMGs, and kinematics while animals walked on a treadmill. We then transected the spinal cord at mid-thoracic levels so that the cord ipsilateral to the implanted hindlimb was fully transected, together with approximately one-third of the contralateral cord. We then recorded cortical activity, EMGs, and kinematics while animals attempted to walk on the treadmill over several weeks after SCI.
Immediately after SCI the hindlimb ipsilateral to the fully transected cord was paralyzed. Over several weeks, animals spontaneously recovered some degree of function. We are currently evaluating predictions of EMGs and limb kinematics from cortical activity following SCI. We are examining predictions immediately after SCI, evaluating whether cortical activity might be related to spontaneous functional recovery. We are also examining whether decoders used to predict EMGs and kinematics before SCI can be used to predict similar EMGs and kinematics immediately after SCI. Using these decoders we will then evaluate the efficacy of repeated training with cortically controlled FES for functional rehabilitation following SCI.

Title: Classification of flexion and extension of upper limb joints from the sensorimotor cortex using electrocorticography

Authors: *T. M. THOMAS[1], D. N. CANDREA[1], N. E. CRONE[2]
[1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Neurol., Johns Hopkins Hosp., Baltimore, MD

Abstract: Because subdural electrocorticography (ECoG) can provide stable and comprehensive recordings of human sensorimotor cortex, it continues to be investigated as a potential brain-computer interface for restoration of communication and upper limb control. To date, these studies have only achieved rudimentary cursor control or simple reaching and grasping movements that involve the simultaneous control of multiple joints. To test whether movements at individual joints in the upper limb can be classified from ECoG recordings, we recorded from electrode arrays of varying spatial resolutions (1-cm, 5-mm, and 0.9-mm spacing) implanted in

three subjects. The subjects performed randomly cued flexions or extensions of the fingers, wrist, or elbow contralateral to the implanted electrodes. Electrodes that showed significant differences (ANOVA, $p < 0.05$) in high-gamma (HG, 70-110 Hz) responses during different movements were selected for decoding. We trained a linear model to classify the individual joint movements using averaged HG power modulations within a 328 ms sliding window at different latencies with respect to movement onset. We tested the model using 10-fold cross validation. Peak classification accuracies for patients S1, S2, and S3 were 54.4%, 57.5%, and 65.3%, respectively (chance 16.7%). When decoding from a longer (1.52-2.24 s) time window, bounded by where the temporal accuracy was significantly higher than chance, classification accuracies for patients S1, S2, and S3 were 62.4%, 67.5%, and 86.9%, respectively (chance as above). When comparing classification accuracies of movements at different joints, flexion and extension of the hand and wrist were classified more accurately than those of the elbow. We also found that the neural activity for different movements was more classifiable at the macro-ECoG scale than at micro-ECoG scale, but this could have been due to suboptimal placement of micro-ECoG arrays. The results of this exploratory study suggest that recording from a larger area of cortex may be useful for classifying the neural representations of individual degrees of freedom at different upper limb joints.

Title: Effects of dorsal root ganglia microstimulation in advance of postural perturbation on hindlimb motor output in behaving cats

Authors: *M. URBIN[1], E. C. BOTTORFF[1], R. A. GAUNT[1], L. E. FISHER[2], D. J. WEBER[3]
[2]Physical Med. and Rehabil., [3]Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: We previously presented findings to demonstrate that microstimulation of the dorsal root ganglia (DRG) can activate reflex pathways projecting onto hindlimb motor neurons in behaving cats. Here, we report on the effects of microstimulation in advance of postural perturbation on hindlimb motor output. Penetrating, 32-channel microelectrode arrays were implanted chronically in the left L6 and L7 DRG of four male cats. Microelectrodes with low thresholds for recruiting antidromic volleys in Group I afferents were selected for delivering 100-ms, 100-Hz pulse trains. Stimulus trains were delivered at 1.5x (low) and 2.0x (high)

threshold, 150 ms (early) and 50 ms (late) prior to forward or backward translation of a platform. EMG and ground reaction forces were recorded in a perturbation-only condition and in four stimulation+perturbation conditions in both translation directions. The initial behavioral response (ie, hindlimb unloading in backward condition; loading in forward condition) was quantified as the peak change in force pre- to post-perturbation. Two different epochs were used to quantify EMG power: A) a window in which a given muscle was active in the perturbation-only condition; B) a fixed window consisting of the first 150 ms after perturbation onset. Results indicated that peak force was increased during backward perturbation ($\chi^2(4)=18.33$, $p<0.001$) for late-low, early-high, and late-high stimulation relative to perturbation only. EMG power was reduced within the active epoch ($\chi^2(4)=14.64$, $p=0.006$) for early-low stimulation relative to perturbation only, but differences in the fixed window epoch failed to reach significance ($\chi^2(4)=8.72$, $p=.068$). In contrast to the backward direction, peak force was reduced during forward perturbation ($\chi^2(4)=22.76$, $p<0.001$) for all stimulation conditions relative to perturbation only. EMG power was reduced within the active epoch ($\chi^2(4)=21.52$, $p<0.001$) for all stimulation conditions relative to perturbation only. EMG power was also reduced within the fixed window epoch ($\chi^2(4)=10.24$, $p=0.037$) but only for early-low, late-low, and late-high stimulation relative to perturbation only. These findings demonstrate that DRG microstimulation drives hindlimb muscle activity, resulting in postural responses that either attenuate or magnify the natural response to surface perturbation. Consistent with our prior findings, activated reflex circuits recruited complex EMG patterns, the net effect of which was an unloading response irrespective of perturbation direction. Further work is needed to understand how other recruitment patterns might be engaged within the heterogeneous somatotopy of the DRG.

Title: Characterizing neural responses and organization in the dorsal root

Authors: *D. SARMA[1], M. F. LIU[2], C. GOPINATH[3], L. E. FISHER[3], R. A. GAUNT[3], D. J. WEBER[2]
[2]Bioengineering, [3]Physical Med. and Rehabil., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The dorsal root ganglion (DRG) is an ideal location to record somatosensory neural signals, which convey body-state information such as tactile and proprioceptive feedback from the limbs. Neural signals from mechanosensory neurons in just one or two DRG can be used to predict the joint angles and the position and velocity of a limb with high accuracy, in addition to providing cutaneous and force information. These signals are ideal for use as control signals in closed loop applications with somatosensory feedback. In a similar way, afferent signals from visceral organs such as the bladder may provide pressure or volume information that could be used for a bladder neuroprosthesis. Recent work in our lab and by other groups has shown the ability to record simultaneously from up to one hundred neurons with arrays of microelectrodes implanted in DRG. However, there are still remaining questions regarding the potential somatotopy of cell bodies and the actual organization of neurons across layers of the DRG. In this study, during intraoperative experiments in feline and macaque DRG, neural responses were characterized along the shanks of 3D microelectrode arrays (4x8-channel, 125 micron vertical spacing, N-form 3D arrays, Modular Bionics), implanted transversely, to examine commonalities in field potentials and spike waveforms across pairs of tightly spaced electrodes. In one experiment conducted in an isoflurane anesthetized male cat, after a laminectomy exposing the L5 to S4 spinal segments, we implanted these probes into the L7 DRG. Neural responses were recorded at each electrode during passive movement and manipulation of the hindlimbs. In most cases, electrodes were most highly correlated to the neighboring electrodes, with the deepest electrode the most independent. In one shank, however, the greatest coactivation was found at the lowest (e1/e2) and highest ends (e7/e8) with the largest amplitude response seen in the middle across all conditions. Further examination is still needed to fully understand the spatial relationships along as well as across the DRG layers. These studies help support the efficacy of recording and decoding neural activity from the DRG for somatosensory feedback and will drive future experiments involving longer-term (sub-chronic and chronic) evaluations of DRG recordings in animal and human subjects with optimized electrodes.

Title: Patterns of cortical population activity during intentional control of single neurons

Authors: *A. S. WHITFORD[1,4,2], S. M. CHASE[3,2], A. B. SCHWARTZ[5,4,2]
[2]Ctr. for the Neural Basis of Cognition, [3]Biomed. Engin., [1]Carnegie Mellon Univ., Pittsburgh, PA; [4]Bioengineering, [5]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: When learning to control an intra-cortical brain-computer interface (BCI), evidence suggests that subjects achieve behavioral goals by re-organizing a fixed repertoire of neural activity patterns. From a computational perspective, this is somewhat unsurprising: searching within a restricted pattern space represents a relatively low-dimensional strategy, in contrast to the high-dimensional search that neuron-by-neuron optimization would entail. However, this contrasts with previous reports suggesting that patterns of cortical population activity are rather labile, and are readily adapted to suit arbitrary behavioral demands. A fundamental difference between the evidence used to support these two conclusions lies in the behavioral task: the former results tend to be derived from population-based BCI experiments, whereas the latter tend to be derived from the single-neuron operant conditioning paradigm.
Here, we aim to characterize patterns of task-relevant population activity during performance of a single unit conditioning task. We recorded from populations (N > 20) of neurons in primary motor cortex as subjects were rewarded for systematically varying the firing rates of individual neurons between high and low frequencies. We found that a substantial percentage of nearby neurons tended to co-vary, even though behavioral goals (i.e., reward) depended only on the activity of single neurons. Further, the exact pattern of task-relevant covariation could change with the identity of the neuron targeted for conditioning. Across conditions, most of the variance in the population could be accounted for by a few principal components, indicating distinct patterns of activity, but also substantial overlap among these patterns. Our results seem to favor the possibility that subjects draw from a fixed repetoire, which is not optimized for the control of single neurons. We suggest that the flexibility of a cortical population is constrained by some intrinsic structure -- perhaps due to network connectivity patterns and/or prior experience.

Abstract: Recently, research on invasive brain-computer interface (BCI) or brain-machine interface (BMI) is growing impressively for both experimental and clinical purposes. To date, most of BCI studies have targeted cortical neurons from motor-related cortex regions to extract neural signals. Based on the motor-related neuronal activities, various algorithms were proposed to control an external actuator such as robot arms, wheel chairs, and so forth. However, BMIs targeting motor-related cortex area are not always acceptable for patient who are suffering from disorders affecting motor-related brain areas including a stroke or a damage in a particular part of motor cortex. Therefore, another brain area to provide reliable neural signals for BMI is required. Previous study identified that prefrontal cortex (PFC) is a reasonable alternative. PFC is well known to be associated with behavioral flexibility, working memory, planning, spatial navigation, and goal-directed behavior. In the present study, 16-channel multi-electrode array is implanted in PFC of a rodent for *in vivo* neural signal recording. The animal was placed in a box with a wall equipped with a small cart containing pellet and controlled by two motors. In order to receive the food reward, the animal is required to control the cart position close to the open hole made on the transparent acrylic wall by modulating its brain activity in PFC.

Title: Local network coordination supports neuroprosthetic control

Authors: *W. A. LIBERTI, III[1,2], L. XUE GONG[2], A. YOU[2], N. VENDRELL LLOPIS[2], T. ROSEBERRY[2], R. M. COSTA[3], J. M. CARMENA[2]
[1]Biol., Boston Univ., Berkeley, CA; [2]UC Berkeley, Berkeley, CA; [3]Neurosci., Columbia Univ., New York, NY

Abstract: Several studies of neuroprosthetic learning have shown that after an initial phase of exploration, particular spatiotemporal activity patterns which lead to desired outcomes are selected and consolidated. Neurons that do not directly control a neuroprosthetic effector, termed ‘indirect’ neurons, show a suppression of modulation depth across learning, but can also

demonstrate tuning relative to the task. This suggests that these neurons become incorporated into functional neuronal assemblies that help coordinate neurons that directly drive an effector- but why this particular subset of neurons becomes involved, and how they act to stabilize and reinforce output- is not known. We used chronic single and multi-photon calcium imaging to create a Brain-Machine Interface (BMI) paradigm in which mice learned to perform a neuroprosthetic task using the coordinated activity of a small ensemble of neurons in layer 2/3 of somatosensory or motor cortex, guided by auditory feedback (Clancy, 2014). This approach provides long-term access to up to thousands of neurons, referenced to an easily quantified output layer of a few neuron's activity.
We find that the local cortical neural population in which these BMI output neurons are embedded rapidly converges to form reproducible activity patterns in order to achieve arbitrary, experimenter-defined neuroprosthetic actions. We find that a sparse population of indirect neurons form sequential patterns that precede and follow the activity of output neurons, and possibly contribute to the coordination of timing of cells that directly drive the effector. In this poster we examine the formation, structure and stability of local and distant neural populations that appear to coordinate individual output neurons in greater detail.

Title: The effects of a hypocretin receptor 1 antagonist on a pup retrieval task relevant for maternal motivation

Authors: A. SELKE, 92096[1], C. J. WHITTEN, 92096[1], *K. L. D'ANNA[2]
[1]Cal State San Marcos, San Marcos, CA; [2]Psychology, California State University, San Marcos, San Marcos, CA

Abstract: Hypocretin (HCRT) is a neuropeptide that is released from the lateral posterior hypothalamic region and has two receptors types, HCRTR-1 and HCRTR-2, with HCRT-1 having a strong affinity for both receptors. The HCRT-1 neuropeptide system has been associated with reward and motivation in drug-seeking behaviors, but unclear if this extends to other reward-linked behaviors such as pup retrieval in lactating dams. Therefore this study was conducted in order to investigate if the HCRT-1 system might be related to reward and

motivation in maternal care. We hypothesized that dams given the HCRT-1 receptor antagonist (HCRTR1A) would retrieve pups less quickly and show less overall more maternal behaviors than those given the control. Lactating dams were given either a HCRTR1 A (n=7) or vehicle control (n=7) and total time in or out of the goal box and number pups retrieved were recorded in a Tmaze. No significant differences in retrieving pups were found between the vehicle and the HCRTR1A groups ($F(22, 22.11) = .046$, $p = .831$). However, dams that were given the HCRTR1A stayed in the goal box longer (M = 490.43) than dams given a vehicle (M = 249.57; $F(12, 10.18) = .892$, $p < .01$). This work suggests that in a novel environment, HCRT-1 neurotransmission may play a role in exploratory behavior in the postpartum period. Future work should include the HCRT-2 system is needed to delineate the separate roles of HCRT-1 and HCRT-2 in our understanding of the neural networks involved with maternal behavior.

Title: The role of hypocretin in postnatal anxiety and reward responses to pup sensory stimuli

Authors: *G. H. LEE[1], J. KUSKE[2], K. L. D'ANNA-HERNANDEZ[2]
[1]California State Univ. San Marcos, Vista, CA; [2]California State Univ. San Marcos, San Marcos, CA

Abstract: Anxiety is associated with heightened arousal impairing daily-life functioning and maternal behavior. Although we are unclear of its underlying neuromechanisms, the hypothalamic neuropeptide hypocretin (HCRT) has been implicated in both anxiety and maternal behavior. During the perinatal period, several changes occur in the mother's body including increased arousal and wakefulness linked with lactation. Past literature has shown that HCRT modulates arousal and influences maternal behavior (e.g., nursing and nesting behavior in lactating dams). In the present study, fifteen lactating dams were injected with HCRTR1-antagonist (SB-334867; n=8) or saline (n=7), tested on the elevated zero maze (EZM) for five minutes, and scored on time and latency to head poke and enter open/closed arms. Time spent in open and closed arms in the EZM were not significant, whereas latency to head poke into the open was significant $t(13) = 2.28$, p = .04. Dams injected with the HCRTR1 -antagonist had a shorter latency to head poke into the open arms than those injected with saline. This suggests that blocking HCRT decreases arousal and anxiety-like behavior as the dams appeared less fearful to begin exploring the exposed areas. As dams had spent limited time on the open arms, a follow-up study was conducted using pups (on postnatal days 3-4) as a potential motivator on the EZM and

another measure of anxiety, the light/dark box (LBD). Transparent boxes were attached on the apparatuses to secure pups and placed in the exposed areas. About 27% and 80% of dams retrieved pups on the EZM and LDB, respectively. Altering anxiety-like tests to include pup retrieval may be more ecologically relevant measures of maternal anxiety. Given that HCRT has been linked to reward and motivation and pups are highly rewarding, HCRT may alter anxiety-like behavior and/or pup retrieval on these modified measures. To determine what aspects of pup stimuli activate HCRT neurotransmission in the brain, dams were exposed to either both their own pups and soiled bedding (n=6), soiled bedding only (n=7), pup-shaped items without bedding (n=9) or a control with no stimuli (n=7). Brains were double-labeled for cFos and prepro-HCRT. Cell counting is ongoing. This work suggests HCRT may play a role in the regulation of postnatal anxiety and reward.

Title: Corticosterone alters genomic activity of the reproductive axis

Authors: *A. M. BOOTH[1], S. AUSTIN[2], A. S. LANG[3], V. FARRAR[2], O. CALISI[4], T. CHEN[2], B. NAVA[2], M. MACMANES[3], R. M. CALISI[2]
[1]?Department of Neurobiology, Physiol. and Behavior, [2]Univ. of California, Davis, Davis, CA; [3]Univ. of New Hampshire, Durham, NH; [4]Boston Univ., Boston, MA

Abstract: Stress is a well-known cause of reproductive dysfunction in many species. The stress response generally involves an increase in adrenal glucocorticoid secretion, which can reduce activity of the reproductive, or hypothalamic-pituitary-gonadal (HPG), axis. Previously, we leveraged a highly replicated and sex-balanced experimental approach using the model of the rock dove (*Columba livia*) to understand how males and females respond to restraint stress at the level of their HPG transcriptome. In this follow-up experiment, we determined the role of the glucocorticoid corticosterone in HPG genomic differential expression. We injected male and female rock doves with corticosterone to mimic natural levels following 30 minutes of restraint stress. We found sex-biased changes in genomic activity specific to our corticosterone manipulation as compared to controls. Our data provide a vital genomic foundation on which sex-specific reproductive dysfunction attributable to corticosterone can be further studied, as well as novel gene targets for potential genetic intervention and therapy investigations.

Title: Assessing behavioral preference for mouse pup calls as a function of maternal experience and oxytocin signaling

Authors: *K. L. FURMAN[1,2], I. CARCEA[2], A. C. MAR[2], R. C. FROEMKE[1,2,3]
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Neurosci. and Physiol., NYU Sch. of Med., New York, NY; [3]Fac. Scholar, Howard Hughes Med. Inst., New York, NY

Abstract: When a mouse pup is removed from its nest, it emits ultrasonic vocalizations (USVs) to signal distress. Mother mice (dams) hear USVs, and respond by retrieving pups into the nest almost immediately. While dams will retrieve pups with 100% accuracy, virgin female mice without previous maternal experience fail to exhibit retrieval behavior. But after several days of cohousing with a dam and pups, virgins can begin retrieving pups reliably (Marlin et al., 2015). However, it is unclear if the USVs themselves have some degree of behavioral salience, are attractive or aversive to adult mice, and how this sensation might be affected by maternal experience.

Here we investigated innate and learned behavioral responses to auditory pup USVs, when these acoustic stimuli are presented through speakers in isolation, i.e., without pups or other pup-related sensory information (visual, olfactory). We behaviorally assessed the salience of these auditory cues in dams, pup-naïve virgins, and experienced (cohoused) virgins.

We performed two behavioral tests of animal spatial preference. First we used a spatial orientation behavioral paradigm, where USVs recorded from isolated pups were presented via ultrasonic speakers on one side of a modified T-maze with acoustically-isolated chambers at either end. We quantified the time animals spent in the chamber with the USV sounds vs the time spent in the other chamber or elsewhere in the T-maze. We found that pup-naïve virgins orient towards pup USVs, while dams and pup-experienced virgins show no orientation trend in either direction. This suggests that the USV stimulus, when played in isolation, is more salient for female mice with less maternal experience, possibly due to its novelty especially outside of behavioral context.

Second, we played different sounds in each chamber at the end of the T-maze arms. In one

chamber, USVs were presented, in the other chamber, pure tones were presented. Animals were sequentially placed in each chamber for 10 minutes during each stimulus presentation. After these two exposures, animals were given access to both chambers with no auditory cue. We found that animals tended to avoid the chamber in which they heard USVs, irrespective of maternal experience. This suggests that the USV stimulus is aversive to all groups, despite being salient to inexperienced virgins in the first behavioral test. Given these results, we are interested in investigating the role of oxytocin signaling in the preference or aversion towards pup USVs. In the future we will use optogenetic and pharmacogenetic approaches to investigate how formation of preference or aversion is affected by alterations to endogenous oxytocin systems.

Title: Late emerging effects of perinatal undernutrition on the dendritic spines of BLA neurons underlying the maternal response in the rat

Authors: *M. ORTIZ, M. REGALADO, C. TORRERO, M. SALAS
Inst. de Neurobiología, UNAM, Querétaro, Mexico

Abstract: Perinatal undernutrition (PU) interferes with the morphofunctional organization of the brain. The long-term effects of PU include alterations in the maternal response of the rat that correlates with perikaryal and dendritic arbor in the multipolar neurons of the basolateral amygdala (BLA) on days 4 and 12 of lactation. The mothers (F0) of the DPP group of (F1) rats, during pregnancy, received food restriction on different percentages (50, 70 and 100) throughout this period. After birth, undernutrition continued by ligating the milk ducts of one mother of a pair and changing dams between the litters every 12h, until weaning at 25 days of age. At 90 days of age, the F1 females were pregnant, and at the delivery evaluated for maternal behavior. Results showed significant prolonged latencies with abnormal retrieval pups; while on the frequency was only significant on day 12, for the DPP group. Reductions in the area and perimeter of perikaryal BLA multipolar neurons were identified on day 4, as well as alterations in the number of crossing and dendritic orders, although less consistent to the reductions in the number of spines in the PU group. The findings suggest that alterations in postsynaptic organization may affect the course of neuronal excitability, for the integration and coding of

signals that trigger the maternal response components altered in the early underfeed.

Title: What makes a parent? Genome to phenome changes in parental care of rock doves (columba livia)

Authors: *S. AUSTIN[1], A. LANG[2], M. MACMANES[2], R. M. CALISI[3]
[1]UC Davis, Davis, CA; [2]Univ. of New Hampshire, Durham, NH; [3]Neurobiology, Physiol. and Behavior, Univ. of California - Davis, Davis, CA

Abstract: The transition to parenting requires major changes to the physiology and behavior of an organism in order to promote offspring survival. Research continues to elucidate crucial endocrine players and pathways associated with this fundamental transition to parenthood, yet we know less about the underlying genomic activity that drives these behaviors. Using a socially monogamous species with biparental care, the rock dove (*Columba livia*), we ask, are the genetic mechanisms that facilitate similar behaviors in males and females the same across sex, or do they differ? Conversely, is the genomic origin of sex-specific behaviors the same or different? To address these questions, we used high-throughput sequencing to determine sex-biased differences in gene activity over the course of parental care. At nine different time points that range from non-breeding through to neonate care, we assessed levels of gene transcription in tissues critical for reproduction in vertebrates: the hypothalamus and lateral septum in the brain, the pituitary gland, and the testes and ovaries. We found a diversity of similar and sex-biased changes in gene expression across parental care stages. For instance, both sexes experience the same amount of differential gene expression in their brains and pituitaries when they transition from incubation to nestling care. However, males and females differ in the genes they express at the nestling care stage sampled by approximately 150 genes in the hypothalamus and 600 genes in the pituitary. We report changes in the activity of genes identified a priori for their known role in facilitating parental care, and we identify novel targets for further investigations. The results of this large-scale study offer significant insight into the genomic mechanisms driving maternal versus paternal care behaviors, from genome to phenome.

Title: Lactating birds: Gene expression of prolactin and its receptor in male and female rock doves

Authors: *V. S. FARRAR[1], B. M. NAVA ULTRERAS[1], S. H. AUSTIN[1], M. MACMANES[2], R. M. CALISI[3]
[1]Univ. of California Davis, Davis, CA; [2]Univ. of New Hampshire, Durham, NH; [3]Neurobiology, Physiol. and Behavior, Univ. of California - Davis, Davis, CA

Abstract: The hormone prolactin (PRL) plays a role in many physiological functions, but it is best known for its role in facilitating lactation and parental care behaviors. In birds, PRL helps initiate and maintain incubation and offspring provisioning. However, in rock doves (*Columba livia*), PRL also drives crop milk production in both sexes, a process akin to lactation in mammals. We asked how the gene activity of PRL and its receptor, PRL-R, change across the parental care stage in the brain and reproductive tissues, and if these changes are driven by an internal clock mechanism or the external environment (offspring presence). We quantified gene expression of PRL and PRL-R in male and female rock dove hypothalamus, pituitary, gonad, and crop organ at multiple time points across the parental care stage. To understand if changes in gene expression are internally or externally driven, we experimentally manipulated egg and hatchling presence. We found sex-, tissue-, and time-specific changes in PRL and PRL-R over the course of parental care. These data offer the highest resolution to date in any species of the behavior of PRL and PRL-R genes during the parental care stage. Specifically, our data offer significant insight into the regulatory mechanisms of avian crop-milk production and parental care.

Title: Effects of pregnancy stress on postpartum socioemotional behaviors and central serotonin 2A and 2C receptor expression

Authors: *E. M. VITALE[1], J. S. LONSTEIN[2]
[1]Behavioral Neurosci. Program, [2]Neurosci Program, Michigan State Univ., East Lansing, MI

Abstract: Mammalian mothers show a unique suite of behavioral responses beginning around the time of parturition, including increased offspring caregiving and low anxiety. The neurotransmitter serotonin (5-HT), which is synthesized by cells in the midbrain dorsal raphe nucleus (DR) and projects to many forebrain sites, regulates many of these postpartum socioemotional behaviors. Recent findings from our lab have revealed normal reproductive state-dependent changes in the expression of central 5-HT receptors, including a decrease in serotonin 2C receptor (5-HT2C) mRNA in the DR and an increase in serotonin 2A receptor (5-HT2A) mRNA in the medial preoptic area (mPOA) at parturition and early lactation. Interestingly, others have found that systemic activation of 5-HT2C or blockade of 5-HT2A during early lactation disrupts maternal behaviors. Stress during pregnancy also reduces maternal caregiving behaviors and leads to long-term changes in serotonergic signaling, suggesting that stress-induced alterations in this system may contribute to the resulting behavioral disruptions. The aim of the current study is to determine whether disrupted maternal caregiving and emotional behaviors due to pregnancy stress are associated with derailments in the normative expression of central 5-HT receptor expression. Repeated variable stress was employed during pregnancy and caregiving, anxiety-like, and depression-like behaviors were observed after parturition. RT-qPCR and western blotting was used to analyze 5-HT2C in the DR and 5-HT2A in the mPOA of stressed and unstressed dams. We predict that pregnancy stress will prevent or even reverse the normal peripartum changes in DR 5-HT2C and mPOA 5-HT2A receptor mRNA, which will be associated with reduced caregiving and increased anxiety. This work could reveal that disruptions in the normative expression of serotonin receptors in the DR and mPOA across reproduction may contribute to the stress-induced maladaptions in maternal caregiving and socioemotional responses often displayed during postpartum depression and anxiety.

Title: Molecular and functional profiling of neural populations involved in parental behavior

Authors: V. M. SEDWICK, I. CARTA, *A. E. AUTRY
Albert Einstein Col. of Med., Bronx, NY

Abstract: Parenting behavior is obligatory in many species and is particularly critical in mammals that rely on nursing for nutrition during early development. In laboratory mice, both fathers and mothers show behaviors associated with parental care such as nest building, pup retrieval, pup grooming, and crouching over pups. Virgin males and females, however, do not show robust parental behaviors and typically show neglect or even attack behavior toward pups. This behavioral change suggests that there are alterations in neural mechanisms that underlie social behaviors toward infants. In our lab, we aim to uncover the molecular and functional changes that lead to these opposite behavioral responses toward infants relative to the physiological status of the adult. In the present study, we profile candidate neural populations involved in both positive and negative regulation of parental behavior. In addition, we manipulate these neurons to determine how they impact parental behavior in various physiological conditions.

Title: RNAseq analysis of the mPOA in early postpartum Wistar-Kyoto rats reveals candidate genes associated with parenting deficits characteristic of postpartum depression

Authors: *S. B. WINOKUR, M. PEREIRA
Psychological and Brain Sci., Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: Postpartum depression (PPD) is a serious psychiatric disorder affecting 10-15% of mothers and their children worldwide. PPD causes deleterious effects on the mother's health and parenting abilities, posing a risk for the mother-infant relationship and infant developmental outcomes. While previous research suggests underlying cognitive, motivational, and affective dysfunctions contribute to the underlying pathology of PPD, little is understood about the underlying neurobiological mechanisms of PPD symptomatology that specifically impact parenting abilities. The present study used the Wistar-Kyoto (WKY) genetic rat model of depression in comparison to control Sprague-Dawley (SD) and Wistar (WIS) rats to identify candidate genes in the medial preoptic area (mPOA) that underlie the cognitive and parenting deficits that are representative of PPD symptomatology. These regions were selected because the mPOA plays a major role in orchestrating cognitive and motivational aspects of maternal behavior. Gestational stress (a known risk factor for PPD) was additionally used across an experimental group containing all strains, with the aim of exacerbating a PPD-like phenotype in SD and WIS mothers and creating a robust high severity PPD phenotype in WKYs. Comparisons across strains and stress vs. non-stress groups allows us to pinpoint possible candidate genes from multiple symptomatic angles. RNAseq transcriptomic analysis was used to identify differentially expressed genes (DEGs) in the mPOA and mPFC of all subjects. RNAseq revealed over 500 genes in the postpartum mPOA that had at least a 2-fold-change in expression between WKY and SD mothers, including oxytocin, mitogen-activated protein kinase, the monoamine signaling genes vesicular monoamine transporter 2 (Vmat2) and tyrosine hydroxylase (Th), and the immediate early genes Fos, FosB, and Egr1. Gene Ontology (GO) and enrichment analyses on DEGs identified signaling pathways associated with cellular metabolic and biological processes, including chromatin organization, synaptic plasticity, and response to stress and hormones. Together, these results provide insight into pathology of key symptoms of postpartum depression.

Title: Auditory cortex dependent reprogramming of an innate maternal behavior

Authors: A. G. DUNLAP[1], *R. C. LIU[2]
[1]Wallace H. Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol. and Emory Univ., Atlanta, GA; [2]Biol., Emory Univ. Dept. of Biol., Atlanta, GA

Abstract: Recent research into the neurobiology of rodent maternal care has revealed how its active motor components, like pup approach and retrieval, can be unlocked by the activation of subcortical circuits involving the medial preoptic area. When animals are in the appropriate internal state (e.g. mediated endogenously by reproductive hormones), natural pup cues trigger the activation of these circuits, releasing these maternal motor programs. However, the degree of flexibility in how these innate behaviors can be triggered by sensory stimuli is not well understood. Presumably, the ability to release these behaviors in response to novel cues that are predictive of infants would be highly adaptive for mothers, but how such new pup-associated stimuli would come to elicit maternal motor programs is unclear. Here, we use a pup reinforcer-based training paradigm to investigate whether female mice can incorporate a new sensory cue to guide their maternal motor program for pup retrieval. Trials begin with mice at its nest in the base of the T-maze. Two speakers are placed at either ends of the T's two arms, and a synthetic, amplitude-modulated noise stimulus is played from one of the two speakers to indicate which arm the mouse should enter to be given a pup. Pups, which are initially held outside the T-maze, are placed at the end of the arm associated with playback only after the mouse enters this "Correct" arm. The mouse then retrieves the pup back to the nest. If the mouse initially chooses the incorrect arm, they are allowed to subsequently investigate the other arm and receive the pup then without any punishments. We found that in this paradigm, mice have an innate strategy on the first day where on ~80% of the trials they return to the last arm where they previously received a pup on the last trial. In contrast, they correctly enter the playback arm on only ~40% of the trials on the first day, suggesting they do not use the novel sound to guide retrieval. Over the course of 8 days of training, the initial strategy shifts, wherein performance based on choosing the playback arm increases to ~60% of trials, while a strategy based on the last rewarded location drops to ~60%. After reversible, bilateral inactivation of auditory cortex with muscimol, we find that mice return to their initial strategy, and performance based on sound playback drops significantly ($n=3$, $p<0.05$). These results indicate that auditory cortex is required for using a learned, pup-associated sound to overcome an innate strategy for guiding pup approach. Our paradigm allows investigating how subcortically mediated maternal behaviors can be "reprogrammed" to utilize cortical representations of pup-associated cues.

Title: Effects of breastfeeding and oxytocin on the perception and recognition of facial expressions in mothers

Authors: *M. MATSUNAGA[1], T. KIKUSUI[2], R. OOYAMA[2], M. MYOWA[1]
[1]Kyoto Univ., Kyoto, Japan; [2]Azabu Univ., Kanagawa, Japan

Abstract: Breastfeeding, which is a highly conserved element of maternal care in mammals, is the first turn-taking interaction between a mother and infant. One mechanism for lactation, *oxytocin,* is necessary for milk let down. Past research has shown that exogenous oxytocin can enhance several social behaviors, including emotion perception and recognition. In this study, we investigated two topics: (i) the relationship between tonic/phasic breastfeeding behaviors and changes in endogenous oxytocin levels and (ii) whether tonic/phasic breastfeeding experience and oxytocin levels could enhance emotional processing (i.e., attention regulation in detecting emotional signals, recognition of emotion category, and/or arousal rating for facial expressions). Thirty-eight primiparous mothers (mean age = 33.29, range 28–43 years; SD = 4.85 years) participated in this study. The mean age of their infant was 6.6 months (19 boys and 19 girls; range 4–8 months; SD = 1.4 months). All participants were Japanese. Two kinds of emotional tasks were conducted, specifically “the emotion perception task” and “the emotion recognition task.” Each mother completed the tasks twice, before and after the manipulation phase. Half of the mothers breastfed (i.e., breastfeed manipulation) and the other half only held their infant (i.e., hold manipulation). In order to measure oxytocin level change, saliva was collected at two time-points: before manipulation (i.e., baseline oxytocin) and after manipulation. Additionally, accumulated breastfeeding experience was assessed by a questionnaire. Data showed the following three findings: (1) no relationship between tonic breastfeeding and baseline oxytocin level; (2) phasic oxytocin levels did not differ between the two manipulation types (i.e.,

breastfeed or hold). Half of mothers increased their oxytocin level just after manipulation, but the other half decreased their oxytocin level after manipulation. (3) Both tonic and phasic breastfeeding affected the detection of emotion signals (i.e., attention regulation). As a tonic effect, levels of accumulated breastfeeding and higher baseline oxytocin levels moderated the sensitivity to detect negative emotions. As a phasic effect, breastfeeding enhanced the sensitivity to detect both positive and negative emotional signals. These findings suggest that nurturing experience may change mother's emotional perception, with the possible mechanism of this effect being endogenous oxytocin function.

Title: Altered maternal investment in vasopressin 1b receptor knockout mice

Authors: *E. A. AULINO[1], S. K. WITCHEY[1], A. R. FREEMAN[2], H. K. CALDWELL[1]
[1]Dept. of Biol. Sci., Kent State Univ., Kent, OH; [2]Dept. of Psychology, Cornell Univ., Ithaca, NY

Abstract: Many mammal species, including mice, alter their reproductive investment based on social and environmental cues. One well-studied example of reduced investment is the Bruce effect, whereby there is the spontaneous termination of pregnancy if a female is exposed to unfamiliar male early in pregnancy. Similarly, there is evidence that exposure to a novel male late in pregnancy can result in diminished maternal care, representing a shift in maternal investment. Interestingly, female vasopressin 1b receptor knockout (Avpr1b –/–) mice do not exhibit the Bruce effect; i.e. no pregnancy block. Thus, we hypothesized that Avpr1b –/– females would not have impaired maternal investment if exposed to a novel male in late pregnancy. To test this hypothesis Avpr1b wild type (+/+) and Avpr1b –/– mice were mated and exposed to familiar or unfamiliar males beginning at approximately gestational day 14. Once born, litter weights were taken every three days, as a proxy of maternal investment, until pups were weaned at postnatal day 21. Weaned mice continued to be weighed until two months of age. Contrary to our hypothesis, preliminary data suggest that Avpr1b –/– dams exposed to novel males have reduced maternal investment, as their pups have low weights compared to controls. This genotypic difference in pup weights is only observed during nursing and is reconciled by weaning age, which is consistent with the literature on maternal investment.

Title: The effect of maternal experiences on spatiallearning and hippocampal neural plasticity

Authors: *M. FURUTA, A. FUKUSHIMA, T. AKEMA, T. FUNABASHI
St. Marianna Univ., Kawasaki, Japan

Abstract: It is well documented that, during postpartum period, many behaviors are affected. For example, an increased spatial learning ability is reported, but mechanisms for this change is obscure. Maternal experiences consist of a series of events including pregnancy, delivery, lactation and rearing. It remained to be determined which events can change the neural system of mother rats to govern their behavior. To determine the role of each maternal event in working memory tests, we studied in four experimental groups: nulliparity control, nulliparity that reared foster pups, primiparity without rearing experience and primiparity with all maternal events of pregnancy, delivery, lactation and rearing. In the present study, postpartum rats that resumed estrus cycle after weaning and nulliparity controls at the same age were subjected. Behavior was analyzed by Y-maze test for spatial learning assessments. In electrophysiological experiments, we induced long-term potentiation (LTP) by stimulating presynaptic fiber at 10 Hz (1.5 min duration) paired with postsynaptic depolarization in CA3 hippocampus using whole-cell patch-clamp. Further, the expression level of GluR1 and 2 was analyzed in the hippocampus by Western blot. As the results, LTP was induced, rectification index (RI: response at -60 mV/that at 40 mV) was high, AMPA/NMDA ratio was high, GluR2 expression was increased and spatial learning score was high in the primiparity group compared to those in the nulliparous group. The primiparity without rearing experience group also showed a significantly higher score of spatial learning than the nulliparity control group. The results suggest that maternal experience of delivery coupled with rearing most drastically change hippocampal function leading to improved spatial learning.

Title: Impaired aspects of maternal behavior in virgin mice lacking melanin concentrating hormone receptors

Authors: *L. ALHASSEN, A. ALACHKAR, K. ONOUYE, H. SHAHARUDDIN, A. LO, O. CIVELLI
Dept. of Pharmacology, Pharmaceut. Sciences, and Developmental and Cell, Univ. of California, Irvine, Irvine, CA

Abstract: Melanin concentrating hormone (MCH) has been implicated in the onset of maternal care in the postpartum period. However, it is not known whether MCH regulates components of maternal behavior that are independent of the hormonal and neurochemical changes associated with pregnancy and parturition. Here, we examined the effects of the deletion of MCH receptors (MCHR1) on maternal-related behaviors in virgin female mice. Our results reveal that deletion of MCHR1 impairs maternal behavior that is induced spontaneously upon pups' exposure. The MCHR1 KO mice spent a longer time in retrieving the pups compared with the WT mice. In support of this finding, we found that, in the three-chamber social test, MCHR1KO female mice spent similar time interacting with the pups-containing cup and the empty cup, indicating a lack of interest in interacting with pups. MCHR1 KO females were unable to detect pups' chemosensory signals and displayed impaired general olfactory discrimination. The number of Fos-positive neurons in brain regions known to be critical for maternal behavior was lower in MCHR1KO mice than WT mice. Our findings indicate that the lack of MCHR1 causes defects in maternal behavior in non-sensitized virgin mice, and that modulation of the olfactory signaling and reward system might be the mechanisms, through which MCH regulate maternal behavior in virgin mice.

Neurosciences, Cambridge, United Kingdom; [6]Div. of Neurosci. and Exptl. Psychology, Univ. of Manchester, Manchester, United Kingdom; [7]Neurobio. Res. Unit, Righospitalet, Copenhagen, Denmark

Abstract: Background: The personality trait neuroticism is associated with increased vulnerability to anxiety and mood disorders, conditions linked with abnormal serotonin neurotransmission and emotional processing. The interaction between neuroticism and serotonin during emotional processing is however not understood. Here we investigate how individual neuroticism scores influence the neural response to negative emotional faces and their sensitivity to serotonergic tone. Methods: Twenty healthy participants performed an emotional face task under functional MRI on three occasions: increased serotonin tone following infusion of a selective serotonin reuptake inhibitor (SSRI), decreased serotonin tone following acute tryptophan depletion (ATD) protocol, and no serotonin challenge (control). During the task, participants performed a gender-discrimination task of neutral, fearful or angry facial expressions. Results: Individual variations in neuroticism scores were associated with the neural response of subgenual anterior cingulate cortex to fearful facial expressions. The association was however opposite under the two serotoninergic challenges. The fear-related response in this region and individual neuroticism scores correlated negatively during the citalopram challenge and positively during the ATD. Conclusions: Neuroticism scales with the relative impact of serotonin challenges on fear processing in subgenual anterior cingulate cortex. This finding may represent a neural mechanism for the variable therapeutic effect of SSRI treatment observed in clinical populations.

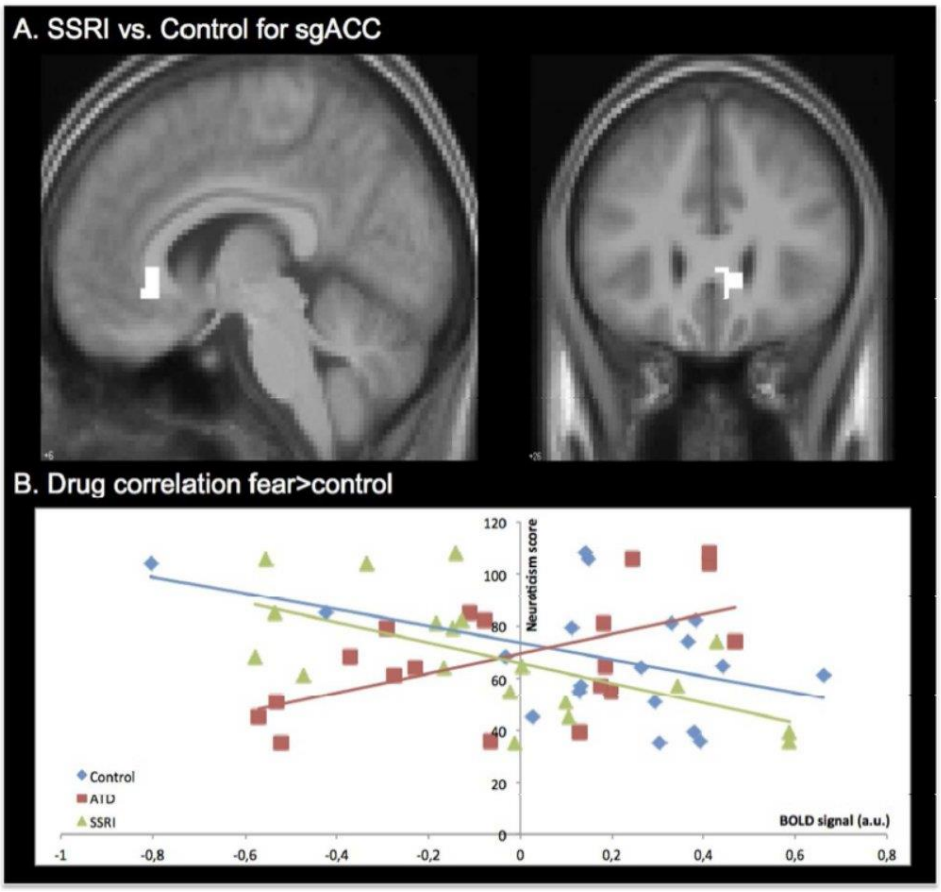

Figure 2: (A) Statistical parametric map (SPM) showing changes in activation for fearful face expressions relative to neutral faces during the SSRI challenge compared to baseline (control) in the subgenual cortex (sgACC). The SPM indicate changes in BOLD signal and are thresholded at p<0.001 (uncorrected). (B) Shows the correlation between the individual neuroticism scores and the BOLD response in the STG for SSRI, control and ATD challenges.

Title: Identify the whole brain inputs to different cell types in the LDT

Authors: *W. XIAOMENG, H. YANG, S. HAO, H. WANG
Institute of Neuroscience,Zhejiang University Scho, Zhejiang, China

Abstract: The laterodorsal tegmentum (LDT) has been recently recognized as a key brain structure involved in distinct behaviors including arousal, reward and innate fear when researchers using optogenetics to strictly manipulate different cell types in LDT. Identification of the cell type's specific inputs is the basis to clearly understand the distinct circuit's functions. Although previous studies have shown the whole brain inputs to the LDT, specific afferents of different cell types in the LDT are still unknown. In this study, using a modification of the rabies virus, we were able to apply a monosynaptic retrograde tracing technique to the whole brain to examine the cell type specific upstream nuclei of the LDT. Overall, the LDT receives very strong midbrain afferents and moderate hindbrain and hypothalamus innervations but exhibited weak connections to both of the cortical areas and the thalamus. Although different cell populations received qualitatively similar inputs, dominated by the afferents from the periaqueductal gray area (PAG), interstitial nucleus (In) and the LDT itself, significant differences were observed in that pavalbemin-positive (PV^+) GABAergic cells were preferentially projected by the local LDT neurons. Additionally, for different subtypes of GABAergic cells, a considerable number of nuclei, including those of the later habenular (LHb), central amygdaloid nucelus (Ce), lateral hypothalamus (LH) and zona incerta (Zi), made greater inputs to somatostatin-positive (SOM^+) cells than to PV^+ cells. Our study reveals a diverse input to the LDT on a system wide level.

Title: Nucleus accumbens cell-type specific control of operant aggression reward and relapse in hybrid transgenic mice

Authors: *S. A. GOLDEN, M. JIN, C. HEINS, M. MICHAELIDES, Y. SHAHAM
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Background: We recently reported that adult male outbred CD-1 mice will lever-press for the opportunity to attack younger male inbred C57 mice. These mice also relapsed to aggression seeking during abstinence. Here we studied the role of nucleus accumbens (NAc) D1- and D2-expressing medium spiny neurons (MSNs) in aggression self-administration and relapse. **Methods**: We first validated a transgenic hybrid breeding strategy, crossing male C57-based inbred D1-Cre and D2-Cre transgenic mice with female outbred CD-1 mice, and tested the hybrid male mice for aggression self-administration or relapse to aggression seeking in an extinction test on abstinence day 1. Next, we validated the use of sub-threshold clozapine as a ligand for DREADD activation by determining the effect of different clozapine doses on aggression self-administration. Finally, we tested the effect of sub-threshold clozapine (0.1 mg/kg) on aggression self-administration and relapse in D1- and D2-Cre hybrids, injected with either DIO-h4MDi or DIO-mCherry in NAc. **Results**: D1-Cre and D2-Cre transgenic mice showed robust aggression self-administration and relapse to aggression seeking. Additionally, systemic clozapine injections decreased aggression self-administration and relapse in D1- but not D2-Cre mice injected with DIO-h4MDi in NAc; clozapine had no effect in D1- or D2-Cre transgenic mice injected with DiO-mCherry. **Conclusions**: Our results indicate that NAc D1- but not D2- MSNs are critical for both aggression self-administration and relapse to aggression seeking. Our study also suggests that hybrid F1 crosses between outbred CD-1 mice and inbred C57-based Cre lines can be used to study mechanisms of operant aggression reward and relapse. Surgery, Weill Cornell Med. Col., New York, NY

Abstract: It has been shown that the level of interleukin 1 beta (IL-1β) in the periphery or cerebrospinal fluid correlates with aggressive traits in humans. Here, we aimed to study the functional role of IL-1β in mediating individual differences in aggression using a resident intruder mouse model. Like humans, outbred CD-1 mice show individual differences in aggressive behavior with two third of mice exhibiting a spectrum of aggressive behavior (termed Aggressors: AGG) and one third of mice showing no aggressive behavior (termed non-aggressors; NON). We first measured peripheral cytokines, and observed a phasic increase in IL-1β in the blood following an intruder encounter in both AGG and NON; however, there was no difference between groups. By contrast, we found significantly higher levels of central IL-1β in the dorsal raphe nucleus (DRN) in NON compared to AGG. To examine the role of IL-1β in the DRN, we injected an IL-1 receptor antagonist into the DRN. Our result showed that intra-DRN microinjection of IL-1 receptor antagonist increased aggressive behavior of male mice. Furthermore, knockdown of the IL-1 receptor (IL-1R1) in the DRN by injecting IL-1R1 shRNA expressing AAV caused an increase in aggressive behavior. Currently, we are examining the possible involvement of 5-HT neuron activity modulated by IL-1β on aggressive behavior. Together, our results indicate that IL-1R mediated pathways in the DRN have an inhibitory role on aggressive behavior.

Title: Aggressive behavior in forebrain-specific Ctgf knockout mice

Authors: *H.-C. CHANG[1], L.-J. LEE[1,2,3]
[1]Grad. Inst. of Anat. and Cell Biol., [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: In the nervous system, connective tissue growth factor (CTGF) is expressed in some distinct areas, such as the olfactory bulb, endopiriform nucleus and cortical subplate, but its

function is still largely unknown. We have generated forebrain-specific *Ctgf* knockout (Fb*Ctgf* KO) mice to investigate the role of CTGF in the brain. Fb*Ctgf* KO mice, being apparently normal, exhibited typical activity in the open field test; while displayed a sign of anxiety in the elevated-plus maze test. In the present study, we further explored the social behaviors of these mice. In the resident-intruder test, Fb*Ctgf* KO male mice showed greater aggressive behaviors than control mice, such as shorter latency of the first attack, greater attack counts and longer attack period. We then selected two aggression-related brain regions, medial amygdala and orbitofrontal cortex, for further exploration. In the medial amygdala, greater number of c-fos-positive cells was observed in Fb*Ctgf* KO mice compared with controls after the intruder test, while the basal levels of c-fos expression and numbers of NeuN-positive cells were similar between two genotypes. In the orbitofrontal cortex, the basal levels of c-fos- and NeuN-positive cells were comparable between control and mutant mice. After intruder stimulus, the numbers of c-fos-positive cells in both genotypes were increased to similar levels. The greater aggressive behaviors in Fb*Ctgf* KO mice might be resulted from by greater neural activity in the medial amygdala which is connected to CTGF-expressing olfactory structures. Our findings suggest a role of neuron-derived CTGF in modulating aggression-related behavior.

Title: Role of medial amygdala - hypothalamic GABA projections in aggression control

Authors: A. BALEISYTE, R. SCHNEGGENBURGER, *O. KOCHUBEY
Brain Mind Institute, EPFL, Lausanne, Switzerland

Abstract: Aggression is a behaviour that is misregulated in many psychiatric conditions such as autism, schizophrenia and bipolar disorder, but our knowledge about the neuronal circuits and synaptic pathways that control and modulate aggression is still incomplete. The medial amygdala (MeA) integrates socially relevant information from olfactory and pheromonal sensory inputs, and regulates social behavior. The majority of neurons in the posterodorsal MeA are GABAergic inhibitory neurons (~70%). However, the role of genetically defined sub-populations of these MeA-GABA neurons in social behavior has not been addressed; a recent study showed that stimulating MeA-GABA neurons led to increased aggression (Hong et al., 2014). Using a Cre-driver mouse line for Somatostatin (SOM-Cre), we found that ~20% of MeA-GABA neurons

express SOM. Surprisingly in light of the previous study, optogenetic activation of SOM+ MeA-GABA neurons *in-vivo* interrupted ongoing inter-male aggression and prevented the onset of new attacks in the resident-intruder test. To test whether the SOM+ sub-population might act antagonistically to all MeA-GABA neurons, we next stimulated all MeA-GABA neurons under the VGAT promoter, which similarly led to a suppression of ongoing aggression. To investigate the mechanism of how MeA-GABA neurons suppress aggression, we investigated the long-range output projections of these neurons. Using virus-mediated anterograde tracing, we found putative output synapses of VGAT+ and SOM+ neurons to similar degrees in the bed nucleus of stria terminalis and in some hypothalamic areas, whereas in the ventro-medial hypothalamus (VMH), a region previously identified in aggression control (Lin et al., 2011), SOM+ fibers from the MeA were sparser than VGAT+ fibers. In *ex-vivo* optogenetic mapping of synaptic connections, GABAergic inhibitory output connectivity in the VMH was sparser for SOM+ than for VGAT+ GABAergic fibers originating from the MeA. Using a second viral vector that drives the expression of eGFP under the VGluT2 promoter in the VMH, we found that MeA-GABA neurons directly inhibit glutamatergic neurons in the VMH. Thus, long-range inhibition from MeA-GABA neurons onto excitatory neurons in the VMH is likely one mechanism of how MeA-GABA neurons suppress inter-male territorial aggression.

Title: Maternal aggression depends on a prolactin- and oxytocin-sensitive switch in ventral premammillary nucleus (PMv) network behaviour

Authors: *A. S. STAGKOURAKIS[1], P. WILLIAMS[1], G. SPIGOLON[1], S. KHANAL[2], K. ZIEGLER[3], L. HEIKKINEN[1], G. FISONE[1], C. BROBERGER[1]
[1]Karolinska Institutet, Stockholm, Sweden; [2]Div. of Neurobio., Ludwig-Maximilians-Universität München, Munich, Germany; [3]Heidelberg Univ., Heidelberg, Germany

Abstract: Aggression is common among male laboratory rodents, but rarely observed in virgin females. Curiously, the female behavioural repertoire changes dramatically at the end of pregnancy and the birth of pups, when the dam can express intense aggression against both male and female intruders. The central adaptation underlying this phenotypic switch is poorly

understood. Dopamine-transporter-expressing neurons in the hypothalamic ventral premammillary nucleus ("PMv^{DAT} cells") have recently been shown to drive intermale aggression, and PMv^{DAT} excitability correlates to aggression phenotype in males. We therefore hypothesized that functional plasticity in PMv^{DAT} neurons may underlie the emergence of aggression in dams. Aggressive encounters in the resident-intruder test induced activation of PMv^{DAT} neurons in dams, in the form of c-fos immunoreactivity. Optogenetic activation of PMv^{DAT} neurons in lactating dams triggered attack in the resident-intruder test; optogenetic inhibition of these cells reduced attack duration. Maternal care was assessed in the pup retrieval test, where optogenetic PMv^{DAT} activation resulted in impaired performance, by a reduction of successful retrieval episodes and an increased latency to the first pup retrieval. Genetic (caspase3-medited) ablation of PMv^{DAT} neurons in dams resulted in reduced maternal aggression, but had no impact on maternal care. We hypothesized that the increased circulating levels of the hormone, prolactin, typical of the lactating dam, might be involved in these behavioural changes. Notably, PMv^{DAT} cells in lactating dams exhibited elevated pSTAT5 immunoreactivity compared to virgins, indicative of increased prolactin receptor-mediated activation. In whole-cell patch clamp slice recordings, application of prolactin (500 nM) to PMv^{DAT} neurons resulted in depolarization and action potential discharge. Similar effects were observed with the hormone oxytocin, which also peaks during nursing. This augmented excitability was associated with a post-synaptic potentiation of T-type Ca^{2+} currents and an increase in synaptic input. Lastly, we tested if maternal behaviours can be induced in virgin females by local application of maternal hormones into the PMv (via bilateral osmotic minipumps over 30 days). Both prolactin and oxytocin inhibited pup retrieval, but did not induce aggression, similar to the effects of optogenetic PMv^{DAT} stimulation in virgins. These results reveal that a *post-partum* switch in PMv^{DAT} neuron activity, which can be stimulated by prolactin and oxytocin, is instrumental in driving maternal aggression, and has a concurrent inhibitory effect on maternal care.

Title: Intranasal vasopressin increases aggression during courtship in a dose-dependent manner in California mice (peromyscus californicus)

Authors: *E. KASTAR, C. D. GUOYNES, A. P. AUGER, C. MARLER
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Intranasal vasopressin increases aggression during courtship in a dose-dependent manner in California mice (*Peromyscus californicus*)
Erin Kastar, Caleigh Guoynes, Anthony Auger, Catherine Marler
Vasopressin (AVP) is a neuropeptide that modulates complex social behaviors such as pair bonding, aggression, and stress. Previous studies have shown different behavioral effects of AVP, possibly because some studies use different doses of AVP or because of cross talk with oxytocin (OT) receptors. There is a gap in our understanding of how AVP in males and females influences aggression in courtship. Here we use a dose response study to examine how different doses of AVP influence social interactions between males and females. In addition, we use intranasal AVP to mimic administration and doses used in human research with potential applications for therapy of social disorders. We assess AVP's effects on aggressive, affiliative, and stress-related behaviors during an encounter with a novel member of the opposite sex in the strictly monogamous and territorial California mouse (*Peromyscus californicus*). Previous studies in our lab demonstrated that OT
decreased aggression during courtship in males, suggesting that neuropeptides may play an important role in social receptivity toward a potential mate. Using a similar paradigm as in the OT study, males and females were administered one of four treatments using intranasal infusions: saline control, 0.05 IU of AVP (low), 0.5 IU of AVP (medium), or 5.0 IU of AVP (high) (N=8 per group). We found that low and medium doses of AVP significantly increased aggression and significantly decreased stress-related behaviors during courtship in both males and females. The high dose in both males and females did not differ from saline. There was no effect on affiliation in either males or females at any dose. We will also examine which brain areas are activated by the different doses of AVP by CREB and p-CREB in social and decision-making brain areas such as the central and medial amygdala, ventral hippocampus, and medial prefrontal cortex using Western blots. We hypothesize that while the saline and high dose of AVP are behaviorally similar, they will be activating different brain regions. Overall, these studies will illuminate our understanding regarding the complex interactions of neuropeptide systems on both affiliative and aggressive behavior.

Title: Prefrontal cortex exerts top down control over the ventromedial hypothalamus to regulate aggressive behaviors

Authors: *N. MACK[1], B. XING[2], W.-J. GAO[3]
[1]Dept. of Neurobio. and Anat., [2]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [3]Dept Neurobiol & Anat., Drexel Univ. Col. Med., Philadelphia, PA

Abstract: Many neuropsychiatric disorders such as schizophrenia, depression, and drug addiction involve abnormal social behavior, increased aggression, and hypofunction of the medial prefrontal cortex (mPFC). As an executive center for top-down control of social behavior in humans, how the mPFC regulates aggressive and social behaviors via subcortical structures remains elusive. The ventromedial hypothalamus (VMH) is well characterized with the ventrolateral sub region (VHMvl) being of a critical aggression locus in rodents. In this study, we explore whether and how the mPFC controls aggression in both male and female mice. Using Cre-dependent retrograde tracer and excitatory DREADD viral vector, we identified several projection cells to the VMHvl from lamina 5/6 of the mPFC. We found that c-fos expression in the mPFC overlaps with the mPFC-VHMvl projection cells following a male-male attack (n=4). With a chemogenetic approach to functionally activate the pathway, our preliminary data suggest that activating the mPFC to VHMvl pathway increases the number of attacks in males (n=6) but not female (n=4) mice subjected to the resident-intruder task without affecting locomotion, indicating a sex difference. Future directions include increasing sample size, confirming the results with optogenetic stimulation, characterizing electrophysiological properties of the projections cells in the mPFC, and identifying the mechanism of sex difference.

Title: Novel mechanistic insights on panic disorder

Authors: *A. WINTER[1], R. AHLBRAND[1], R. SAH[2]
[1]Psychiatry, Univ. of Cincinnati, Cincinnati, OH; [2]Psychiatry & Behavioral Neurosci., Univ. Cincinnati, Cincinnati, OH

Abstract: Panic disorder (PD) is a prevalent anxiety disorder. Existing treatments are limited and many patients are unresponsive, highlighting the need for improved mechanistic understanding and identification of therapeutic targets. PD's hallmark is recurrent panic attacks; episodes of extreme fear and physical discomfort. Often, panic attacks occur spontaneously without external threats, suggesting internal homeostatic disturbances as triggers. Accordingly, PD patients are sensitive to pH imbalances, as panic attacks are triggered by acidosis-evoking agents such as carbon dioxide (CO_2). *We hypothesized that specialized homeostatic sensory regions in the brain would play a relevant role*. The subfornical organ is a homeostatic regulatory area devoid of a blood brain barrier. Previous work from our lab reported unique CO_2 detecting mechanisms within the SFO. Utilizing, site-directed brain infusions and transgenic mice, coupled with FOS mapping as methods, the current project a) investigated whether acidosis within the SFO was sufficient to evoke fear b) identified angiotensin receptors as a novel target in CO_2-evoked fear c) mapped contributory circuits. We report that infusion of acidified aCSF into the SFO evoked significant freezing in mice. Importantly, mice lacking CO_2-chemosensing receptors within the SFO did not elicit this response. Infusion of angiotensin receptor antagonist, losartan, near the SFO resulted in significant attenuation of CO_2-evoked fear. FOS mapping identified forebrain (IL, BNST) and midbrain (PAG) fear regulatory areas as significant contributors to the behavioral effects. Ongoing studies are utilizing chemogenetic and optogenetic manipulations to modulate identified circuits. Our studies identify novel mechanisms and circuits (Fig 1) by which homeostatic pH imbalance may trigger extreme fear associated with panic attacks, leading to therapeutic interventions for PD.

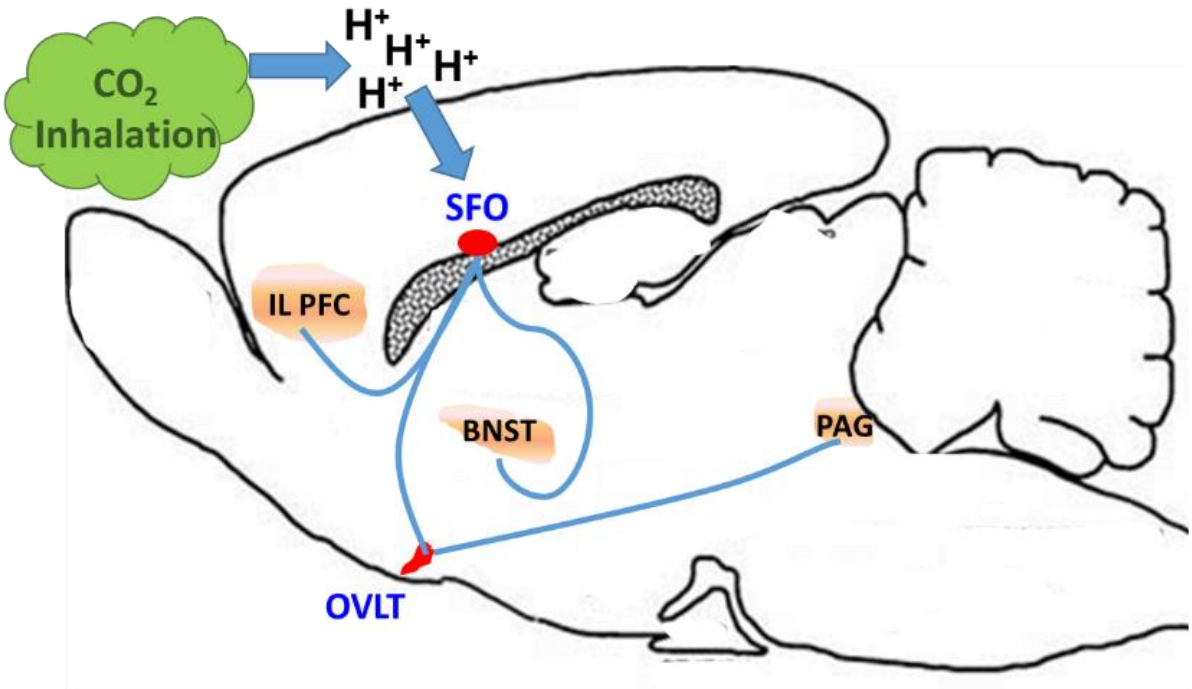

Figure 1: Circuits recruited in homeostatic pH threat-evoked fear: SFO detects acidosis and engages downstream fear regulatory regions. (IL, infralimbic cortex; BNST, bed nucleus of the stria terminalis; PAG, periaqueductal gray)

Title: Effects of prenatal exposure to endocrine disruptors and chronic exposure to estradiol in adulthood on stress-related behavior in female rats

Authors: *A. KAIMAL[1], J. M. HOOVERSMITH[2], A. D. CHERRY[1], N. M. MARTIN[1], H. E. BUECHTER[1], P. V. HOLMES[2], S. M. MOHANKUMAR[1], P. S. MOHANKUMAR[1]
[1]Vet. Biosci. and Diagnos. Imaging, [2]Biomed. and Hlth. Sci. Inst. (BHSI) Neurosci. Div., Univ. of Georgia, Athens, GA

Abstract: Developmental exposure to low doses of endocrine disrupting chemicals (EDCs), including the widely prevalent bisphenol A (BPA) and di(2-ethylhexyl) phthalate (DEHP), has been shown to produce a predisposition to behavioral disorders in later life. Additionally, changes in estrogen are associated with the development of mood and anxiety disorders in women. We examined the combined effects of prenatal exposure to these chemicals followed by chronic estradiol exposure in adulthood on behavior in female rats. Dams were orally administered saline (control; 10 µL/kg), BPA (5 µg/kg), DEHP (7.5 mg/kg) or a combination of BPA+DEHP during days 6 through 21 of pregnancy. Adult female offspring were sham-implanted or implanted with pellets that release 17β-estradiol (E2) for 90 days (20 ng/day; Innovative Research America). Rats were tested in the shock probe defensive burying (SPDB) paradigm. E2 treatment reduced rearing and probe exploration and increased immobility time in control animals, compared to control shams. This suggests that E2 exposure may induce a phenotypic shift to a passive threat response. Prenatal exposure to BPA had no effect on any of the parameters in the SPDB compared to control shams. E2 treatment did not change the response in BPA-exposed animals. This suggests that prenatal BPA exposure may reduce the sensitivity to E2 in adulthood. Prenatal exposure to DEHP reduced rearing and probe exploration compared to control shams. E2 treatment reduced these behaviors even further. However, the DEHP-treated groups resembled the control groups in the amount of time spent burying and immobile. Prenatal exposure to BPA+DEHP did not affect any of the measures except for reducing rearing frequency after E2 treatment. In conclusion, 1) E2 exposure induces differential threat responses in control offspring 2) offspring prenatally exposed to BPA appear to be desensitized to these estrogenic effects, 3) prenatal exposure to DEHP produces a partially aberrant response, and 4) BPA+DEHP offspring do not show robust differences in any behavioral measure, but exhibit similarities to BPA-exposed offspring in the SPDB.

Title: Tactile stimulation facilitates flight responses via ventral zona incerta

Authors: *X. WANG[1], X. CHOU[2], L. I. ZHANG[2], H. TAO[3]
[1]USC, Monterey Park, CA; [2]Zilkha Neurogenetic Inst., Los Angeles, CA; [3]USC Keck Sch. Med., Los Angeles, CA

Abstract: Zona incerta (ZI), a functionally mysterious subthalamic nucleus, receives extensive inputs from cortical regions and projects to both the motor thalamus and midbrain nuclei. Previous studies have suggested involvements of ZI in several physiological functions including defense regulation. The present study provides evidence that the parvalbumin positive neurons in the ventral division of ZI (ZIv) directly modulate sound-induced flight response via its projection to the motor part of the posterior complex of the thalamus (POm). Moreover, we found that tactile stimulation could enhance sound-induced flight response, likely through the activation of the projection from the somatosensory cortex to ZIv. Together these findings suggest that somatosensory information may modulate sound-induced flight through recruitments of ZIv.

Title: Subcortical circuits balancing attack and defense during predatory hunting

Authors: *D. ROSSIER, V. LA FRANCA, C. GROSS
Epigenetic and Neurobio. Unit, European Mol. Biol. Lab. (EMBL) Rome, Monterotondo, Italy

Abstract: Adaptation of innate behaviors to their potential risk and benefit is essential for the survival of most animal species. In predatory hunting, prey defensive responses can represent a significant danger to the predator. To engage in hunting, the predator's motivation to hunt needs to overcome prey fearing. The circuits involved in balancing fear and attack during predatory hunting remain largely unexplored. When mice are given access for the first time to cockroaches, a natural murine prey, they show intense defensive behaviors that are gradually replaced, with experience, by predatory behaviors. Using mice as a model for predatory hunting, we found that optogenetic stimulation of a subset of GABAergic neurons in the *lateral hypothalamus* (LHA) specifically drives hunting behaviors. Stimulation of these neurons' axonal projections to the *periaqueductal grey* (PAG) decreased defensive behaviors to prey and drastically reduced the latency to hunt in naïve animals. We compared neuronal activity in the LHA of naïve and

hunting-trained animals using *in-vivo* calcium imaging. Consistent with our optogenetic experiments, we observed that the activity of a defined subset of LHA GABAergic neurons correlates with hunting episodes. Together, our results suggest that this neuronal subpopulation encoding the motivation to hunt inhibits defensive behaviors through projections to the PAG to counter-balance fear associated with attacking prey.

Title: Functional mapping of periaqueductal gray cell types identifies innate defense circuits

Authors: *E. F. TSANG, I. PRANKERD, C. T. GROSS
EMBL Epigenetics & Neurobio. Unit, Monterotondo, Italy

Abstract: The midbrain periaqueductal gray (PAG) is commonly recognised as the exit relay for the coordination and execution of a wide range of instinctive behaviours, such as defense, reproduction and predation. In line with its functional diversity, are the range of inputs it receives from higher cortical and subcortical areas as well as ascending spinal pathways, and the various neurotransmitter and neuromodulatory mechanisms active in its different subregions. However, the lack of a comprehensive cell-type classification of the PAG hinders systematic investigations into the intricacies of its many behavioural roles. Here, we applied high-throughput single neuronal nucleus RNA sequencing to profile transcriptomes of adult mouse PAG neurons. In addition, using a combination of optogenetically manipulations and a carefully designed defense test battery, we identified key excitatory and inhibitiory PAG neuronal populations important for triggering and modulating defensive behaviour. Our work aims to provide a comprehensive transcriptional perspective of the PAG, and demonstrates a framework towards a systematic dissection of cell-type specific functions of complex brain regions.

Title: Social challenge: Understanding dynamics of VMH in defence and aggression

Authors: *P. KRZYWKOWSKI[1], C. T. GROSS[2]
[1]European Mol. Biol. Lab., Monterotondo, Italy; [2]Epigenetics & Neurobio. Unit, EMBL, Monterotondo, Italy

Abstract: Exposure to a threatening conspecific can elicit either avoidance or aggression depending on the context and history of the encounter. Neural activity in the ventrolateral division of the ventromedial hypothalamus (VMHvl) has been shown to be both necessary and sufficient for defensive and aggressive behavioural responses to conspecific threats. In male mice, inhibition of neural activity in VMHvl reduces avoidance behavior following exposure to an aggressive male as well as attack behavior following exposure to a subordinate male. However, it remains unknown whether the same or different neurons in VMHvl are responsible for defense and aggression toward social threat and how experience affects these responses. We performed serial cFos labelling experiments and found that defence and aggression recruited partially overlapping populations in VMHvl, consistent with a recent study. Using in vivo calcium endoscopy of VMHvl neuron activity during social defense and aggression we found that strong calcium responses were elicited upon exposure to the social stimulus and these were further modulated as the animal exhibited defensive or aggressive behaviours. Notably, specific calcium responses were identified that were entrained to defensive behaviours and these could be tracked across multiple exposures to the social stimulus. In parallel, we performed optogenetic stimulation of cell-types in VMHvl and identified two populations that elicited defensive responses to a social threat. These results demonstrate that the VMHvl encodes and controls both specific and overlapping features of defensive and aggressive behavioural responses to social threat.

Title: Localization of aggression-induced c-Fos immunoreactivity in the brain of male layer chicks

Authors: *S.-I. KAWAKAMI
Hiroshima Univ. Grad. Sch. of Biosphere Sci., Hiroshima, Japan

Abstract: Although aggression is a normal display of an instinct in almost all animals, excessive aggression leads to serious economic problems in poultry industries. We have recently reported that a kind of behavioral test, named resident-intruder test, is an effective tool for monitoring aggressive behavior of male layer chicks (J. Poult. Sci., 54: 296-302, 2017), the aim of the present study was, therefore, to examine the localization of aggression-induced c-Fos immunoreactivity in the brain of male layer chicks under the test. From 3 days of age, the chicks were divided into 2 groups, isolated-housing (residents: 1 chick per cage, as aggressors) and grouped-housing (intruders: 3 or 4 chicks per cage, as opponents), and a group-raised chick (opponent) was transferred to the home cage where a chick of isolated-raising (aggressor) was reared. The frequencies of aggressive behavior (pecking, biting, kicking, threatening, and leaping) and latency of both the aggressor and the opponent were recorded for 10 minutes. After 2 h of the treatments, the aggressor chicks were anesthetized with sodium pentobarbital and then perfused transcardially with phosphate buffered saline followed by 4% paraformaldehyde. The brains were coronally cut using a cryostat to make 20 μm-frozen sections. The sections were incubated with mouse primary antibody against c-Fos, then with biotinylated horse anti-mouse IgG followed by incubation in avidin-biotin-peroxidase complex. Digital images were captured using fluorescence microscope and analyzed with image processing software (ImageJ). The sum of the frequencies of aggressive behavior significantly increased and latency significantly decreased in the aggressors compared to those in the opponents. Aggression-induced c-Fos immunoreactivities were mainly observed in the hypothalamus and limbic system of the chick brain. In the hypothalamus, c-Fos immunoreactivities were localized in the median preoptic nucleus, the nucleus of the hippocampal commissure, the paraventric nucleus rostral and parvicellular part, the arcuate hypothalamic nucleus (ARC), and the ventromedial nucleus of hypothalamus (VMH). c-Fos immunoreactivities were localized sparsely in the VMH and densely in the ARC as compared to the previous reports of rodents. In the limbic system, c-Fos immunoreactivities were localized in the amygdalohippocampal area and mammillary body.

These results suggest that the localization of aggression-induced c-Fos immunoreactivities in chick brain, except in the VMH and ARC, corresponded approximately to the brain area in which the immunoreactivities had been previously reported on rodents.

Title: The *Drosophila* nervy gene functions in octopaminergic neurons to suppress aggressive behaviors

Authors: *K. ISHII, K. ASAHINA
The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Aggressive behaviors are generally important for animals to gain competitive advantages over other individuals. On the other hand, excessive aggression is energetically costly and often interferes with other behaviors. To appropriately balance aggressive and non-aggressive behaviors, animals must have evolved sophisticated systems for modulating action choices. Recent studies have focused primarily on the activation of aggression by neuromodulatory systems, but how aggression is suppressed remains poorly understood.
We performed an RNAi-based behavioral screen in *Drosophila* to identify genes that suppress aggressive behaviors. Among >1,400 RNAi strains, we found that pan-neuronal RNAi against the gene *nervy* significantly increased aggression. Temporal RNAi of *nervy* during larval and pupal stages was sufficient to induce an aggressive phenotype in adults, suggesting it plays a role in neuronal wiring during development.
We generated CRISPR/Cas9-mediated knockout mutants of *nervy* (*Δnervy*), and confirmed that *nervy* was indeed necessary to dampen aggressiveness. Interestingly, not only males but also females were more aggressive in *Δnervy* than in the wild-type. The hyper-aggressive phenotype of *Δnervy* flies were rescued by pan-neuronal expression of the full-length *nervy* gene. Genetic rescue was not achieved by expressing a truncated version of Nervy that lacked its conserved NHR2 domain, which was required to form homo-multimers of Nervy proteins. Furthermore, expression of *MTG8* and *MTG16*, human homologs of *nervy*, reduced levels of aggression in *Δnervy* mutants.

To determine the neurons in which *nervy* acts, we performed a screen using selected GAL4 lines combined with a *nervy* RNAi line. Expressing the *nervy* RNAi construct via Tdc2-GAL4, which specifically labels 30-40 octopaminergic neurons in the adult brain, increased aggressiveness. In addition, expressing the full-length *nervy* gene via Tdc2-GAL4 resulted in cell type-specific rescue of the *Δnervy* hyper-aggressive phenotype.
To our knowledge, *nervy* is the first *Drosophila* gene implicated in the quantitative regulation of aggressive behavior in both sexes. The *nervy* gene therefore provides an entry point for uncovering the conserved, sex-invariant genetic mechanisms that control aggression.

Title: Characterization of the olfactory response in the establishment of hierarchical order in crayfish

Authors: I. HERNÁNDEZ-PRIOR, Z. PEÑA-LEAL, F. U. ROSAS-VALDÉZ, Y. PITALUGA-JAVIER, K. MENDOZA-ÁNGELES, *J. HERNANDEZ-FALCON
Univ. Nacional Autónoma de México, Ciudad de Mexico, Mexico

Abstract: Sensory systems provide an organism with information about both the inner and the external environments. This information is then processed in higher centers of the brain in order to produce an adequate response. Agonistic behavior in crayfish seems to depend mainly on olfactory information carried out by a putative compound released in urine streams that each contender release during social interactions. This putative compound has not been identified but the lack of olfactory information, by the blockade of olfactory receptors, induces long-lasting fights between contenders even after the hierarchical order was previously established. The main goal of this work was to identify brain and chemoreceptor, electrical responses during the establishment of dominant-submissive hierarchical order in adult crayfish.We used adult male crayfish implanted, under cold anesthesia, with a brain electrode, on the olfactory lobe, and simultaneously a peripheral electrode that recorded chemoreceptor activity from the ipsilateral antennule. In triads of crayfish we videotaped agonistic interactions until a hierarchical order was established. Then we applied urine from the dominant animal on the recorded antennule of a submissive one and recorded the central and peripheral response as well as the behavior of the

animal. We also recorded the response of the dominant animal when urine of a submissive one was applied on the antennule. Urine from the dominant animal induced a bimodal electrical response, an immediate reduction in the electrical activity of both the brain and the antennule, followed by bursts of discharges with variable duration. Behaviorally, the stimulated animal increased locomotor activity and showed even an escape response. Urine from a submissive crayfish applied to a dominant one, was accompanied by less intense electrophysiological response without behavioral changes. These results point out to a putative compound released in urine during agonistic encounters that allow the recognition of conspecifics and, probably, the hierarchical status.

Title: Analytical and behavioral characterization of procambarus clarkii after chronic serotonin exposure

Authors: *N. K. MCLAUGHLIN, I. J. HARRIS, K. STUMPO
Univ. of Scranton, Scranton, PA

Abstract: Crayfish often serve as a common model of agonistic behavior due to their innate aggression towards each other. As recorded, both sexes show similar characteristics of behavior when fighting each other. Crayfish aggression can be classified based on its interaction allowing for simplistic observation and recording of data. Additionally, crayfish offer an elementary and well understood nervous system that is prime for chemical manipulation. With these factors in mind, crayfish are a suitable choice for experimentation in this research.In this experiment, crayfish(n=16) were immersed to 424 ng/L of serotonin(5-HT) that was directly injected into their water. Additional crayfish (n=16) were also subjected to standard conditions (tap water) with no drug injection. These conditions were maintained everyday for two weeks, with daily water changes. Ideally, this concentration represents the amount of serotonin that selective serotonin reuptake inhibitors (SSRI) would provide crayfish in natural locations owing to the rise of antidepressant usage and the subsequent release of these compounds from wastewater treatment plants After the prolonged period of drugging, the crayfish were then fought and their aggression score was recorded. As hypothesized, the preliminary behavioral data shows that the serotonin does have an effect on the crayfish aggression score. Additionally, this experiment will serve as a baseline comparison to that of SSRIs.Chemical analysis of the crayfish brain will

provide additional understanding into the neuromodulatory system of crayfish. Due to the chronic effect of 5-HT and Sertraline it is unknown what kinds of effects are present. Further work will be done to quantify and localize serotonin in the brain of crayfish. Analytical chemistry techniques such as High Performance Liquid Chromatography with electrochemical detector (HPLC-ECD) and Mass Spectrometry Time-of-Flight (TOF-MS) will be used to achieve such goals

Title: Effects of testosterone manipulation and personality traits on arginine vasopressin immunoreactivity in brook trout (salvelinus fontinalis)

Authors: *E. G. PLOPPERT[1], C. GOWAN[2], M. BARDI[1]
[1]Behavioral Neurosci., [2]Biol., Randolph-Macon Col., Ashland, VA

Abstract: In social animals, decision-making regulatory systems encode the salience of social stimuli that ultimately determine the adaptive response of the animal (O'Connell & Hofmann, 2011). The preoptic area (POA) is a central node in these neural systems, which regulates both sexual male behavior and aggressive behavior in most vertebrate species (Hull & Dominguez, 2007). The activity of sex steroids such as testosterone (T), peptides hormones such as oxytocin (OT) and arginine vasopressin (AVP), and various monoamines (such as dopamine) may play a crucial role in the decision-making during agonistic encounters. Little is known, however, of how individual personality influences these neural processes. Personality is defined as consistent behavior of an individual within a given context. Previous studies in our laboratory have identified a significant correlation between personality and aggressive behavior in social context (White & Gowan, 2012). In the first phase of the current study, 20 brook trout were exposed to the open field test (OFT) for three consecutive days. Subsequently, pairs of subjects were size matched to eliminate the effect of fish size on behavior and introduced to a novel arena where social interactions were recorded over a 2.5 hour period. Blood was drawn from each fish at the end of the period and blood was analyzed for levels of testosterone and cortisol. A significant negative relationship was found between cortisol and testosterone. Additionally, although no relationship was found between hormone levels and OFT scores or the amount of aggression displayed during agonistic interactions, using multidimensional scaling we were able to correctly predict the decision-making of individuals on the basis of their personality and T levels.

Following this phase, exogenous T was administered to the fish. A significant spike in peripheral T levels was observed after the injection, which was related to a significant increase in aggressive behavior during the OFT. In the final phase of the study, brains will be exposed to immunocytochemistry to determine the effects of exogenous T and personality on c-Fos-, glucocorticoid receptor-, and AVP-immunoreactivity in the POA, as a way to assess the role of personality in encoding information from the social environment and in shaping adaptive behavior.

Title: Expanding the use of recognition memory paradigms with the what-when-where episodic-like memory task to assess effects of gonadal hormones on cognitive function in adult rats

Authors: *M. CONNER[1], B. J. ANDERSON[2], M. F. KRITZER[1]
[1]Neurobio. and Behavior, [2]Psychology, Stony Brook Univ., Stony Brook, NY

Abstract: Gonadal hormones influence complex cognitive and mnemonic function of the prefrontal cortex and hippocampus. However, obtaining clear behavioral evidence for this influence in rodents can be difficult due to hormone effects on non-cognitive endpoints such as sensitivity to stress and reward. These actions can impact behavioral performance in positively or negatively motivated tasks in ways that are independent of any effects on cognition. However, a recent review highlights the benefits of object recognition memory tasks for isolating neuroendocrine influence on cognitive behaviors; as described, novel object recognition and location paradigms are low stress and rely on rodents' natural preference for novelty, making them especially well suited for parsing estrogen and androgen effects on higher order processes (Luine, Behav. Brain Res., 285, 2015). Here, we used a different sort of object recognition paradigm-- the What-Where-When (WWWhen) episodic-like memory task, to further explore hormone effects on cognitive and mnemonic operations. The WWWhen task involves sequentially exposing rats to two distinct arrays of four identical objects and a third test exposure where two objects from the second array are presented in original positions and two objects from the first array are presented with one in a new position. Using adult male, female and gonadectomized (GDX) male rats with and without estradiol (GDX-E) or testosterone propionate

(GDX-TP) we analyzed rats' differential object explorations during the test trial. As expected, gonadally intact rats preferentially explored objects from the first over the second array (What, When) and among first array objects further preferred those that were displaced (Where). GDX rats, however, showed no object preferences based on spatial location or recency. Finally, data from hormone-replaced GDX rats showed that both E and TP rescued recognition of novelty based on 'What' and 'When' while TP alone preserved recognition of novelty based on 'Where'. Together these data support the utility of recognition memory tasks for studying hormone effects on cognition and link estrogens and androgens to processes of object recognition memory and spatial cognition, respectively, for the first time in the context of an episodic-like memory task. We further suggest that the co-occurrence of discrete estrogen- and androgen-sensitive behaviors in the WWWhen task may confer unique advantages to this paradigm over other recognition memory tasks that should be exploited in future studies using rodents to examine hormone effects on cognitive function and its dysfunction in preclinical models of neuropsychiatric disease.

Title: Structural changes of songs in adult zebra finch by chronical application of thyroid hormone

Authors: *M. IWANAGA[1], K. HOTTA[2], K. OKA[3]
[1]Keio Univ., Yokohama-Shi, Japan; [2]Keio Univ., Yokohama-shi, Japan; [3]Keio Univ., Yokohama, Kanagawa, Japan

Abstract: It has been well known that song learning in zebra finches (*Taeniopygia guttata*) has similar mechanism to speech acquisition in humans (Doupe and Kuhl, 1999). Male juveniles first learn songs from tutors, adult birds nearby, and around 30 days post-hatching, they start imitating songs (Immelmann, 1969; Tchernichovski *et al*., 2001). They correct their vocal outputs by feedback mechanism; they compare their own songs with tutor songs (Immelmann, 1969; Konishi, 1965; Tchernichovski *et al*., 2001). Once they acquire their own songs, they will never sing any other songs (crystallisation). In zebra finch, sensitive period for song learning lasts 90 to 100 days after hatching (Lipkind *et al*., 2017). On the other hand, chicken (*Gallus gallus domesticus*) is a typical example to show sensitive period, and new-born chicks recognise objects moving in front of them as their parents and start following them (imprinting). We tested whether application of thyroid hormone (T_3) can change the structure of bird song because it is

known that application of thyroid hormone triggers reopening of learning period after its closure around 2 to 3 days post-hatching (Yamaguchi *et al*., 2016). In this study, we measured T_3 effects on song structures in adult zebra finches. We continuously injected T_3 into adult male zebra finches, and followed song changes by recording their songs with software, Audacity. Songs were then analysed by Sound Analysis Pro (SAP) 2011. Data were processed with Principal Component Analysis (PCA) using R. We found that daily injection of 50 ng hormone has affected mean syllable structures. However, birds showed significant decrease in the number of motifs. Now we are investigating an optimal injection condition to acquire continuous recording from the same bird with its song structure changing.

Title: Role of estrogen in mediating the effects of exposure to space radiation on cognitive performance in female rats

Authors: *B. M. RABIN[1], M. G. MILLER[2], E. M. HAWKINS[1], A. N. LARSEN[1], C. SPADAFORA[1], N. N. ZOLNEROWICH[1], L. DELL'ACQUA[1], W. PAGDEN[1], V. ROTTMAN[1], B. SHUKITT-HALE[2]
[1]Univ. Maryland Baltimore County, Baltimore, MD; [2]USDA, ARS, USDA-ARS Human Nutr. Res. Ctr. on Aging, Boston, MA

Abstract: During exploratory class missions to other planets, astronauts will be exposed to types and doses of radiation not experienced in low earth orbit, where the space shuttle and International Space Station operate. While it is likely that both male and female astronauts will comprise the crew on these missions, the majority of the research using animal models has utilized only male subjects.
The subjects were ovariectomized (OVX) and intact female rats, approximately two months of age at the time of irradiation. The OVX subjects were given implants of estradiol or vehicle. Following head-only exposure to ^{12}C or ^{4}He particles at Brookhaven National Lab, the rats were shipped to UMBC and tested on novel object recognition and operant responding on an ascending fixed-ratio schedule. All behavioral tests were conducted at least 2 months after irradiation, such that the hormonal status of all OVX rats was the same.
Results indicate that the effects of exposure to these particles on the cognitive performance of

female rats varied as a function of the specific particle, hormonal status at the time of irradiation, and the specific task. Exposure to either ^{12}C or ^{4}He did not cause a reliable disruption of performance on the novel object task. Estradiol provided partial protection against the deleterious effects of exposure on novel object performance. The presence of estradiol at the time of exposure did not prevent the disruption of operant performance by exposure to either particle. In the intact rats, exposure to both particles increased the responsiveness of the subject to the changes in reinforcement contingencies.
These results suggest that the effects of exposure to space radiation on cognitive performance among female subjects are more variable than they are for males. While hormonal status at the time of irradiation may be a factor influencing the effects of exposure on cognitive performance, the mediating effect of female hormones are not uniform, and vary as a function of the specific particle and task.

Title: Rapid ejaculator rats have more copulatory analgesia that intermediate and sluggish ejaculator rats

Authors: *C. E. AGUILAR PÉREZ, SR[1], R. A. LUCIO[2], J. C. MORALES-MEDINA[3], P. GÓMORA ARRATI[4], O. GONZÁLEZ FLORES[4]

Abstract: Analgesia is the absence of the pain perception without loss of consciousness, and can be produced by different factors, such as copulatory behavior. In male rats, analgesia is produced during the execution of mounts, intromissions and immediately after ejaculation. However, as humans, male rats have different copulatory phenotypes depending on the duration of the

ejaculation latency, i.e., rapid (200-400 sec), intermediate (700-900 sec) and sluggish (1200-1400 sec). Additionally, the rapid males have a shorter inter-intromission interval (iii) compared to intermediate or sluggish males. These data allow us to hypothesize that rapid-ejaculators will present more analgesia than the intermediate/sluggish ejaculators during copulation. To demonstrate this hypothesis, we used adult Wistar male rats with sexual experience after a copulatory training of six tests. Afterwards male rats were identified as rapid (n=22), intermediate (n=7) or sluggish (n=5). In the 7th copulatory test, males were behavioral registered in another laboratory equipped with an analgesia system. Only in the 8th copulatory session, we recorded mount, intromissions and ejaculation latencies, and the number of mounts, intromissions, and it was calculate the iii. We measured the vocalization threshold to tail shock test (VTTS) before, and during the copulatory behavior of rapid, intermediate and sluggish males during two consecutive ejaculatory series including their respective post-ejaculatory intervals. Rapid ejaculators increased their VTTS (44.16% compared to their basal value), also the sluggish ones (4.86% compared to their basal value) during the first ejaculatory series. The same happened during the second series (44.86%, 15.31%, rapid and sluggish, respectively). At the first postejaculatory interval the rapid and intermediate ejaculators increased their VTTS (21.08%, 3.59%, respectively). However, the sluggish males decreases it (-3.62%). In addition, a simple linear regression analysis indicated a stronger association between copulatory induced analgesia and rapid ejaculation. These results suggest that the nervous pathway of analgesia and that of the sensory genital information are close related.

Title: Physiological markers and personality differences in first and lastborn students

Authors: *K. C. SÁNCHEZ[1], V. REYES[2], R. HUDSON[3], A. BAUTISTA[4]
[1]Ctr. Tlaxcala Biología De La Conducta, Tlaxcala, Mexico; [2]Psychology/Upaep, Puebla, Mexico; [3]Inst. de Investigaciones Biomédicas, México, Mexico; [4]Ctr. Tlaxcala Biología de la Conducta, México, Mexico

Abstract: From an evolutionary psychological perspective, family structure has been suggested as a source of individual differences among siblings, particularly effects of birth order on

personality traits. Traditionally, firstborns are considered more conscientious, introverted and reserved than lastborns. However, other studies suggest this to be an artefact due to methodological limitations of classical studies. We reinvestigated the relation between birth order and individual differences in personality, as well as potentially associated differences in three physiological markers: heart rate variability, skin conductance, and skin temperature. We predicted that birth order would be associated with personality traits as traditionally suggested, and with differences in physiological responses in three stressful contexts: a) talking about oneself before a camera, b) solving mathematical problems, c) speaking about a controversial issue before judges. We predicted that firstborns will score higher in consciousness and will be more introverted in front of the camera than lastborn. Additionally, firstborn will increase their hearth rate variability, skin conductance, and skin temperature more than lastborns. We used the Ten Item Personality Inventory, the psychophysiological measuring device NEXUS, and a thermographic camera to register individual differences in personality traits and physiological responses, respectively. Preliminary results showed no significant differences in personality traits; physiological data are being analyzed.

Title: Hippocampus-synthesized estrogen and androgen modulate dendritic spines and LTP in non-genomic manner

Authors: *S. KAWATO[1], Y. KOMATSUZAKI[2], M. SOMA[3]
[1]Univ. of Tokyo, Tokyo, Japan; [2]Dept. of Physics, Col. of Sci. and Technology, Nihon Universit, Tokyo, Japan; [3]Dept. of Cognitive Neurosci., Teikyo Univ., Tokyo, Japan

Abstract: We have demonstrated (1) hippocampal synthesis of estrogen and androgen, and (2) non-genomic synaptic modulation by these sex-steroids. [Synthesis] We showed expression as well as neuronal/synaptic localization of essential enzymes (mRNA and protein) in the adult male rat hippocampus. Mass-spectrometric analysis demonstrated that exact levels of estradiol (E2), testosterone (T), dihydrotestosterone (DHT) were 8 nM, 18 nM and 7 nM, respectively, which are much higher than their levels in plasma. Castration significantly decreased T and DHT in the hippocampus, indicating that plasma-derived T is efficiently converted to DHT within the

hippocampus. Even after castration to deplete circulating T, the male hippocampal E2 level was not decreased, indicating that E2 is mainly synthesized from hippocampal T. Female hippocampal levels of E2 (0.5-4 nM), and T (1 nM) were less than those of male, but much higher than those in female plasma. [Synaptic Modulation] E2-induced rapid non-genomic modulation (1- 2 h) was demonstrated by analysis of spinogenesis and LTP of adult male rat hippocampal 'acute' slices (steroid-depleted slices). Spine analysis was performed for pyramidal neurons in hippocampal slices. The density of spines and their head diameters were obtained by mathematical and automated software Spiso-3D which identifies spines by calculating geometrical parameters. E2 at 1 nM rapidly increased the density of small-head spines, in CA1 pyramidal neurons. T and DHT at 10 nM increased the density of small-head spines and large-head spines, respectively. Signaling pathways are: synaptic ERalpha or AR→LIMK, MAPK, Src, PKA, PKC →cofilin or cortactin → actin polymerization→ new spines. LTP analysis showed that 1 nM E2 induced full-LTP (E2-LTP) upon weak sub-threshold stimulation, although without E2 the weak sub-threshold stimulation did not induce full-LTP. Kinase inhibitors against MAPK, PKA, PKC blocked E2-LTP. Only 20 min application of letrozole (aromatase inhibitor) suppressed full-LTP upon full teta-burst stimulation, indicating that rapid E2 synthesis is necessary for LTP in hippocampal slices. Title: Chronic stress and mental health from a psychobiological approach

Authors: *L. P. MORERA, SR[1], M. TRÓGOLO[2], L. LAPUENTE[3], L. A. MEDRANO[3]
[1]Univ. Siglo 21, Argentina; [2]Univ. Siglo 21, Córdob, Argentina; [3]Univ. Siglo 21, Córdoba, Argentina

Abstract: Historically, stress has been an object of attention and interest for the scientific community due to the important impact this variable has on people's health and functioning (Moretti & Medrano, 2014). Chronic stress is associated with both physical and psychological problems. Specifically, the influence of stress on the immune system (Lorentz, 2006), somatic problems and low antibody response (Phillips, Burns, Carroll, Ring and Drayson, 2005) have been corroborated, among other factors. Scientific evidence also corroborates the role of stress as a predictor of different psychological disorders, such as generalized anxiety (Hoehn-Saric, McLeod, FunderBurk and Kowalski, 2004), panic attacks (Wood, Cano-Vindel, and Salguero, in press), depression (Hammen, 2005; Liu and Allow, 2010) and interpersonal problems. In the present work we applied a comprehensive survey that included clinically validated scales for anxiety (GAD07) and depression (PHQ09) in sample of 100 postgraduate students from the National University of Córdoba, Argentina. We also assessed stress biomarkers, such as Cortisol (C) from saliva. Methods: A survey was delivered in person to each postgraduate student from different Institutions within, National University of Córdoba (UNC). Participants were instructed to collect all samples during a regular day, avoiding stressful situations and intense physical activity, and refraining from eating, drinking, smoking, or brushing teeth in the 15 min prior to saliva collection. Saliva samples were obtained at awakening, 30 and 50 min after awakening by passive drooling into a plastic tube. This collection method was also recommended by previous studies because other collection methods, such as the use of Salivette, which uses cotton, interfere with the salivary immunoassay results for IL-6. HPA axis function was assessed using CAR (Cortisol awakening response) test. It represents a discrete and distinct component of the cortisol circadian cycle, with characteristics unrelated to those of cortisol secretion throughout the rest of the day. In the present study, the CAR was calculated using the area under the curve with respect to the increase, as suggested by Pruessner et al. (Pruessner et al., 2003), and included three sampling points (awakening, 30′ post-awakening, and 60′ post-awakening). IL-6 levels were assessed from the same samples by salivary immunoassay. In this study we found a high prevalence of anxiety and depression in the population of graduate students from UNC, Argentina. Also, a high correlation between anxiety or depression and C levels or IL-6 its observed.

Title: Oxytocin decreases impulsive choice in rats

Authors: *M. D. SINGSTOCK, D. TAPP, M. S. MCMURRAY
Psychology, Miami Univ., Oxford, OH

Abstract: Gambling disorders are characterized by an increase in risky behavior due to the progressive loss of impulse control, even in the presence of negative financial and social consequences. Despite their prevalence in society and the severity of their consequences, few targeted pharmacological therapies exist to combat them, and current treatments are not widely effective. Alternative approaches to treatment need to be considered, which rely on new pharmacological targets. One such target may be the oxytocin system. Oxytocin (OT) is a hormone implicated in social behavior, reward preference, motivation, and modulation of dopaminergic neurons in the mesocorticolimbic system. These relationships suggests that OT may play a role in decision-making and impulsivity, although this relationship has yet to be investigated. The purpose of this study was to determine if OT administration influences impulsive decision-making in rats. We predicted that increased OT receptor activation would significantly decrease impulsive decisions. To assess its effect on impulsivity, animals were tested daily on probability and delay discounting tasks. In the probability discounting task, animals chose between a small-certain reward or a large-risky reward, which paid off at declining probabilities across days of testing. In the delayed discounting task, animals chose between a small-immediate or a large reward delivered with increasing delay across days. Reward sensitivity was also analyzed using the intracranial self-stimulation rate frequency (RF) curve-shift method. Animals received OT or vehicle immediately prior to testing (0.1ug OT, 10ug OT, or vehicle intracerebroventricular (ICV); or 6mg/kg or vehicle intraperitoneal). We found that the oxytocin (regardless of administration route) dose-dependently decreased impulsivity in both tasks. ICV infusions also dose-dependently decreased reward sensitivity in RF curve-shift. These results suggest that oxytocin could be an effective treatment for gambling disorders and other impulse control disorders.

Title: Effects of dorsal hippocampal inhibition of actin polymerization or protein synthesis on rapid estrogen-facilitated social recognition, dendritic spines, and Arc protein expression in ovariectomized female mice

Authors: *P. A. SHEPPARD[1], H. A. ASLING[2], S. E. ARMSTRONG[1], V. M. ELAD[3], A. WALCZYK-MOORADALLY[2], J. LALONDE[2], E. CHOLERIS[1]

Abstract: While the long-term, genomic mechanisms of estrogens are established, the mechanisms by which these hormones rapidly affect different forms of cognition are not yet fully understood. Estrogens can rapidly facilitate social recognition - the ability of an animal to recognize another. In ovariectomized female mice, social recognition was facilitated within 40 min of systemic (Phan et al., 2012) or dorsal hippocampal (Phan et al., 2015) administration of 17β-estradiol (E2). Within the same timeframe, E2 increases dendritic spine density in CA1 dorsal hippocampal neurons (Phan et al., 2012; 2015). Mechanisms underlying these effects remain unclear. Estradiol rapidly stimulates changes in actin cytoskeletal dynamics through rapid enhancement of actin polymerization (Briz & Baudry, 2014), increases dendritic spine scaffolding protein PSD-95 expression in an Akt pathway-dependent manner in cultured NG108-15 neurons without a concurrent increase in PSD-95 mRNA (Akama & McEwen, 2003), and increases translation of dendrite-localized mRNA in an ERK-dependent manner in primary cultured hippocampal neurons (Sarkar et al., 2010). Although we previously found dorsal hippocampal activation of both the ERK and Akt pathways is necessary for the rapid facilitation of social recognition by E2 in ovariectomized female mice (Sheppard et al., 2016; 2017), the necessity of protein synthesis or actin polymerization has not yet been examined. Here, we first determined the highest doses of either actin polymerization inhibitor latrunculin A (LAT) or protein synthesis inhibitor anisomycin (ANI) that do not block social recognition when infused into the dorsal hippocampus of ovariectomized female mice 15 min prior to testing. We then determined whether these treatments could prevent the enhancing effects of E2 (as in Phan et al., 2015) in a task where control mice do not typically perform social recognition. The paradigms are completed within 40 minutes of E2 administration, thus enabling investigation of rapid effects of estrogens. Both actin polymerization and protein synthesis were found to be necessary for E2 to rapidly facilitate social recognition. Brains from these animals were collected and either stained with Golgi-Cox solution to evaluate dendritic spine density and length in the dorsal CA1 or were used to determine the effects of treatment on Activity-regulated cytoskeleton-associated protein (Arc) expression, as a potential target of estrogen action. These studies provide a mechanism through which estrogens rapidly facilitate social recognition.

Title: Genomic and non-genomic effects of progesterone on memory bias in female rats

Authors: *J. M. LACASSE[1], W. G. BRAKE[2], S. PATEL[2], V. PERONACE[2], A. LESTAGE[2], C. GAGNE[2]
[2]Psychology, [1]Concordia Univ., Montreal, QC, Canada

Abstract: When ovariectomized female rats are given low levels of 17B-estradiol (E2) they are biased towards using response memory while navigating a T-maze. Contrarily, if they are given high levels of E2, they are biased towards using spatial memory to navigate. Here we examine the effects of E2 and progesterone (P) on memory bias. Ninety-six female Long-Evans rats were split into 4 groups: low E2 (n =24), high E2 (n=24), high E2+P (4h; n=24), and high E2+P (15min; n=24). All rats were tested in an ambiguous T-maze to differentiate whether they were predominantly using place or response memory while navigating. No statistically significant differences were found between the four hormone conditions. However, when odds ratios were calculated for each hormone condition, some clear differences between conditions emerged. Rats in the low E2, as well as when P was administered 4h and 15min prior were 2.78x more likely to use response memory. Whereas rats in the high E2 alone condition were 2.78x more likely to use place memory.

Title: Modulation of postmenopause and premenopause on interhemispheric electroencephalographic activity on resting-state in women

Authors: *E. G. GONZÁLEZ-PÉREZ[1], M. S. SOLIS-ORTIZ[2]
[1]Med. Sci., Univ. de Guanajuato, León, Mexico; [2]Med. Sci., Univ. of Guanajuato, Leon, Mexico

Abstract: Postmenopause is characterized by a decrease in estrogen levels, while premenopause in its ovulatory phase, is characterized by elevated estrogen levels. The influence of these

different hormonal states on cortical electrical activity in women is not well known. Therefore, the aim of this study was to explore the modulation of postmenopause and premenopause on electroencephalographic activity (EEG) recorded during resting-state, as a measure of the functional state of the brain. EEG activity was recorded during resting-state in 10 postmenopausal healthy women between 48 and 60 years old and 10 premenopausal healthy women in ovulatory phase between 40 and 45 years old. All subjects were instructed to close their eyes during the recording of the EEG activity. Absolute power was obtained for delta, theta, alpha1, alpha2, beta1 and beta2 and were compared between both hemispheres in frontal, central, parietal and occipital regions. When compared to the premenopausal women in ovulatory phase, postmenopausal women displayed higher EEG power in the left hemisphere for alpha2 ($p = 0.001$) and beta1 ($p = 0.002$) bands in the frontal region. The present findings indicate a higher activation of left frontal region in postmenopausal women, which may suggest a compensatory brain mechanism for behavior and cognition functions.

Title: Exposure to bisphenol-a and estrogen during adolescence: Effects on behavior and spine density

Authors: *R. E. BOWMAN, E. MADDEN[1], J. HAGEDORN[1], M. FRANKFURT[2]
[1]Sacred Heart Univ., Fairfield, CT; [2]Sci. Educ., Donald and Barbara Zucker Sch. of Med. at Hofstra/Northwell, Hempstead, NY

Abstract: Bisphenol-A (BPA) is a mixed estrogen/androgen receptor agonist/antagonist known to be an endocrine disrupter that alters a variety of neural, physiological, and behavioral measures. We have previously shown that BPA exposure, in adolescent gonadally intact rats, increases anxiety, impairs spatial memory, and decreases dendritic spine density when measured in adulthood (Bowman et al, 2014, 2015). Additionally, in adult rats estrogen is neuroprotective, enhances memory, and increases dendritic spine density. However, BPA and estrogen effects in adolescence are limited. Thus, this experiment examined the effects of adolescent BPA exposure in juvenile rats under controlled hormone conditions on behavioral and neural alterations in adolescence. Female Sprague-Dawley rats were ovariectomized at postnatal day (PND) 21 and received subcutaneous injections of either BPA (40 μg/kg/bodyweight), 17β-Estradiol (EST, 50

µg/kg/bodyweight), or saline control during adolescence (PND 38-49). Immediately following injections, subjects were tested for anxiety and locomotor activity levels (elevated plus maze and open field), spatial memory (object placement), and non-spatial visual memory (object recognition) (PND 49-58). Animals were sacrificed at PND 59, trunk blood was collected for hormonal assay of estradiol and corticosterone and brains processed for Golgi impregnation. There were no significant group differences on any of the elevated plus maze or open field behavioral measures. Adolescent BPA exposure impaired spatial memory; however, all groups demonstrated intact object recognition performance. While there were no group differences in E2 or CORT levels, there were region specific effects of adolescent hormone treatment on dendritic architecture following behavioral testing. Basal and apical dendritic spine density in pyramidal cells in the CA1region of the hippocampus was increased by EST treatment and granule cells of the dentate gyrus was decreased by BPA. BPA also decreased basal and apical spine density in the mPFC. The current study provides novel data on the effects of adolescent BPA exposure and EST replacement in an adolescent OVX model.

Title: Cue-triggered food seeking is modulated by ovarian hormones in female rats

Authors: *Y. ALONSO CARABALLO, C. FERRARIO
Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: In females, naturally occurring elevations in estradiol reduce food intake and estradiol treatment in ovariectomized rats is sufficient to reduce food intake and body weight. However, stimuli paired with food (food cues) also influence feeding behavior, e.g., by increasing food-seeking, and the amount of food consumed. We previously found that male rats predisposed to obesity are more sensitive to the motivational properties of a food cue compared to obesity-resistant rats. However, whether a similar difference exists in females, and how cue-triggered motivation varies across the cycle are unknown. Here, we determined how conditioned approach,

a measure of cue-triggered food-seeking, and instrumental responding for food, differ between female selectively-bred obesity-prone (OP) and obesity-resistant (OR) rats as well as female Sprague Dawley rats. Additionally, we determined how these behaviors change across the estrous cycle. We found that female OP, but not OR rats, show greater conditioned approach during phases of the estrous cycle where estradiol is low (metestrus/diestrus) compared to phases where estradiol is high (proestrus/estrus). Interestingly, in both OP and OR females, motivation for food assessed by progressive ratio responding was lower during proestrus and estrus compared to metestrus and diestrus. Thus, in OP, cue-triggered food-seeking and consumption were similarly modulated by the cycle, whereas consumption but not food-seeking was affected in OR females. Furthermore, when OP and outbred rats were ovariectomized and given repeated cycles of hormone replacement (estradiol and progesterone) a reduction in conditioned approach was observed, demonstrating a role for ovarian hormones in modulating this behavior. This is the first demonstration that ovarian hormones modulate this behavior. In ongoing studies, we are dissecting whether estradiol, progesterone, or a combination of the two are needed to reduce conditioned approach. This study addresses interactions between individual susceptibility to obesity and incentive motivation within females and demonstrates a role of ovarian hormones in regulating food-seeking behaviors.

Title: 3beta-OH is a novel sedative/hypnotic with sex specific effects

Authors: *F. M. MANZELLA[1], D. WILKEY[2], D. F. COVEY[3], S. M. TODOROVIC[1]
[1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [2]Univ. of Colorado, Boulder, CO; [3]Dept Developmental Biol., Washington Univ. Sch. Med., Saint Louis, MO

Abstract: A new anesthetic agent has not been approved for use in humans in over 20 years. Traditional sedative/hypnotic drugs (SHDs) that target $GABA_A$ and NMDA receptors, such as sevoflurane, propofol, and ketamine are associated with neurotoxicity and neurocognitive impairments in rodents and non-human primates. Moreover, traditional SHDs do little to treat post-surgical pain, a problem contributing to the opioid epidemic. Our group recently developed 3β-OH, a novel 5β-reduced neurosteroid that is a potent analgesic, which inhibits neuronal T-type calcium channels, as a safe alternative to traditional SHDs. However in basic science there

is a disparity in experiments using male and female models despite the importance of understanding the differential effects in men and women in clinic. Thus, it is important to recognize any sex differences of 3β-OH early in drug development in order to understand the best potential clinical use of this novel drug.
A dose response curve for 3β-OH-induced hypnosis was generated using both male and female 3-5 month old C57BL/6J mice. Mice were administered a range of doses between 20 and 120 mg/kg as a single intra-peritoneal (IP) bolus injection. After drug administration, animals were monitored for time to loss of righting reflex (LORR) and time to gain of righting reflex (GORR) as a measure of hypnosis. We found that females were significantly more likely to lose their righting reflex than males at lower doses. Effective dose 50 (ED_{50}) for females to achieve LORR was 48 mg/kg compared to males, which had an ED_{50} of 80 mg/kg. Time to LORR was also two-fold higher for males compared to females. Females also experienced longer duration of hypnosis (2- to 5-fold depending on dose). For example, ED_{50} to achieve maximal hypnotic effect was 72 mg/kg in females and 88 mg/kg in males. At these doses respectively, duration of hypnotic effect was 132 minutes in females, 2.6-fold longer than in males (51 minutes).
To test if this effect was hormonally dependent, we conducted a LORR experiment in male and female juvenile animals at postnatal day (P)21, before the time of sexual maturity. All animals were given a 100 mg/kg bolus of 3β-OH IP, which was the lowest dose in which all animals achieved LORR. Again, animals were monitored for time to LORR and time to GORR. In contrast to the adult animals, we found that at P21, males and females did not differ in achieving LORR, time to LORR, or duration of hypnosis.
Our results indicate that 3β-OH acts as a potent hypnotic in adult mice, with higher potency in females. These effects are dependent on sexual maturity. Further studies are needed to elucidate the mechanisms of sex differences and their potential impact on clinical practice.

Title: Sex-specific effects of dietary isoflavones on peripheral estradiol and brain estrogen α and β receptor expression in the rat

Authors: *C. FINNEY[1], N. W. PROSCHOGO[2], N. M. HOLMES[1], R. F. WESTBROOK[1], K. J. CLEMENS[1]

[1]Psychology, Univ. of New South Wales, Randwick, Australia; [2]Sch. of Chem., Univ. of Sydney, Sydney, Australia

Abstract: Standard laboratory diets contain high levels of soy-based products, and are therefore high in phytoestrogens. Isoflavones, a class of phytoestrogen found in soy, are similar in conformation to estradiol and can act as selective estrogen receptor modulators at estrogen receptors (ER) α and β. However, little is known about the impact of dietary isoflavones on estrogen signaling in the brain and in the periphery. To investigate this, adult male and female Sprague-Dawley rats (n=10/group) were maintained on either a diet marketed as phytoestrogen free (AIN-93G), or one of two standard diets (Gordon's Premium Rat and Mouse Pellets or Specialty Feed's Irradiated Rat and Mouse Diet). We first examined the isoflavone context of these diets, and then assessed their effects on peripheral estradiol levels, as well as the impact of each diet on ERα and β mRNA expression in the hippocampus and prefrontal cortex, two brain regions known to be high in ERs. LC-APCI-MS analysis of isoflavone content in the diets revealed variations in the quantity of isoflavones present (Gordon's > Specialty Feeds > AIN-93G), and in the presence of individual isoflavones in each diet. Critically, the diet had doubly dissociable effects on peripheral estradiol (assessed through LC-APCI-MS of plasma) and brain ER expression (assessed through qRT-PCR) in male and female rats. In male rats, the standard Specialty Feeds diet increased peripheral estradiol levels, but had no effect on either ERα or β expression in the hippocampus or prefrontal cortex. In contrast, in female rats, diet had no effect on peripheral estradiol levels, but significantly affected ER expression in the hippocampus and prefrontal cortex: specifically, the Gordon's standard diet decreased both ERα and β in the prefrontal cortex, and ERβ (but not ERα) in the hippocampus. Combined, these data suggest that standard laboratory diets affect estradiol signaling in a sex specific manner. These results may have implications for rodent models of neurobiological disease that are influenced by estrogen signaling, such as anxiety and affective disorders.

Title: Impact of oral hormonal contraceptives on the CNS: Developing a population neuroimaging study

Authors: *C. TAYLOR, E. G. JACOBS
Psychological & Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: INTRODUCTION: Oral contraception (OC) is used by more than 100 million women worldwide. OC use suppresses the endogenous production of sex steroid hormones. Few human studies have investigated the impact of chronic ovarian suppression on brain regions modulated by these hormones. In animal models, estradiol and progesterone act on cortical and subcortical brain regions to alter synaptic morphology. A comprehensive study of the macro-structural brain changes that may result from long-term OC use is long overdue. To that end, we launched a large-scale neuroimaging database at UCSB dedicated to women's health research. By leveraging the activity of the UCSB neuroimaging community, we are pooling standard neuroimaging sequences collected on all Brain Imaging Center participants. We then pair participants' neuroimaging data with a detailed clinical-demographic battery. A core aim of the database is to understand OC's influence on regional brain morphology. We began by asking three questions: Does regional gray matter volume (GMV) differ between current OC users relative to never-users; does the duration of OC use impact regional GMV; and does OC use impact sex differences in regional GMV? METHODS: In a discovery dataset based on the first 150 database participants (aged 18-33), high-resolution T1 (MPRAGE) scans were analyzed in conjunction with clinical-demographic data. Participants were excluded for previous parity, psychiatric/mood disorder, substance use, or low-quality MPRAGE, yielding a sample of 48 women: 24 current OC users and 24 never-users, matched on age, age of menarche, education, and BMI. Age-matched men (n=27) were included for comparisons by sex. RESULTS: Whole brain analyses (VBM in SPM12, FDR-corrected) revealed greater cerebellar GMV in OC users compared to never-users. Further, duration of OC use (9-84 mos) was positively correlated with greater cerebellar GMV. Finally, sex differences in regional brain volume observed between men and never-users were obscured in OC users. Results are being tested for replication in additional cohorts.

Title: Developmental exposure to the synthetic progestin 17α-hydroxyprogesterone caproate alters decision making in adulthood

Authors: *A. PHILLIPS[1], G. LI[2], C. K. WAGNER[3], R. I. WOOD[4]
[1]Psychology, Univ. At Albany State Univ. of New York, Albany, NY; [2]USC, Los Angeles, CA; [3]Univ. Albany, Albany, NY; [4]Keck Sch. Med. USC, Los Angeles, CA

Abstract: 17α-hydroxyprogesterone caproate (17-OHPC) is a synthetic progestin commonly administered to women considered at risk for preterm birth. At this time, there is very little understanding of the potential effects of exposure to 17-OHPC on the developing fetus. Administration of 17-OHPC typically begins during the second trimester and can be found in both maternal and fetal plasma a month after the last injection. The period of administration coincides with critical stages of development of the mesocortical dopaminergic pathway, which originates in the ventral tegmental area (VTA) and projects to the medial prefrontal cortex (mPFC). This pathway is important for mediating complex cognitive functions and higher order executive tasks. In rodent models, progesterone receptors (PR) are expressed in dopaminergic cells of the VTA that project to the mPFC. Neonatal exposure to 17-OHPC in rats induced changes in both the innervation patterns and density of dopaminergic fibers at postnatal day 7 in the mPFC. In addition, 17-OHPC exposure during neonatal life impaired cognitive flexibility in adulthood, a complex cognitive behavior regulated by dopamine activity in the mPFC. Impulsive decision making is observed in children born prematurely and has been shown to be dependent on the mesocortical pathway. In this study, we examined the effects of administration of 17-OHPC during postnatal life (P1-14) on performance in a delay-discounting task, in which animals choose between a larger delayed reward or a small reward delivered immediately. Rats treated with 17-OHPC were significantly more likely to wait for the larger, delayed reward and were significantly less likely to choose the small, immediate reward with increasing delays. Interestingly, 17-OHPC treated rats were significantly more likely to not respond at all (omissions). Together, these results suggest that 17-OHPC may decrease impulsivity, but may also interfere with general decision making abilities.

Inst. on Alcohol Abuse and Alcoholism Lab. of Neurogenetics, Rockville, MD

Abstract: The risk of depression increases 2-3 fold for women during the menopause transition compared to premenopausal women. Additionally, peri/postmenopausal women with even minor depression are at an increased risk of cardiovascular mortality (Wassertheil-Smoller et al, 2004). Clinical studies show both the therapeutic benefits of estradiol (E2) in perimenopausal depression (PMD) (Schmidt et al, 2000, Soares et al, 2001) and the symptom-provoking effects of E2-withdrawal (E2WD) in women with past PMD, which are not experienced by those without past PMD (Schmidt et al, 2015). It has been suggested that a heightened sensitivity to changes in ovarian steroids such as E2 may contribute to the onset of PMD. We hypothesized that the differential affective/behavioral responsivity to E2WD in PMD could be observed on a cellular level. To test this hypothesis, we used lymphoblastoid cell lines (LCLs) derived from women with a past PMD (n=8), or asymptomatic controls (AC) (n=9). These LCLs were examined in 3 different experimental conditions: 1) vehicle-treated media, 2) E2-treated media, or 3) E2-treated media which was changed to vehicle-treated media and collected 24 hours later, to mimic E2WD on a cellular level. Levels of E2 in cell culture media were confirmed using High Performance Liquid Chromatography/Tandem Mass Spectrometry. Cells were collected and examined for changes in gene expression levels using whole-transcriptome RNA sequencing. EDGE-R analysis of differential gene expression revealed significant transcript expression changes between women with PMD and AC in all three treatment conditions, as well as several molecular pathways that appear to be differentially altered in women with PMD. Of particular interest, the gene *CXCL10*, which has been previously linked to cardiovascular disease, is significantly upregulated in the cells of women with past PMD, and had the most extreme increase in transcription in the E2WD treatment condition. In contrast, a gene coding an enzyme *CYP7B1*, which is responsible for the metabolism of the steroids DHEA and pregnenolone, is also significantly upregulated in PMD, but E2-treatment or withdrawal had no further effect on transcript expression. We are currently working to replicate these findings in an independent cohort of AC and PMD cases. These data may suggest that both intrinsic genetic differences as well as differential sensitivity to E2WD could underlie the behavioral symptomology of PMD.

Title: The role of brain FNDC5/irisin in synaptic plasticity and memory in mice

Authors: *R. A. LIMA-FILHO[1], M. V. LOURENCO[2], O. ARANCIO[3], S. T. FERREIRA[4], F. G. DE FELICE[5]
[2]Inst. of Med. Biochem. Leopoldo De Meis, [1]Federal Univ. of Rio De Janeiro, Rio de Janeiro, Brazil; [3]Dept of Pathol, Columbia Univ., NEW YORK, NY; [4]Inst. of Biophysics Carlos Chagas Filho, [5]Inst. of Med. Biochem. Leopoldo de Meis, Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Irisin is an exercise-induced myokine released upon cleavage of a precursor protein termed FNDC5, recently reported to be expressed in the hippocampus. Irisin has been reported to regulate peripheral energy metabolism and to trigger neuroprotective mechanisms. However, physiological roles of FNDC5/irisin in the brain remain poorly understood. We used lentiviral vectors harboring two different shRNA constructs targeting FNDC5 to study the role of irisin in synapse plasticity and memory. Here we show that downregulation of brain FNDC5/irisin impairs hippocampal long-term potentiation and object recognition memory, but not contextual fear memory or radial arm water maze, in C57BL/6 mice. These data support the idea that FNDC5/irisin acts in the central nervous system and impacts selective forms of memory expression and hippocampal synaptic plasticity. Thus, boosting FNDC5/irisin pathway and/or using exercise-based therapies may offer new strategies to tackle memory loss in neurodegenerative diseases.

Abstract: The effects of maternal consumption of sucrose (table sugar) on offspring brain, hormones, and behavior are largely unknown. Here, we explored whether human-relevant levels of sucrose consumption by rat dams influenced the offspring phenotype. We examined offspring metabolic function, neurosteroid and dopamine signaling, and motivated behaviors. Dams were fed either a high-sucrose diet (25% of kCal) or an isocaloric, matched, control diet (0% sucrose) during gestation and lactation. After weaning, offspring were placed on standard lab chow until behavioral testing (~4 mo). When given a choice of diets [control diet (10% fat, 0% sucrose) vs. high-sucrose diet (10% fat, 25% sucrose) vs. high-fat diet (40% fat, 0% sucrose)] in a food preference test, sucrose-exposed male (but not female) offspring consumed more of the high-sucrose and high-fat diets. Motivation to obtain a sugar reward was assessed using a progressive ratio schedule of reinforcement. Sucrose-exposed male (but not female) offspring displayed increased motivation to obtain sugar. These behavioral differences might be related to changes in neurosteroid or dopamine signaling in the mesocorticolimbic system. We used ultra-sensitive liquid chromatography-tandem mass spectrometry to examine systemic and local levels of steroids (e.g., testosterone, estradiol, corticosterone), and we used qPCR to examine mRNA levels of steroidogenic enzymes, steroid receptors, and dopamine receptors. Perinatal sucrose exposure affected neurosteroids, steroidogenic enzymes, and dopamine receptors. In males, perinatal sucrose exposure decreased 17β-hydroxysteroid dehydrogenase I (*Hsd17b1*) mRNA in the nucleus accumbens and D1 dopamine receptor (*Drd1*) mRNA in the medial prefrontal cortex. Thus, early-life exposure to human-relevant levels of sucrose disrupts steroid and dopamine signaling in the mesocorticolimbic system. The results suggest that maternal sucrose

consumption has enduring sex-specific effects on offspring brain and behavior, particularly with regard to choosing and obtaining highly palatable foods. These findings might be critical for understanding and addressing the consequences of sugar overconsumption, including the current epidemics of obesity and Type 2 diabetes.

Title: Gradual loss of ovarian function exacerbates age-dependent cognitive dysfunction in an Alzheimer's disease mouse model

Authors: *S. V. MAURER[1], S. S. VASHISTH[1], C. GRANT[1], E. M. REYNOLDS[1], E. A. GRZESIAK[1], C. A. COLTON[2], E. A. FINCH[2], C. L. WILLIAMS[1]
[1]Duke Univ., Durham, NC; [2]Duke Univ. Med. Ctr., Durham, NC

Abstract: Over two-thirds of individuals with Alzheimer's Disease (AD) are female, implicating biological sex as a major risk factor for the onset and progression of AD. Biological differences between males and females – most notably the gradual loss of ovarian hormones during the perimenopausal transition – are thought to be critical factors contributing to the greater female risk. To investigate the possibility that menopause exacerbates the development and progression of AD, we are inducing transitional menopause (TM) in female mice with the ovotoxin 4-vinylcyclohexene diepoxide (VCD). We are using the APPSwDI/mNos2$^{-/-}$ AD (CVN-AD) mouse model, which mimics familial AD with the expression of mutated APP and creates a human-like immune environment through lowered NOS2 expression. CVN-AD mice exhibit many of the neuropathological features of human AD, as well as exacerbated AD-like neuropathogenesis and resistance to therapeutic intervention in females. Both wild-type C57BL/6 and mNos2$^{-/-}$ mouse lines serve as controls. To evaluate cognitive function and the impact of TM in female CVN-AD mice, we are using a Barnes Maze task to evaluate spatial learning and memory. As expected based on their neuropathogenic progression, 4-month old CVN-AD mice do not differ from control mice on latency to locate the escape hole, while 14-month old CVN mice are significantly impaired. However, when we analyzed the strategies used to locate the escape hole we found that both young and old CVN-AD mice used a non-spatial,

serial-search strategy, whereas control mice were more likely to navigate to the hole directly using spatial cues. We also determined that while TM did not adversely alter spatial learning in control mice, loss of ovarian hormones in CVN-AD mice drastically impaired their ability to locate the escape hole. TM also increased the likelihood that CVN-AD mice used a serial search strategy. Our findings support previous reports that CVN-AD mice show progressive, age-related spatial learning deficits, and reveal that young CVN-AD mice are likely performing well on the Barnes Maze task by using a compensatory, non-spatial strategy to locate the escape hole. Moreover, our study demonstrates that a gradual, menopause-like loss of ovarian hormones exacerbates AD-like cognitive decline. Ongoing and future studies will investigate the effects of TM on other aspects of AD-like disease progression, and the response of females to therapeutic interventions at various stages of the menopausal transition.

Title: Prenatal testosterone affects social and anxiety-like behaviours in a sexually dimorphic and hormone-dependent manner

Authors: *E. R. MARTIN, C. S. WASSON, C. HOWES, A. J. GIUGA, M. CASTRO, H. A. WILSON, N. J. MACLUSKY, E. CHOLERIS
Univ. of Guelph, Guelph, ON, Canada

Abstract: Gonadal hormones, such as testosterone (T), organize sexually dimorphic brain regions during development and consequently sex differences in behaviour later in life. Abnormal levels of prenatal T have been associated with Autism Spectrum Disorder (ASD), which is partially characterized by deficits in social communication and social interaction. We assessed the effects of elevated prenatal T on social learning (SL), object recognition, social recognition (SR), sociability, and anxiety-like behaviour, in mice. Pregnant CD1 female mice were treated subcutaneously with 10 µg of T propionate or sesame oil vehicle control on gestational days 12, 14 and 16. Experimental litters were assessed in the above listed behavioural

tests during adolescence (age 35-42 days; n=12-47). Mice then underwent sham surgery, gonadectomy (GDX), or GDX with silastic capsules, [T for males and estradiol (E) for females] and were re-tested for the same behaviours in adulthood (age 68-76 days; n=5-24). Prenatal T increased anxiety-like behaviour in adult male mice, but females were resilient to the effects of this treatment. Prenatal T enhanced SR in both males and females during adolescence. In adulthood, prenatal T impaired SR in gonadally intact and GDX males and this was reversed by T replacement. In females, GDX impaired SR but E replacement did not reverse this effect. For SL, castration improved learning in male controls but blocked SL in adult mice treated prenatally with T, an impairment that was not reversed by T replacement. Conversely, in ovariectomized mice, SL was impaired following prenatal T treatment, but recovered after estradiol replacement. These results are reminiscent of the effects of prenatal stress and suggest that prenatal T exposure may alter the development of normal social and anxiety-like behaviours, resulting in long-term effects that modify responses to gonadal hormone exposure in adulthood. The molecular mechanisms through which prenatal T acts remain to be elucidated, but may involve pathways similar to those activated by prenatal stress.

Title: Assessment of peripheral BDNF variability over 30 days in healthy adults

Authors: S. HANG, J. RODRIGUEZ-ZAMORA, B. CHU, R. C. GARCIA, H. M. KILGORE, *E. B. GAHTAN
Psychology, Humboldt State Univ., Arcata, CA

Abstract: Brain-derived neurotrophic factor (BDNF) has been studied extensively for its potential role in brain and cognitive health. Lower levels of BDNF are associated with neuronal apoptosis, decreased hippocampal volume and conditions including schizophrenia, depression and Alzheimer's, whereas elevated levels are associated with neurogenesis and improved cognitive functioning, particularly memory. In most human studies, BDNF is measured in peripheral tissues, most commonly blood or saliva. Many studies have shown BDNF changes related to physical exercise, hormone levels, and gene polymorphisms, while others have not, signaling unknown sources of variability in peripheral BDNF levels. To better understand its normal degree of variability, the current study examined circulating BDNF in whole blood in healthy adults (N=9; 5 female) over 30 days. The main goal was documenting long-term BDNF

variability, but we also analyzed the relationship of BDNF levels to recent physical exercise, exercise intensity, sex, body mass, and (in female participants) hormone cycle. Samples were obtained through safety lancet finger-pricks three times per week over four weeks and participants' recent physical exercise information was recorded at each collection. Whole blood BDNF concentrations were quantified using enzyme-linked immunosorbent assay. Across 30 days, within-subjects BDNF levels fluctuated by an average of 5.92 pg/ml (SD) around the mean of 29.80 pg/ml, yielding a coefficient of variance (*CV*) of 19%. No association of BDNF to recent physical exercise, exercise intensity, sex, body mass, or hormone cycle was found. This estimate of variability in circulating BDNF levels is based on a longer duration of observation than previous reports and may be useful for assessing the statistical power of BDNF studies.

Inst. of Mental Hlth., Bethesda, MD; [9]Lab. Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism Lab. of Neurogenetics, Rockville, MD

Abstract: Premenstrual dysphoric disorder (PMDD) is characterized by recurrent affective and behavioral symptoms during the luteal phase of the menstrual cycle. A study of lymphoblastoid cell lines (LCLs) of PMDD women revealed an intrinsic difference in ovarian steroid responsive genes at baseline. Clinical studies show that PMDD symptoms recur after re-exposure to estradiol (E2) or progesterone (P4) during GnRH-agonist-induced ovarian suppression.

Furthermore, women with PMDD show symptom reduction after blocking conversion of P4 to its neurosteroid metabolite, allopregnanolone (ALLO). These clinical studies suggest that *change* in steroid hormone levels leads to symptoms. To learn if there is an intrinsic difference in neural cells as well as LCLs, and to investigate effect of change in ovarian steroid levels, we differentiated neural stem cells (NSCs) from induced pluripotent stem cell (iPSC) lines from women with PMDD and asymptomatic controls (n=4, 4, respectively; 2 technical replicates per individual). Immunofluorescent staining of neuronal markers verified differentiated cells as NSCs. NSCs were exposed to vehicle (DMSO), E2, P4, or ALLO for 24hrs at 100nM, and examined for gene expression differences via AmpliSeqRNA Transcriptome Sequencing. EdgeR was used to detect differential expression, follow by DAVID and GSEA for pathways, and WGCNA for correlated gene clusters. Unsupervised hierarchical clustering revealed diagnosis- and hormone treatment-specific clusters. Genes were differentially expressed at baseline as well as in response to hormone. At baseline (i.e., vehicle), PMDD NSCs showed upregulation (FDR corrected p=0.04) of *STAR*, which enhances conversion of cholesterol to pregnenolone (a GABA receptor modulator and precursor of other neurosteroids), perhaps playing a role in differential sensitivity to changing steroid hormone levels. Furthermore, NSCs from women with PMDD showed upregulation of a similar subset of genes in response to treatment with either P4 or ALLO, suggesting the two steroids may affect gene expression through similar pathways. Presently, we are further investigating differentially expressed genes via qRT-PCR and protein analyses.

Title: Working to run: Assessing motivation for wheel running in female rats

Authors: *K. K. SOMA, W. A. KRIEGER, D. J. TOBIANSKY, M. A. TURCOTT, C. MA, S. B. FLORESCO
Psychology, Univ. British Columbia, Vancouver, BC, Canada

Abstract: Running appears to be a rewarding activity for rodents. However, most rodent studies use reinforcers such as sugar pellets or drugs (e.g., cocaine) for instrumental learning. The use of running as a reinforcer in complex operant tasks and the neural mechanisms for motivation to

run have not been well examined. In this study, we explored a) whether running can be used as an effective reinforcer for operant tasks, and b) whether caloric restriction (CR) increases motivation to gain access to the running wheel. Adult female Long-Evans rats were group housed and given unlimited access to a running wheel for 2 wk (4 females/bin). Thereafter, females were pair-housed and randomly assigned to be CR (n = 10) or fed *ad libitum* (AL; n = 10). After 1 wk of exposure to the feeding paradigm, the subjects were introduced to an operant chamber with a running wheel attached. The subjects were trained to press a retractable level to open the guillotine door, which gave them access to a running wheel for 30 min on fixed ratio (FR) 1, FR2, and FR5 schedules of reinforcement. Motivation to gain access to a running wheel was assessed using a progressive ratio (PR) schedule of reinforcement. For each ratio, the subject was given 20 min to complete the number of lever presses required to gain access to the running wheel for 5 min. Subjects were exposed to the subsequent ratio on the following day until they failed to complete the task. All subjects readily learned to press the lever to gain access to the wheel. There was no difference in the number of ratios completed [mean = 13 ratios (62 lever presses)] between AL and CR subjects, but CR subjects ran significantly more than AL subjects during the 5-min running period. After all subjects completed the PR task, they were run on three (3) FR4 sessions with 5-min access to the running wheel and were euthanized at 90 min after the last running period. Local steroid concentrations and c-Fos expression will be examined in relevant brain regions to determine whether CR influences steroid signaling and neuronal activity. This study lays the groundwork for future studies examining the neuroendocrine regulation of the motivation for voluntary exercise.

Abstract: Gonadal status modifies the ratio of GABA expressing neurons in limbic areas of the rat brainAUTHOR BLOCK *V. S. HERNANDEZ1, A. NAVA-KOPP1, O. HERNÁNDEZ PEREZ1, L. E. EIDEN2, L. ZHANG1; 1Dept. of Physiology, Fac. of Med., Natl. Autonomous Univ. of Mexico, Mexico City, Mexico; 2Sec Molec Neurosci, NIH, NIMH-IRP, Bethesda, MDAbstract:Gonadal steroids act upon classical nuclear receptors to alter the function of many brain areas including limbic system areas involved in affective and cognitive processing. However, how the sexual steroids modulate the activity of the neurons that constitute the limbic system remains unclear. Previously we have reported the existence in the medial habenula of a population of neurons that receive inputs from hypothalamic homeostatic nuclei and may be induced to change to a GABAergic phenotype by local (synaptic) conversion of the gonadal steroid testosterone to estrogen vía aromatase contained in nerve terminals.In this study we used the RNAscope technique to evaluate the densities of neurons expressing the vesicular GABA transporter (VGAT) mRNA in several limbic regions, as well as the RNA of receptors for estrogen (ERa and ERb), testosterone (AR) and the enzyme aromatase. We compared male rats under four different gonadal status (castrated "GNX", sexually inactive "SI", sexually active "SA" and testosterone administration). Preliminary results show that GNX rats have diminished number of VGAT expressing neurons compared to SA rats in the following limbic structures: Anterior Cingulate Cortex (64% of that in SA rats); Anterior Olfactory Nucleus (44%); accumbens (56%); Lateral Septum (72%); Oval Nucleus of Stria Terminalis (72%). These data provide an evidence that gonadal status modify the emotion through GABAergic neuronal plasticity in limbic regions.

Abstract: Estrogen has been directly and indirectly linked to dopaminergic signaling in preclinical literature - a finding with clinical relevance to addictive disorders, which differ in prevalence, course, and consequences between men and women. However, no human studies have tested whether circulating estrogen levels influence striatal dopamine D_2-type receptor availability, a marker of dopamine function that is significantly lower in people with addictive disorders compared to healthy controls. We tested whether dopamine D_2-type receptor availability, measured with [^{18}F]-fallypride and positron emission tomography, changed significantly over the course of the menstrual cycle to influence inhibitory control. The latter was measured with self-report inventories, a motor response inhibition task (Stop Signal), and an emotion regulation task using cognitive reappraisal. Contrary to our hypothesis that estradiol would decrease striatal dopamine and thereby reduce inhibitory control, there was no relationship between striatal D_2-type receptor availability and circulating 17β-estradiol levels, and no effect of menstrual phase on inhibitory control. An exploratory analysis, however, revealed a parabolic (inverted-U) relationship between the estrogen:progesterone ratio and thalamic D_2-type receptor availability. These data suggest that menstrual phase (and other neuroendocrine events) may not influence striatal D_2-type receptors, but may instead exert influences on behavior by affecting D_2-type receptors in the thalamus, which is structurally and functionally connected to both the striatum and cortical regions.

Title: Artificial sweetener consumption induces changes in expression of c-Fos and NeuN in hypothalamus and hippocampus of rats

Authors: *L. E. MACIAS[1], M. DE LA CRUZ[2], D. MILLAN ALDACO[3], D. SORIANO NAVA[2], R. DRUCKER COLÍN[3], E. MURILLO RODRÍGUEZ[2]

Abstract: Obesity is the result of the interaction of multiple variables, including the excessive increase of sugar-sweetened beverages consumption. Diets aimed to treat obesity suggest the uses of sugar substitutes, such as aspartame, sucralose, or saccharin. Despite current evidence suggests that consumption of these sugar substitutes may prevent obesity, the effects of intake of artificial sweeteners in biomarker expression of neurons remain unclear. This study was aimed to investigate the effects of consumption of artificial sweetener on c-Fos or NeuN expression in hypothalamus and hippocampus. Artificial sweetener was diluted in water (25,75 or 250 mg/100 mL) and orally given to rats during 2 weeks. Next, animals were sacrificed by decapitation and brains were collected for analysis of c-Fos or NeuN inmunoreactivity. Consumption of artificial sweetener provoked an inverted U-shaped dose-effect in c-Fos expression in ventromedial hypothalamic nucleus while similar findings were observed in dentate gyrus of hippocampus. In addition, NeuN inmunoreactivity was enhanced in ventromedial hypothalamic nucleus at 25 or 75 mg/100mL whereas an opposite effect was observed at 250mg/100mL. Lastly, NeuN positive neurons were increased in CA2/CA3 fields of hippocampus from rats that consumed artificial sweetener (25,75 or 250mg/100mL). Consuming artificial sweet tasting (no caloric/reduced-calorie beverage) in water induced effects in neuronal biomarkers expression. To our knowledge, this study is the first description of the impact of consumption of artificial sweetener on c-Fos and NeuN inmunoreactivity in hypothalamus and hippocampus.

Abstract: Cerebrospinal fluid (CSF) is a complex fluid circulating around the nervous system whose composition dramatically changes as a function of the physiological state of an individual and in particular during bacterial meningitis. At the interface with the CSF in vertebrates, we discovered a singular class of spinal sensory neurons that surrounds the central canal and apically projects a ciliated extension into its lumen. We showed that these CSF-contacting neurons respond to changes in pH and CSF flow, and that their mechanosensitivity relies on the transient receptor potential channel PKD2L1. Here we investigated the physiological relevance of CSF-cN chemosensory properties. In particular, we tested whether CSF-cNs detect pathogen invasion in a zebrafish model of bacterial meningitis we previously developed by injecting red fluorescent mCherry labelled Streptococcus pneumoniae in the hindbrain ventricle. When injected in 2 days old larvae, the pathogen invades the entire CSF including the central canal within 24 hours. In response to the infection, we show that CSF-cNs undergo drastic changes in their activity. While basal activity goes down for most CSF-cNs, a fraction of CSF-cNs exhibits massive calcium transients lasting for tens of seconds. In order to identify novel receptors underlying CSF-cN activity, we isolated CSF-cNs by fluorescent-activated cell sorting and generated the transcriptome of CSF-cNs using RNAseq. Among genes enriched in CSF-cNs, we identified novel receptors modulating their activity by inactivating them with transient CRISPR/Cas9 injections and subsequently observing CSF-cN activity in vivo. This screen identified a novel receptor whose activation mimics the activation of CSF-cNs during the pathogen invasion. In addition, we found a multitude of peptides expressed by CSF-cNs known to carry antimicrobial functions and referred to as defensins. We are now investigating the molecular pathways enabling the massive activation of neurons contacting the CSF in vivo and the occurrence of peptidergic release to fight pathogen invasion in the CSF. Our study reveals a novel role for CSF-cNs in the detection of pathogens and deployment of the innate immune response during bacterial meningitis in vertebrates.

Title: Complement and psychiatric disorder: The role of C3/C3aR in fear and anxiety

Authors: *L. J. WESTACOTT[1], N. HAAN[1], S. MITTON[2], E.-L. BUSH[2], T. HUGHES[3], J. HALL[1], P. MORGAN[3], W. GRAY[1], T. HUMBY[2], L. WILKINSON[1]
[1]Neurosci. and Mental Hlth. Res. Inst., [2]Sch. of Psychology, [3]Systems Immunity Res. Inst., Cardiff Univ., Cardiff, United Kingdom

Abstract: Recent genetic findings indicate that the complement system, a branch of the innate immune system, plays a causal role in risk for schizophrenia. However, the biological mechanisms that link complement and psychiatric disease remain unknown. The objective of this research is to investigate the impact of complement on behavioural phenotypes relevant to psychiatric disorders.

We studied the C3/C3aR pathway using two knockout mouse models; $C3^{-/-}$ and $C3aR^{-/-}$. C3aR is the canonical receptor for C3a, a breakdown product of C3 activation. Male mice ($C3^{-/-}$, $C3aR^{-/-}$, WT; 3-9 months of age; $n \geq 10$ per group) were tested in a battery of behavioural tasks to assay anxiety and learned fear. Additionally, subsequent to an acute stressor, blood samples were collected for analysis of corticosterone, and brain regions were dissected for gene expression analysis.

In the elevated plus maze (EPM), $C3aR^{-/-}$ mice were highly anxious, evidenced by markedly reduced open arm exploration compared to WT and $C3^{-/-}$ subjects. This pattern of results was replicated in the open field (OF) and other tests of anxiety, indicating an anxiogenic effect of C3aR deficiency that was not present in the $C3^{-/-}$ mice.

We next explored the sensitivity of this anxiety phenotype to the anxiolytic diazepam. The drug had no effect on the marked anxiogenic effects of C3aR deficiency at a dose that proved anxiolytic in WT subjects, and there were no effects in $C3^{-/-}$ subjects, suggesting an altered sensitivity to benzodiazepines and a potential alteration in the $GABA_A$ receptor system in the knockouts.

The fear potentiated startle paradigm was used as a test of learned fear. While both knockouts demonstrated elevated acoustic startle responses at baseline, indicating heightened fear, only $C3^{-/-}$ subjects demonstrated a significantly enhanced potentiation of the startle reflex in response to a conditioned stimulus, suggesting that C3, but not C3aR, is involved in learned fear.

These behavioural effects were accompanied by reductions in the reactivity of the HPA axis to an acute stressor in both knockouts, consistent with a chronic stress state. Pilot data also indicates that in both knockouts, there is altered expression of the glucocorticoid receptor gene NR3C1 in the brain following acute stress.

In conclusion, this research provides new insights linking manipulations of the complement C3/C3aR pathway and emotion. The behavioural differences between the mutants suggest dissociable mechanisms underlying the impact of discrete complement components on fear and anxiety, which are core symptoms of many psychiatric disorders, including schizophrenia.

Title: Two-year safety and efficacy of ultra-low duty cycle stimulation of the vagus nerve as a first-in-class bioelectronic therapy in rheumatoid arthritis

Authors: *Y. A. LEVINE, D. CHERNOFF
Setpoint Med. Corp., Valencia, CA

Abstract: Introduction Despite the availability of multiple pharmaceutical and targeted biological drugs for treatment of rheumatoid arthritis (RA), significant unmet clinical need remains for those who are intolerant or fail to respond. Modulating innate anti-inflammatory neuro-immune pathways through electrical stimulation of the vagus nerve may represent a novel, nonpharmacological means of treating RA and other inflammatory diseases. We recently reported a 12-week proof of concept study with an implanted neuromodulation device, showing reductions in the DAS28-CRP disease activity score and in TNFα and IL-6 levels (PNAS, 2016. 113(29): 8284). To understand the long term safety and efficacy of this treatment approach, we followed the subjects for 24 months in a long term extension study. **Method** In the primary study, neuromodulation devices were implanted into 17 RA subjects, mostly with inadequate responses to multiple conventional and targeted biologic drugs. The cervical vagus nerve was stimulated at ultra low duty cycle (10 Hz, 1-4 min/day) with output current intensity titrated to subjects' upper comfort level. On completion, subjects were offered enrollment in a follow-up study, where study physicians were given flexibility to alter electrical dosing parameters and/or to add a biologic to the treatment regimen. DAS28-CRP and Health Assessment Questionnaire-Disability Index (HAQ-DI) were collected over 2 years. **Result** All subjects electively continued on neuromodulation treatment through 24 months follow-up study. Biologics were started in 9 of 17 subjects; of these, 4 were non-responders to therapy in the primary study, and 5 had improvement but had not yet achieved disease remission with neuromodulation alone. At the start of the follow-up study, the mean DAS28-CRP and HAQ-DI were significantly reduced compared to the pre-implant baseline, and the depth of effect was retained through 24 months. No association between DAS28-CRP and stimulation frequency (Range= 1-8X/day) was observed. At 24 months, there was no significant difference in DAS28-CRP between the subjects

treated with neuromodulation as monotherapy or those treated with a combination of neuromodulation and biologics. No difference in the adverse events profile between the two groups was detected. **Conclusion** These data demonstrate that this first in class bioelectronic therapy substantially reduced disease activity and disability in subjects with RA, and the therapeutic benefits were sustained for up to 24 months without untoward safety signals. These results support further development of implantable neuromodulation devices as an alternative therapeutic approach to treating RA.

Title: Circadian gating of hepatic spinal inflammatory input shapes cytokine response by liver and spleen

Authors: *E. C. SOTO-TINOCO, E. SANTACRUZ, R. M. BUIJS
Cell. Biol. and Physiol., Univ. Nacional Autónoma De México, Mexico City, Mexico

Abstract: The autonomic nervous system (ANS) regulates the intensity of the inflammatory response to peripheral endotoxin exposure, but how is the brain informed about the immune challenge has remained largely elusive. We hypothesized that the sensory afferent part of the ANS is responsible for sensing lipopolysaccharide (LPS) and allow the efferent ANS to immediately mount an adequate inflammatory response. We show that sensory neurons in the spinal cord and not in the circumventricular organs become activated shortly after an LPS challenge by LPS-induced prostaglandin production. Denervation studies show that the inflammatory signal is transmitted by liver spinal afferents. The circadian system, which strongly

influences ANS output, imposes rhythmicity on the gating of hepatic sensory input, fine-tunning the sensitivity to LPS and allowing an efficient inflammatory response to happen during the active period of the animal, while preventing this process during the resting phase of the animal . This study unravels the circuit used to transmit the peripheral LPS signal to the brain. The hepatic spinal sensory nerves, strongly influenced by the circadian system, allow the spleen to mount an efficient inflammatory response only at the moment when it is most likely needed.

Title: A pilot randomized control trial investigating brain-body mechanisms of Qigong meditative movement practice for cancer-related fatigue

Authors: C. ZIMMERMAN[1], C. PENNER[2], *S. TEMEREANCA[2], D. DANIELS[2], B. CULLEN[3], S. JONES[2], C. E. KERR[1]
[1]The Warren Alpert Med. Sch., [2]Dept. of Neurosci., Brown Univ., Providence, RI; [3]Dept. of Psychology, Univ. of Oregon, Eugene, OR

Abstract: Meditative movement and exercise practices are both beneficial for health, and have been validated to improve fatigue levels in cancer survivors with cancer-related fatigue (CRF). Compared to exercise, less is understood about the specific brain-body mechanisms by which meditative movement practices may improve health. Qigong, a form of meditative movement, emphasizes gentle movements with a specific training of the mind to focus and engage those movements. In this pilot clinical trial, we employ a parallel, randomized non-inferiority design to test whether ten-weeks of Qigong training is not inferior to an exercise-nutrition control program in reducing fatigue (via the FACIT-Fatigue Questionnaire) in 48 female cancer survivors with CRF. While our primary hypothesis is that Qigong and exercise-nutrition will both reduce subjective reports of fatigue, we utilize multi-modal physiological measures of brain, cardiorespiratory, and muscle dynamics as well as inflammatory immune markers to assess whether Qigong improves fatigue via a distinct neuro-immune mechanism compared to exercise-nutrition. Specifically, this study utilized (1) Electroencephalography (EEG) during a tactile discrimination task to examine whether the meditative focus cultivated by Qigong enhances pre-stimulus control of alpha (7-14 Hz) rhythm over somatosensory cortex during a tactile acuity task (2) Simultaneous EEG and electromyography (EMG) during a precision grip task, to test

how Qigong differentially alters sensorimotor function indexed by enhanced beta (15-30 Hz) cortico-muscular coherence and decreased force variability (3) Electrocardiography (ECG) to assess whether high-frequency heart rate variability (HRV) as a measure of parasympathetic activity was correlated with peripheral inflammation and improved by the stress-reduction aspects of Qigong training (4) Laser Doppler Flowmetry (LDF) to evaluate effects on peripheral blood flow dynamics and (5) Neuroimmune interactions were tested to investigate if enhanced attentional modulation of alpha rhythms post-training were correlated with decreased inflammatory markers. Further, we examined if these post- vs pre-training effects on physiological measures were larger in the Qigong group compared to the exercise-nutrition control group. This study helps identify potential EEG and other physiological biomarkers of clinical effects of Qigong meditative movement therapy.

Title: Sexual dimorphism of the CCL2/CCR2 chemokine system in the lateral hypothalamus (LH) as it relates to the neuropeptide melanin-concentrating hormone (MCH), responds to ethanol exposure during pregnancy, and contributes to excess ethanol consumption in adolescent offspring

Authors: *S. F. LEIBOWITZ, G.-Q. CHANG, O. KARATAYEV, V. HALKINA, J. EDELSTIEN, E. RAMIREZ, V.-S. KEWALDAR
Rockefeller Univ., New York, NY

Abstract: Ethanol consumption and inflammatory agents during pregnancy similarly increase alcohol drinking in adolescent offspring. To investigate how neuroimmune and neurochemical systems interact to mediate these behavioral disturbances, we examined a specific population of neurons in the LH which express the inflammatory chemokine CCL2 or its receptor CCR2 that are positively related to ethanol intake and also co-express the orexigenic neuropeptide MCH that similarly promotes ethanol consumption. Our published evidence in Sprague-Dawley rats (Chang et al., 2015) shows that maternal oral administration of ethanol at low-to-moderate doses (1-3 g/kg/day) from embryonic day 10 (E10) to E15 increases the expression and levels of CCR2 in the LH, its colocalization with MCH, and the drinking of ethanol in male offspring. We

additionally find that these neuronal and behavioral effects of maternal ethanol administration are blocked by a CCR2 antagonist administrated during pregnancy, suggesting that this CCL2/CCR2 chemokine system is involved in mediating ethanol's actions. Further investigations have yielded 3 main results: 1) Injection of CCL2 (4 and 8 ug/kg/day) during pregnancy (E10-E15) compared to its vehicle produces similar effects as maternal ethanol administration (2 g/kg/day, i.g.), significantly stimulating CCR2 and MCH neurons and their colocalization in the LH and ethanol intake in adolescent offspring; 2) These neuronal and behavioral effects of maternal CCL2 administration like ethanol are sexually dimorphic, consistently stronger in the female adolescent offspring, with both ethanol and CCL2 having a particularly strong stimulatory effect on CCR2 expression which is increased by ~250% in females compared to only 40% in males; and 3) Neurons expressing CCL2 are also detected in the LH, closely associated with MCH neurons, and increased by maternal administration of ethanol (2 g/kg/day). There are two distinct types of CCL2-expressing neurons stimulated by ethanol, namely, large CCL2 neurons that are concentrated in the LH and colocalize CCR2 along with MCH and small CCL2 neurons that while scattered throughout the hypothalamus are seen in the LH immediately adjacent to and surrounding the large MCH neurons. These results demonstrate that this neuronal CCL2/CCR2 system in the LH, which is closely linked to MCH neurons and involved in maternal ethanol's stimulatory effects on this neuropeptide and ethanol drinking in adolescent offspring, is sexually dimorphic with females showing greater responsiveness to ethanol and thus may contribute to the higher levels of adolescent risk factors for alcohol use disorders described in women.

Title: The human brain microbiome; there are bacteria in our brains!

Authors: *R. C. ROBERTS, C. B. FARMER, C. K. WALKER
Psychiatry and Behavioral Neurobio., Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: The gut-brain microbiome has received an abundance of attention recently. It is thought that gut microbiota can influence brain function and behavior, but how that happens is

still unknown. It has been proposed that bacteria can enter the brain through the blood brain barrier, and/or via nerves that innervate the gut. Here we show the presence of bacteria in the human and mouse brain under noninfectious or nontraumatic conditions. We first found the bacteria, identified by morphological criteria, in ultrastructural samples of human postmortem brain (n=34 cases). We did serial section analysis for identification and quantification. All cases contained bacteria in varying amounts. Bacteria were rod shaped, and contained a capsule, nucleoid, ribosomes and vacuoles. The average diameter of the short axis was 0.496um. Many were segmented, with the long axis averaging approximately 1.78um between segments. Others did not appear to be segmented and were approximately 0.866um in the long axis. The vast majority of the profiles had a thick capsule of approximately 100nm. The density of the bacteria varied according to the brain region, with abundant bacteria in the substantia nigra, hippocampus and prefrontal cortex but sparse numbers in the striatum. Bacteria were present in intracellular locations, predominantly in astrocytic end feet at the blood brain barrier, dendrites and the soma of glial cells. They were also abundant adjacent to and within myelinated axons. To address the possibility that the bacteria in human tissue was a result of postmortem artifact, we examined mouse brains that were fixed immediately at death (n=10); there were abundant bacteria in similar intracellular locations. To eliminate the possibility that the presence of bacteria was due to contamination, we examined germ free mouse brains (n=4) processed in an identical way; we did not detect any bacteria. The observation that the location of the bacteria was highly specific and deep within the specimens also argues against contamination. Interestingly, there were no structural signs of inflammation in any of the brains examined. It is presently unclear the route of entry bacteria take to the brain, but the evidence of them in axons and at the blood brain barrier supports previous speculation.

Title: The alternation of the molecules associated with chronic inflammation in the postmortem brains from patients with schizophrenia

Authors: A. WADA[1], *Y. KUNII[2,3], M. HINO[3], J. MATSUMOTO[3], A. NAGAOKA[3], S.-I. NIWA[2], A. TAKESHIMA[4], H. NAWA[5], A. KAKITA[4], K. KASAI[1], H. YABE[3]

Abstract: The effectiveness of current drug therapy for schizophrenia based on the dopamine hypothesis combined with various psychosocial treatments is insufficient. Thus, there is a need to explore molecular targets for novel drugs for schizophrenia. Previous studies have indicated the possible involvement of chronic neuroinflammation in schizophrenia, with reports of elevated levels of proinflammatory cytokines. One of many similar reports, Zhang et al. found decreased levels of interleukin (IL)-2, IL-4, and IL-8 in patients with schizophrenia compared to healthy controls. Epidemiological studies have also shown a high risk of subsequent autoimmune disease in patients with schizophrenia. Meanwhile, genetic markers in the major histocompatibility complex locus appear to have a high genetic correlation with schizophrenia. However, a 2016 systematic review of 119 articles related to neuroinflammation in schizophrenia found no consistent results regarding levels of glial fibrillary acidic protein, microglial markers, cytokines, chemokines, products of the arachidonic acid cascade-related molecules, and substance P-related molecules in postmortem brains with schizophrenia. The present study aimed to elucidate part of the mechanism of schizophrenia onset using the postmortem brains from 24 patients with schizophrenia, 7 patients with bipolar disorder and 31 controls. Using the Luminex assay, the expressions of molecules involved in immunity and chronic inflammation were measured in postmortem brains with schizophrenia and the relationship between these levels and genetic polymorphisms was analyzed to investigate the association between inflammatory mediators and schizophrenia. The data obtained from the postmortem brains with schizophrenia were also analyzed regarding the relationship between each molecular level and clinical profile, including age, sex, duration of illness, antipsychotic dose, and postmortem interval. The following results were obtained. 1) The schizophrenia group had lower interferon-inducible protein (IP)-10 mass/mg total protein (pg/mg) compared to healthy controls ($p=0.012$). 2) The schizophrenia group had lower IL-17A protein mass/mg total protein (pg/mg) compared to healthy controls ($p=0.003$). 3) Data regarding antipsychotic dose were available for 22 patients in the schizophrenia group. Spearman's rank correlation analysis of the relationships of IP-10 and IL-17A protein mass/mg total protein with mean antipsychotic dose (chlorpromazine equivalent) over the 3 months antemortem found a positive correlation for IP-10 ($p=0.032$). No correlation was observed for IL-17A.

Title: Sex differences in the expression of neuroimmune genes during withdrawal from acute or chronic ethanol exposure: A comparison of adolescent and adult ethanol exposures

Authors: *P. MARSLAND, A. S. VORE, A. GANO, T. DEAK
Binghamton Univ., Vestal, NY

Abstract: Prior work has shown that acute ethanol intoxication and subsequent withdrawal ("hangover") produces phase-specific fluctuations in neuroimmune genes. Although males and females did not differ in the acute rise in IL-6 during acute intoxication, subtle differences in neuroimmune gene expression during acute ethanol withdrawal were observed, warranting further examination of sex differences. In Experiment 1, male and female Sprague Dawley rats were injected with 3.5 g/kg of ethanol or saline (i.p.), with brains and blood samples collected at various time points post-ethanol (15, 18, 24, or 72 hr). Gene expression analyses in the paraventricular nucleus of the hypothalamus revealed increased expression of cytokines predominantly at the 15 hr time point (i.e., early in withdrawal), with TNFα being increased in both sexes. Sex-specific alterations were also observed at 15 hr (increased IκBα in males; increased expression of IL-1β in females). Consistent with prior studies, females displayed substantially higher ambient circulating corticosterone (CORT) than males, regardless of injection timepoint. However, progesterone showed a time-dependent increase during withdrawal that was only observed in females. Experiment 2 utilized a chronic ethanol exposure procedure in which early adolescent (starting at P30) or young adult (P70 start) male and female Sprague Dawley rats received 4.0 g/kg ethanol (i.g.) or water intubations for 3 days, followed by 2 days of withdrawal and abstinence. This cycle was repeated 4 times. Tissue was collected 24 hr after the final ethanol exposure to assess withdrawal from chronic ethanol exposure. Once again, female rats displayed higher circulating CORT than males, regardless of age. However, rats with a history of chronic vehicle exposure displayed significantly higher CORT than the ethanol group, an effect that was only observed in female rats, regardless of age. Sex differences were also observed in IL-6 expression, with adult males showing decreased IL-6 expression during ethanol withdrawal, and adult females showing increased IL-1β and TNFα expression. Taken together, these results demonstrate that withdrawal from acute ethanol exposure produces a relatively rapid increase in neuroimmune genes shortly after ethanol clearance, an effect that

appears to be sustained after repeated cycles of binge-like ethanol exposure. Although certain genes appeared to be mutually elevated in both males and females (TNFα), other neuroimmune genes appeared to be regulated in a sex-specific manner (IL-1β, IκBα). Finally, these data suggest that adolescents and adults do differ in the expression of withdrawal-related cytokines.

Title: Assessment of neuroinflammation in the aging brain using large-molecule microdialysis: Sex differences and involvement of purigenic receptors

Authors: *T. BARNEY[1], A. E. PERKINS[3], M. PIAZZA[2], T. DEAK[4]
[1]Psychology, [2]SUNY Binghamton, Binghamton, NY; [3]Binghamton Univ., Binghamton, NY; [4]Behavioral Neurosci. Program, Dept. of Psychology, Binghamton University-SUNY, Binghamton, NY

Abstract: Neuroinflammation has long been considered a hallmark characteristic of neurodegenerative disease, but recent work has suggested that inflammation may be a vital feature of natural aging as well. While much research has utilized animal models to investigate neuroinflammation, most studies have utilized static procedures such as immunohistochemistry (IHC) or *ex vivo* studies in which microglia or other resident immune cells of the CNS are extracted and stimulated in culture. Thus, very little is known about regulation of neuroinflammatory responses in the awake, behaving rat. Thus, the goal of the current study was to investigate time-dependent expression of extracellular cytokine and chemokine concentrations in young adult (3-month old) and aged (18-month old) Fischer 344 (F344) rats of both sexes using *in vivo* microdialysis. We further investigated the potential involvement of purinergic receptors in neuroinflammation by reverse dialysis of the purinergic P2X7 agonist Bz-ATP. Male and female F344 rats aged 3- or 18 months were acquired from the NIA colonies and underwent stereotaxic surgery to implant guide cannula into the dorsal hippocampus. On the day of testing, microdialysis probes were inserted and large molecule microdialysis was performed. Probe stabilization occurred for 3 hr followed by a 2-hr baseline period, after which BZ-ATP (100 mM) was delivered for 1 hr by reverse dialysis. Then, aCSF was administered for a 2-hr recovery period. Multiplex technology was used to simultaneously measure several analytes in dialysate samples. With the exception of IL-6, the release of cytokines, chemokines, and growth

factors was largely unaffected by age. The results demonstrated that males had greater overall release of IL-1β, IL-6, IL-10, MIP-1α and MIP-3α relative to females. Furthermore, IL-6, IL-10 and MIP-1α were greater in males relative to females following initial probe insertion, while this trend was seen in IL-10, IL-17, MIP-1α and TNF-α following drug administration. Lastly, modulation of cytokines by Bz-ATP (a P2X7 agonist) suggested selective regulation of individual factors by the P2X7 receptor (IL-1α, IL-1β, IL-6, IL-17, GRO-KC, MCP-1, MIP-1α and MIP-3α). Overall, this study revealed relatively few age differences in cytokine, chemokine, and growth factor release following probe insertion. However, males displayed enhanced reactivity in many of the target proteins relative to females. Overall, these findings provide critical information regarding characteristics of the individual (age, sex) that profoundly influence neuroinflammatory responses and their regulation by the P2X7 receptor.

Abstract: *Toxoplasma gondii (T.gondii)* is a neurotropic parasite with a life cycle involving oocyst-producing cats and any warm-blooded animals as intermediate hosts. Toxoplasmosis is commonly acquired via ingestion of oocysts (deficits in washing hands after gardening/farming, vegetables, contaminated water and food, cat litter) or tissue cysts (most common undercooked meat). Oocysts, more resilient to environment and disinfectants, have also been hypothesized to be more virulent and neurotropic than tissue cysts, although direct evidence is lacking. Although, in the immunocompetent host, *T.gondii* establishes latency in the CNS, brain-imaging data in chronic "latent" toxoplasmosis are scarce. Considering that cortical thinning has been previously reported in schizophrenia and suicidal behavior, conditions linked with *T.gondii*, we now relate the average whole brain cortical thickness (AWBCT) to *T. gondii* seropositivity and serointensity for IgG, IgM, and, oocyst-specific IgG, by ELISA. MRI scans were obtained from a convenience sample of 85 Old Order Amish with 48 (56.47%) women, with a mean age of 47.55 ± 17.95, with 10% diagnosed with any mental illness, and used to compute AWBCT (in mm). Linear regressions were used to analyze associations between T.gondii antibodies and AWBCT with adjustment for age, sex, diagnosis of any psychiatric disorder, and diagnosis of only bipolar or psychotic disorders. We found a negative association between AWBCT and oocyte IgG serointensity ($p= 0.0004$, $n=86$), robust to adjustment for age and gender ($p=0.0066$) and psychiatric diagnosis ($p=0.0151$). The IgM and IgG serointensity and seropositivity for all antibodies were not significantly related to AWBCT. Reverse causality potential and confounding by recency of infection notwithstanding, the link between *T.gondii* oocyst infection and cortical thinning uncovers a morphological connection, potentially through neuroimmune activation or neuroprotective defects, thus suggesting potentially modifiable preventative and treatment targets.

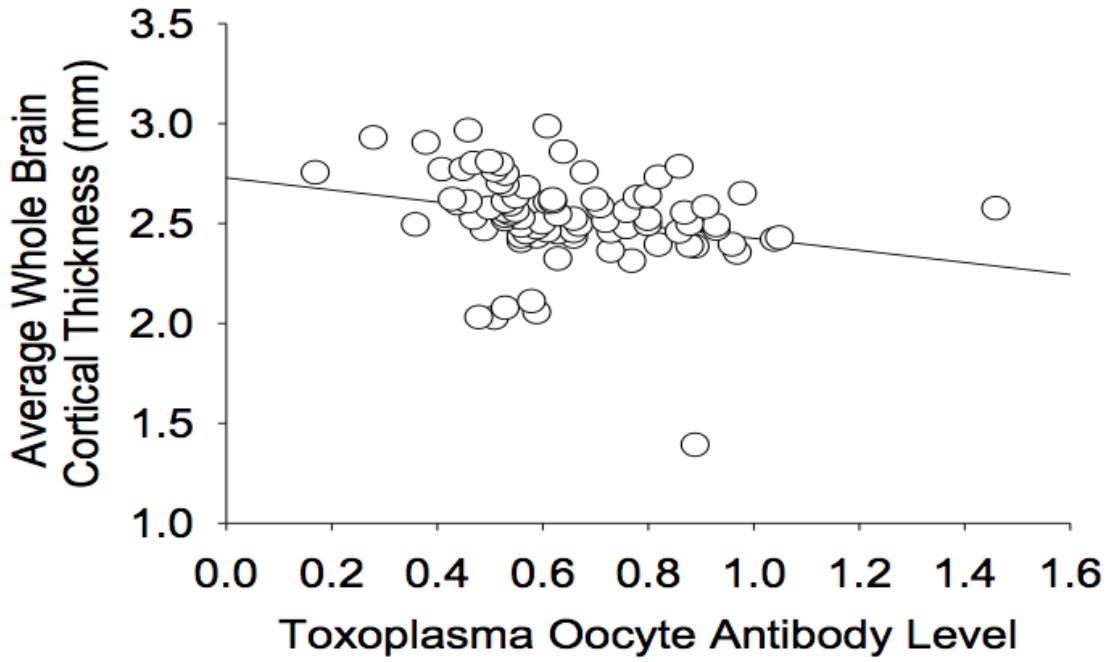

Figure 1: Association between T. gondii oocyte and Average Whole Brain Cortical Thickness: Spearman'rho = 0.37, p=0.0004, n=86

Corrected for age (partial correlation), partial r=0.31, p=0.003. Removing 'outlier' case with cortical thickness less than 1.5: Spearman's rho = 0.36, p=0.001, n=85. Corrected for age (partial correlation), partial r=0.30, p=0.006. Fully adjusted for age, sex and mental illness, p=0.015)

Abstract: Different brain areas present specific cellular and molecular response, here we examined the expression of modulatory cytokines and growth factors which can change their expression depending on cortex location. We used 3 months old 6 rats to study the gene expression of the anterior (sensorimotor cortex) and posterior (auditory and visual cortex) area of the cerebral cortex. Thirty-eight genes were evaluated involving cytokines, angiogenesis molecules, extracellular matrix components and oxidative nitric related genes by quantitative reverse transcription PCR (RT-qPCR). After Wilcoxon matched-pairs signed-ranks test for matched pairs of observations, we found that transforming growth factor beta (Tgfb-1), its receptor (Tgfbr1), VEGF receptor 1 and Angiopoietin-1 receptor changed their expression when compared anterior and posterior cortex area (P=0.046, 0.028, 0.028, 0.028, respectively). Those genes were upregulated in the anterior area of the brain and presented about 1.5 fold of increase. Collective this data report differential expression in normal brain areas which involve the regulatory cytokine Tgfb-1 and angiogenesis-related genes.

Title: Galantamine, a cholinergic drug for treating Alzheimer’s disease alleviates inflammatory responses and liver injury induced by APAP/Tylenol in mice

Authors: *V. A. PAVLOV[1,2], X. XUE[1], P. K. CHATTERJEE[1], M. ADDORISIO[1], K. J. TRACEY[1,2], C. N. METZ[1,2]

Abstract: Galantamine is a centrally-acting acetylcholinesterase inhibitor and an FDA-approved drug for Alzheimer’s disease. We have previously demonstrated the anti-inflammatory and hepatoprotective effects of galantamine in mice with endotoxemia and metabolic syndrome. Here, we examined the effect of galantamine on liver injury and inflammation in a mouse model of APAP/Tylenol-induced hepatotoxicity. C57BL/6 male mice (10wks) fasted for 10hrs were

treated with either saline or galantamine (4mg/kg,ip) 1hr prior to APAP (350mg/kg, ip) or 1hr post-APAP (350mg/kg). 12h post APAP mice were euthanized; serum and livers were collected and assessed for liver injury (e.g. ALT, AST) and liver and systemic inflammation. Administration of galantamine before APAP significantly reduced liver injury. Moreover, galantamine given 1hr post-APAP significantly reduced APAP-liver injury. While no changes in serum IFNγ, IL-1β, IL-10, or TNF levels were observed 12h post APAP, serum IL-6 was significantly increased by APAP and this was reduced when galantamine was given 1hr post APAP ($P<0.05$). Similarly, APAP-induced liver IL-1β and TNF protein levels were significantly reduced by galantamine ($P<0.05$). qPCR analyses using liver RNA showed that liver *Il1b, Il6,* and *Tnfa* mRNA expression induced by APAP was significantly reduced by galantamine ($P<0.001$). Our results demonstrate that galantamine is hepatoprotective and anti-inflammatory when administered following APAP overdose. NAC (N-acetylcysteine) is the mainstay therapy for APAP overdose. However, not all patients benefit because it requires early administration, high doses, and long treatments for success. APAP overdose patients exhibit severe neurological pathologies and can die from brain edema and multi-organ failure caused, in part, by immune dysregulation and enhanced cytokine production. Our data support further investigating the role of galantamine and cholinergic modulation in reducing APAP-induced liver and brain injury.

Title: Characterization of white adipose tissue in young and aged rats and its possible role in neuroinflammation

Authors: *R. M. BARRIENTOS[1,2], L. S. TODD[1], M. KOVACS[1], E. R. LANGDON[1]
[1]Dept. of Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]Inst. for Behavioral Med. Research, and Dept of Psychiatry and Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Aged rats are more susceptible than young adult rats to long-lasting memory impairments following acute inflammatory insults (e.g., bacterial infection, surgery, or high-fat diet). We have previously reported that this vulnerability is due to aging-induced sensitization of hippocampal and amygdalar microglia which produce exaggerated levels of proinflammatory

cytokines following these insults, and these in turn impede synaptic plasticity mechanisms such as LTP. However, what causes this microglial sensitization in aged rats in the first place remains elusive. An obvious, but over-looked characteristic of aged rats that may play a role in microglial sensitization is their increased body mass compared to young adult rats. White adipose tissue (WAT) is known to be proinflammatory, and depending on its anatomical location and the circulatory system into which they drain could differentially affect neural processes. Thus, we characterized distribution and inflammatory phenotype of several WAT compartments (retroperitoneal, epididymal, subcutaneous, and omental) of young and aged rats fed chow or high fat diet (HFD). We found that aged rats have significantly greater WAT than young rats in all compartments measured, with epididymal and subcutaneous compartments having the greatest percentage of WAT to body mass. Furthermore, HFD-fed aged rats showed an exaggerated increase in retroperitoneal fat over chow-fed controls after just 3 days on that diet. Cytokine expression in WAT from each compartment was also measured and will be reported and correlated to cytokine levels in the hippocampus and amygdala. We previously demonstrated that voluntary wheel running ameliorates contextual memory deficits induced by HFD in aged rats. Here we found that wheel running among chow- and HFD-fed aged rats significantly reduced WAT from the retroperitoneal compartment compared to sedentary HFD-fed aged rats. These findings suggest that WAT from the retroperitoneal compartment may be an important contributor to neuroinflammatory responses in aged rats.

Title: Impact of neonatal hypoxia-ischemia and inflammation on cerebellum development

Authors: *S. E. ARAMBULA[1], E. L. REINL[1], J. WADDELL[2], M. M. MCCARTHY[1]
[1]Pharmacol., [2]Pediatrics, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Neonatal Hypoxic-ischemic injury (H/I; concurrent oxygen/blood deprivation) occurs in approximately 2 out of 1,000 term births and is associated with an increased risk of death or major neurodevelopmental disability. Studies in rodent models suggest that preceding inflammatory events can increase the magnitude of brain injury caused by H/I and influence its response to therapeutic intervention. While clinical evidence demonstrates that gross cerebellar

development is profoundly but diffusely damaged by neonatal H/I, the cellular impact of H/I on the cerebellum is not well characterized. Here, we use a modified version of the Rice-Vannucci model of H/I that results in moderate brain injury to quantify the impact on cerebellar development in male and female rat pups with and without prior inflammation. To mimic an inflammatory reaction occurring prior to birth, Sprague Dawley rat pups were given a single intraperitoneal injection of lipopolysaccharide (200 μg/kg) or PBS (vehicle) on postnatal day (PN) 9. On PN10, animals underwent unilateral ligation of the carotid artery followed by exposure to 8% oxygen air for 60 min. Control animals for all experiments were sham-operated. On PN17, animals were euthanized and cerebellar vermis were dissected and processed for western blot analysis. Initial results show that H/I decreases both forms of glutamic acid decarboxylase (GAD65 and GAD67) in the anterior zone (lobules 1-5) of males only. This discovery, coupled with the knowledge that the second postnatal week is a sensitive period in cerebellar development, suggests that H/I may alter the maturation of GABAergic neurons. Further studies are underway to determine how H/I, with and without prior inflammation, affects astrocytes, microglia, Purkinje cells, granule cells and neurons of the cerebellar vermal zones. In addition clinical data indicates a sex-difference in H/I outcomes, with males exhibiting greater behavioral and cognitive deficits relative to females.

Title: Inflammatory mediators regulate DNA methylation during sexual differentiation of the brain

Authors: *E. L. REINL, C. L. WRIGHT, S. L. STOCKMAN, M. M. MCCARTHY
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The study of sex differences in healthy neural development can inform on the mechanisms leading to disorders with sex-differences in their susceptibility. The most well studied neural sex differences lie in the organization of brain regions necessary for sexual behavior, including the preoptic area (POA), established by the neuroendocrine milieu of the early postnatal period. The POA is masculinized by endogenous testosterone produced by the male testes in late gestation and shortly after birth, or by exogenous testosterone or estradiol in

females. Our group has shown that during this period estradiol masculinizes the POA by 1) recruiting degranulating mast cells to activate local microglia producing the pro-inflammatory prostaglandin E_2 (PGE_2), and 2) reducing DNA-methyltransferase (DNMT) activity leading to de-repression of a subset of masculinization genes. The work presented herein aimed to examine the connection between these two currently unrelated mechanisms. We hypothesize that estradiol inhibits DNMTs indirectly through mast cell degranulation and microglia PGE_2 production, resulting in DNA de-methylation in males. We measured DNMT activity in PN2 POA and hippocampus from males, females, females treated intracerebroventricular (ICV) on PN0 and PN1 with 1 µg 48/80 (a mast cell degranulation agent), and females treated ICV with 2.5 µg PGE_2 using the Epigentek EpiQuik DNMT Activity Assay Kit. Global DNA methylation (5mC) was measured in POA, hippocampus, and amygdala of males, males + PGE_2, females, and females + PGE_2 using the Epigentek MethylFlash Global DNA Methylation ELISA Kit. Our results show that treatment of females with PGE_2 decreased DNA methylation and DNMT activity in the POA to male levels. Females treated with 48/80 showed decreased DNMT activity even below male levels in the POA. In the hippocampus where DNA methylation and DNMT activity are also greater in PN2 females than males, PGE_2 had no effect in reducing DNMT activity, and 48/80 had only a subtle effect in doing so. Initial results show that PGE_2 also decreased 5mC in the female amygdala, and increased 5mC in both the male amygdala and POA. We conclude that inflammatory mediators may serve as a connecting point between estradiol and DNA demethylation. Future studies will extend this analysis to the prefontal cortex, will employ the use of HPLC to more precisely quantify 5mC, and will include treatment with the cox enzyme inhibitor indomethacin to probe the necessity of PGE_2 in masculinization.

Title: Microglial phagocytosis shapes the cellular composition of the neonatal rat amygdala in a sex dependent manner

Authors: *A. E. MARQUARDT[1], J. W. VANRYZIN[1], M. M. MCCARTHY[2]
[2]Dept. of Pharmacol., [1]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The amygdala, a sexually dimorphic brain region, mediates a conserved male bias in juvenile social behavior in which males engage in more frequent and intense physical play. During the process of sexual differentiation of the amygdala, males exhibit fewer newborn cells than females across the first four days of life. We hypothesized that microglia, the brain's immune cells, may underlie this sex difference, as microglia are significantly more phagocytic in the male amygdala during this time period. Results from immunohistochemical analysis support this hypothesis, as the majority of Iba1-labeled microglial phagocytic cups in both sexes co-label with NucRed, a DNA binding dye, and PCNA, a marker of recently divided cells, indicating microglia actively phagocytose newborn cells in the developing amygdala. To explore how this sex difference in phagocytosis, mainly of newborn cells, affects the amygdala's architecture later in life, we used a fate mapping approach. Pups were treated with BrdU on postnatal day 0 (PN0) to PN4 to label newborn cells and sacrificed at PN26. Tissue sections were stained for BrdU and markers of various cell types. In the medial amygdala (MeA), the site of masculinization of play, BrdU+ cells predominantly (~80%) co-labeled with GFAP, an astrocyte marker, and this was true in both sexes. However, females had a higher density of BrdU+ cells including a higher density of GFAP+/BrdU+ cells specifically in the posterodorsal MeA (MePD). Because of this, we hypothesized that microglia generate the sex difference in postnatally born cells by phagocytosing cells fated to differentiate into astrocytes. To test this, we co-labeled histological sections from PN4 animals with Iba1 and the astrocyte-specific marker ALDH1L1, which is expressed much earlier in differentiation than GFAP. Microglia showed an enrichment for ALDH1L1 within the phagocytic cup and in their processes, and a greater percentage of phagocytic cups co-labeled with ALDH1L1 in males compared to females. This indicates that microglia phagocytose astrocytes in the developing amygdala and that they do so more frequently in males, likely producing the observed sex difference in postnatally-born astrocytes seen at the juvenile age. Future analysis will explore whether this developmental sex difference impacts the density of neurons, microglia, and astrocytes in the MePD and other MeA subregions.

Title: Microglial phagocytosis of newborn cells is induced by endocannabinoids and sculpts sex differences in social play

Authors: *J. W. VANRYZIN, A. E. MARQUARDT, S. E. ARAMBULA, K. J. ARGUE, M. M. MCCARTHY
Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: The amygdala is a sexually dimorphic brain region important for juvenile social play behavior. During neonatal development, the male amygdala contains fewer newborn cells than females. This sex difference inversely correlates to the expression of juvenile social play, a process we demonstrated to be the result of a higher developing endocannabinoid (ECB) tone in the male amygdala (Krebs-Kraft et al. PNAS 107(47), 2010). We now report that microglia, the resident immune cells of the brain, are more phagocytic in the male amygdala during this postnatal window, suggesting a possible mechanism by which ECBs affect the number of newborn cells. Based on these data, we hypothesized that microglia control the number of newborn cells in the postnatal rat amygdala by phagoptosing (targeted phagocytosis of viable cells) newborn cells in an ECB-dependent manner. We find that males have more phagocytic microglia between postnatal day 0 and 4, during which they also have a higher ECB tone. Administering testosterone or cannabinoid receptor agonists to female pups masculinized the number of phagocytic microglia and correspondingly decreased the number of newborn cells as indicated by BrdU labeling. Further analysis found that phagocytic microglia engulf newborn cells, which are enriched for the complement protein C3b. To directly implicate microglia phagoptosis, we utilized a complement receptor 3 (CR3) function-blocking antibody to inhibit phagocytosis, which increased the number of BrdU+ cells only in males demonstrating that newborn cells can survive if phagocytic activity is prevented. Furthermore, administering the anti-CR3 antibody to neonatal males prevented the masculinization of their play behavior when grown to the juvenile age. Together, these data suggest that sex differences in the local environment of the developing amygdala instruct microglia to actively phagoptose newborn cells as a means to sculpt the later life architecture of the amygdala and produce sex differences in juvenile social play.

Title: Disrupted place cell dynamics in the CA1 region of the hippocampus in long-term sepsis survivors

Authors: *J. J. STROHL, T. S. HUERTA, P. T. HUERTA
The Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: Sepsis is defined as a "life-threatening organ dysfunction caused by a dysregulated host response to infection" (Singer et al. JAMA 315:801 2016). Although the chance of surviving the initial shock has improved considerably, it has become apparent that long-term survivors suffer sepsis-related cognitive impairment. Preclinical studies using the cecal ligation and puncture (CLP) model of sepsis in mice reveal clear deficits in spatial memory tasks and contextual fear conditioning. Here, we use the CLP model to investigate the neural substrate of sepsis-induced memory impairment by studying place cell dynamics in the hippocampus. Male mice (Balb/C, n=8, C57BL/6, *n* = 8) underwent CLP or Sham surgery and allowed to fully recover. Following a 6-week survival period, mice were implanted with tetrodes lowered into dorsal CA1 and tested in open field environments. Recordings consisted of multiple *run* sessions interspersed with *rest* sessions in the homecage. Analysis included quantifications of mean and peak firing rates, in-field and out-of-field firing rates, place field size, stability, spatial coherence, spatial information, and navigational error rate calculated during path reconstruction (software: Cheetah, Spike2, NeuroExplorer, Matlab). Cells recorded during multiple sessions were categorized as active, emerging, or vanishing according to whether they remained active from one session to the next. CLP survivors have expanded place fields with lower spatial information and spatial coherence, and higher mean, in-field, and out-of-field firing rates compared to sham animals. Furthermore, when introduced to a new environment, CLP animals have a larger fraction of cells that remain active between the two environments. Finally, an algorithm (Bayesian path reconstruction, BPR) was implemented to test the ability of the ensemble of place cells to accurately determine the path traveled by the animal. The error between the BPR-estimated path and the actual path traversed by the animal was calculated. CLP animals demonstrated a significantly larger error rate compared to Sham. This indicates that the changes to CA1 place cell dynamics after CLP cause a distorted representation of the animals' location in its environment. These results suggest the dorsal CA1 network is disrupted in sepsis survivors and provide insight into potential therapeutics.

Title: Modulation of proinflammatory cytokine production by specific vagus nerve stimulation parameters

Authors: *T. TSAAVA[1], T. DATTA-CHAUDHURI[2], M. E. ADDORISIO[1], E. B. MASI[1,3], H. A. SILVERMAN[1], J. E. NEWMAN[1], C. BOUTON[2], K. J. TRACEY[1,2], S. S. CHAVAN[1,2]

Abstract: Vagus nerve stimulation (VNS) has been shown to be effective in treatment of inflammatory disease models. However, the impact of different electrical pulse parameters on the nerve activation and physiological responses is not understood. In the current study, we analyzed the effect of a range of stimulation parameters, which include amplitude, frequency, and pulse width on cytokine levels. The left cervical vagus nerve was stimulated for four minutes in naïve Balb/C mice using a range of asymmetric charge-balanced electrical pulses. The pulse parameters were: short (50µs) and long (250µs) pulse width, frequencies: 30Hz, 100Hz, 200Hz, and amplitudes: 50µA, 200µA, 750µA. Animals recovered for 2 hours, and circulating cytokine levels quantitated using multiplex ELISA assay. To assess the directionality of the signals, groups of animals were subjected to unilateral or bilateral vagotomy prior to vagus nerve stimulation. At 30Hz, amplitude-dependent increases in serum IL-6 and IL-10 were observed for both short and long pulses ($p<0.001$). Serum TNF levels were unchanged at 50uA and 200µA amplitudes with both pulses, however there was a significant increase with the long pulse at 750µA, compared to the short pulse. ($p<0.0001$). With unilateral vagotomy, levels of TNF and IL-6 were unchanged, whereas IL-10 levels increased significantly ($p=0.03$). With bilateral vagotomy, distal or cranial left vagus nerve stimulation did not affect TNF and IL-6 levels, but significantly increased serum IL-10 ($p=0.002$). Our data demonstrate that systemic cytokine levels can be modulated by selectively stimulating the vagus nerve using specific combinations of frequency, amplitude, and pulse width. Refinement of the specific parameters may enable controlled neuromodulation of immunity. This study was funded in part by DARPA (HR0011-15-2-0016) and NIH (1R35GM118182-01).

Title: Optogenetic stimulation of cholinergic neurons in the brainstem induces splenic nerve activity and attenuates systemic inflammation

Authors: *A. M. KRESSEL[1,2,3], T. TSAAVA[1], E. H. CHANG[1], Q. CHANG[1], V. A. PAVLOV[1,4], S. S. CHAVAN[1,4], K. J. TRACEY[1,4]
[1]The Lab. of Biomed. Sci., Feinstein Inst. of Med. Research-Northwell, Manhasset, NY; [2]Dept. of Surgery, Northwell Hlth., Manhasset, NY; [3]The Elmezzi Grad. Sch. of Mol. Med., Manhasset, NY; [4]Ctr. for Bioelectronic Med., The Feinstein Inst. for Med. Res., Manhasset, NY

Abstract: The inflammatory reflex is a well-defined neural circuit composed of afferent and efferent fibers that travel via the vagus nerve to regulate peripheral tumor necrosis factor (TNF) production. Previous studies have demonstrated that electrical stimulation of the efferent fibers reduces splenic TNF output in an endotoxemia model. However, the exact origin of these vagus nerve fibers in the brainstem and the means by which they innervate the spleen to alter its activity remain incompletely understood. Using optogenetics, we selectively stimulated cholinergic neurons in the dorsal motor nucleus of the vagus nerve (DMV), the brainstem nucleus from which the vagus nerve fibers responsible for the inflammatory reflex may originate. A fiber-optic cannula was inserted using stereotactic guidance into the DMV of transgenic mice expressing channelrhodopsin under the choline acetyltransferase promoter (ChAT-ChR2-EYFP mice). Mice were subjected to either optogenetic stimulation or no light/sham surgery (n=15 per group) for five minutes (473nm laser, 20Hz, 25% duty cycle). During DMV stimulation, splenic nerve activity was recorded using a cuffed two-channel electrode and analyzed for changes in neural activity. After 24 hours, inflammation was induced with intraperitoneal lipopolysaccharide (0.25mg/kg) and blood was collected 90 minutes later for analysis. Systemic TNF was measured using a commercially available ELISA. Optogenetic stimulation of the cholinergic neurons in the DMV of ChAT-ChR2-EYFP mice significantly decreased endotoxin-induced serum TNF levels compared to sham controls ($p=0.0004$). Furthermore, splenic nerve activity during DMV optogenetic stimulation was significantly increased over baseline, demonstrating the physiological connection between the vagus and splenic nerves. Together, these studies demonstrate that cholinergic fibers originating in the DMV regulate splenic TNF production by means of splenic nerve activation. Understanding the anatomic pathway of the

efferent arc of the inflammatory reflex will further aid in therapeutic developments for patients with inflammatory conditions.

Abstract: Electrical signals within central and peripheral nerves form the basis of communication throughout the brain and body. The vagus nerve is a major conduit for sensory information carrying electrical signals from the major internal organs, including the heart, stomach, lung, and abdominal viscera. Cell bodies of the vagus nerve fibers reside in the nodose ganglion at the base of the skull. In order to study how specific afferent information is organized within this vagus nerve, we developed an *ex vivo* preparation to image, record, and electrically stimulate intact NG and vagus nerve. To image calcium transients, which indirectly reflect action potentials, we created *Vglut2*-GCamp3 mice that express fluorescent calcium indicators in glutamatergic neurons. Then we examined the distribution of transient receptor potential ankyrin 1 (TRPA1) ion channels in the nodose ganglion. We observed that 8.3% of identified active neurons responded to polygodial (200 μM), a specific agonist of TRPA1, when applied directly to the perfusing solution. An additional 26.7% of neurons responded to capsaicin (100 μM) through activation of TRPV1 (vanilloid 1) channels. Amongst the TRPA1-responsive neurons, a subset responded with fast rise-time fluorescence intensity changes, while another subset exhibited a gradual intensity change. This may reflect differential activation of TRPA1 channels that reside at the cell bodies or on the vagus nerve fibers. TRPV1-selective responses were more uniform with a fast rise-time of fluorescence intensity change. Electrical stimulation of the attached vagus nerve via two-channel electrodes failed to replicate this selective activation.

Together, these results reveal a TRPA1-specific subset of sensory neurons in the nodose ganglion with varying neural response properties. We intend to utilize this *ex vivo* imaging preparation to dissect molecular details of afferent vagus circuitry by combining it with transgenic, knockout, or cre-loxP mice.

Abstract: Bioelectronic medicine requires the ability to monitor and/or stimulate neural signals longitudinally to treat disease states. Currently, there exists no effective electrode implants to record and stimulate autonomic nerves chronically in the mouse model. The implicit design challenges of chronically interfacing with the mouse cervical vagus nerve include developing an electrode that will be minimally invasive and conform to the 100 µm diameter nerve, as well as remain chronically viable for stimulation and recordings *in vivo*. Here we characterize a microfabricated flexible electrode through initial bench studies to validate the chronic insulation and stimulation integrity to determine device lifetime. Two- and three-contact flexible electrodes were fabricated using state-of-the-art iridium oxide for metallization and polyimide (PI-2611) for insulation. To evaluate the integrity of the polyimide, an accelerated soak test in phosphate-buffered solution (PBS) was conducted. Interdigitated electrodes (IDEs) were placed in PBS at 57°C (4x acceleration) for 20 days. The electrical impedance spectroscopy (EIS) was measured before, at regular intervals during, and after the test. No changes were observed in the EIS plots over time, suggesting insulation stability for > 180 days. To evaluate the stability of the iridium oxide, stimulation stability tests were performed. Flexible electrodes were placed in PBS and up to 100 million biphasic pulses (166 µs phase with a 66 µs interphase delay) with current

amplitudes ranging from 100 µA to 1000 µA were applied. EIS and cyclic voltammetry (CV) were measured before and after the pulse trains were applied. Initial results suggest that iridium oxide is a stable metal for long-term stimulation applications. These bench test results corroborate our *in-vivo* chronic performance, where viable SNR and impedances were obtained throughout a 21 day implantation period from the mouse cervical vagus nerve. Development of such technology will allow chronic electrophysiological experiments on mechanisms and treatments of disease and provide real-time closed loop treatment for bioelectronic medicine, with a goal of eventual clinical translation.

Title: Disrupted place cell encoding and theta-gamma coupling in the hippocampus of a murine model of lupus

Authors: *T. S. HUERTA[1], J. J. STROHL[2], P. T. HUERTA[3]
[2]Lab. of Immune and Neural Networks, [1]Feinstein Inst. For Med. Res., Manhasset, NY; [3]Lab. of Immune and Neural Networks, Northwell Hlth., Manhasset, NY

Abstract: A poorly understood facet of lupus is its neurological component, known as neuropsychiatric systemic lupus erythematosus (NPSLE). Patients with NPSLE display severe cognitive impairment, particularly in the spatial domain. We have studied a mouse model of NPSLE in which animals carry a lupus antibody (termed DNRAb) that binds DNA and the GluN2A and GluN2B subunits of the NMDAR. Female mice (Balb/c, C57) are passively immunized over a 6-week period with either a lupus-inducing antigen (DNRAb+) or a control antigen (DNRAb–). A month later, the blood brain barrier is abrogated to allow antibody entry to the hippocampus. We measure spatial cognition with the object-place memory (OPM) task, consisting of 3 phases (T1, T2 and T3). For T1, mice navigate an empty chamber (40x40 cm) for 15 min. For T2 (5 min), mice are placed in the chamber with two identical objects. After 10-min rest, for T3 (5 min), they return to the chamber in which one of the objects has been moved. A discrimination ratio (based on the time exploring the objects in T3) reveals that DNRAb+ mice

examine the moved object significantly less than controls, indicating that they have a reduced ability to recognize the novel position of an object. To further investigate the neural substrate for this impairment, mice (9 DNRAb+, 11 DNRAb–) were implanted with tetrode arrays targeting the CA1 region of hippocampus, which is a crucial brain structure for spatial encoding. *In vivo* electrophysiology recordings were conducted during the OPM task and were analyzed via spike sorting (Spike2) to reveal place cell properties of CA1 neurons, as well as power spectral densities of network oscillations (Matlab, Chronux). We find abnormal place cell properties in DNRAb+ mice, such as expanded place field size, reduced stability, and lower spatial information when compared to DNRAb– mice. Vector analysis of object movement vs. place cell remapping (between T2 and T3) show that DNRAb– place cells shift in the direction of the moved object, whereas DNRAb+ place cells have no preferential shift directionality. Bayesian path reconstruction analysis reveal that DNRAb+ place cells have significantly higher error compared to the DNRAb– group. Moreover, we find significantly altered co-modulation of theta-gamma oscillations when the mice examine the moved object. Thus, our studies reveal that the CA1 ensemble encodes critical aspects of the OPM task through place cell dynamics and theta-gamma coupling. The disruptions of these processes caused by DNRAbs may explain the abnormal spatial encoding that occurs in NPSLE. Our data offer a neural substrate for bioelectronic therapies aimed to alleviate NPSLE-related cognitive impairment.

Title: Validation of awake chronic functional recordings in the murine cervical vagus nerve with a low-cost, rapid prototype wrappable microwire electrode for high-throughput chronic interfacing

Authors: J. D. FALCONE[1], T. LIU[2], L. GOLDMAN[2], D. D. POGUE[2], M. STRAKA[2], L. RIETH[2], C. E. BOUTON[2], *H. SOHAL[2]

Abstract: Bioelectronic medicine requires the ability to monitor and modulate nerve activity longitudinally for rectifying disease states, in a closed-loop manner. Currently, no effective rapidly-manufactured, low-cost chronic peripheral interfacing strategies exists in rodents,

particularly in mice. Additionally, for clinical relevance, preclinical recordings and stimulation should be conducted in awake animals to better mimic the clinical environment and to eliminate anesthesia as a confounding variable in preclinical studies. Here we present, to our knowledge, the first functional recordings for the cervical vagus nerve in an awake mouse model in a chronic period ranging up to 60 days.
BALB/c mice and Sprague Dawley Rats were implanted with custom-designed wrappable microwire electrodes on the cervical vagus nerve. Three or more teflon-insulated platinum wires (50 μ;m diameter) were de-insulated and wrapped around the vagus nerve in an overhand knot, after which kwik-sil (silicone elastomer) was applied to provide insulation. Electrodes were compared to commercial Cortec and Microprobe electrodes in an anesthetized acute model in terms of compound action potential (CAP) quality. Next we developed a novel awake model for recording from the mouse cervical vagus nerve and evaluated CAP quality.
The wrappable microwire electrode showed similar cervical vagus nerve recording performance (mean signal-to-noise (SNR) and mean peak-to-peak (P2P) amplitude) to commercial Cortec and Microprobes cuff in the acute anesthetized preparation for compound action potential (CAP) quality. For spontaneous chronic awake recordings, we recorded cervical vagus nerve activity across multiple days with all animals achieving recordings between 30 and 60 days (n = 8) with acceptable SNR (>1.3). There was no significant differences in SNR over time or between animals, showing the stability and reproducibility of this method. Further 5 out of 8 animal had stable impedances across the chronic implantation period hinting at a stable electrode-tissue interface. Initial Hematoxylin and Eosin staining of the electrode implanted nerve compared to the control naive nerve showed no significant differences in the number of visible axons. We translated this design into a chronic rat cervical vagus nerve interfacing model, where we recorded viable signals for a period of 105 days.
These initial results suggest an effective strategy for producing a rapidly-manufactured, low-cost chronic interface for the mouse cervical vagus nerve and other small nerves in acute and chronic experimental paradigms, which can be easily adopted by other research groups.

Title: A novel flexible microelectrode for stimulation and recording in acute and chronic awake models in murine small diameter nerves for bioelectronic medicine

Authors: *J. FALCONE[1], T. LIU[1], J. WONG[1], M. OCHANI[1], D. POGUE[1], R. SHARMA[2], T. LEVY[1], T. ZANOS[1], T. DATTA[1], L. RIETH[1], H. SOHAL[1]

Abstract: Bioelectronic medicine utilizes recording, stimulation, and modulation of neural tissue to monitor and relieve disease symptoms. Currently, there exists no effective electrode implant for autonomic nerves in the chronic mouse model, especially in models of inflammatory diseases (e.g. cervical vagus nerve). The design challenges of chronically interfacing with the mouse cervical vagus nerve include placement of electrodes to induce minimal damage while ensuring good electrical contact with the nerve (~100 μm in diameter). Here we characterize a microfabricated, flexible electrode designed to overcome these challenges with bench studies, and both acute and chronic preparations, in terms of stimulation and recording.
Two- and three-contact flexible electrodes were fabricated using state-of-the-art iridium oxide for metallization and polyimide (PI-2611) for insulation. Bench tests to evaluate the lifetime of the electrode included an accelerated saline soak and a stimulation stability test, and electrical impedance spectroscopy were measured. The recording and stimulation efficacy of the electrodes was tested in an acute *in vivo* mouse preparation. Briefly, the left cervical vagus nerve of the mouse was exposed, and the electrodes were placed around the nerve. The nerve was stimulated with a train of 10 biphasic pulses at current amplitudes from 200 to 1000 μA. The resulting compound action potentials (CAPs) were recorded. The electrodes were chronically implanted and characterized through weekly stimulation, and evoked CAP quality was accessed. Further, we tested a recently characterized novel awake model for spontaneous chronic recordings of the cervical vagus nerve in mice (this data is being presented at this conference).
Accelerated saline soak tests determined a lifetime over 180 days for the polyimide, which is compatible for chronic murine electrophysiology**.** Acute stimulation produced high-fidelity CAPs (SNR > 1.3) demonstrating initial validation of the device. In the chronic model, we were able to evoke and record CAP activity through stimulation. High fidelity CAPS were recorded from spontaneous activity for 21+ days along with acceptable *in vivo* impedances at 1 kHz (< 100 kΩ), showing viability of the implant over the indwelling period.
A flexible electrode for interfacing with the mouse vagus nerve has been developed. Bench testing and *in vivo* characterization demonstrated chronic stability at 21 days for both recording and stimulation. Development of such technology will allow for chronic electrophysiological studies on mechanisms and treatments of disease and provide real-time closed loop treatment for bioelectronic medicine.

Title: Electrical stimulation of the afferent cervical vagus nerve mediates skeletal muscle glucose uptake

Authors: *E. B. MASI[1,3], H. SILVERMAN[1], T. TSAAVA[1], J. NEWMAN[1], M. ADDORISIO[1], C. BOUTON[2], S. S. CHAVAN[1], K. J. TRACEY[1,2,3]

Abstract: The central nervous system regulates glucose homeostasis. The vagus nerve is a major conduit of autonomic sensory and motor information that innervates all of the major organs involved in glucose homeostasis. Here, we describe a novel mechanism by which afferent vagus nerve signaling lowers circulating blood glucose by mediating increased glucose uptake in skeletal muscle. We observed that selective vagus nerve stimulation lowers blood glucose levels within 20 minutes. Interestingly, glucose modulating effects of vagus nerve stimulation is abrogated in animals subjected to proximal vagotomy, indicating that afferent vagus nerve signaling is required. No significant changes in circulating levels of insulin, glucagon, leptin or GLP-1 were observed following vagus nerve stimulation. Skeletal muscle glucose uptake through the GLUT4 transporter is a major contributor to maintaining glucose homeostasis. To determine whether glucose uptake in the muscle is necessary for this effect, we generated transgenic mice devoid of the GLUT4 transporter in MCK skeletal muscle using the cre-lox system. While littermate controls had a significant drop in circulating glucose after vagus nerve stimulation, the animals with the GLUT4 transporter deficiency in skeletal muscle failed to respond to vagus nerve stimulation. Next, to test whether vagus nerve stimulation can modulate glucose homeostasis during hyperglycemia, obese ob/ob mice with baseline glucose over 250 mg/dl were subjected to vagus nerve stimulation. A significant decrease, with an average of 70 mg/dl drop in blood glucose levels was observed in ob/ob mice as compared to the unstimulated

controls. Together, these findings describe an insulin-independent mechanism of increasing glucose uptake in skeletal muscle *via* afferent vagus nerve signaling, leading to an acute decrease in circulating glucose levels in hyperglycemic animals.

Nell Hodgson Woodruff Sch. of Nursing, Atlanta, GA

Abstract: The etiology of Parkinson's disease (PD) remains uncertain, and by the time the characteristic motor impairments manifest, extensive, irreversible neurodegeneration has already occurred. Gastrointestinal (GI) problems are also common features of PD, however, and they frequently manifest years before the development of motor symptoms. This has led to the theory that PD pathology could initiate in the intestine before advancing to the central nervous system (CNS). Given the abundant evidence supporting a role for inflammation in neurodegenerative disease, we investigated whether intestinal inflammation could mediate the progression from digestive dysfunction to CNS neuropathology in PD. In a large-scale human study, we confirmed that the majority of PD patients experienced GI problems, and we identified elevated levels of specific soluble inflammatory mediators in stool from PD patients compared to controls. We determined that this inflammatory profile did not emerge as a result of advanced age or disease duration, suggesting that GI inflammation is involved in earlier stages of PD. Evaluation of colonic biopsies from PD patients affirmed these findings, revealing evidence of substantially increased immune cell infiltration, proinflammatory activity, and oxidative stress in gut tissue

from PD patients compared to controls. We then utilized mouse models to evaluate the impact that colonic inflammation could exert on neuron health and function in the brain. Dextran sodium sulfate was used to induce colitis in wild type mice and mice lacking RGS10, a regulator of G-protein signaling which has been reported to suppress inflammatory activity in myeloid cells and to protect against inflammation-induced parkinsonian neuropathology. We discovered that the induction of damage and inflammation in the intestine was sufficient to perturb the functionality of dopaminergic neurons on its own, reducing levels of tyrosine hydroxylase and modulating dopamine transporter expression. We also found that colitis rendered mice more susceptible to the effects of the neurotoxic agent MPTP. The severity of certain neurological changes correlated with the severity of colitis in our model, further substantiating the relationship between GI inflammatory activity and central neuropathology. Our findings confirm that intestinal inflammation is present in PD and that such inflammation can induce dopaminergic neuropathology, lending support for the gut-to-brain theory of PD pathogenesis.

Title: Immune system response in zebrafish with disrupted sleep

Authors: A. R. PHILLIPS[1], C. N. NGO[2], D. A. LEE[3], G. OIKONOMOU[3], D. A. PROBER[3], *A. CHEN[4]
[1]Pomona Col., Claremont, CA; [2]Harvey Mudd Col., Claremont, CA; [3]Div. of Biol., Caltech, Pasadena, CA; [4]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Immune interactions with the central nervous system (CNS) are critical nodes in neurological disease pathology; however immune-CNS interactions have been less studied in the role of sleep homeostasis. Recently, cytokines released from immune cells have been shown to act as neuromodulatory factors. In sleep regulation, acute sleep deprivation activates pro-inflammatory pathways; however, chronic sleep deprivation appears to suppress the immune system. Here, we utilize zebrafish to examine if cytokine expression differs between wild-type and zebrafish sleep mutants and whether newly identified sleep regulators modulate sleep-wake behavior through an immune-related mechanism. Zebrafish larvae serve as a simple and cost-

effective model to study the interaction between the immune system and neural circuits. Activation of the inflammatory pathway was examined by quantifying interleukin 1β (IL-1β), Interleukin 6 (IL-6) and nuclear factor κB (NF- κB) transcripts using qPCR. We report upregulation of IL-1β in serotonin-deficient (tph2-/-) mutants. We were unable to detect a difference in cytokine expression in our examination of zebrafish larvae with hypocretin overexpression (hsp:hcrt), neuropeptide VF overexpression (hsp:NPVF), deletion of neuropeptide VF (npvf -/-), deficiency of melatonin production (aanat2-/-), deficiency of histamine production (hdc -/-), or pharmacologically inhibited histamine receptor 1 (Hrh1) signaling when compared to wild-type relatives. Our data suggest that not all sleep regulators noticeably impact the immune system; however there may be an activated immune response in serotonin mutants. This data further validates the use of zebrafish in understanding vertebrate sleep mechanisms and opens new avenues in using zebrafish to explore neuroimmunological regulation of behavior.

Title: Adult and aged TLR4 deficient mice show sex-dependent enhancements in spatial memory and alterations in interleukin-1 related genes

Authors: *R. A. KOHMAN, O. V. POTTER, M. E. GIEDRAITIS, C. D. JOHNSON, M. N. COX
Psychology, Univ. of North Carolina Wilmington, Wilmington, NC

Abstract: Toll-like receptor-4 (TLR4) is a transmembrane receptor that initiates an immune response following a bacterial infection or host derived molecules associated with cellular distress. Beyond triggering inflammation, TLR4 has been implicated in modulating behavior and cognitive processes in a physiologically normal state, as young adult TLR4 deficient mice show learning enhancements in select tasks. Currently unknown is whether these benefits are present in both sexes and persist with aging. The present study evaluated spatial memory, anxiety-like behavior, and central levels of pro- and anti-inflammatory molecules in adult (4-5 months) and aged (18-19 months) TLR4 deficient (TLR4-/-) and wild type (WT) male and female mice. Results confirmed that TLR4-/- mice show enhanced spatial memory compared to WT mice.

These effects were age- and sex-specific, as memory retention was superior in the TLR4-/- adult males and aged females. While TLR4-/- mice showed aged-related changes in behavior, these changes were attenuated relative to aged WT mice. Further, aged TLR4-/- mice showed differential expression of molecules involved in interleukin (IL)-1 signaling in the hippocampus. For instance, aged TLR4-/- females showed heightened expression of IL-1 receptor antagonist (IL-1ra) and the IL-1 accessory proteins AcP and AcPb. Collectively, these data provide the initial evidence that TLR4 deficiency enhances cognitive function and modulates the inflammatory profile of the hippocampus in a sex- and age-dependent manner.

Title: Central immune alterations in a gestational stress model of postpartum depression

Authors: *C. POST[1], A. CASTANEDA[1], P. BANTA[2], L. NELSON[2], A. SAULSBERY[1], K. LENZ[3], B. LEUNER[3]
[1]Psychology, [2]Neurosci., [3]Psychology & Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Postpartum depression (PPD) is a common complication following childbirth experienced by 15% of all new mothers. Despite its prevalence and adverse consequences for women and their children, the causes of PPD remain unclear. To date, research investigating the factors contributing to PPD has largely focused on hormonal fluctuations, although increasing attention has been given to the potential role of the immune system. Importantly, immune mediators have only been examined peripherally in depressed mothers and thus little is known about how the brain's immune system is modified in PPD. To address this gap, we used an animal model of PPD based on a well-known risk factor, gestational stress, and evaluated the maternal neuroimmune system focusing on the medial prefrontal cortex (mPFC), a key mood-related brain region implicated in PPD. Pregnant Sprague-Dawley rats were subjected to chronic variable stress from gestation days (GD)7-20 or were unstressed and then sacrificed either one day before (GD21) or one week after (postpartum day 8, PD8) delivery. Brain tissue was collected for qPCR to assess mRNA expression of the pro-inflammatory cytokines interleukin (IL)-1β, interferon (IFN)γ, and tumor necrosis factor alpha (TNFα) as well as the growth factor, insulin-like growth factor (IGF)1. Additionally, CD68, integrin alpha M (ITGAM), complement

component 3 (C3) and complement component 1 (C1q), markers associated with microglial phagocytosis of synaptic elements, were analyzed. Our results show increased expression of IL-1β and IFNγ in the mPFC of gestationally stressed mothers on GD21, suggesting a shift to a pro-inflammatory state. In addition, expression of ITGAM and C1q were increased on GD21 which may further suggest that stress leads to microglia-mediated synaptic remodeling. There was no effect of gestational stress on PD8 for any marker analyzed. Together, these data suggest that gestational stress impacts the maternal neuroimmune system which may contribute to the development of PPD.

Title: Examining the impact of a two-hit model of neuroinflammation on social behavior in male and female juvenile rats

Authors: *A. TURANO, M. S. WOOD, N. A. HAAS, J. M. SCHWARZ
Univ. of Delaware, Newark, DE

Abstract: Autism is characterized by impaired social interactions, inadequate verbal and nonverbal communication, restricted interests, and stereotyped behaviors but, the biological causes of these symptoms remain inconclusive. In addition to genetic factors, epidemiological data indicate that environmental factors also contribute to the risk of autism. Neonatal exposure to infectious pathogens is one of these environmental factors, suggesting that activation of the neonatal immune system may contribute to autism pathology. Microglia, the resident immune cells of the brain, perform functions crucial for normal brain development and behavior. According to a "two-hit model of neuroinflammation," neonatal neuroimmune activation causes persistent deficits in microglial functioning, resulting in an exaggerated immune response and significant behavioral deficits following subsequent immune activation later in life. Importantly, males are more likely than females to be diagnosed with autism. During early development, males and females exhibit different microglial phenotypes, possibly leaving males more susceptible to the negative outcomes associated with early-life neuroinflammation. Our goal was to better understand the impact of the two-hit model of neuroinflammation on the development and expression of social behaviors in male and female rats. We first piloted behavioral

paradigms to characterize the development of social behavior in juvenile rats, and then applied the two-hit model of neuroinflammation to determine how immune activation may affect the expression of these social behaviors. We concurrently measured cytokine expression in the male and female juvenile brain. These experiments may help to elucidate when and how a specific environmental risk factor contributes to behavioral outcomes associated with autism**.**

Title: The impact of exercise in an enriched environment on Parkinson's disease pathology

Authors: *U. ROY[1], M. GIL[2], G. A. DE ERAUSQUIN[3]
[1]Univ. of Texas Rio Grande Valley, Brownsville, TX; [2]Dept. of Psychological Sci., The Univ. of Texas Rio Grande Valley, Brownsville, TX; [3]Neurol. and Psychiatry, UTRGV Sch. of Med., Harlingen, TX

Abstract: Parkinson’s disease (PD) is a neurodegenerative disorder affecting 4.6 million people worldwide with a projected increase to reach 9.3 million by 2030. Many research studies have shown that exercise in PD helps alleviate some of the clinical symptoms. However, underlying molecular mechanisms about the effect of exercise on the neurodegeneration is poorly understood. A few studies have indicated that physical exercise helps prevent the loss of dopaminergic neurons, which is a hallmark of PD pathology. Nonetheless, these studies didn’t include the environmental factors that might contribute to the neuronal pathology in PD. In this regard, our current work has established that enriched environment (EE) has a neuroprotective effect in PD utilizing an animal model. Briefly, EE for *in vivo* study is referred to as an enriched animal cage containing tubes, shelves, ramps, stairs, and miscellaneous ‘toys’. This set-up is changed twice a week with the aim of continuously encouraging exploration of the environment where two animals were housed together for social interaction. Based on our previous observation, we would like to explore the effect exercise in EE has on PD pathology in a mouse model. Our central hypothesis is that a voluntary exercise in EE will promote the survival of dopaminergic neuron (DAN) in substantial nigra in the brain. Preventing the loss of DAN in the brain can dramatically improve the brain pathology of PD patients. Furthermore, we will also monitor the expression of BDNF, EGF, and DJ1 proteins in the brain which are considered to be hallmark proteins for PD pathology. The proposed work was done with the transgenic mouse

model expressing the mutant A53T human alpha-synuclein protein (A53T mutant). The A53T-mutant mice were exposed to the EE in the laboratory setting as per our previous publication. Their performance-based test was on a running wheel test for behavior performance, open field for general motor activity, and rotarod to measure the motor cognition measurement etc. Following the incubation, animal brain tissue was characterized by BDNF, EGF, DJ1 expression and survival of DAN. This study will further help us in developing novel therapeutic molecules that can be called 'enviromimetics' which can be incorporated into the therapy.

Title: Interaction of light, sex and gut microbiota in a diurnal model of depression

Authors: *H. XIONG, Y. LIU, W. LIAO, L. YAN
Neurosci. Program, Michigan State Univ., East Lansing, MI

Abstract: Gut microbiota plays an important role in human health and has been implicated in mental illness including anxiety and depression. In animal models, it has been shown that alterations in gut microbiota influence depression- and anxiety-like behaviors, likely through modulating the GABAergic and serotoninergic pathways in the brain. However, how gut microbiota is influenced by sex and season, and the extent to which the sex differences and seasonal variation contribute to the prevalence of mood disorder remains unknown. To probe these questions, we utilized a diurnal rodent model, the Nile grass rats (*Arvicanthis niloticus*). In contrast to the commonly used animal models that are nocturnal, the grass rats are active during the day, like humans. When they are housed in a winter-like dim light condition, they show increased depression- and anxiety-like behaviors compared to those in summer-like bright light condition, thus serve as a model for human seasonal affective disorder. Using this model, we explored interactions between host-intestinal microbial communities, sex and lighting conditions. Animals were housed in 12:12 hr light/dark cycle with either dim (~50 lux) or bright light (~1000 lux) during the day (n=6/sex/condition). After 4 weeks, animals were euthanized, then gut and intestines were extracted. Feces in the cecum were collected from each animal for metagenomic analysis of microbial communities. Illumina MiSeq (pair-end 250 bp) targeting on V3_V4 hypervariable regions was used to carry out the sequencing. Fastq files from the high-throughput sequencing were analyzed using Qiime2 to generate taxonomic/phylogenetic data for

statistical analysis. The non-metric multidimensional scaling analysis (NMDS) at phylogenetic levels indicated that light has significant effects on microbial community at levels of Genus (p = 0.03), Order (p = 0.04) and Class (p = 0.04). Further analysis indicated that the abundance of *Ruminococcaceae Oscillospira* was higher under bright light compared to in dim light (5.5 *vs.* 2.2%); while *Verrucomicrobiaceae Akkermansia* was lower under bright light than in dim light (10.5 *vs*. 18.1%). Analysis of variance at Phylum level revealed significant sex differences in *Bacteroidetes* (p = 0.02), and marginal differences in *Firmicutes* (p = 0.07) and *Proteobacteria* (p = 0.06). These results suggest that seasonal fluctuation in ambient light can influence the composition of gut microbial community and the relative abundance of certain gut bacteria differs between males and females. Future studies will explore how the changes in gut microbiota contribute to the depression- and anxiety-like behaviors seen in animals housed in dim light.

Title: Unique neurophysiological vulnerability of the orienting network in inflammation - Evidence from the vaccination model of inflammation

Authors: *L. J. BALTER[1], S. HIGGS[2], S. ALDRED[2], J. A. BOSCH[2], M. T. DRAYSON[2], J. J. C. S. VELDHUIJZEN VAN ZANTEN[2], J. E. RAYMOND[2], A. MAZAHERI[3]
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [3]Psychology, [2]Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Individuals with a psychiatric disorder such as major depression often show poorer cognitive performance including attention deficits. The underlying cause of these deficits may be related to inflammation. However, to date, there has been very little direct investigations into how immune system activation affects attentional control. The current electroencephalography (EEG) study investigated the effects of experimentally induced inflammation on three distinct attentional processes: alerting, orienting and executive control. This double-blinded placebo-controlled within-subjects study (N = 20 healthy males, mean age = 24.5, SD = 3.4) used salmonella typhoid vaccination (0.025 mg; Typhim Vi, Sanofi Pasteur) to induce transient low-grade inflammation; saline was used as placebo-control. In both conditions, participants completed the Attention Network Test while EEG was recorded. Analysis was focused on

modulation of oscillatory EEG activity in the alpha (9-12 Hz) band as well as changes of the N1 event related potential (ERP), locked to onset of cues providing temporal and/or spatial information about upcoming targets.Vaccination increased inflammation, as assessed by IL-6 levels (vaccination +3.9 pg/ml; placebo -.08 pg/ml; p < .001). Greater post-cue alpha suppression (200-350 ms) for the orienting network (double vs. spatial cue) was evident in the inflammation condition relative to the placebo condition (p = .021), suggesting that inflammation led to increased processing of the orienting cue. The N1 amplitude was not affected by condition; however, a greater inflammatory response was associated with an attenuated N1 amplitude in the inflammation condition (rs = -.750, p = .002), suggesting that early sensory processes are inhibited with greater inflammation. No behavioural differences were observed between conditions.The current results revealed a unique neurophysiological vulnerability of the orienting network with increased inflammation, as shown by changes in the modulation of post-cue alpha oscillatory activity and the early N1 ERP component.

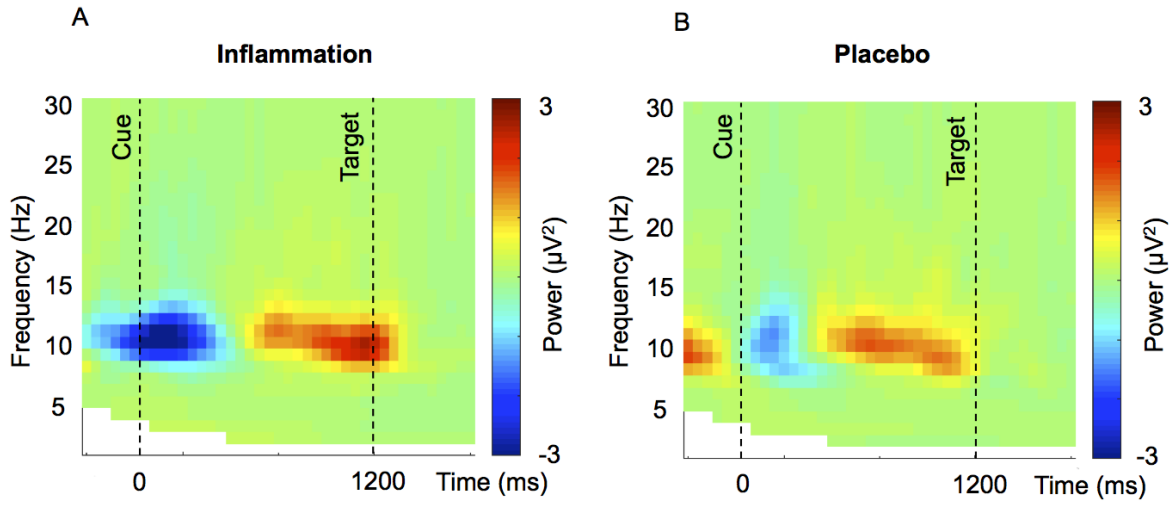

Figure 1a,b. Grand average time-frequency representations of double - spatial cue alpha power difference averaged over parietal-occipital channels for the inflammation (a) and placebo (b) condition. Dotted lines represent cue and target onset, respectively.

Title: Treatment with heat-killed mycobacterium vaccae enhances fear extinction in the rat fear-potentiated startle paradigm

Authors: *J. E. HASSELL, JR, K. T. NGUYEN, J. H. FOX, M. R. ARNOLD, P. H. SIEBLER, M. W. LIEB, D. SCHMIDT, E. J. SPRATT, T. M. SMITH, C. A. GATES, K. S. HOLMES, K. S. SCHNABEL, K. M. LOUPY, M. ERBER, C. A. LOWRY
Integrative Physiol., Univ. of Colorado, Boulder, CO

Abstract: The hygiene hypothesis or "Old Friends" hypothesis proposes that inflammatory diseases are increasing in modern urban societies, due in part to reduced exposure to microorganisms that drive immunoregulatory circuits, and a failure to terminate inappropriate inflammatory responses. Inappropriate inflammation is also emerging as a risk factor for anxiety disorders, affective disorders, and trauma-and stressor-related disorders, including posttraumatic stress disorder (PTSD), which is characterized as persistent re-experiencing of the trauma after a traumatic experience. Traumatic experiences can lead to long-lasting fear memories and fear potentiation of the acoustic startle reflex. The acoustic startle reflex is an ethologically relevant reflex and can be potentiated in both humans and rats through Pavlovian conditioning. *Mycobacterium vaccae* is a soil-derived bacterium with immunoregulatory and anti-inflammatory properties that has been demonstrated to enhance fear extinction in the fear potentiated startle paradigm when given prior to fear training. To determine if immunization with *M. vaccae* after fear conditioning also has protective effects, adult male Sprague Dawley rats underwent fear training on days -37 and -36 followed by immunizations (3x), once per week, with a heat-killed preparation of *M. vaccae* NCTC 11659 (0.1 mg, s.c., in 100 µl borate-buffered saline) or vehicle, and, then, 3 weeks following the final immunization, were tested in the fear-potentiated startle paradigm (n = 12 per group). Rats underwent fear extinction training on days 1 through 6 followed by spontaneous recovery 14 days later (day 20). Rats were euthanized on day 21 and brain tissue was sectioned for analysis of *tph2*, *htr1a*, *slc6a4*, *slc22a3*, *crhr1*, and *crhr2* mRNA expression throughout the brainstem dorsal and median raphe nuclei. Immunization with *M. vaccae* did not affect fear expression on day 1. However, *M. vaccae*-immunized rats showed enhanced between-session and within-session extinction on day 2, relative to vehicle-immunized controls. Immunization with *M. vaccae* and fear-potentiated startle altered serotonergic gene expression in a gene- and subregion-specific manner. These data are consistent with the hypothesis that immunoregulatory strategies, such as preimmunization or treatment with *M. vaccae*, have potential for both prevention and treatment of trauma- and stressor-related psychiatric disorders.

Title: Sensitization to a cow's milk protein results in behavioral changes and altered expression of genes associated with neuroinflammation and vascular integrity in the brain

Authors: *N. A. SMITH, D. L. GERMUNDSON, K. NAGAMOTO-COMBS
Pathology, Univ. of North Dakota Sch. of Med. and Hlth. Sci., Grand Forks, ND

Abstract: Allergic diseases are often comorbid with neuropsychiatric disorders. In particular, food hypersensitivity to cow's milk has been suspected to elicit or exacerbate behavioral symptoms in attention deficit hyperactivity and autism spectrum disorders. Besides genetic susceptibility, etiology of neuropsychiatric disorders may be attributed to epigenomic regulation of the genes that are important for neural functions. We hypothesized that peripheral allergic responses to cow's milk would lead to altered gene expression and DNA modification in the brain, ultimately affecting behavior. Using a mouse model of cow's milk allergy, we investigated transcriptional changes in the intestine and brain as well as DNA hydroxymethylation in the brain. Four-week-old male and female C57BL/6J mice were sensitized to a milk allergen, β-lactoglobulin (BLG), via five weekly oral administrations of 1 mg BLG with cholera toxin (CT) as an adjuvant. Sex-matched sham mice were given the vehicle only containing CT. In the 6th week, all mice were challenged with 50 mg BLG, and anxiety-like and repetitive behaviors were assessed by monitoring their activity on an elevated-zero maze and their grooming behavior, respectively. Transcriptional changes in 4 regions of the brain were determined using RNA sequencing and RT-qPCR. BLG-sensitized mice presented with increased anxiety-like and repetitive behaviors that were associated with elevated BLG-specific serum IgE levels. Expression of a tight junction protein, occludin, was decreased in the gut and midbrain of BLG-sensitized mice, indicating potential degradation of intestinal and blood-brain barrier integrity, respectively. Additionally, expression of the cytokine, TNFα, was induced in the hippocampus of BLG mice, suggesting the presence of an inflammatory response in this region. Furthermore, transcripts of genes implicated in neurovascular development and myelination were differentially regulated in the midbrain of BLG-sensitized mice. When changes in DNA hydroxymethylation

were examined by immunohistochemical staining of brain tissue, a significant increase in 5-hydroxymethylcytosine immunoreactivity was observed in the cerebral cortex of BLG-sensitized brain. These results demonstrated that milk allergy results in behavioral changes and neuroinflammation and suggested that regulation of associated genes may occur via epigenetic DNA modifications.

Title: Hypothalamic lipotoxicity leads to microglia activation and ghrelin signaling disruption in rats

Authors: *R. MALDONADO[1], M. RODRIGUEZ PADILLA[2], A. CAMACHO[3]
[1]Autonomous Univ. of Nuevo Leon, Santa Catarina, Mexico; [2]Fac. of Biol. Sciences, Univ. Autonoma de Nuevo Leon., San Nicolas de los Garza, Mexico; [3]Univ. Autónoma de Nuevo León, Nuevo León, Mexico

Abstract: Obesity associates with chronic systemic inflammation and insulin resistance. Hypothalamic microglia activation by lipids oversupply has been shown to negatively regulate energy-sensing processes at central and peripheral sites. Here we used an *in vitro* and *in vivo* model to address whether lipid-induced toxicity correlates with an increase in inflammatory cytokine profile and changes in food intake during hypothalamic ghrelin stimulation. Primary microglia cultures and SIM-A9 cell line were incubated by 100 mM palmitic acid, palmitoleic acid, linoleic acid, stearic acid, N-Hexanoyl-D-sphingosine, or 0.1 μg/mL LPS (0111: B4) for 24h. IL-1β, IL-6 and TNF-α production were quantified by ELISA assays. *In vivo* lipotoxicity was performed by i.c.v. administration of LPS (0.1 μg/mL) or palmitic acid (32.4 mM) or artificial cerebrospinal fluid (ACSF) for 5 days following by ghrelin administration. Inflammatory activation was identified by TBK1-NFkbeta protein expression using western blot and ghrelin effects was analyzed by food intake quantification. Our results show that primary microglia and SIM-A9 stimulation by palmitic acid, palmitoleic acid or N-Hexanoyl-D-sphingosine promotes IL-1β, IL-6 and TNF-α and TNF-α release, respectively. Palmitic acid stimulation partially correlates with TBK1 activation evidenced by western blot. Also, we identified that lipotoxic stimulus by i.c.v. palmitic acid administration for 5 days does not disrupt

plasma glucose homeostasis, however, it sensitizes
ghrelin signaling pathway promoting positive food intake following ghrelin administration when compare to rats i.c.v. administered with ACSF. Food intake sensitive to palmitic acid administration correlates with inflammatory activation evidenced by NF-κB whereas a reduction in TBK1 activation in the arcuate nucleus of hypothalamus. In summary, central lipotoxic insult by i.c.v. palmitic acid administration exacerbates the orexigenic effect of ghrelin promoting food intake stimulation which potentially correlates with TBK1-NF-κB pathway activation in arcuate nucleus.

Title: Microglia regulate developmental myelination, mood-related behavior and stress axis function

Authors: *L. H. NELSON[1], S. WARDEN[1], K. M. LENZ[2]
[1]Ohio State Univ., Columbus, OH; [2]Psychology, Ohio State Univ. Dept. of Psychology, Columbus, OH

Abstract: Microglia, the brain's resident immune cells, are important for many developmental processes. However, less is known about how microglia program behavior. We have previously shown that reversibly depleting microglia from the neonatal brain, using central infusion of liposomal clodronate, decreased anxiety, behavioral despair, and the acute stress response in adulthood (Nelson et al., 2017). To determine the brain region(s) responsible for the dampened stress response we previously observed, we assessed the number of neurons expressing cFos, a marker of neural activation, in limbic brain regions after acute restraint stress in adults. We found decreased cFos expression in the medial prefrontal cortex (mPFC), a stress and anxiety regulating brain area, in clodronate-treated rats relative to controls, suggesting there could be decreased recruitment of stress regulating brain areas following early life microglia depletion. We are currently assessing cFos staining in other brain regions that regulate anxiety and the

stress response such as the amygdala, bed nucleus of the stria terminalis (BNST) and the paraventricular nucleus of the hypothalamus (PVN). Microglia are known to regulate synaptic patterning and developmental myelination, and both of these developmental processes and microglia have been previously linked to early life programming of mood and the HPA axis (Wei et al., 2015; Singh-Taylor et al., 2015; Delpech et al., 2016). Thus we assessed gene expression of dendritic spine protein (*spinophilin)*, myelin-related proteins (*Mbp, Plp1*), and microglia-related genes that have previously been shown to support oligodendrogenesis (*Tnf, Il1b, Igf1)* (Shigemoto-Mogami et al., 2014; Hagemeyer et al., 2017). We analyzed gene expression the mPFC and amygdala at P6, P12 and P22 following microglia depletion to determine whether microglia program behavior via these underlying mechanisms. Relative to controls, microglia depleted animals showed decreases in *Mbp* and *Plp1* at P12 in the amygdala and mPFC, and these decreases persisted to P22 in the amygdala. There was no difference in *spinophilin* gene expression across conditions at any age. At P6 we found decreased *Igf1* in the prefrontal cortex and amygdala, and decreased *Tnf* in the amygdala, but there was no difference in *Il1b*. We are currently determining whether microglia regulate oligodendrocyte progenitor cell proliferation or differentiation into oligodendrocytes in stress-regulating brain areas and white matter tracts throughout the brain and if there are changes in myelination following early life stress. These studies will elucidate the role of microglia in normal and abnormal brain development.

Title: Calorie restriction only partially attenuates sickness behaviour induced by a viral mimic polyinosinic:polycytidylic acid (poly I:C)

Authors: *S. KENT, L. KIVIVALI, K. CHONG, A. KIRBY
Psychology & Publ. Hlth., La Trobe Univ., Melbourne (Bundoora), Australia

Abstract: Calorie restriction (CR) extends mean and maximum lifespan in a variety of animals and we have previously demonstrated that CR dose-dependently attenuates lipopolysaccharide (LPS)-induced fever and sickness behaviour. LPS is a bacterial mimetic; however, few studies have explored this phenomenon utilising a viral mimic, such as polyinosinic:polycytidylic acid (poly I:C). The current study aimed to investigate whether a 50% CR for 28 days could attenuate poly I:C-induced fever and sickness behaviour. METHOD: C57BL/6J male mice implanted with biotelemetry devices were housed at 30 ± 2 °C under a 12:12 LD cycle. In a pilot experiment

increasing doses (500, 1000, 2000, and 5000 μg/kg) of poly I:C or vehicle were administered and core body temperature (T_b) and locomotor activity measured for 24 hours. In the main experiment mice with implanted biotelemetry devices were assigned to either *ad libitum* (AL; n = 16) or CR50% (n = 16) groups for 28 days. On day 29, either 5000 μg/kg poly I:C or vehicle was injected and sickness behaviour assessed for 24 hours. RESULTS: In the pilot experiment poly I:C induced a dose-dependent increase in T_b, with the largest dose (5000 μg/kg) resulting in a 1.62 ± 0.23 °C T_b increase from baseline at 7 hours post-injection (p = .016), which was associated with reduced locomotor activity during the subsequent dark phase post-injection (p = .001). The main experiment demonstrated that CR partially attenuated poly I:C-induced fever and sickness behaviour. The AL group experienced a peak in T_b of 2.02 ± 0.22 °C 7 hours post-injection compared to a 0.94 ± 0.27 °C increase in the CR poly I:C at the same time post-injection (p = .004). Locomotor activity was reduced in the CR group only during the light phase (p = .019), most likely due to decreased food-related anticipatory behaviour whereas activity declined in the AL group only during the dark phase post-poly I:C (p = .002). The CR and AL mice demonstrated similar responses after poly I:C on other sickness behaviour measures (weight loss and reduced food intake). CONCLUSION: Poly I:C evoked a partial sickness behaviour response in CR mice, with increased T_b, reduced activity, and weight loss; however, these mice ate all of their allotted food. Given CR can fully attenuate bacterial mimic (LPS) induced sickness behaviour it appears poly I:C may initiate subtlety different pathways and that these pathways may be differentially impacted on by CR. Future research should investigate whether CR impacts on the number or activity of Toll-like receptors 3 and 4 that recognise viral and bacterial mimics.

Abstract: Supported in part by the Herman Dana Foundation.
Abstract:
Background: Altered systemic reactivity during the development of depression after delivery, may point to biomarkers and potentially implicate inflammatory involvement. Methods: Platelet indices after delivery were compared between mothers prospectively diagnosed with depression and resilient mothers. **Results:** Mean platelet volume was significantly increased immediately following delivery suggesting altered activation that accompany the triggering of postpartum depression. Pathway involvement implicate relevant molecular candidates. **Discussion:** Our findings replicate previous reports of platelet activation in depression in the context of a postpartum depressive episode.
Platelet markers may serve as biomarkers, and point to mechanistically relevant molecular targets contributing to the triggering of depression.

Title: Vulnerability to inflammation-induced neuropsychiatric symptoms in obese individuals: Using the model of lipopolysaccharide administration in humans

Authors: *J. LASSELIN, K. BOY, V. WESKAMP, A. HANDKE, M. UNTEROBERDÖRSTER, A. BRINKHOFF, S. BENSON, H. ENGLER, M. SCHEDLOWSKI
Inst. of Med. Psychology, Univ. Hosp. Essen, Essen, Germany

Abstract: Obesity is associated with an increase prevalence of neuropsychiatric symptoms and diseases, such as depression. Based on the facts that pro-inflammatory cytokines are able to modulate behavior and that obesity is characterized by a chronic low-grade inflammatory state, inflammation has been hypothesized to contribute to the neuropsychiatric comorbidity in obese individuals. However, a causal link between inflammation and the development of neuropsychiatric symptoms is hard to establish in humans. Here, we used an inflammatory stimulus, i.e. the intravenous injection of lipopolysaccharide (LPS), in a double-blind placebo-

controlled design to determine the vulnerability of obese individuals to inflammation-induced behavioral changes. The hypothesis was that obese individuals would show heightened behavioral response compared to normal-weight subjects for the same inflammatory stimulus, reflecting an increased sensitivity to the behavioral effects of pro-inflammatory cytokines. LPS (dose 0.8 ng/kg body weight, adjusted for blood volume in obese subjects) and placebo (saline) were intravenously injected in 14 obese healthy subjects and 23 normal-weight healthy subjects (age 18-34; 19 women/18 men) in a randomized order with 3-4 weeks wash-out. LPS administration induced, in both groups, an acute increase in blood concentrations of the pro-inflammatory cytokines interleukin (IL)-6 and tumor necrosis factor (TNF)-a, as well as in cortisol, sickness symptoms, fatigue, negative mood and state anxiety that peaked 2-3h after the administration. Obese subjects exhibited a faster recovery in IL-6 and cortisol (lower concentrations 3-6h after LPS administration) compared to normal-weight subjects. Similar pattern was observed for the behavioral changes, although this was not statistically significant. The cytokine and cortisol responses to LPS were significantly correlated with the behavioral changes, and obesity did not modulate this association. Taken together, although obesity was associated with an altered immune response to the immune challenge, this population of young and healthy obese individuals appeared to exhibit similar sensitivity to the behavioral effects of pro-inflammatory cytokines as the normal-weight subjects. Further studies will need to determine whether additional psychological and biological factors interact with the state of obesity to increase the risk for inflammation-induced neuropsychiatric symptoms.

Title: Brain-derived neurotrophic factor polymorphism val66met expression in mice is associated with exaggerated behavioral and neuroinflammatory response to peripheral immune challenge

Authors: *A. M. GARRISON, J. C. O'CONNOR
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Depression is a debilitating mental illness that affects millions of people worldwide and is not effectively treated with current therapies in all patients. Stress or inflammation, both

environmental factors that can precipitate depression, reduce signaling of brain-derived neurotrophic factor, a growth factor important for survival and function of neurons. Further, the expression of the high frequency human BDNF single nucleotide polymorphism Val66Met results in reduced activity-dependent release of BDNF and is a risk factor for the development of mood disorders. These observations suggest that reduced BDNF contributes to the development of depression, but the neurobiological mechanisms are unknown. We used a mouse model expressing human Val/Val or Val/Met polymorphism to investigate behavioral and neuroinflammatory responses to peripheral injection of the endotoxin lipopolysaccharide (LPS). Following 24 h after LPS injection, we measured preference for a sucrose solution, locomotor activity, and depressive response using tail suspension test. Brain hemispheres were collected for analysis of pro-inflammatory cytokine expression measured via qPCR. We found that Val/Met-expressing mice were sensitive to the LPS-induced reductions in sucrose preference and increases in pro-inflammatory cytokines. These data suggest that functional BDNF is required to maintain inflammatory homeostasis in the brain and prevent subsequent depressive-like behaviors.

Title: An IL-6 receptor antagonist effectively attenuates postpartum anhedonia in the female rat, but has no effect on anhedonia precipitated by sub chronic stress

Authors: N. A. HAAS, J. GOMEZ, *J. M. SCHWARZ
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: The National Institute of Mental Health has identified postpartum depression as one of several types of depression that affects 10-15% of all mothers; however, the exact underlying mechanisms that precipitate postpartum depression are still unknown. Similar to the dramatic change in hormone levels that occurs during pregnancy, the peripheral immune system is also significantly altered throughout pregnancy to protect the developing semi-allogenic fetus from being rejected by the maternal immune system (Fallon et al., 2002). We recently determined that there is also a dramatic change in the central immune system during and just after pregnancy in female rats (Sherer et al., 2017). Specifically, we observed depressive-like behaviors on the day of birth that was associated with increased IL-6 expression in the maternal brain on the day of

birth. (Posillico and Schwarz, 2016). Thus, the current study sought to determine whether blocking the function of IL-6, by infusing an IL-6 receptor antibody specifically in the postpartum brain, may prevent the anhedonia observed following birth. For comparison, we also examined whether blocking the function of IL-6 in the brain could prevent the expression of anhedonia caused by a week of forced swim in female rats. Similar to our previous findings, we measured significant anhedonia in postpartum female rats and in female rats that had a week of sub chronic stress. Treatment with an IL-6 receptor antibody into the brain effectively attenuated depressive-like behavior immediately postpartum ($p = 0.026$ vs postpartum IgG control treatment), but interestingly had no effect on the anhedonia produced by sub-chronic stress ($p = 0.790$). Analysis of cytokine expression in the brain revealed that the IL-6 receptor antibody could effectively attenuate the expression of IL-6 ($p = 0.026$) and Brain Derived Neurotrophic Factor ($p = 0.034$) in the medial prefrontal cortex of postpartum females. In contrast, the antibody had no effect on IL-6, BDNF, or other IL-6 signaling molecules in the brain following sub chronic stress. These results suggest that the molecular mechanisms that underlie the onset of anhedonia after birth and sub-chronic stress may be distinct. Moreover, the successful attenuation of postpartum anhedonia following the infusion of an IL-6 receptor antibody suggests that this antibody, or other drugs that affect IL-6 signaling in the brain, may be important potential targets for the relief for the symptoms associated with postpartum depression that may not be fully alleviated by typical antidepressants.

Title: Effects of chemogenetic inhibition of the ventral hippocampus on anxiety-like defensive behaviors in rats

Authors: *C. R. MAESTAS-OLGUIN[1], S. J. BOUQUIN[2], J. W. FENELLY[2], N. S. PENTKOWSKI[2]
[1]Psychology, [2]Univ. of New Mexico, Albuquerque, NM

Abstract: Previous research in rodents and humans has implicated the ventral hippocampus in regulating anxiety. However, many rodent studies examining ventral hippocampal neuronal pathways have utilized lesion studies that create nonspecific, nonreversible alterations to the targeted area. To increase specificity, the present study sought to characterize the unique role of glutamatergic pyramidal neurons located within the ventral hippocampus in the manifestation of anxiety-like behavior during exposure to a variety of threatening stimuli. Five weeks prior to

testing, Long-Evans hooded rats received ventral hippocampal viral-vector infusions expressing either the inhibitory pAAV-CaMKIIα-hM4D-mCherry (DREADD) receptor or pAAV-CaMKIIa-EGFP (GFP). DREADD transfection allowed for the direct, noninvasive inhibition of ventral hippocampal glutamatergic neurons immediately before threat presentation. Animals were evaluated for anxiety-like behaviors including freezing, risk assessment and avoidance during testing in the elevated plus maze, light-dark exploration test and footshock-induced fear conditioning. Analysis revealed a significant effect of DREADD inhibition that was dependent on the type of threat exposure. Specifically, compared to GFP controls, DREADD-induced silencing of ventral hippocampal glutamatergic neurons reduced anxiety-like behavior in the elevated plus maze and light dark test, without affecting fear conditioning. The present results confirm that exposure to anxiety-inducing stimuli provokes activation of ventral hippocampal glutamatergic pyramidal neurons. These data add to a growing literature implicating the ventral hippocampus as a key region involved in modulating anxiety.

Title: The effects of early-life prebiotic feeding on adult rat hippocampal function, behaviour and gut bacteria

Authors: *S. O. SPITZER[1,2], A. TKACZ[3], E. O. MANN[6], P. S. POOLE[3], D. M. BANNERMAN[4], D. C. ANTHONY[5], P. W. J. BURNET[2]
[2]Dept of Psychiatry, [3]Plant Sci., [4]Exptl. Psychology, [5]Pharmacol., [1]Univ. of Oxford, Oxford, United Kingdom; [6]DPAG, Oxford Univ., Oxford, United Kingdom

Abstract: The intake of oligosaccharide prebiotics – dietary fibres that augment the growth of beneficial gut bacteria – have neurobiological and behavioural effects in adult rodents and can improve cognitive performance. We have shown that neonatal supplementation with Bimuno galacto-oligosaccharides (BGOS) increases NMDA receptor GluN2A protein in the hippocampus of adult rats up to 8 weeks after treatment. It is important to confirm whether early-life prebiotic supplementation is able to improve and maintain brain processes in adulthood, possibly imparting resilience to age-related brain disorders.

This study tested the effects of perinatal BGOS supplementation on hippocampal electrophysiology, behaviour and the gut microbiome at various time points starting immediately after weaning up to adulthood. Suckling SD rat pups were gavaged daily with BGOS or control solution for 21 days, followed by behavioural tests or whole-cell patch-clamp recordings of hippocampal slices.
NMDA/AMPA ratio in CA1 neurons from BGOS rats were no different to controls at any age tested (P22, P56, P128+). However, decay time 1 (double exponential fit on NMDA currents) was diminished in BGOS animals (no interaction effect with age). In spontaneous synaptic events (sEPSCs), BGOS significantly reduced amplitude size (no interaction effect with age) and changed frequency depending on treatment and age (significant for treatment and interaction treatment x age).
In the elevated plus maze (EPM), perinatal BGOS supplementation had anxiolytic effects specifically at P22, when BGOS-treated rats spent more time in open arm, whilst no differences were observed across 3 time points.
To link behavioural and electrophysiology data with metagenomic profiles of gut microbiota, 16S gene was sequenced from faecal samples obtained weekly. Whilst preliminary data showed no differences in abundance of bacterial phyla, it is possible that differences occur on a smaller scale. Studies are underway to test whether the effects of transient post-weaning BGOS supplementation has more sustained effects on brain function throughout the life course.
Our data show that early-life BGOS feeding in healthy rats might not affect overall NMDA receptor expression in CA1, but may change receptor kinetics, which is sustained for at least 8 weeks after treatment. Since sEPSCs characteristics seemed to undergo age-specific changes, BGOS might induce more widespread changes on the hippocampal network long-term. The anxiolytic effects are only short-lived, which may suggest that unlike cognitive processes, changes in emotional behaviour are induced more robustly when bifidobacteria levels are augmented.

Title: Latent infection of Herpes Simplex Virus Type I impacts exploratory behavior in mice

Authors: I. HOUGH[1], E. KAIN[1], N. SHAW[2], *G. D. GRIFFIN[3]
[1]Biol., [2]Psychology, [3]Departments of Biol. and Psychology, Hope Col., Holland, MI

Abstract: Herpes Simplex Virus Type I (HSV-1) forms a lifelong infection and affects 70% of the American population (Looker et al., 2015). Tarter and colleagues demonstrated that being seropositive for HSV-1 is associated with diminished cognitive functioning, specifically working memory (2014). To date, no study has tested the direct link between HSV-1 and working memory. In light of this gap, the goal of our study was to examine the impact HSV-1 latency has on behavior, including working memory. The BALB/c and C57/BL6 mouse strains were both used in this study. At six weeks of age, animals were inoculated with the F strain (10^5 plaque-forming units) of HSV-1 via corneal scarification. Forty-five days post infection (dpi) behavioral studies commenced. This included the open field test, a modified Morris Water Maze, alternating T-test, and a novel object recognition task. Thus far, preliminary results reveal that female C57/BL6 mice infected with HSV-1 have a longer latency to enter the center region (compared to uninfected control females; $p<0.05$) at 45 dpi. There was a trend for this when animals were tested again in the open field arena at 166 dpi. The behavior in the open field arena of female BALB/c mice was not affected by HSV-1 latency. However, infected male BALB/c mice did demonstrate a trend to have a greater latency to enter the center zone of the arena (compared to uninfected males; $p<0.1$). HSV-1 latency did not impact locomotor behaviors (total distance traveled and average velocity) of any strain or sex of mice. Analysis of the other behavioral tests is ongoing. Overall, these preliminary results highlight the importance of testing multiple mouse strains and both sexes to understand the impact of infection on adult animal behavior. Lastly, they provide evidence that HSV-1, even while not producing viral proteins, prompts long-lasting changes in animal behavior. These results lend support to the human behavior correlational studies on HSV-1 and provide a platform to better understanding central consequences of the chronic immune response to HSV-1 and similar viruses.

Title: Neurochemical alterations underlying traumatic memory formation in a predator exposure model of post-traumatic stress disorder (PTSD)

Authors: *D. P. KELLEY[1], K. E. VENABLE[1], P. EBENEZER[1], C. C. LEE[2], J. FRANCIS[1]
[1]Comparative Biomed. Sci., Louisiana State Univ., Baton Rouge, LA; [2]Comparative Biomed. Sci., Louisiana State Univ. Sch. of Vet. Med., Baton Rouge, LA

Abstract: Innate immune activation is associated with a multiplicity of diseases ranging from diabetes to depression and is associated with activation of the enzyme, indolamine 2,3 dioxygynase (IDO). IDO activity reduces tryptophan availability and produces deleterious tryptophan catabolites (TRYCATS) that are associated with suicide, depression, and aggression. Post-traumatic stress disorder (PTSD) is also associated with excessive innate immune activation as well as elevated rates of suicide, depression, and aggressive behavior, but neither IDO activity or the TRYCAT pathway has been explored in this disorder. Previously, we demonstrated that superoxide, total reactive oxygen species (ROS) and inflammatory factors (TLR4, NF-κB, NALP3, IL-1β, IL-18) are significantly elevated in the brain and plasma and serotonin levels are reduced in the hippocampus and frontal cortex of our predator exposure model of PTSD compared to control animals. Here, we report that IDO expression levels, IDO activity, and TRYCATS are elevated in the hippocampus and plasma ($p<.05$, $n=6$/ group) of our PTSD model. Furthermore, these factors are associated with traumatic memory, anxious behaviors, and neurotransmitter abnormalities. IDO and TRYCATS may contribute to the establishment of the traumatic memory itself through glutamatergic mechanisms as well as link ROS and inflammation to the neurotransmitter malfunction previously observed in this model. Through these mechanisms, TRYCATS may be responsible for a wide range of symptoms in PTSD and connect a preexisting inflammatory milieu with the development of PTSD.

Title: Persistent memory deficits and neuroimmune dysfunction after immune challenge

Authors: *D. TCHESSALOVA[1], N. C. TRONSON[2]
[1]Neurosci. Grad. Program, [2]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: The neuroimmune system is critical for maintaining normal neural plasticity and memory function, and acute inflammatory signaling results in striking behavioral changes and memory deficits. Memory impairments and cognitive decline are also observed in patients long after recovery from inflammatory insults, such as major illness or injury. In this study, we aimed

to examine whether dysregulation of memory emerges or persists long after an immune challenge, and the changes in neuroimmune mechanisms that mediate lasting alterations in neural function in females and males. We have recently established a mouse model of memory deficits emerging over the weeks and months following a subchronic peripheral immune challenge in males and females. Mice were given five injections of lipopolysaccharide (LPS: 250 μg/kg), Polyinosinic: Polycytidylic acid (Poly I:C: 6 mg/kg), or saline over 14 days. We evaluated novel object recognition memory and context fear conditioning at one or eight weeks after immune challenge. In females, memory deficits were evident at both one and eight weeks, whereas males only showed memory deficits eight weeks after the last injection. There were also sex differences in the types of memory that were impacted. Males showed disruption of object recognition memory and context fear conditioning, whereas only object recognition memory was impaired in females. To examine whether neuroimmune changes also persist after immune challenge, we assessed blood-brain barrier function using dextran labeling to detect leakage, and microglial activation using Iba-1 staining and morphological analysis. We used RNA-sequencing to identify changes in gene expression that persisted at least 12 weeks after the last injection. We observed dysregulation of immune-related gene expression primarily in males (e.g. complement genes). Together, these findings demonstrate that prior inflammatory insults induce long-lasting memory deficits in both sexes, and that different types of impairments are evident in males and females. Persistent neuroimmune mechanisms may underlie these long-lasting changes in memory. Further, these data suggest that distinct molecular mechanisms mediate memory deficits in males and females. Future work will explore the causal link between memory impairments and long-lasting neural changes following an immune challenge. These studies will help to identify possible mechanisms contributing to memory decline, memory-related disorders, and dementias in men and women following recovery from illness or surgery.

Abstract: Sleep is evolutionarily conserved across organisms from nematodes to humans, however its role and function remains only partially understood. Here we aim to quantify the sleeping brain at near-cellular resolution, with brain-wide coverage using GCaMP. We compared the sleeping duration during one photon and two photon point scanning illumination in an effort to later move onto selective volume illumination (SVI). Using SVI along with lightfield microscopy, it is possible to achieve the temporal and spatial resolution needed to capture brain-wide cellular GCaMP signal and it enables the quantification of previously unrecognized neural activity. Our second aim is to determine whether differences exist between induced sleep, sleep after sleep deprivation, and natural sleep.
In a related but parallel effort, we investigated the intrinsic brain activity of flies with a mutation in the insomniac gene during sleep deprivation. This mutation is known to cause a decrease in sleep that is independent from the canonical circadian clock pathway and that does not result in sleep rebound. By expressing GCaMP6s in insomniac positive cells, we expect to find increased neuronal activity in insomniac mutants during sleeping hours and less perturbation after sleep deprivation.

Title: The bantam microRNA regulates cell proliferation and sleep in multiple mushroom body output neurons in *Drosophila melanogaster*

Authors: *K. DORFMAN, M. HOBIN, L. C. GRIFFITH
Brandeis Univ., Waltham, MA

Abstract: Post-transcriptional gene regulation by microRNA plays an important role in the regulation of sleep. Using miRNA sponge technology to inhibit miRNA function, a reverse genetics screen to identify microRNAs that regulate sleep in *Drosophila melanogaster* was previously performed. This screen identified the well-conserved microRNA encoded by the *bantam* gene as a positive regulator of sleep. This study sought to further characterize the role of bantam in sleep regulation by mapping its effects to a specific sleep circuit. Cell-type specific knock-downs of bantam were performed using the binary GAL4:UAS expression system, and

sleep was measured using the *Drosophila* Activity Monitoring (DAM) system. We mapped the effect of bantam on sleep to the Mushroom Body Output Neurons (MBONs), a class of neurons divided into 21 subtypes that serve as the output of the mushroom body circuit, and which have been previously implicated in sleep regulation. Using split-GAL4 lines to express the bantam sponge in specific subtypes of the MBONs, it was found that bantam positively regulates nighttime sleep through at least three diverse MBONs: the cholinergic γ2α'1 neurons, the GABAergic γ3 and γ3β'1 neurons, and the glutamatergic γ5β'2a neurons. The effects of bantam on neuronal morphology and cell number of the γ2α'1 and γ5β'2a neurons were assessed by co-expressing a fluorescent marker with the bantam sponge and imaging the neurons using confocal microscopy. Preliminary results indicate that flies expressing the bantam sponge in γ2α'1 and γ5β'2a neurons have a higher number of cells expressing the fluorescent marker. To determine if bantam's effects on sleep occurred through developmental processes or active adult regulation, the temperature inducible *Tubulin-GAL80* was used to knockdown bantam specifically during development or adulthood. These experiments revealed that bantam regulates different aspects of sleep in different developmental stages: expression of bantam early in development is required for normal daytime sleep, whereas expression of bantam in adulthood is necessary for normal daytime and nighttime sleep. Our results identify a role for bantam in the adult regulation of sleep in specific subtypes of MBONs, and a further role in the regulation of MBON cell number.

Title: Evolutionarily conserved regulation of sleep by epidermal growth factor receptor signaling

Authors: *D. A. LEE[1], J. LIU[1], Y. HONG[1], A. J. HILL[1], J. M. LANE[2,3], H. WANG[2,3], G. OIKONOMOU[1], U. PHAM[1], J. ENGLE[1], R. SAXENA[2,3], D. A. PROBER[1]
[1]Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Harvard Med. Sch., Boston, MA; [3]Broad Inst., Boston, MA

Abstract: Sleep is an evolutionarily conserved behavioral state whose regulation remains poorly understood. One approach towards discovering key sleep regulatory mechanisms is to identify systems that do so in both invertebrates and vertebrates. Using zebrafish, we asked whether epidermal growth factor receptor (EGFR) signaling is necessary and sufficient for vertebrate sleep, as for invertebrates. We found that overexpression of the EGFR ligand transforming growth factor alpha (TGFa) increased sleep, while loss of EGFR signaling decreased sleep. Downstream mechanisms through which EGFR signaling promotes sleep are also conserved, as TGFa-induced sleep was suppressed by inhibition of MAPK/ERK, as suggested in *Drosophila*, and by mutation of the RFamide neuropeptide VF (NPVF), similar to *C. elegans*. Additionally, we found that EGFR signaling regulates NPVF expression and NPVF neuronal activity, providing a mechanistic link between these systems. Finally, in a sleep multi-trait genome-wide association study performed using humans from the UK Biobank, we identified significant associations at genomic regions encompassing *ERBB4*, *KSR2*, and *VRK2*, genes in the EGFR signaling pathway. These signals were driven primarily by genetic associations with sleep duration and/or daytime sleepiness. Taken together, these results demonstrate that sleep regulation by EGFR signaling is conserved between invertebrates and vertebrates, and suggests an ancestral role in the regulation of human sleep.

Title: Unraveling miR-190 and its role in sleep

Authors: *E. J. RIVERA, P. GOODWIN, M. HOBIN, Z. BLEICHER, L. C. GRIFFITH
Brandeis Univ., Waltham, MA

Abstract: Sleep is a widely conserved behavior and it is known to be regulated by changes in gene expression. However, the molecular basis of the regulation of sleep remains poorly understood. Research from our lab, and elsewhere, supports the idea that microRNAs (miRs) are involved. miRs are short non-coding RNA transcripts (20-24 bp in length) that target specific mRNAs, downregulating their expression. Results from a genetic screen in which miRs were downregulated by expression of transgenes which specifically bind particular miRs (*miR-SPs*), demonstrated that miR-190 is involved in *Drosophila* sleep regulation. Pan-neuronal expression of *miR-190-SP* or mutation of the *miR-190* gene both elicited dramatic changes in *Drosophila*

sleep behavior, including decreased and fragmented total sleep, as well as deficient sleep homeostasis. Expression of *miR-190-SP* in limited numbers of cells in different brain regions using the *Gal4/UAS* system showed that disruption of miR-190 function must occur in a large number of neurons to affect *Drosophila* sleep regulation. At the molecular level, our preliminary data from RNA seq of adult heads showed that pan-neuronal expression of *miR-190-SP* induces an up or downregulation of multiple genes, including 6 genes which are intimately involved in dopamine (DA) signaling, the major pro-arousal system of the fly. Temporally-controlled expression of *miR-190-SP* demonstrated a developmental effect of miR-190 on the regulation of sleep: flies in which miR-190 function was decreased during development showed fragmented and decreased sleep whereas reduction of miR-190 only in the adult stage did not. Taken together, our data suggest that miR-190 functions during development to specify the activity of the adult arousal system.

Title: Daytime illumination modulates spatial learning through the orexinergic pathways in the diurnal Nile grass rat (arvicanthis niloticus)

Authors: *L. YAN, J. SOLER, A. NUNEZ
Psychology, Michigan State Univ., East Lansing, MI

Abstract: Environmental lighting conditions play a significant role in cognitive function, with the level of illumination positively correlated with cognitive performance in a diverse population of human subjects. However, the underlying neural mechanisms are not-well understood. Utilizing a diurnal rodent model, the Nile grass rat (*Arvicanthis niloticus*), our group has found that the levels of daytime illumination are associated with strength of spatial memory assessed via the Morris Water Maze (MWM) task, such that grass rats housed in a 12:12hr bright light-dark (brLD) cycle over 4 weeks showed superior MWM performance, compared to animals housed in a 12:12hr dim light-dark (dimLD) cycle. The animals in brLD condition also had higher level of hypothalamic orexin A (OXA) expression. Based on those findings, the present study tested the hypothesis that in diurnal mammals, light modulates hippocampal function via

the orexinergic system. In the first experiment, animals housed in dimLD for four weeks were then assigned to two groups to receive either OXA or vehicle solution (intranasally) 2hr prior to the MWM training session over five training days (n=8/group). The OXA treated animals exhibited faster escape latencies during the training sessions and spent more time in the target quadrant during the following probe test compared to controls, suggesting that impaired hippocampal function in dimLD was due to attenuated orexinergic output. In the next experiment, two groups of grass rats (n=12/group) received hippocampal injection of viral vector (AAV) containing either shRNA targeting orexin receptor 1 (OX1R) or scrambled (SC) shRNA into the dorsal CA1 hippocampal subregion, followed by 4 weeks of housing in brLD prior to MWM training/testing. Animals that received OX1R-shRNA showed longer escape latencies during training session compared to the SC-shRNA group, and performed at chance level during the probe trial. The results suggest that brighter illumination enhances spatial learning through the orexin-OX1R pathway to the hippocampus. These findings support the hypothesis that the orexinergic system mediates the effects of light on hippocampal-dependent learning and memory.

Title: Intermittent fasting increases slow wave sleep duration in mice

Authors: *R. WAN, Y. LIU, M. MATTSON
Lab. of Neurosciences, Natl. Inst. On Aging/ Natl. Inst. Of Hlth., Baltimore, MD

Abstract: We previously found that the intermittent fasting (IF; alternate day fasting) enhances parasympathetic tone in rats and mice, which manifests as reduced resting heart rate and blood pressure, increased heart rate variability, and enhanced cardiovascular stress resistance. Here we investigated the possible effects of IF on brain neuronal network activity and sleep duration and quality in mice. A radio telemetric device was implanted and used to monitor the cortical and hippocampal electroencephalogram (EEG) and locomotor activity in C57BL/6j mice maintained either with *ad libitum* (AL) or IF regime (Every-Other-Day fasting) for an over 5 weeks' period. The EEG activity and response to body restraint stress were examined prior to and 5 weeks after the IF regime was initiated. The results showed that: 1) IF mice increased their sleep time, particularly in 'deep sleep (slow wave sleep 2 ; SWS2), during night period on a fasting night; 2)

IF mice became more active during day period, particularly, an increased locomotive activity indicating an anticipatory food availability as the feeding time getting closer at the end of fasting day time; 3) IF reduced EEG power in lower frequencies mainly in delta (0-4 Hz), theta (4-12 Hz), sigma (12-16 Hz) and beta (16-24 Hz). The reductions occurred mostly in day period; 4) The blood glucose level and body temperature increased in response to body restraint stress. However, the magnitude of increase in blood glucose level was significantly lower when the stress response was retested on fasting and feeding days 5 weeks after mice were maintained with IF regime. Although there was a significant reduced lower spectral power in IF mice prior to stress, there was discernable effect of IF on EEG activity during or after stress.

Title: Neural circuits in the VTA govern vigilance state

Authors: *X. YU, N. P. FRANKS, W. WISDEN
Imperial Col. London, London, United Kingdom

Abstract: We screened for novel circuits in the mouse brain that determine vigilance states. Using chemogenetic activation/inhibition combined with EEG/EMG recordings, we converged on specific neurons in the VTA. We found that activation of glutamatergic neurons, which were wake- and REM-active, produced long-lasting wakefulness. In contrast, chemogenetic activation of GABAergic VTA neurons elicited long-lasting NREM-like sleep akin to sedation. This occurred via local inhibition of glutamatergic and dopaminergic neurons in the VTA. Our findings suggest that the VTA, widely investigated for its contribution to goal- and reward-directed behaviors, contains circuitry with an unexpected role in sustaining and limiting wakefulness.

Title: Role of parabrachial glutamatergic signaling in the regulation of arousal

Authors: *M. A. KHANDAY[1], S. KAUR[1], C. B. SAPER[2]
[1]Neurol., Beth Israel Deaconess Med. Ctr. & Harvard Med. S, Boston, MA; [2]James Jackson Putnam Prof, Harvard Med. Sch. Dept. of Neurol., Boston, MA

Abstract: The parabrachial nucleus (PB) of the brainstem is known to regulate cortical activation and behavioral arousal. Chemogenetic and optogenetic activation of PB increases wakefulness while cell specific lesion or chronic deletions of glutamatergic transmission in PB neurons induce non rapid eye movement sleep (NREM sleep). Based on the varied outputs of the PB, this area exerts powerful control over a wide range of neurobiological functions, including cortical arousal and therefore, it is important to understand how different subnuclei of PB affect cortical arousal. As chronic deletions of cells suffer from compensatory effects over time, it is important to address this using acute inhibition of various PB subnuclei. Therefore, in our study, we acutely modulated lateral (PBl) and medial part of PB (PBm), and investigated its effects on sleep-wakefulness. We used adult male mice which express Cre- recombinase in the glutamatergic cells, also called vesicular glutamate transporter 2 (Vglut2)-Cre. Vglut2-Cre mice (n=9) were bilateral injected stereotaxically with Adeno-associated virus (AAV) that express Ef1α::hM4Dq-mCherry into either PBm (AP = -5.2 mm, ML = ± 1.1 mm, DV = -2.6 mm), or PBl (AP = -5.3 mm, ML = ± 1.3 mm, DV = -2.4 mm) and implanted with EEG/ EMG electrodes for recording sleep. AAV was optimally expressed at 4weeks post injection, after which mice were recorded for sleep after acclimatization to the recording apparatus for a week, after intraperitoneal injection of either saline (Sal) or 0.3mg/Kg of clozapine N-oxide (CNO). Both injections were done at the early dark onset (7pm). Sleep-wake data was analyzed and compared between the Sal and CNO injection days. The injection sites for the hM4Dq were analyzed by immunohistochemistry post-hoc. We observed that out of n=9 injected mice, some had hM4 localized to PBl (n=4) and other were localized to the PBm (n=5). CNO induced inhibition of the PBm increased NREM in the dark phase by 55%; while inhibition of PBl promoted 43% increase, compared to after Sal injection. Furthermore, animals with PBl inhibition showed almost doubling of NREM 4-6h post CNO and then returned to baseline, while animals with PBm inhibition showed sustained increases of 30-90% for the entire 8-9h post CNO period. The

differential effects on NREM sleep due to inhibition of PBm and PBl could be attributed to varied PB afferent projections to arousal centers. Further, investigations are needed using cell specific markers for the PB subnuclei that can delineate the precise circuitry regulating the arousal

Title: Adiponectin and leptin regulate VLPO activity

Authors: *O. RAMÍREZ PLASCENCIA, S. CÁRDENAS-ROMERO, L. AZUARA-ALVAREZ, A. BÁEZ-RUIZ, M. MIRANDA-MORALES, M. ATZORI, N. SADERI, R. C. SALGADO-DELGADO

Abstract: An increasing amount of evidence indicates that overweight and obesity modify the physiological patterns of sleep and the chronotype, in both humans and rodents. Currently, there is a little understanding regarding the mechanisms of this association, with the exception that several areas within the central nervous system involved in sleep regulation, express receptors for leptin, which is a hormone secreted by the white adipose tissue and up-regulated in obesity. Leptin receptors are expressed in the Ventrolateral Preoptic nucleus (VLPO) and Median Preoptic nucleus (MnPO), two hypothalamic areas that promote sleep by inhibiting the wake-promoting nuclei [Tuberomammillary nucleus (TMN), Locus Ceoruleus (LC)] and receives circadian input by the master clock, the suprachiasmatic nucleus (SCN). The increased leptin levels in obesity are associated with the down-regulation of another adipokyne, adiponectin, which has insulin-sensitizing and anti-inflammatory properties. With the hypothesis that the increase in the leptin/adiponectin ratio might contribute to sleep disorder in obesity, in the present work, with first explore whether adiponectin receptors AdipoR1 and AdipoR2 are expressed in same brain areas as leptin. By immunohistochemistry to AdipoR1 and AdipoR2 in the rat brain, we found that these receptors are expressed in VLPO, as well as in the SCN, MnPO, TMN and LC. Given the key role of VLPO in sleep regulation, we then investigated whether the activity of this nucleus is affected by leptin and adiponectin. For that, the

electrophysiological response of VLPO neurons to leptin (10 nM) and adiponectin (200 μM) was assessed in rat brain slices (300 μm) containing the VLPO, by path-clamp in current clamp mode. Results showed that leptin increases the spontaneous activity of VLPO neurons, while adiponectin displayed inhibitory effects. These data imply that VLPO activity might be modulated by metabolic information, suggesting a new model for sleep-metabolism interaction, which might account for the sleep disturbances reported in obese subjects.

Title: Sleep rebound and orexin administration change neuroglobin immunoreactivity in the rat brain

Authors: *F. A. GARCÍA-GARCÍA[1], L. RENDON[2], M. A. MELGAREJO[4], C. MORGADO-VALLE[1], G. HERNANDEZ-MARQUEZ[3]

Abstract: Neuroglobin (Ngb) is a protein member of the globin family, expressed mainly in the central and peripheral nervous system. It is involved in the transport of oxygen, in the response to hypoxic/ischemic and oxidative stress-related insults. Recently, we showed that sleep deprivation reduces the number of Ngb positive (Ngb^+)cells in brain areas related to sleep. However, it is poorly understood whether Ngb expression depends on sleep occurrence and/or on waking promoting factors. Here, we aimed to study if sleep rebound restores the number of Ngb^+cells and if orexin-A administration affects Ngb expression in areas related with sleep-wake regulation. Male Wistar rats were sleep-deprived for 24 h using the gentle handling method.After sleep deprivation, rats were allowed a sleep rebound for 3 or 6 h. After sleep rebound, rats were euthanized, and their brains processed for Ngb immunohistochemistry. In a different group of rats, orexin-A was injected into the left lateral ventricle using a cannula. Three hours post-injection, rats were euthanized, and their brains processed for Ngb immunohistochemistry.We found that a 3-h sleep rebound is enough to restore the number of Ngb^+cells in all the analyzed

areas. A similar result was observed after 6-h sleep rebound. The injection of orexin-A increased the number of Ngb^{+}cells in areas associated with sleep-wake regulation. These results suggest that Ngb expression is sleep depend, and that orexin modulates its expression. We suggest that Ngb expression is involving in preventing cell damage due to prolonged wakefulness.

Title: A neuronal hub binding sleep initiation and body cooling in response to a warm external stimulus

Authors: *E. HARDING, W. WISDEN, N. P. FRANKS
Imperial Col. London, London, United Kingdom

Abstract: Animals actively thermoregulate in preparation for sleeping. Mammals build nests and curl up, humans use bedding and environmental adaptation to create warm microclimates that are permissive for sleep. This strongly conserved behaviour may function to facilitate better or deeper sleep but it may also just be a matter of comfort without such function. To assess this hypothesis and evaluate whether mice sense environmental temperature to directly influence the onset of sleep we utilised a pharmacogenetics method to label and reactivate warm-sensing neurons within the preoptic hypothalamus. This method of Tet-Tagging allows us to understand the functions of neurons responding to specific stimuli, based on their expression of c-Fos. We found that within the MnPO/MPO hypothalamus distinct populations of warm-tagged neurons could induce sleep as well as body cooling, whereas an alternative population of warm-tagged MnPO/MPO neurons could induce sleep without hypothermia. We suggest the existence of a neuronal hub that uses sensory temperature cues to promote simultaneous sleep and body cooling. The efficient linking of these physiologies suggests that one function of sleep is to reduce energy expenditure.

Title: Chemogenetic activation of corticotropin releasing factor neurons in the hypothalamic paraventricular nucleus does not disrupt the homeostatic response to acute sleep deprivation

Authors: *J.-C. HSIEH[1,2,4], S. KUMAR[1,4,5], D. J. MCGINTY[3,1], R. S. SZYMUSIAK[1,2]
[1]VA Greater Los Angeles, North Hills, CA; [2]Med., [3]Psychology, UCLA, Los Angeles, CA; [4]Websciences Intl., Los Angeles, CA; [5]Pharmaceut. and Biomed. Sci., California Hlth. Sci. Univ., Clovis, CA

Abstract: Introduction: Our recent studies have shown that acute activation of corticotropin releasing factor (CRF) neurons in hypothalamic paraventricular nucleus (PVN) causes disruption of spontaneous sleep followed by sleep rebound, while the activity of the CRF neurons in PVN is implicated for the loss of homeostatic sleep response during chronic sleep restriction. In the present study we investigate if activation of CRF neurons in the PVN neurons during 6 hr sleep deprivation in mice disrupts suppresses the homeostatic response to sleep loss.
Methods: Male CRF-ires-Cre mice received bilateral injections of pAAV-hSyn-DIO-hM3D(Gq)-mCherry excitatory DREADD targeting the PVN. Mice were implanted with chronic EEG/EMG electrodes at the time of AAV injection. Mice were maintained 12/12 hr light dark cycle. Three weeks after AAV injections, intraperitoneal injections of vehicle or CNO (1 mg/kg) were administered at zeitgeiber time (ZT) 0, followed by 6 hours of total sleep deprivation by gentle handling. EEG slow-wave activity (SWA) of delta frequency (0.4 to 4 Hz) in NREM sleep and sleep wake measures were analyzed during the first 6 hrs of recovery sleep in the light period (ZT6-12).
Results: The mice displayed hyperactivity and heightened arousal after receiving CNO injections and showed little sign of drowsiness for the most part of the 6-hhr sleep deprivation, compared to the condition with vehicle injections, but did exhibit sleepiness and required repeated handling to maintain wakefulness during the final 1-2 hrs of sleep deprivation. During recovery period, there were no differences in time in Wake, NREM or REM, or the wake-sleep bout lengths between CNO and vehicle conditions in each of the 2-hour time blocks of undisturbed recovery sleep. The ratio of total NREM SWA or delta power during 6-hour recovery between CNO and vehicle conditions is 98.9% ± 5.3%, indicating the same homeostatic EEG response in both conditions, despite a heightened arousal caused by the activation of CRF neurons in the PVN during sleep deprivation.

Conclusion: The recovery sleep following the acute activation of CRF neurons in the PVN does not differ from the homeostatic sleep rebound following 6-hour total sleep deprivation.

Title: Dopamine terminal neurotransmission varies across sleep-wake state

Authors: *I. P. ALONSO[1], J. A. PINO[2], G. E. TORRES[2], R. A. ESPAÑA[1]
[1]Neurobio. and Anat., Drexel Univ., Philadelphia, PA; [2]Dept. of Pharmacol. and Therapeut., Univ. of Florida, Gainesville, FL

Abstract: The dopamine transporter (DAT) is a homeostatic regulator that governs the temporal dynamics of DA neurotransmission. For example, DAT modulates extracellular DA levels across the light/dark cycle where peak extracellular DA tone is observed during the dark phase when animals are usually awake. The DAT can also undergo adaptations in response to physiological demands. For example, we recently demonstrated that DAT function varies in a diurnal fashion such that DA uptake and release are most efficient during the light phase when rats are typically asleep. What remains unclear is whether these fluctuation in DA release and uptake are associated with specific sleep-wake activity states or to other diurnal factors. To address these issues, we examined whether sleep-wake activity has an impact on DA terminal neurotransmission and which components of DA homeostasis are affected across sleep-wake activity. Rats were implanted with EEG/EMG electrodes to determine sleep-wake state (Wake, NREM, REM) immediately prior to ex vivo fast scan cyclic voltammetry detection of DA release, uptake, inhibition of DA uptake following cocaine challenge, or tissue quantification of key DA proteins. We observed a significant impact of sleep-wake state on DA terminal neurotransmission, with rats that were asleep exhibiting higher DA release and DA uptake relative to rats that were awake. Interestingly, we also observed a positive relationship between maximal DA uptake rates and the percentage of time spent in each sleep state. Further, we found that the effects of cocaine at inhibiting the DAT varied across arousal state. These results demonstrate that DA release and uptake are dynamically regulated and suggest that sleep-wake activity impacts DA neurotransmission in a manner that may influence DA-dependent processes such as cognition, drug-associated behavior, motor activity, and learning and memory.

Title: Beta3-adrenergic receptor agonist-induced sleep in tumor necrosis factor alpha knockout mice

Authors: *E. SZENTIRMAI[1], A. MASSIE[2], L. KAPAS[3]
[1]Elson S. Floyd Col. of Med., [2]Washington State Univ., Spokane, WA; [3]WWAMI Med. Educ. Program, Washington State University, Spokane, Spokane, WA

Abstract: Introduction:
The interaction between sleep, metabolism and immune functions is well recognized. Shared central regulatory circuits and peripheral signaling and effector mechanisms, such as tumor necrosis factor alpha-α (TNFα), are likely to underpin the tight connection among these functions. The aim of the present study was to investigate the role of endogenous TNFα in spontaneous and β3-adrenergic receptor (β3-AR)-induced sleep in mice. β3-AR stimulation-induced sleep is mediated, in part, by the activation of brown adipose tissue. Since β3-AR stimulation also causes TNFα release, we investigated if the brown adipose tissue-independent component of β3-AR-induced sleep is mediated by TNFα.
Methods:
Male wild-type (WT) and TNFα knockout (KO) mice (n = 10, both genotypes) were instrumented with EEG and EMG electrodes and an intraabdominal transmitter. Spontaneous sleep-wake activity, body temperature and motor activity were recorded for three days. Baseline metabolism was recorded using indirect calorimetry three days after the completion of sleep recordings. In a separate experiment, mice were injected with i.p. saline on the control day and with 0.2 mg/kg β3-adrenergic receptor agonist (CL-316,243) on the experimental day. Sleep, body temperature and motor activity were recorded for 24 h after each treatment. Data were analyzed by using ANOVA followed by t-test.
Results:
Under baseline conditions, TNFα KO and WT mice showed normal diurnal rhythms of sleep-wake activity, body temperature and motor activity. TNFα KO mice had significantly more NREMS (WT: 269.1 ± 12.6 min vs KO: 297.4 ± 9.6 min, $p = 0.05$) and REMS (19.8 ± 2.9 min vs 35.1 ± 1.3 min, $p < 0.001$) during the dark phase than WTs. The increases in the amounts of NREMS and REMS were due to the increased number of sleep episodes in the TNF KOs. Body

temperature and motor activity in TNFα KO mice was significantly lower during the entire dark phase. TNFα KO mice had slightly lower heat production during the dark phase and lower respiratory quotients during the entire day compared to WTs. β3-AR-induced NREMS increase was slightly attenuated and body temperature increases were completely absent in the TNFα KO mice.
Conclusions:
Present results further support the role of TNFα in the regulation of sleep and metabolism.

Title: Sleep and fever caused by cell wall components of bacteria: The role of tumor necrosis factor-α

Authors: *A. R. MASSIE[1], N. MILLICAN[2], L. KAPAS[1], E. SZENTIRMAI[1]
[1]Elson S. Floyd Col. of Med., [2]Washington State Univ., Spokane, WA

Abstract: Introduction:
Muramyl peptides (MPs) and lipopolysaccharide (LPS) are components of the bacterial cell wall. Systemic injections of MPs and LPS elicit the so-called sickness syndrome, which includes fever, sleep, anorexia and behavioral withdrawal. Further, bacterial cell wall components induce the production of pro-inflammatory cytokines. Since pro-inflammatory cytokines, such as tumor necrosis factor-α (TNFα) produce similar sleep- and fever-promoting effects as MPs and LPS, it is widely assumed that symptoms of the sickness syndrome are due to the release of those cytokines. Muramyl dipeptide (MDP), the simplest MP with full immune stimulant activity, acts on NOD2 receptors, while iEDAP and LPS, components of the cell wall of gram-negative bacteria, act on NOD1 and TLR4 receptors, respectively. The aim of the present study was to investigate the role of endogenous TNFα in NOD1, NOD2 and TLR4 receptor activation-

induced sleep and febrile responses.
Methods:
Male wild-type (WT) and TNFα knockout (KO) mice (n = 10, both genotypes) were instrumented with EEG and EMG electrodes and an intraabdominal transmitter to record sleep-wake activity, body temperature and locomotion. The effects of the intraperitoneal injection of 25 mg/kg MDP, 25 mg/kg iEDAP and 0.4 µg/mouse LPS were determined in a counter-balanced order with one week between the treatments. Polygraphic recordings were scored blinded. Data were analyzed by using ANOVA followed by t-test.
Results:
MDP caused significant increases in rapid-eye-movement sleep (REMS; 6.0 ± 1.5 min/4 h), non-REMS (NREMS; 38.2 ± 8.7 min/4 h) and body temperature (0.41 ± 0.1°C) in WT animals. The effects in TNFα KO mice were significantly attenuated (NREMS: 13.3 ± 5.4 min/4 h; REMS: 1.8 ± 1.3 min/4 h; temperature: 0.30 ± 0.1°C). iEDAP did not have any significant effect on sleep and body temperature in WT animals. In TNFα KO mice, however, NREMS and body temperature were significantly elevated after iEDAP treatment (NREMS: 22.2 ± 6.5 min/4 h; temperature: 0.14 ± 0.04°C). Sleep- and fever-inducing effects of LPS were not different in the two genotypes.
Conclusions:
Endogenous TNFα is likely to play a role in sleep and fever induced by MPs, but not in the effects of LPS.

Title: The effects of antibiotic-induced gut-microbiome depletion on sleep in mice

Authors: *N. S. MILLICAN[1], A. R. MASSIE[1], E. SZENTIRMAI[2], L. KAPAS[3]
[2]Elson S. Floyd Col. of Med., [1]Washington State Univ., Spokane, WA; [3]WWAMI Med. Educ. Program, Washington State University, Spokane, Spokane, WA

Abstract: Introduction: Bacterial cell-wall components (BCWCs; e.g., lipopolysaccharide, peptidoglycan) and pro-inflammatory cytokines are well documented to increase sleep when injected systemically. The gut contains the body's largest reserves of both immunologically-active tissue and bacteria. Since BCWCs continuously enter the circulation from the intestines even under normal conditions, we hypothesized that translocated microbial molecules may contribute to the maintenance of sleep-wake activity. To test this, we investigated the effects of gut-microbiome depletion on sleep in mice.Methods: Male C57BL/6J mice (n = 6; 3 months old) were instrumented with electroencephalographic and electromyographic electrodes. Following surgeries, mice were individually housed in temperature controlled (29 ± 1°C), sound-attenuated chambers on a 12:12 hour light-dark cycle. Food and water were available *ad libitum*. Sleep recordings were performed after 10 days of recovery. After recording baseline sleep-wake states, mice were gavaged daily with 0.01 ml/g bodyweight of a broad-spectrum antibiotic cocktail (2.5 mg/ml ampicillin, 2.5 mg/ml metronidazole, 2.5 mg/ml neomycin, 1.0 mg/ml vancomycin—made fresh just prior to gavaging) within 30 min of dark onset for 24 days. On day 25, mice were gavaged with water. On days 26-28, to expedite gut-microbiome repopulation, mice were gavaged with fecal suspension made of feces from non-antibiotic treated mice. Somnographic recordings were scored by a blinded scorer. Paired t-tests were used to compare baseline with days 25 (maximal microbiome depletion; day 25 was used as the day of maximal microbiome depletion, rather than the final antibiotic-administration day, due to an acute effect of the antibiotics) and 26 (fecal gavage).Results: Microbiomial depletion reduced dark-phase non-rapid-eye movement sleep (NREMS) by 16.8% ($p = 0.05$) and fecal gavage returned sleep to baseline ($p = 0.44$).Conclusions: Antibiotic-induced gut-microbiome depletion significantly reduced dark-phase NREMS by ~17% and repopulation reinstituted baseline NREMS. Our findings support the hypothesis that gut-microbiome products contribute to normal sleep. At least 3 groups of microbial signals my mediate these effects: BCWCs; microbial metabolites, such as short-chain fatty acids and secondary bile acids; intestinal hormones modulated by bacteria, such as melatonin and serotonin.

Title: Role of macrophages in bacterial cell wall components-induced sleep in mice

Authors: *L. KAPAS[1], N. S. MILLICAN[2], E. SZENTIRMAI[3]
[1]Dept. of Biomed. Sci., Washington State University, Spokane, Spokane, WA; [2]Biomed. Sci., [3]Elson S. Floyd Col. of Med., Washington State Univ., Spokane, WA

Abstract: Bacterial cell wall products (BCWPs), such as the peptidoglycan derivative muramyl dipeptide (MDP) and lipopolysaccharide (LPS), translocate from the intestinal lumen to the portal circulation and are present in detectable quantities in various organs, including the liver, under physiological conditions. BCWPs, acting on the pattern recognition receptors TLR4, NOD1 and NOD2, activate Kupffer cells, the resident hepatic macrophages, and elicit the production of cytokines, such as interleukin-1β and tumor necrosis factor-α. Since both BCWPs and pro-inflammatory cytokines induce sleep, we hypothesized that activated macrophages play a role in the somnogenic actions of LPS and MDP by secreting somnogenic cytokines. To test this hypothesis, we determined the effects of LPS and MDP on sleep in macrophage-depleted (MD) mice.

Male C57 mice (n = 10) were instrumented with EEG and EMG electrodes and an intraabdominal transmitter to record sleep-wake activity, body temperature and locomotion. First, the effects of the intraperitoneal (ip) injection of 25 mg/kg MDP and 0.4 µg/mouse LPS were determined in a counter-balanced order with one week between the treatments. Then, the animals received ip injection of clodronate-containing liposomes (CCL) to induce MD. 7-10 days after the CCL treatment, the sleep and thermoregulatory effects of LPS and MDP were determined again during the macrophage-depleted stage. Data were analyzed by using ANOVA followed by paired t-test.

MDP caused significant increases in rapid-eye-movement sleep (REMS; 6.0 ± 1.5 min/4 h), non-REMS (NREMS; 38.2 ± 8.7 min/4 h) and body temperature (0.41 ± 0.1°C) in mice before macrophage depletion. The sleep-inducing, but not the febrile, effects of MDP were completely abolished in MD animals. LPS significantly increased NREMS and REMS before MD treatment (NREMS: +96.8 min/8 h; REMS: +9.0 min/8 h); the effects were significantly suppressed after MD treatment (NREMS: +53.0 min/8 h; REMS: -14.6 min/8 h). Before macrophage depletion, the mice developed monophasic fever in response to LPS; in the MD stage, LPS elicited robust monophasic hypothermia.

Conclusion: Macrophages play a pivotal role in the sleep-inducing effects of BCWPs and play a role in the febrile effects of LPS, but not MDP.

Abstract: After deprivation of rapid eye movement (REM) sleep, land mammals increase REM sleep time, supporting the idea that REM sleep is homeostatically regulated. The semiaquatic northern fur seal (*Callorhinus ursinus*) is unique in showing both the bilateral SWS (BSWS) seen in most mammals and the unihemispheric sleep (USWS) reported in cetaceans. We recorded electroencephalogram (EEG), electromyogram, electrooculogram and electrocardiogram in freely mowing fur seals (n=4) using a datalogger during 2 days on land (baseline, B), 10-14 days in seawater, and then another 2 days on land (recovery). When in water, the average daily amount of REM sleep in seals was reduced to 3 minutes a day vs. 80 minutes when on land or in B (a 96.4+1.0% reduction) (one way ANOVA, $F_{13,33}=27.506$, $P<0.001$). The number of REM sleep episodes per day decreased to 20±3% of B ($F_{13,33}=10.754$, $P<0.001$) and the average duration of REM sleep episodes decreased to 13±1% of B ($F_{13,33}=6.508$, $P<0.001$). No REM sleep was recorded in the seals during the first 3-7 days in water. By the end of the 10th day an accumulated "loss" of the expected amounts of REM sleep averaged 765±72 minutes or 974±8% of projected daily B amounts. On the first recovery day (R1), the amounts of REM sleep were not significantly greater than during B (Tukey post hoc test, $P>0.05$, df =6). For all seals combined, the average amount above B values on R1 was only 3.2±2% of REM sleep lost in seawater. The number and duration of REM sleep episodes on R1 did not significantly differ from that in B. The amount of REM sleep on R1 did not correlate

with the amount of REM sleep lost. In contrast to REM sleep, the total amounts of slow wave sleep in seals in seawater ranged from 45-129% of B. The amount of BSWS in water was significantly smaller than that in B with a decrease from 7.5 to 0.5% of the 24-h ($F_{12,25}=22.868$, $P<0.001$). After return to B conditions the amount of BSWS on both R days doubled with respect to the average B amounts ($P<0.001$). Our data are consistent with the hypothesis that REM sleep may serve to reverse the reduced brain temperature and metabolism effects of bilateral non-REM sleep, a state which is greatly reduced when the fur seal is in the seawater, rather than REM sleep being directly homeostatically regulated.

Title: The effect of ketamine on slow-wave activity (SWA) in patients with treatment resistant depression compared with healthy controls

Authors: *M. OPPENHEIMER, N. HEJAZI, B. FALODUN, W. DUNCAN, C. A. ZARATE, JR
Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Background**:** Sleep disturbance and reduced slow-wave activity (SWA) are common features of depression. Slow-wave activity (SWA) increases with duration of prior wakefulness and declines during sleep, suggesting regulation by a sleep homeostat. Ketamine is a glutamatergic drug with rapidly acting antidepressant properties associated with altered levels of SWA, with possible effects on sleep homeostasis and neural plasticity. Previous research has also demonstrated significant age and gender effects on SWA in depressed as well as healthy populations, suggesting that these factors influence sleep homeostasis, and contribute to mood disorder. The present study evaluates the effect of ketamine on SWA in patients with Treatment Resistant Depression (TRD) compared to healthy controls (HC), and examines the influence of sex and age on SWA.
Methods: Participants were TRD patients (n= 30: f= 22; BD= 9; $\bar{X}$= 41.5 y) and HCs (n= 11; $\bar{X}$= 32.9 y) who received a single infusion of ketamine (0.5 mg/kg over 40 minutes). Polysomnography was performed the night before (baseline; BL) and after ketamine (post-K) infusion. Fast Fourier transform power spectral analysis was used to analyze SWA for C3-A2 and C4-A1 EEG channels. SWA data were log-transformed prior to analysis. Linear mixed models were used for analysis.

Results: At baseline, SWA was lower in patients with TRD (232.3 ±21.4 [$\overline{X}$ picowatt ±SEM]) compared to HC (390.9 ± 92.1), [F(1,47)=5.18, p=.03]. In TRD, total night SWA increased to 287.3 ±28.6 from 232.3 ±21.4; post K vs. BL, respectively [F(1, 38)=7.24, p=.01]. The ketamine effect did not differ between TRD and HC [F(1,48.1)=1.29, p=.26], between females (325.3 ±37.14 vs. 266.4 ±30.7; post K vs. BL, respectively) and males (238.23 ±42.23 vs. 188.2 ±25.97) [F(1,37)=0.04, p=.85], or with age [F(1,37)=0.21, p=.65].
Conclusion: The increase in SWA post-ketamine infusion in patients with TRD is consistent with our earlier finding suggesting effects on homeostatic sleep mechanisms and plasticity. The current finding indicates that ketamine's effect on SWA is not influenced by age and sex. In HC, ketamine's effect is similar to TRD, but this result may be related to the small sample. Future analysis will explore the relationship between antidepressant response and change in SWA. Further analyses with larger samples are warranted.

Title: Roles for state-dependent corticothalamic and thalamocortical activity in visual system plasticity

Authors: *J. DURKIN[1], A. K. SURESH[4], B. C. CLAWSON[2], E. J. PICKUP[2], S. J. ATON[3]
[1]Neurosci. Grad. Program, [3]Molecular, Cellular, and Developmental Biol., [2]Univ. of Michigan, Ann Arbor, MI; [4]Univ. of Chicago, Chicago, IL

Abstract: Orientation Specific Response Potentiation (OSRP) is a form of plasticity in primary visual cortex (V1), which is initiated by waking visual experience and dependent on subsequent sleep. Our recent data suggest that presentation of a novel visual stimulus (a single oriented grating) causes immediate, instructive changes in the firing of mouse lateral geniculate nucleus (LGN) neurons - leading to increased firing rate responses to the presented stimulus orientation

(relative to other orientations). However, stimulus presentation alone does not affect V1 neurons, which show response changes only after a period of subsequent sleep. During post-stimulus Non Rapid Eye Movement (NREM) sleep, LGN neurons' overall spike-field coherence (SFC) with V1 delta (0.5-4 Hz) and spindle (7-15 Hz) oscillations increased, with neurons most responsive to the presented stimulus showing greater SFC. Furthermore, visual response changes in V1 correlated with changes in the synchrony of thalamocortical oscillations, specifically during NREM sleep. Thus, we hypothesize that state-specific features of thalamocortical communication, like NREM-specific oscillatory activity, are crucial for OSRP. To address this hypothesis, we first tested the role of layer 6 corticothalamic (CT) V1 neurons in coherent firing within the LGN-V1 network. Optogenetic interference with CT feedback to LGN during post-stimulus NREM sleep (but not REM or wake) disrupts coherent oscillations between LGN and V1, and also blocks sleep-dependent response changes in V1. We conclude that NREM oscillations relay information regarding prior sensory experience between the thalamus and cortex to promote cortical plasticity. Current studies are aimed at determining the role of cortically-projecting thalamic relay neurons in OSRP, by disrupting LGN activity in a state-dependent manner.

Title: Role of activity across cortex and striatum during sleep in motor skill learning

Authors: *S. M. LEMKE[1], D. S. RAMANATHAN[2], K. GANGULY[1]
[1]Univ. of California, San Francisco, San Francisco, CA; [2]UCSD, San Diego, CA

Abstract: Motor skill learning describes the transition from the naïve execution of variable movements to a fluid, fast, and consistent motor action. Intriguingly, this process is known require both "online" training and "offline" sleep periods. Such sleep-dependent improvements during motor learning mirror offline improvements in declarative learning and memory tasks.

The neural basis of offline improvements in these tasks is often linked to coordinated activity across relevant brain regions. While motor skill learning is known to require contributions from a distributed motor network, the network basis of sleep-dependent motor improvements has not been explored.
Here, we recorded neural activity, including single unit activity and local field potentials (LFP), across primary motor cortex (M1) and dorsolateral striatum (DLS) as rats learn a reach-to-grasp skill. Evolving activity across M1 and DLS has been implicated in the refinement and binding of movements during motor skill learning. By monitoring neural activity during both online training periods and offline sleep periods, we examined how patterns of activity across M1 and DLS during sleep play a role in motor skill learning.
We report that evolving activity across M1 and DLS is correlated with motor skill learning. Coordinated activity emerges across M1 and DLS during offline periods that is linked to increases in measures of functional connectivity across M1 and DLS. This work has relevance to the neural basis of how motor skills are learned and our understanding of sleep-dependent motor improvements.

Title: Role of the OLM interneurons during sleep-dependent memory consolidation

Authors: *M. A. FRAZER, G. POE
Univ. of California Los Angeles, Los Angeles, CA

Abstract: While it has long been established that sleep is critical for memory consolidation, the specific mechanisms by which this occurs are still largely unknown. Hippocampal population dynamics at each sleep stage facilitate the flow of information through the consolidation process, with interneurons acting as important regulators of oscillations and dynamics in the system. OLM interneurons are one subtype of hippocampal neurons that have been shown ito gate the information flow between entorhinal cortical and CA3 inputs, and are required for hippocampal learning tasks. Using freely behaving calcium imaging, we have observed sleep-state dependent changes in the activity of this cell population, as well as investigated the consequences of altering its activity during sleep, allowing us to elucidate changes to hippocampal information flow into the hippocampus at different sleep states and its importance to learning and memory.

Title: Differential suppression of locus coeruleus activity in REM during low estrogen phases compared with males may contribute to memory processing differences

Authors: *Y. CABRERA[1], J. JIMENEZ[1], J. HOLLOWAY[1], C. V. CHEN[2], I. LIBERZON[3], G. R. POE[1]

Abstract: The locus coeruleus (LC), a brainstem structure recognized as the major producer of norepinephrine (NE) in the brain, plays a vital role in the alteration of arousal states. Increased LC firing during times of stress induces greater NE release at cortical synapses and contributes to the “fight or flight” response. This produces an adaptive behavioral response and strengths memory formation. LC firing decreases to almost nothing during REM sleep. Compared to men, women are more commonly diagnosed with psychiatric conditions like depression and PTSD, conditions that may be due to dysfunction in LC activity. Sexual dimorphism in LC structure and variable NE activity through the estrous cycle might play a role in these effects. Since estrogen influences LC firing and availability of NE in synapses, we hypothesized that low estrogen phases will be associated with altered responses to stressors. In addition, normal LC quiescence during REM may be dysregulated, causing errors in memory. This study addresses the role of estrogen presence in the activity of LC through the sleep/wake cycle and over the estrus cycle. I hypothesized that higher LC activity during low estrogen phases in times of physiologically advantageous quiescence (i.e. REM) produces an increase in maladaptive behaviors. Male (n=7) and female rats (high estrogen phase n=7, low estrogen phase n=7) were instrumented with tetrodes in the LC, and EEG and EMG wires to track electrophysiological activity through the estrous cycle. Presence of NE in synapses of memory circuits does not allow for normal depotentiation required for reorganization of memory components. Any presence can thus contribute to memory problems after trauma.

Title: Sex differences in murine cataplexy following conditional hypocretin degeneration

Authors: *M. D. SCHWARTZ[1], C. WONG[1], T. DATTOLO[1], S. R. MORAIRTY[1], A. YAMANAKA[2], T. S. KILDUFF[1]

Abstract: The hypothalamic hypocretin/orexin (Hcrt) neurons are critical for the regulation of sleep/wake, metabolism and reward. In humans, degeneration of Hcrt neurons results in the sleep disorder narcolepsy. Several recent studies report an increased incidence of narcolepsy in women compared to men, along with shorter sleep latency and an earlier age of onset for excessive daytime sleepiness in women. Differences between male and female rodents have been found in Hcrt peptide and receptor expression, as well as in the response of the Hcrt system to stress and reward seeking, suggesting that sex differences in Hcrt regulation and/or signaling may underlie observed gender differences in narcolepsy symptoms in humans. In the present study, we determined whether the expression of narcoleptic symptoms is modulated by sex in *orexin-tTA;TetO diptheria toxin* (DTA) mice in which Hcrt degeneration is conditionally triggered by removal of dietary doxycycline (Dox). Male and female DTA mice maintained on ad lib Dox chow were prepared for telemetric EEG/EMG recording at ~14 weeks of age. Following recovery, undisturbed 24 h baseline EEG recordings were conducted weekly starting at ~18 weeks of age prior to Dox removal and then for 7 weeks during the Dox(-) condition. Mice were housed with running wheels from the first week of Dox(-) onwards. By week 3 of Dox(-), both males and females exhibited unambiguous cataplexy, with the majority of episodes occurring in the dark phase for both sexes. Cataplexy time and bout number were consistent with levels of cataplexy observed in our previous studies of male DTA mice. In males, cataplexy levels remained stable from week 3 to week 6. By contrast, cataplexy time and bout number in females decreased from week 3 to week 6 to approximately half that seen in males. By week 6 of Dox(-), wake time was also significantly increased in the late dark phase and early light phase, with females having fewer wake bouts across the light and dark phases, suggesting reduced sleep fragmentation and improved wake consolidation in females compared to males. These observations suggest that female mice compensate for the loss of Hcrt neurons over time through

an unknown mechanism. Such compensatory mechanisms, if they exist in humans, could contribute to observed delays in diagnosing narcolepsy in women compared to men.

Title: Hippocampal ripples initiate cortical-hippocampal communication

Authors: *H.-V. V. NGO[1], J. FELL[2], B. STARESINA[1]
[1]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [2]Dept. of Epileptology, Univ. of Bonn, Bonn, Germany

Abstract: One of the most important functions of sleep is the consolidation of memories. Not only does sleep provide shelter from external sensory input, but it has been proposed that sleep actively promotes memory formation by facilitating reprocessing of information acquired during wakefulness. In particular, according to the active systems consolidation framework, newly encoded information is initially stored in hippocampus and reactivated during subsequent sleep, leading to a strengthening of corresponding memory traces in the neocortex for long-term storage. More importantly, this process relies on an interplay of three cardinal sleep rhythms, cortical slow oscillations, thalamo-cortical sleep spindles and hippocampal sharp-wave ripples. However, how exactly do these rhythms mediate the hypothesised 'information transfer' from hippocampal to neocortical sites? Cross-area communication strongly relies on temporal co-occurrence of activation. Here we analysed whole-night sleep recordings from eleven pre-surgical epilepsy patients with depth electrodes implanted in medial temporal lobe and cortical sites. Focusing on intracranial recordings from hippocampus, entorhinal cortex and lateral temporal cortex as well as scalp EEG recordings, we set out to unravel the interregional dynamics between slow oscillations, spindles and ripples. While our findings corroborate a top-down migration of slow oscillations from cortical to medial temporal sites, we further found that hippocampal sharp-wave ripples trigger upward directed hippocampal-cortical communication, mediating the information transfer thought to underlie memory consolidation.

Abstract: High-frequency hippocampal ripples mark the time when hippocampal cells replay sequences from waking during slow wave sleep. Evidence in rodents is consistent with ripples sending information to the cortex to permit memory traces to be transferred during consolidation. However, hippocampo-cortical interactions during ripples are poorly characterized in humans. Cross-dynamical Delay Differential Analysis (CD-DDA) is a new tool to study causal connections between time series signals. Based on embedding theory from nonlinear dynamics, the classical formulation of Delay Differential Analysis (DDA) relates the differential and delay embeddings of a single time series in a functional form to uncover dynamical differences in the data. The features obtained from DDA provide a powerful basis for time-domain classification of data. In CD-DDA, we investigate causal interactions between two time series. Here, we apply this technique to intracranial recordings from patients undergoing treatment for epilepsy. By applying CD-DDA to recordings from electrodes placed in both hippocampus and remote cortical areas, we can uncover distinct patterns of directional information flow around the times when ripples occur. For many such channel pairings, there is a marked increase in cortex-to-hippocampus information flow around the time of the ripple, and this is followed by a longer period (hundreds of milliseconds) of hippocampus-to-cortex information flow. This same pattern seems to be characteristic of connections between hippocampus and a range of other cortical areas considered during ripples. Further analysis of data from additional brain areas in more subjects could help to characterize information flow in the brain more broadly.

Title: Role of glutamate produced by melanin-concentrating hormone neurons in sleep-wake regulation

Authors: F. NAGANUMA[1], S. BANDARU[1], G. ABSI[1], M. CHEE[2], *R. VETRIVELAN[3]
[1]Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Carleton Univ., Ottawa, ON, Canada; [3]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: Melanin-concentrating hormone (MCH) neurons located in the lateral hypothalamus (LH) play a key role in the regulation of rapid eye movement sleep (REMs). Optogenetic and chemogenetic activations of MCH neurons increase REMs whereas the ablation of MCH neurons affects the diurnal variation of REMs. MCH neurons also contain several other neuropeptides and neurotransmitters, many of which may participate in REMs regulation. We hypothesized that glutamate, which is present in almost all (>98%) MCH neurons, is involved in REMs regulation. We tested this hypothesis by deleting the vesicular glutamate transporter (Vglut2), which is necessary for synaptic glutamate release, from MCH neurons in mice and studying the consequent changes in sleep-wake amounts and architecture. Specific deletion of Vglut2 from MCH neurons was achieved by crossing MCH-Cre mice that express Cre recombinase (Cre) specifically in MCH neurons with Vglut2$^{flox/flox}$ mice that express lox-P modified alleles of *Vglut2*. Daily (24-h) percentages of wake, NREMs or REMs in these mice missing Vglut2 in MCH neurons (MCH-Vglut2KO mice) were not significantly different from control mice. However, the diurnal variation of REMs was significantly higher in MCH-Vglut2KO mice (142.0±11.92% of controls). These data indicate that glutamate in MCH neurons may be necessary for normal expression of diurnal rhythms in REMs in mice. We next chemogenetically activated MCH neurons in MCH-Vglut2KO mice and tested if MCH neurons can still promote REMs. We found that chemoactivation of MCH neurons in MCH-Vglut2KO mice increased REMs by 158% during the first 3 hours. These data indicate that MCH neurons can promote REMs even in the absence of glutamate.

Title: An *in vitro* study of parahypoglossal cholinergic inputs to hypoglossal motor neurons in adult mice

Authors: *L. ZHU, E. ARRIGONI
Neurol., Beth Israel Deaconess Med. Center/ Harvard Med. Sch., Boston, MA

Abstract: Introduction. In REM sleep, the genioglossus (GG) muscle undergoes a dramatic suppression of activity. A current hypothesis is that the loss of GG activity during REM sleep is mediated by a combination of 1) monoaminergic disfacilitation and 2) a cholinergic inhibition of hypoglossal motor neurons. Strikingly, blockade of cholinergic receptors in the hypoglossal motor nucleus fully restores REM sleep tonic and inspiratory-modulated components of GG activity (Grace et al., 2013), suggesting that the cholinergic signal is largely responsible for the REM sleep suppression of GG activity. Respiratory rhythm generator neurons of the pre-Bötzinger complex drive the activation of hypoglossal motor neurons through glutamatergic premotor neurons in the parahypoglossal region (PH). Previously, we have shown that carbachol, an agonist of acetylcholine, inhibits PH glutamatergic input to hypoglossal motoneurons through a presynaptic mechanism. However, the sources of cholinergic inputs are not well understood. In this study, we investigate the PH cholinergic input to hypoglossal motor neurons.
Methods. We stereotaxically injected the PH region of ChAT-*cre* mice with a cre-dependent AAV-ChR2-mCherry to expressed channelrhodopsin2 (ChR2) in PH cholinergic neurons. We then performed whole-cell recordings in hypoglossal neurons while photostimulating PH cholinergic inputs expressing ChR2.
Results: Photostimulation of the cholinergic PH input evoked excitatory postsynaptic currents (EPSCs) in hypoglossal motor neurons. These photo-evoked EPSCs were maintained in TTX(1μM) and 4-AP(1mM), indicating monosynaptic connectivity. Bath application of scopolamine (muscarinic receptor blocker) and/or a cocktail of nicotinic receptors failed to block the photo-evoked EPSCs in hypoglossal neurons. The photo-evoked EPSCs were abolished with bath application AMPA-receptor blocker DNQX (20μM).
Conclusions: Our results suggest that 1) PH cholinergic neurons directly innervate hypoglossal motor neurons. 2) PH cholinergic neurons primarily release glutamate and excite hypoglossal motor neurons. 3) PH cholinergic inputs are unlikely responsible for the suppression of hypoglossal motor neurons during REM sleep.

Title: Lateral parabrachial neurons innervate arousal-promoting regions in the rat brainstem via orexin neurons in the hypothalamus

Authors: *Y. ARIMA, S. YOKOTA, M. FUJITANI
Dept. of Anat. and Neurosci., Shimane Univ., Izumo, Japan

Abstract: Orexin (ORX) is a small hypothalamic neuropeptide, which has a critical role in the regulation of sleep-wakefulness. ORX neurons are specifically localized in the tuberal hypothalamus, including the perifornical area, lateral hypothalamus, and dorsomedial hypothalamic nucleus and project to arousal-promoting brain regions. We recently showed that the glutamatergic lateral parabrachial nucleus (LPB) neurons innervated hypothalamic ORX neurons. These findings indicated that LPB neurons could regulate sleep and wakefulness by the projections to arousal promoting brain regions via ORX neurons. To show this, we examined this potential projection by a combination of antero- and retrograde tract-tracing techniques in male Wistar rats. We injected the anterograde tracer, biotinylated dextranamine (BDA), into the LPB and the retrograde tracer, cholera toxin B subunit (CTb), into the ventral tegmental area (VTA), pedunculopontine tegmental nucleus (PPT), laterodorsal tegmental area (LDT), locus coeruleus (LC), or dorsal raphe nucleus (DR). By immunohistochemical analysis, we observed the prominent overlapping distributions of BDA-labeled fibers and CTb-labeled ORX positive neurons in the lateral part of the dorsomedial nucleus and dorsal perifornical areas. In these areas, we further observed that BDA-labeled axons showed synaptic bouton like morphology and also synaptophysin immunoreactivity were in contiguity with CTb-labeled ORX-immunoreactive neurons. From these results, we concluded that LPB neurons form functional synapses with ORX neurons that project to the VTA, PPT, LDT, LC, and DR. These results strongly suggest that LPB neurons could promote arousal via ORX neurons in the hypothalamus.

Abstract: The homeostasis of sleep-awake cycle is modulate by orexins. The myelin mutant *taiep* rats had immobility episodes (IEs) with a rapid eye movement (REM) sleep pattern, because they had desynchronized cortical activity with theta rhythm in the hippocampus and significant reduction on the electromyography (EMG) amplitude in nuchal muscles. They also showed a disorganized sleep-wake pattern with higher transitions between them. In base of that we propose *taiep* rats as an adequate model of narcolepsy-cataplexy. The aim of this study was to analyze the effects of the intracerebroventricular (i.c.v.) administration of orexin agonist [Ala11, D Leu15] -Orexin B in male *taiep* rats at 9 months old. The subjects (Ss) were maintained under standard conditions with a 12/12 light-dark cycle (lights on at 0700) and free access to rodent food pellets and purified water. All Ss were anesthetized by i.p. injection of ketamine/xylazine mixture and implanted electrodes for EEG, EMG and EOG recordings under stereotaxic coordinates. We analyzed the effects of i.c.v. administration of orexin B agonist (1, 3, 10 nM) and evaluate sleep-wake cycle and the frequency and mean duration of IEs during continuous electrographic recordings along 8h after administration. All procedures followed the NIH rules and the protocol was approved by BUAP-IACUC. Our results showed that the administration of orexin B significantly increased progressively the awake phase with the doses administered ($P<0.05$). Additionally, the orexin agonist decreased the frequency and mean duration of IES ($P<0.05$), as well as total amount of REM sleep being more pronounced in the first 4h after administration. We conclude that the myelin mutant *taiep* rats is an adequate model of narcolepsy-cataplexy with a good response to central administration of orexin B agonist suggesting an impairment in orexinergic transmission.

Title: The response of nitrergic neurons in the dorsal raphe nucleus to acute sleep loss

Authors: *I. S. NICHOLS, E. CHIEM, C. VAN, A. TUCKER, F. NAJJAR, K. PAUL
Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Nitric Oxide (NO) is active in many of the neurons and brain regions that regulate sleep and its responses to the environment. In the dorsal raphe nucleus (DRN) of the brainstem, alterations in NO synthase (NOS) activation are associated with decreased REM sleep amount. While mounting evidence shows that NO is an important molecule for sleep regulatory mechanisms, the role of NO in the ability to recover from sleep loss is largely unexplored. It has been revealed that inhibition of NOS activity in DRN neurons decreases REM sleep amount in rats. Since inhibition of DRN NOS activity decreases sleep, we explored whether inhibition of sleep had effects on NOS neurons in the DRN. In order to determine the effects of sleep loss on DRN NOS, male and female mice in a 12:12 light:dark cycle were sleep restricted for 24 hrs. Sleep restricted mice were singly housed in slowly rotating wheels (1 revolution/min). Controls were allowed *ad libitum* sleep under the same conditions. We also examined NOS in cholinergic neurons of the basal forebrain, since those neurons are important regulators of the ability to recover from sleep loss. Coronal sections were obtained from the BF and DRN and processed with NADPH-d (a marker for NOS activity). The sections were imaged using Evos Fl cell imaging system, neurons displaying NADPH were counted, and optical density was obtained on ImageJ. Mice that underwent sleep restriction exhibited no differences ($p > .05$) in NADPH levels, in either the DRN or the basal forebrain, from controls. These data suggest that NOS neurons in the DRN are not responsive to acute sleep restriction.

Title: Thalamic dual control of sleep and wakefulness

Authors: *A. R. ADAMANTIDIS, Dr[1], M. BANDARABADI[3], C. G. HERRERA[4], T. GENT[2]
[1]Dept of Neurol., [2]Univ. of Bern, Bern, Switzerland; [3]Neurol., Hosp. Univ. of Bern, Bern, Switzerland; [4]Dept of Neurol., Inselspital Univ. of Bern, Bern, Switzerland

Abstract: Slow-waves (0.5 - 4 Hz) predominate in the cortical electroencephalogram during non-rapid eye movement sleep (NREM) in mammals. They reflect the synchronisation of large neuronal ensembles alternating between active (UP) and quiescent (DOWN) states and propagate along the neocortex. However, the thalamic contribution to cortical UP-states and sleep modulation remains unclear. Using multisite tetrode recordings in freely behaving mice, we show that spontaneous centromedial thalamus (CMT) neuronal firing is phase advanced to global cortical UP-states, as well as NREM-to-Wake transitions but not temporally-locked to sensory thalamic neuronal firing. Optogenetic tonic activation of CMT neurones induce rapid NREM-to-Wake transitions, whereas burst activation mimics UP-states in the cingulate cortex enhanced brain-wide synchrony of cortical slow-waves during sleep, through a thalamic relay located in the antero-dorsal thalamus. Finally, we demonstrate that both CMT and AD relay neurones are necessary for slow-wave traveling and sleep recovery following a period of extended wakefulness. These findings suggest that CMT neuronal firing patterns alone can modulate brain-wide cortical activity during sleep and provides dual control of sleep-wake states.

Title: An intracellular study of GABAergic processes in the control of activity of neurons in the pontine reticular formation of the cat

Authors: M. XI[1], S. J. FUNG[1], S. SAMPOGNA[1], *M. H. CHASE[1,2]
[1]Websciences Intl., Los Angeles, CA; [2]UCLA Sch. of Med., Los Angeles, CA

Abstract: Our previous experimental data have provided compelling evidence that GABAergic processes in the nucleus pontis oralis (NPO) play a critically important role in the generation and maintenance of wakefulness (W) as well as active (REM) sleep (AS). These data emanate from our behavior studies in chronic cats in which the microinjection into the NPO of GABA and its agonists induces prolonged periods of W. On the other hand, the injection of GABA antagonists into the NPO results in the rapid induction of AS and an increase in this behavioral state. However, the neuronal mechanisms of GABAergic actions in the NPO to promote W and suppress AS are undetermined. Consequently, the present study was designed to explore the cellular mechanisms of GABA actions on NPO neurons that generate AS (AS-generator neurons), and provide evidence that the effects of GABA are due to a direct inhibitory action on NPO AS-generator neurons. Accordingly, the effects of the juxtacellular application of GABA and bicuculline, a $GABA_A$ antagonist, on the activity of putative AS-generator neurons which were recorded intracellularly in the NPO were examined in chloralose-anesthetized cats. The juxtacellular application of GABA hyperpolarized the membrane potential of NPO neurons, and significantly decreased the amplitude of spontaneous EPSPs and the frequency of discharge of these cells; in contrast, the juxtacellular microejection of bicuculline depolarized NPO neurons and significantly increased the amplitude of spontaneous EPSPs and the frequency of their discharge. Some of these recorded NPO neurons were intracellularly marked with neurobiotin, and identified morphologically upon immunostaining. They were medium to large, multipolar cells with diameters >20 μm, which resemble glutamatergic AS-generator cells that have been previously identified in the NPO. The present results demonstrate, at a single cellular level of analysis, that inhibitory GABAergic inputs are capable of controlling the activity and discharge frequency of AS-generator neurons in the NPO, and indicate that these NPO neurons are under tonic GABAergic inhibitory control during W. Therefore, we believe that the pontine GABAergic mechanism functions in such a way that wakefulness is induced and maintained due to the activation of GABAergic process, which results in the suppression of discharge of AS-Generator neurons in the NPO.

Title: Spatio-temporal organization of sleep spindles and slow waves in naturally sleeping cats

Authors: *O. BUKHTIYAROVA[1,2], S. CHAUVETTE[2], S. SOLTANI[1,2], I. TIMOFEEV[1,2]
[1]Dept. of Psychiatry and Neurosci., Univ. Laval, Quebec, QC, Canada; [2]CERVO Brain Res. Ctr., Quebec, QC, Canada

Abstract: Sleep spindles are brain oscillations in the frequency range of 8-16 Hz that play a role in synaptic plasticity, learning and memory consolidation. During deep sleep, spindles co-occur with slow waves (SW). Several studies separate spindles on slow (8-12 Hz) and fast (12-16 Hz) and demonstrate their difference in spatial distribution, relation to slow-wave activity and impact on global brain functions.
The aim of this study was to investigate the presence of fast and slow spindles, their features and relationship to slow waves in local field potential (LFP) of sleeping cats.
LFP recordings were performed during sleep in 7 adult cats (6 males, 1 female), 47 cortical channels total. We developed a method of automatic detection of sleep spindles based on continuous wavelet transform and Gaussian Mixture Model clustering, followed by exclusion of non-rhythmic events in post-processing. Shortest spindle had 3 cycles. SW were detected with feed-forward artificial neural network that was trained to recognize their specific pattern.
During slow-wave-sleep, spindles were detected in all investigated cortical areas. They occurred 5-20 times per minute and lasted on average 477±98 ms with the most frequent and the longest spindles in medial prefrontal cortex and the least frequent and the shortest ones in ectosylvian gyrus. Both ‘fast’ and ‘slow’ spindles could be found in each channel as a continuum of frequencies, but not as separate sets. However, frontal and fronto-lateral areas had larger number of faster spindles, and medial and posterior cortical areas had more of slower spindles. The probability of spindle onset was significantly higher in 100-300 ms period following the peak of a SW, in particular in suprasylvian gyrus, but it was less pronounced in somatosensory areas, marginal, and ectosylvian gyri. Termination of spindles more likely occurred 200-100 ms before SW peak. There was no significant difference in frequency of spindles that followed or preceded SW. Most of detected spindles were local. In male cats, if spindles were global, they tended to propagate.

We did not find a clear separation between fast and slow spindles. Our results point to cortical area-dependent specific control of spindle generation.

Title: Spatiotemporal dynamics in human infant sleep spindles

Authors: L. MULLER[1], S. E. PETERS[2], A. A. BENASICH[3], *T. J. SEJNOWSKI[1]
[1]Salk Inst., La Jolla, CA; [2]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ; [3]Neurosci., Rutgers University-Newark, Newark, NJ

Abstract: During sleep, the thalamus generates a characteristic pattern of transient, 11-15 Hz sleep spindle oscillations, which synchronize the cortex through large-scale thalamocortical loops. In previous work (Muller et al., *eLife* 5, 2016), we found that sleep spindles, rather than being either perfectly synchronized across the cortex or highly localized, often organize into a neural traveling wave (nTW), rotating globally across the cortex from temporal to parietal and to frontal lobe. In adult humans, these waves travel with a peak speed between 2-5 m/s, consistent with the conduction speeds of the short- and long-range association fibers in cortex. The specific spatiotemporal patterning of neuronal spiking activity during these waves has important implications for the process of memory consolidation during sleep. In this exploratory work, we test the hypothesis that global spindle waves are present in 3 to 7-month-old, typically developing infants, using high resolution (124 electrodes) scalp recordings during a daytime nap. This developmental period is characterized by a high rate of active cortical myelination which follows a spatiotemporal trajectory from occipital and parietal cortical regions to temporal and frontal regions over the course of several months. We hypothesize that the developing topography and spatiotemporal dynamics of infant sleep spindles are associated with myelinating fibers in cortex. We analyze EEG recordings of infant sleep and compare sleep spindle activity between 3.5-4 months and 6.5-7 months-of-age. The thin cranium at these ages allows EEG to capture neural activity with relatively high spatial resolution, because of reduced signal blurring by the skull. By applying a phase-based method for detecting traveling waves in noisy

multichannel data, we quantify the relative proportion of nTW and non-nTW patterns across these age groups. We interpret the results of the analysis at different ages with a computational model of cortical synchronization under axonal time delays. Preliminary analyses suggest that spindle nTWs appear in the infant by 6.5-7 months of age and their appearance may coincide with the development of cortical white matter tracts. These results will be compared with our earlier reported findings that sleep spindle power decreases over centro-parietal regions and increases over frontal regions between these two age groups, and that this change is correlated with measures of expressive and receptive language (Peters and Benasich, *Cog Neuro Soc Conf*, 2017). [LM and SP contributed equally to this work]

Title: Characterizing the functional role of global and local sleep slow oscillations using ECoG

Authors: *N. NATRAJ, E. F. CHANG, K. GANGULY
Univ. of California, San Francisco, San Francisco, CA

Abstract: Slow oscillations, with a peak power at ~0.8Hz, are one of the primary brain rhythms observed during sleep. Slow oscillations represent synchronized down (hyperpolarized) and up (depolarized) states of neuronal activity (Steriade and Amzica 1998), originate primarily over frontal areas, are distinct from delta or slow waves (1-4Hz) and occur most frequently in NREM sleep stage 3 and stage 4 (Massimini 2004). Slow oscillations are important for memory consolidation (Marshall et al. 2006) as they group faster rhythms such as sleep spindles (8-16Hz) (Klinzing et al. 2016) and hippocampal ripples (>70Hz) (Staresina et al. 2015). Typically, slow oscillations in humans have been studied using electroencephalography (EEG) and are characterized as unitary events of global, cortex-wide neural synchrony. However electrocorticography (ECoG) data, that offers much higher spatial resolution, has shown slow oscillations are largely regional and local events (Nir et al. 2011) distinct from the cortex-wide global EEG slow oscillation. As such, the functional role of global and local sleep slow oscillation on memory related information processing, such as the nesting of sleep spindles, remain unclear. To address this issue, we analyzed over-night, multi-site electrocorticography (ECoG) data from 5 patients undergoing neurosurgical evaluation for epilepsy. Slow oscillations at individual channels were detected using an adaptive amplitude threshold (greater than at least 85% of all down-state to up-state peak amplitudes, if not higher), duration (900-3000ms cycle

duration) and sleep stage (NREM sleep). The local or global specificity of any given slow oscillation at any channel and time in sleep was quantified by its co-occurrence with slow oscillations across all other channels within a 500ms window. Results showed that the specificity of slow oscillations occupied a continuum; while the vast majority of slow oscillations at any given ECoG channel were local, global and more regional slow oscillations were also observed. Moreover, local slow oscillations tended to have smaller peak to peak amplitudes while global slow oscillations tended to have larger peak to peak amplitudes. Global slow oscillations largely occurred in stage 3 and 4 of NREM sleep while local and regional sleep oscillations were observed in all sleep stages. Preliminary analyses also showed that global slow oscillations tended to preferentially nest ongoing sleep spindles when compared to local sleep slow oscillations. Together, our findings shed new light on the functional role of slow oscillations based on its local or global specificity.

Title: Vagal-evoked cortical potentials in monkeys follow a circadian pattern

Authors: *I. REMBADO[1], D. SU[3], A. LEVARI[4], L. SHUPE[5], E. E. FETZ[2], S. ZANOS[6]
[1]Dept. of Physiol. & Biophysics,, [2]Physiol. and Biophysics, Univ. of Washington, Seattle, WA; [3]Neurolog. Res., Roslyn, NY

Abstract: Left vagus nerve stimulation (VNS) is used as therapy for epilepsy and major depression and has been tested clinically in the treatment of headaches, sleep disorders and in augmentation of rehabilitation with physical therapy after stroke [1, 2]. VNS produces afferent volleys that generate vagal evoked potentials (VEPs), recorded at different brain sites. The clinical significance of VEPs remains unclear but they are modulated by several VNS parameters, including current intensity and frequency of stimulation [3]. It is unknown whether they are also modulated by ongoing brain activity, which is known to change during the course

of day-night cycles. We sought to determine whether VEPs in macaque monkeys are modulated by time of day and night, during many hours of free behavior. In two male macaque monkeys epidural and intracortical electrodes were implanted in prefrontal, sensorimotor and parietal cortical areas and a bipolar cuff electrode was implanted on the left cervical VN. We used an updated version of Neurochip2 [4] to deliver trains of stimuli to the VN while simultaneously recording cortical activity continuously for 12-15 hours, while the animals were freely behaving in their cages. We tested several different pulsing frequencies (from 5 to 300 Hz), and 2 different pulse counts in a train (5 and 10 pulses). VEP responses in different cortical sites were compiled by averaging of corresponding cortical recordings triggered by the last stimulus in the train. The magnitude of the VEP responses was quantified by calculating the root-mean square (RMS) of the VEP between 15 and 400 ms after the last stimulus in the train. Both animals showed larger magnitude of VEP responses with stimulation at higher pulsing frequencies. In both animals, the VEP response was significantly modulated with time of day: VEP magnitude was minimal during early morning hours and maximal during late evening hours. VEPs in prefrontal sites showed a stronger modulation compared to sensorimotor and parietal sites. This study shows that VEPs change in a cyclical, circadian manner, with the time of day during which VNS is delivered. We are investigating whether ongoing cortical activity, which correlates with different brain and behavioral states, mediates this effect. These findings could have implications for experimental studies on the effects of VNS on brain function, for clinical trials studying VNS in brain diseases and for optimizing currently approved therapies involving VNS. Title: Quantitative analysis of polysomnograms can stratify risk of adverse cardiovascular events in older adults with sleep disordered breathing

Authors: *S. V. GLISKE
Sleep Disorders Clinic, Dept. of Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Objective. At the population level, sleep disordered breathing (SDB) is known to have adverse effects on cardiovascular health. However, more information is needed to understand how severity of SDB modulates this risk at the individual patient level. The objective of this study was to identify quantitative sleep metrics which stratify risk of adverse cardiovascular events better than the existing measure (apnea hypopnea index (AHI)) in older adults with sleep apnea .
Methods. Subjects were selected from the Sleep Heart Health Study, with the inclusion criteria of 1) having a high quality EEG recording, and 2) being a non-smoker. This yielded 1,036 subjects. EEG data was quantified using a linear combination of the mean power spectrum per sleep stage. ECG data was quantified using a linear combination of 108 features, assessing variability in R-wave amplitude and inter-beat timing. Cox proportional hazard models for time to first adverse cardiac event were computed to assess utility of various combinations of predictors.
Results. After accounting for age, gender, and BMI, inclusion of AHI resulted in negligible improvement in the model ($p = 0.7$). However, inclusion of either of our novel, quantitative metrics did improve over the age, gender, BMI model with high statistical significance (EEG, $p<10^{-9}$; ECG, $p<10^{-11}$).
Conclusions. Quantitative analysis of EEG and ECG portions of polysomnograms provides additional information about the relationship between SDB and adverse cardiovascular events which is not captured by the standard apnea severity index (AHI).

Abstract: Slow waves (SWs, <4Hz) are the most prominent field potential oscillations during NREM sleep and may provide a temporal frame for a cortical-hippocampal dialogue that promotes memory consolidation. At present, there is a formidable gap between invasive mechanistic studies in animals linking temporal coordination between the hippocampus and cortex to memory consolidation and non-invasive human studies. Building upon animal models in which precisely timed electrical stimulation reinforced the endogenous coordination between hippocampal sharp wave-ripples, cortical slow wave up-states and sleep spindles, we set out to implement a real-time closed-loop (RTCL) system that could trigger electrical stimulation during sleep in the neocortex of humans timed precisely relative to sleep signatures recorded in the hippocampus. Upon informed consent, 12 patients with pharmacoresistant epilepsy, who had been implanted with intracranial electrodes for clinical monitoring in preparation for a possible surgical cure at UCLA, participated in recordings and intracranial electrical stimulation during 8 daytime naps and 6 overnight sleep sessions. Depth electrodes recorded detailed spiking activity (>500 unit clusters), local field potentials (8 microwires per electrode), and intracranial EEG (average of 9 electrodes per patient, 7-8 contacts per electrode) across multiple brain regions (including medial, temporal and extra-temporal cortical regions) during sleep. We developed a RTCL system that monitored sleep activity in the medial temporal lobe (MTL) and triggered brief (50ms) electrical stimulation in the neocortex, locked to a specific phase of MTL slow waves. Here, we demonstrate the ability of the RTCL loop to deliver electric stimulations robustly locked to MTL SWs up-states and find that stimulation locked to up-states enhanced subsequent slow wave activity. We present analysis of both the immediate (msec) and delayed (minutes) effects of such phase-locked stimulation on spindle power, as well as on single-unit entrainment to slow-wave phase. These effects are separately examined near the stimulating channel, in the MTL, as well as in additional brain areas. Additionally, we investigate the effects of RTCL stimulation on the coupling between SWs, spindles and hippocampal ripples, as well as on sleep-dependent memory consolidation.

Abstract: The clinical evaluation of disorders of consciousness (DOCs) in severely brain-injured patients relies on their ability to connect to the surrounding environment and demonstrate their subjective experience through motor behavior. To overcome this clinical problem, it has been recently developed a theory-driven, objective measure of the level of consciousness (Perturbational Complexity Index - PCI) calculated as the algorithmic complexity of the spatiotemporal pattern of the cortical responses obtained by perturbing the cortex with transcranial magnetic stimulation (TMS) (Casali et al. Sci Tr Med 2014). In awake healthy subjects, the EEG response to TMS (TEP) show multiple components possibly reflecting recurrent and causal interactions among different cortical areas (Sarasso Clin EEG Neurosci 2014) and results in high values of PCI. On the contrary, in vegetative state patients as well as in anesthesia and during the deepest stages of sleep (non-REM sleep), TEPs results in a positive-negative deflection highly resembling sleep slow-waves associated to low values of PCI. It is well known that spontaneous sleep slow-waves emerge from the bistable dynamics given by the alternation of neuronal intense firing (up-states) and silence (down-states) (Steriade J Neurosci 1993). It has been suggested, by means of intracranial electrical stimulation and recordings, that neuronal bistability could be responsible for loss of complexity in non-REM sleep (Pigorini et al. NeuroImage 2015). However, a direct link between bistability and loss of complexity is still missing. To this aim, the present work combines intracortical single pulse electrical stimulation (SPES) in humans undergoing pre-surgical evaluation, simultaneous intracortical recordings and scalp high-density electroencephalography (hd-EEG, 256 channels). Preliminary results show that during wakefulness the complex spatiotemporal dynamics observable at the scalp level are sustained by recurrent, causal interactions among different cortical areas. During non-REM sleep, when consciousness fades, the occurrence of cortical down-states after a transient activation (i.e. bistability) prevents the emergence of deterministic interactions leading to low PCI at the scalp level. Although very preliminary, these results draw a first link between local bistable dynamics characterizing cortical neurons during sleep and loss of complexity, a theoretical requirement for consciousness. Future studies should investigate whether sleep-like mechanism may account for the collapse of thalamo-cortical complexity detected by perturbations in pathological conditions such as in the DOCs patients.

Abstract: During non-REM sleep, the brain generates sleep spindles which are large amplitude oscillations that have complex spatiotemporal structure. Sleep spindles are ~1 s, 10-16 Hz oscillations that are thought to originate in the thalamus, however extensive corticothalamic feedback have been proposed to trigger, synchronize, and terminate spindle occurrence. The coordination of sleep spindles with slower (down state) and faster (hippocampal ripples) rhythms is believed to be important for sleep dependent memory consolidation. Here, we assess whether sleep spindles reflect periods of causal interactions between two brain regions. To detect causality between two time series, we developed cross-dynamical delay differential analysis (CD-DDA). We believe this nonlinear measure is complementary to traditional measures of directed influence, such as granger causality. We validated our measure on two simulated datasets, a Rössler system driving a Lorenz system, and one population of Izhikevich neurons driving another population. For our main analysis, we used data from three patients (2 women, 1 man, age: 40.7 ± 8.1) with intractable epilepsy implanted with depth sEEG electrodes in the cortex and thalamus. Here we analyze one night of sleep, from stages 2 and 3, and 64 corticothalamic pairs across all subjects. Spindles were detected on thalamic channels using a previously published protocol, and analyses were restricted to -500 ms to +500ms relative to the spindle onset in the thalamus. When applying CD-DDA, 53/64 corticothalamic pairs showed

significant cortical to thalamic directionality compared to baseline, and 56/64 showed significant thalamus to cortex directionality. Across trials, most channels showed asymmetrical causality after spindle onset. For example, 10/22 centroparietal sites and 25/42 frontal sites showed greater cortex to thalamus influence than thalamus to cortex after spindle onset. Thus compared to non-spindle times, spindle epochs reflect periods of information flow between brain regions. Future work will explore patterns of control across spindles at a given cortical site, as well as how association of spindles with down states or ripples affects causal interactions between brain regions.

Title: Effect of sigma-1 receptor antagonist PD144418 on motivational aspects of feeding behaviors in male and female rats

Authors: *M. TAPIA, J. R. LEE, D. K. MILLER, M. J. WILL
Univ. of Missouri., Columbia, MO

Abstract: A contributing factor to the obesity epidemic is the lack of balance between energy intake and energy expenditure. An increase in energy intake can lead to an increase in food consumption therefore, it is important to find ways to decrease food intake. Accumulating evidence regarding the sigma-1 receptor (σ1R) suggests its involvement in rewarding and motivational processes, through the effects vary based upon the ligand studied. While σ1R antagonist BD1047 did not alter reinforced behavior, BD1063 dose dependently reduced operant binge-like eating. In addition, pretreatment with BD1063 significantly reduced palatable, but not normal, chow intake in mice. PD144418 [1,2,3,6-tetrahydro-5-[3-(4-methylphenyl)-5-isoxazolyl]-1-propylpyridine] has been characterized as a potent and selective σ1 ligand, exhibiting a high affinity and selectivity for σ1Rs. In rodent behavioral studies, PD144418 has been found to produce a dose-dependent attenuation of locomotor activity of cocaine and by itself does not suppress basal locomotor activity in mice. However, nothing is known about its effects on motivation related to food. Therefore, two behavioral tasks were used to examine PD144418's effect on motivation and food consumption: 1) a progressive ratio (PR) operant task to examine motivation for food and 2) a free feeding paradigm, where no operant task was required to earn food. Male and female rats (n=8/group) were first trained on a fixed ratio (FR)

schedule of reinforcement. Following FR training, rats were tested under a PR schedule of reinforcement. 15-minutes prior to testing, each rat received a single dose of PD144418 (0 or 10 µmol/kg, ip). Pretreatment with PD144418 (0 or 10 µmol/kg, ip) on the consumption of freely available sucrose pellets was also examined. To determine the effects of acute (24-hr) food deprivation on the motivational effort to work for sucrose pellets, home-cage chow availability was altered in the final experiment. Findings revealed that when rats are pretreated with a 10umol/kg dose of PD144418, there is a significant reduction in their motivational effort to work for chow and sucrose pellets under a PR schedule of reinforcement but not of consumption when chow and sucrose pellets are freely available. Moreover, when homeostatic aspects of feeding were altered via acute food deprivation, pre-treatment with PD144418 suppressed the effects of acute food deprivation on the motivational effort to work for sucrose pellets but did not alter consumption under acute food deprivation when sucrose pellets were freely available. These effects were moderated by sex.

Title: Mice lacking PTP1B in astrocyte protect against obesity induced by a high fat diet

Authors: *M. SUGIYAMA[1], R. BANNO[1,2], H. YAGINUMA[1], K. TAKI[1], A. MIZOGUCHI[1], T. TSUNEKAWA[1], H. TAKAGI[1], Y. ITO[1], K. YAMANAKA[3], H. ARIMA[1]

Abstract: There are several lines of evidence that astrocyte regulates energy metabolism via leptin and insulin signaling, and also, the inflammatory signaling in astrocyte is required for hypothalamic inflammation induced by a high fat diet (HFD). Protein tyrosine phosphatase 1B (PTP1B) is a ubiquitously expressed protein tyrosine phosphatase which has been shown to negatively regulate both insulin and leptin signaling, and the expression of PTP1B is increased by inflammatory mediator such as TNFα. Recent studies utilizing mice with tissue-specific knock-out of PTP1B found the brain to be the primary site for PTP1B regulation of body weight. However, the specific sites mediating this effect in the brain are completely unknown. Especially, the role of PTP1B in astrocyte in the regulation of energy metabolism still remains unclear. In the present study, we investigated the role of PTP1B in astrocyte under HFD conditions. We generated astrocyte specific PTP1B deficient mice (KO) by crossing PTP1B

loxP/loxP mice with GFAP-Cre heterozygous mice. To assess whether energy balance is affected by PTP1B deficiency in astrocyte, we examined body weights in mice placed on either HFD or a chow diet at weaning. Body weights of KO mice were significantly lower than those of WT mice on HFD after 15 and 18 weeks of age (male and female, respectively). In contrast, on a chow diet, male and female mice showed no significant differences in body weight between genotypes. These results suggest that deficiency of PTP1B in astrocyte protects against obesity induced by HFD. Our data are also consistent with several recent studies showing an important role for astrocyte in energy metabolism and implicate PTP1B as a potentially important component of astrocyte in the regulation of energy balance under HFD conditions.

Title: High-fat feeding causes microglial activation and inflammation in ventral tegmental area in mice

Authors: *A. MIZOGUCHI[1], R. BANNO[1,2], H. YAGINUMA[1], K. TAKI[1], M. SUGIYAMA[1], T. TSUNEKAWA[1], H. TAKAGI[1], Y. ITO[1], H. ARIMA[1]

Abstract: The feeding behavior is regulated not only by the hypothalamus but also the limbic system. In the limbic system, dopaminergic neurons in the ventral tegmental area (VTA) project to the nucleus accumbens (NAc). This neurocircuit processes information related to food reward, such as hedonic values of food, and is activated by consuming palatable food and provides emotional satiety. Recent studies reveal interactions between this system and diet induced obesity, which is one of the major health issue in many countries. One recent study shows that the inflammation in NAc is induced by a high fat diet (HFD) in mice, accounting for the dysfunction of reward system and heightened food cravings in saturated fat and sugar. In turn, it is widely known that HFD is responsible for hypothalamic inflammation via microglial activation, which is accompanied by leptin resistance in the arcuate nucleus becoming the cause of obesity. However, it is still unclear whether HFD causes inflammation in VTA in the reward system.
To clarify this, we placed 10-week-old male C57BL/6J mice on a chow diet or HFD for 3 days, 7

days and 28 days, respectively. Mice VTA were delivered immediately after they were perfused by 1×PBS for 5minutes under anesthesia, and their mRNA expressions of inflammatory cytokines (TNFα, IL1β and IL6) and microglial activation markers (Iba1, CD11b, Emr1 and CD68) were analyzed by quantitative real-time PCR. We found that in the group on HFD, there were significantly elevated mRNA expressions of IL1β for 3 days, TNFα, IL1β, IL6 and Iba1 for 7 days, and TNFα, IL1β, Iba1, CD11b and Emr1 for 28 days compared to the group on a chow diet, respectively.
These results suggest that the inflammation in VTA is induced by HFD, and there is a possible mechanism in which the inflammation is occurred via the activation of microglia in VTA, providing an insight into the pathophysiology of obesity caused by the dysfunction of reward system under HFD conditions.

Title: Reward sensitivity deficits in rats following intermittent access to a palatable diet

Authors: *C. F. MOORE, V. SABINO, P. COTTONE
Lab. of Addictive Disorders, Departments of Pharmacol. and Psychiatry, Boston Univ., Boston, MA

Abstract: Eating disorders and forms of obesity are associated with brain reward dysfunction. In this study we investigated the sensitivity of the brain reward system of subjects undergoing chronic diet cycling by testing the effects of *d*-Amphetamine, a dopamine releaser. For this purpose, a group of male Wistar rats was provided a regular chow diet 7 days a week (*Chow/Chow*), whereas a second group of rats was provided chow for 5 days a week, followed by a 2-day access to a highly palatable sucrose diet (*Chow/Palatable*). Following 5 weeks of diet alternation, we investigated *d*-Amphetamine sensitivity during access to the palatable diet (*'P Phase'*) as well as during withdrawal from it (*'C Phase'*). We measured the effect of *d*-Amphetamine on locomotor activity and brain stimulation reward (BSR), home-cage self-

administration of *d*-Amphetamine, and *d*-Amphetamine-induced conditioned place preference. In addition, we used quantitative polymerase chain reaction (qPCR) to investigate diet-induced molecular neuroadaptations. Palatable diet cycling resulted in hypophagia of the standard chow, overeating of palatable food upon renewed access, and compulsive-like eating. During the *P*, but not the *C phase*, diet cycled rats showed decreased sensitivity to both the locomotor stimulating and the threshold-reducing effects of *d*-Amphetamine. The rewarding effects of *d*-Amphetamine were also reduced in *Chow/Palatable* rats during the P Phase, shown by blunted place conditioning. In addition, during access to the palatable diet, *Chow/Palatable* rats showed increased self-administration of *d*-Amphetamine in the home cage, as compared to controls. Furthermore, we found that intermittent access to a palatable diet altered expression of dopamine signaling targets. These results indicate that diet cycled rats show a phase-dependent deficit in the brain reward system, as revealed by a decreased sensitivity and reward to *d*-Amphetamine, as well as increased self-administration of *d*-Amphetamine when the highly palatable food access is renewed following withdrawal from the diet. In summary these results suggest that, in pathological eaters, brain reward dysfunction may be dependent upon the feeding state of the individuals.

Title: A locus coeruleus to lateral hypothalamus circuit for suppression of feeding

Authors: *N. R. SCIOLINO[1], C. M. MAZZONE[1], N. W. PLUMMER[1], J. AMIN[1], K. G. SMITH[1], C. A. MCGEE[1], C. X. YANG[1], M. J. KRASHES[2], A. V. KRAVITZ[2], M. R. BRUCHAS[3], J. D. CUSHMAN[1], G. CUI[1], P. JENSEN[1]
[1]Lab. of Neurobio., NIH - NIEHS, Research Triangle Park, NC; [2]NIH, Bethesda, MD; [3]Departments of Anesthesiol. and Anatomy-Neurobiology, Washington Univ., Saint Louis, MO

Abstract: Clinical evidence implicates altered norepinephrine (NE) signaling in overeating and excessive weight gain. Although modulators of NE signaling are currently the most effective drugs for weight loss, they result in adverse side-effects due to their broad actions throughout the nervous system. Thus, there is a critical need to identify specific NE circuits that suppress feeding without other effects. Towards this goal, we used chemogenetics in combination with fiber photometry to reveal that activation of NE-locus coeruleus (LC) neurons results in

suppressed feeding and weight loss. This key finding, along with evidence that feeding is also suppressed by delivery of NE agonists into the lateral hypothalamus (LHA), suggests that increased NE-LC activity suppresses feeding through select inputs to the LHA. To test this hypothesis, we used optogenetics to activate the LC-LHA circuit in our knock-in mouse line that expresses cre recombinase under control of the noradrenergic dopamine beta-hydroxylase (*Dbh*) promoter. We injected the LC of *Dbh*^{cre} mice *with a cre-responsive virus expressing* channelrhodopsin-2 (ChR2) or eYFP control, *and then* implanted optical probes over the LHA. We found that photostimulation (10 Hz) of the LC-LHA circuit rapidly suppressed feeding in ChR2 mice relative to controls**.** To rule out the possibility that this effect was due to changes in anxiety, mice were tested in the elevated plus maze and real-time place aversion test. In both tests, photostimulation had no effect on anxiety-like behavior in ChR2 mice relative to eYFP controls, demonstrating the LC-LHA circuit regulates feeding independent of anxiety. To ascertain if NE signaling from LC neurons is required to suppress feeding, we used our *Dbh* conditional knockout allele in combination with *En1*^{cre} (LC-Dbh mutants) to disrupt NE synthesis selectively in LC neurons. LC-Dbh mutants and littermate controls were pretreated with vehicle or the alpha-2 adrenoceptor antagonist yohimbine (3 mg/kg i.p.), which is known to activate LC neurons. We found that yohimbine suppressed feeding in littermate controls but had no effect in LC-Dbh mutants. Collectively, these findings reveal a novel role for LC neurons in the suppression of feeding that is mediated by release of NE in the LHA. The findings suggest that targeting specific NE neural pathways may yield improved weight loss therapies without anxiety side-effects.

Title: Effects of lisdexamfetamine on instrumental and consummatory behaviors supported by foods with varying degrees of palatability: Exploration of a binge eating model

Authors: *R. PRESBY[1], R. A. ROTOLO[1], J.-H. YANG[1], M. CORREA[2], J. D. SALAMONE[1]
[1]Psychological Sci., Univ. of Connecticut, Storrs, CT; [2]Psicobiologia. Univ. Jaume I, Castello, Spain

Abstract: It is widely recognized that overconsumption of high-sugar or high-fat diets is associated with multiple conditions, including obesity, hypertension, and type 2 diabetes. Furthermore, binge eating disorder (BED) affects approximately 2% of the US adult population, and occurs more frequently in females. Thus, it has become important to develop animal models of palatable food consumption that may have relevance for BED and other conditions associated with intake of highly palatable foods. Operant behavior tasks that involve food reinforcement have been used in order to allow animals choices between high value rewards that are obtained by a high degree of effort vs. low-effort/lower value options. The catecholamine uptake blocker lisdexamfetamine (LDX) has been approved for the treatment of BED. The present experiments studied the effect of LDX on both food intake and food-reinforced behavior, as assessed in singly housed, female Wistar rats. Three groups of rats received different food exposure conditions in the home cage randomly spread over several weeks: the chocolate exposure group (CE) was exposed to brief access of chocolate and additional lab chow (n=15), a lab chow exposure (LChE) group was given additional access to lab chow (n=8), and a third group was given empty food dishes (n=7). In tests of food intake under non-restricted conditions, injections of LDX (0.1875-1.5 mg/kg) significantly reduced intake of both chocolate and chow in the CE group. In the LChE group, there was a trend towards reducing chow intake induced by LDX. All rats were trained on the Progressive Ratio (PROG)/chow feeding choice task, in which they had the option of working for high carbohydrate chocolate flavored pellets by lever pressing (high value reward/high effort) or approaching and consuming a concurrently available lab chow (low effort/low value reward). The LChE group and the empty food dish group were combined to create one control group (n=15). There was a significant overall dose related suppressive effect of LDX on lever pressing but no group difference, and no dose x group interaction. A significant reduction in lever pressing was seen at the 3 highest doses of LDX. LDX significantly decreased chow intake in the CE group at the 3 highest doses, but not in the control group. In conclusion, LDX appears to affect both food intake and food-reinforced operant behavior across all groups, with larger effects seen in the group exposed to chocolate.

Title: The endocannabinoid AEA amplifies food preferences in *C. elegans*

Authors: S. FAUMONT, S. LEVICHEV-CONNOLLY, R. BERNER, *S. R. LOCKERY
Inst. Neurosci, Univ. of Oregon, Eugene, OR

Abstract: The endocannabinoid system, comprised of the endocannabinoids AEA (N-arachidonoyl-ethanolamine) and 2-AG (2-Arachidonoylglycerol), their receptors, CB1 and CB2, and their metabolic enzymes, is believed to integrate internal energy state and external food cues to modulate feeding. For example, cannabinoids, acting on CB1, can increase preference for rich, "tasty" food, a response called hedonic amplification. In mammals, cannabinoids can increase sensitivity to odors and sweet tastes, which may underlie amplification. We are developing *C. elegans,* an omnivorous bacterivore, as a model in which to investigate the neurophysiology of hedonic amplification. We found that exposure to AEA, an endogenous cannabinoid in *C. elegans*, increases the worms' preference for preferred, high quality bacteria over less preferred, low quality bacteria, mimicking hedonic amplification in mammals. Furthermore, AEA acts bidirectionally, increasing consumption of high quality bacteria while decreasing consumption of low quality bacteria. We also found that deletion of the CB1 homolog, *npr-19,* eliminates hedonic amplification in *C. elegans*. Amplification was rescued by expression of wild type *npr-19* or human CB1 driven by the endogenous *npr-19* promoter, establishing a humanized worm for cannabinoid signaling studies. Deletion of the olfactory neuron AWC, which directs chemotaxis to food, abolished hedonic amplification measured in terms of food attraction. Consistent with this finding, calcium imaging revealed that AEA bidirectional modulates AWC, increasing and decreasing its responses to high and low quality food, respectively. We are testing the hypothesis that AEA acts directly on AWC to modulate food preferences in hedonic amplification.

Title: Effects of maternal docosahexaenoic acid (DHA) supplementation on lipid peroxidation products in offspring mouse

Authors: *T. WOO[1], B. YANG[4], R. LI[2], K. FRITSCHE[3], G. Y. SUN[5], M. GREENLIEF[4], D. Q. BEVERSDORF[6]
[2]Biochem. Dept., [3]Dept. of Nutr. and Exercise Physiol., [1]Univ. of Missouri, Columbia, MO; [4]Chem., Univ. of Missouri-Columbia, Columbia, MO; [5]Univ. Missouri, Columbia, MO; [6]Dept Radiol, Neurol, Psychol Sci, DGS of INP, Univ. of Missouri Columbia, Columbia, MO

Abstract: The brain and retina are known to comprise of high levels of docosahexaenoic acid (DHA). Recent studies have demonstrated beneficial effects of dietary supplementation of DHA in the form of fish oil, including alleviating autism-associated behaviors in a gene/stress mouse model, but the mechanism(s) of action are not fully understood. Recent studies have focused on 4-hydroxy hexenal (4-HHE) and 4-hydroxy nonenal (4-HNE) which are peroxidation products of DHA and arachidonic acid (ARA), respectively. In this study, we determined the levels of these alkenals in heart, plasma, and brain tissue of weanling pups after being nursed by mothers given a DHA-supplemented diet. In the heart tissue, pups with a maternal DHA diet resulted in a 4.3-fold increase in 4-HHE. In the plasma, the maternal DHA diet induced a 1.7-fold increase in 4-HHE and a significant decrease in 4-HNE. Analysis of brain tissue indicated a significant increase of 4-HHE levels in cerebral cortex and hippocampus, but not in striatum and cerebellum, suggesting differences in lipid peroxidation activities within brain regions. Consistent with the results of lipid peroxidation products, analysis of fatty acids revealed a significant increase in DHA and decrease in ARA levels in offspring plasma, heart and brain regions, albeit to different extent. Taken together, this study demonstrates how maternal supplementation of DHA can influence fatty acid concentrations and their lipid peroxidation products in brain and body organs. It is possible that these changes in fatty acids and peroxidation products underscore the redox homeostasis and behavioral outcomes during the developmental period. Now we are using the SERT-KO/S mouse model to examine whether maternal stress alters lipid peroxidation activity in the brain and whether DHA supplement can mitigate these changes.

Title: Non-canonical dopamine circuit causes metabolic disorganization and obesity

Authors: *R. M. GRIPPO[1], Q. TANG[1], Q. ZHANG[1], S. R. CHADWICK[1], A. M. PUROHIT[2], M. D. SUNKARA[1], M. M. SCOTT[1], A. D. GÜLER[1]
[1]Univ. of Virginia, Charlottesville, VA; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Across the globe, widespread availability of energy-dense, rewarding foods is increasing the prevalence of obesity. In addition to inducing overconsumption, hypercaloric diets disorganize circadian feeding pattern, switching food intake from a meal-centered schedule to one based on frequent snacking. This out of phase consummatory behavior results in weight gain and metabolic disease. However, the mechanism of how palatable foods disrupt daily rhythms of feeding and metabolism is unknown. Since midbrain dopamine is released in response to rewarding sensory cues such as food rich in sugar and fat, we explored the role of dopamine circuitry in mediating energy-dense diet induced perturbation of feeding schedule. Here, we demonstrate that energy-dense foods modulate dopaminergic signaling within the central circadian pacemaker, disrupt daily rhythm of feeding and cause metabolic desynchrony in peripheral tissues. In addition to a delayed rate of photic entrainment (Grippo *et al.*, 2017 *Current Biology*), we observe that D1 dopamine receptor (Drd1) null mice are resistant to diet induced obesity and metabolic syndrome. Genetic rescue of Drd1 expression specifically within the suprachiasmatic nucleus (SCN) of these mice restores rest phase consumption, weight gain and obesogenic symptoms on an energy dense, high-fat diet. This work identifies SCN-Drd1-dependent signaling as a promising therapeutic target for the prevention of obesity.

Title: Acquisition and expression of sucrose conditioned flavor preferences following dopamine D1, opioid and NMDA receptor antagonism in C57BL/6 mice

Authors: B. ISKHAKOV, G. FAZILOV, M. SHENOUDA, A. BURAS, D. BHATTACHARJEE, P. DOHNALOVA, J. ISKHAKOVA, F. BOURIE, *R. J. BODNAR
Psychology- Neuropsychology, Queens Col., Flushing, NY

Abstract: In addition to the abilities of sucrose and saccharin to induce intake in non-deprived rodents, conditioned flavor preferences (CFP) are elicited by sucrose relative to saccharin in rats and inbred mice. Both acquisition (learning) and expression (maintenance) of sucrose-CFP can be modified by pharmacological receptor antagonism that is further subject to murine genetic variance. Thus, muscarinic cholinergic receptor antagonism with scopolamine eliminated the acquisition (learning) of sucrose-CFP in BALB/c mice, reduced its magnitude in SWR mice, but failed to affect the response in C57BL/6 mice. This pattern differed from the greater potency of scopolamine to reduce sucrose and saccharin intake in C57BL/6 and BALB/c mice relative to SWR mice. The three strains also display differential sensitivity to dopamine D1 and opioid receptor antagonists in reducing sucrose or saccharin intake. Whereas dopamine D1 receptor antagonism eliminates acquisition of sucrose-CFP in SWR, but not BALB/c mice, opioid receptor antagonism eliminates this response in SWR, but not BALB/c mice. N-methyl-D-aspartate (NMDA) receptor antagonism is more potent in eliminating acquisition of sucrose-CFP in BALB/c relative to SWR inbred mice. The present study examined whether naltrexone, SCH23390 or MK-801 altered acquisition and expression of sucrose-CFP in C57BL/6 mice. In acquisition experiments, male food-restricted C57BL/6 mice were treated with vehicle, naltrexone, SCH23390 or MK-801 30 min prior to each of ten daily sessions in which they alternately consumed a flavored (CS+, e.g., cherry) 16% sucrose solution and a differently-flavored (CS-, e.g., grape) 0.05% saccharin solution followed by six two-bottle CS choice tests mixed in 0.2% saccharin without injections. SCH23390 and MK-801, but not naltrexone eliminated sucrose-CFP acquisition in C57BL/6 mice. In expression experiments, C57BL/6 mice underwent the ten training sessions without injections followed by two-bottle CS choice tests 30 min following vehicle, naltrexone, SCH23390 or MK-801. SCH23390 more effectively reduced the magnitude of sucrose-CFP expression than naltrexone or MK-801 in C57BL/6 mice. Thus,

dopamine D1 and NMDA receptor signaling is essential for learning of sucrose-CFP in C57BL/6 mice. This pattern of antagonist effects differed from BALB/c and SWR strains, further indicative of murine genetic variance.

Title: Blockade of dopamine D2 receptors in the nucleus accumbens prevents the behavioral changes induced by intermittent access to sucrose

Authors: *R. ESCARTIN-PEREZ[1], J. SUÁREZ-ORTÍZ[1], A. MALAGÓN-CARRILLO[1], V. LÓPEZ-ALONSO[1], A. HERNÁNDEZ-GUTIÉRREZ[2], J. MANCILLA-DÍAZ[1]

Abstract: Excessive consumption of highly-palatable food is frequently found in patients with binge eating disorder (BED), bulimia nervosa (BN), and in some obese patients. Specifically, in individuals diagnosed with BED and BN, bingeing is a key eating disorder feature, even in absence of energy restriction. According to the experimental evidence, alterations in the mesolimbic dopaminergic transmission produced by non-homeostatic feeding behavior may be associated with changes in the reward system analogous to those produced by drugs of abuse. Although it is known that changes in dopaminergic transmission mediated by D2 receptors in the nucleus accumbens shell (NAcS) are related to binge-eating symptoms, it has not been evaluated whether these receptors may be a potential target for the treatment of eating pathology with binge-eating. Correspondingly, the aim of the present study was to evaluate whether sugar bingeing induced by intermittent access to a sucrose solution produced changes in the structure of feeding behavior and if blocking D2 receptors in the NAcS prevented these changes. We used the intermittent access to a 10% sucrose solution (2 h/day for 4 weeks) model to induce sugar bingeing in Sprague Dawley female rats. After 28 days, experimental subjects consumed in a 2-hour period more than 50% of the caloric intake consumed by the subjects with *ad libitum* access to the sweetened solution without any increase in body weight or fat accumulation. Once established the binge-like behavior, we characterized the structure of feeding behavior

(microstructural analysis) and evaluated the motivation for palatable food (breakpoints). We found that feeding episodes had short latencies, high frequencies, as well as short durations and inter-episode intervals. Furthermore, we observed that the intermittent access to sucrose protocol did not increase breakpoints, as occurred in subjects with *ad libitum* access to the sucrose solution. Finally, we evaluated the effects of D2 receptor blockade in the NAcS, and found that raclopride (18nM) administration blocked the increase of sucrose consumption, as well as the changes in the frequency and duration of episodes induced by intermittent access to the sucrose solution. In summary, our results suggest that alterations in behavioral patterns associated with binge-eating behavior depend in part on the dopaminergic transmission in the NAcS and that the antagonism of D2 receptors should be considered as a plausible therapeutic tool for feeding pathology with binge-eating.

Title: Dopamine neuromodulation of host-seeking behavior in the female mosquito

Authors: *T. R. SORRELLS, L. B. VOSSHALL
Rockefeller Univ., New York, NY

Abstract: Dopamine circuits integrate sensory information, internal state, and experience to control goal-directed behavior in widely diverged species. It is unclear how these circuits are repurposed during evolution to control the different behavioral drives in different species. Mosquitoes, along with several other independent insect taxa, have evolved to seek out and bite human hosts to acquire protein for egg development. Host cues such as human body odor, carbon dioxide, and heat synergize to increase mosquito arousal and initiate search and feeding behaviors. Although mosquitoes also feed on plant nectar for energy, this source of food is insufficient for reproduction and its acquisition is behaviorally distinct from blood-feeding. We are studying the control of host-seeking drive in the *Aedes aegypti*mosquito through genetic manipulation of dopamine circuits in the brain. Blood-feeding behavior specifically requires one of the four dopamine receptors present in the mosquito genome. The expression patterns of these receptors are substantially diverged from those of the vinegar fly Drosophila melanogaster,

suggesting that evolutionary changes in this neuromodulatory system may have contributed to the distinct behavioral drives of these two insects. We are currently developing additional driver and effector lines to further dissect the role of dopamine circuits in the behavior of this important human disease vector.

Title: Central effects of the satiety signal oleoylethanolamide in an animal model of frustration stress-induced binge eating disorder

Authors: *C. A. GALLELLI[1], A. ROMANO[1], M. V. MICIONI DI BONAVENTURA[2], J. B. KOCZWARA[1], M. E. GIUSEPPONI[2], T. CASSANO[3], C. CIFANI[2], S. GAETANI[1]
[1]Dept. of Physiol. and Pharmacol. V. Erspamer, Sapienza Univ. of Rome, Roma, Italy; [2]Sch. of Pharmacy, Pharmacol. Unit, Univ. of Camerino, Camerino, Italy; [3]Sch. of Med., Univ. of Foggia, Foggia, Italy

Abstract: Binge-eating disorder (BED), characterized by compulsive and uncontrollable overeating of highly palatable food (HPF), has been associated to altered dopamine (DA) and serotonin (5-HT) brain signalling. The satiety signal oleoylethanolamide (OEA) has emerged as a potential novel pharmacological tool for controlling aberrant eating patterns, by restoring a normal brain dopaminergic response, when it is deregulated by an excessive dietary fat intake. Based on these premises in this study we investigated in a rat model of BED the effects of OEA: 1) on Fos expression and tissue monoamine (DA, 5-HT, Noradrenaline) concentrations in brain areas controlling feeding and reward; 2) on the modulation of DA release within the shell of the nucleus accumbens (AcbSh). In our model, female rats with a history of intermittent food restriction and HPF consumption showed binge-like food intake after the exposure to a "frustration stress" consisting of the sight of unreachable HPF (BED rats). Control rats were exposed to the same experimental manipulations except for food restriction and did not show any binge eating behaviour. OEA was administered (10 mg/kg i.p.) to two different sets of both BED and control rats. A first set was sacrificed 2 hours after OEA administration; their brains were partly sliced into 20 μm coronal sections (immunostained for Fos), and partly microdissected for monoamine determination by HPLC.The second set of rats was subjected to in vivo microdialysis of the AcbSh, collecting dialysates every 15 min, and was first intraperitoneally

treated with OEA (10 mg/kg) and then challenged with a subcutaneous dose of amphetamine (0.5 mg/kg). DA dialysate levels were analysed by HPLC. OEA administration was able to restore a "normal" brain activity, by reducing the stress-induced Fos increase in brain areas regulating feeding and the dopaminergic signalling. Moreover, we found that OEA treatment decreased DA efflux in the AcbSh, following either stress exposure or amphetamine challenge. At tissue level, we found that OEA also reduced DA concentration within the Acb of BED rats. As far as the serotonergic system, we found that OEA is able to enhance 5-HT transmission in most of the brain areas analysed, selectively in bingeing rats. Overall, these results further enrich our current knowledge on the central effects of OEA and support, for the first time, the hypothesis that OEA might represent a novel potential pharmacological target for the treatment of BED.

Title: Common neural underpinnings between anorexia, memory and addiction

Authors: *V. COMPAN[1], G. CONDUCTIER[2]
[1]Sci., Nimes Univ., Nimes, France; [2]Monash Inst., Clayton, Australia

Abstract: In neurons of the nucleus accumbens, activation of a cAMP signaling is a means of transforming an immediate reduction of drugs' rewarding effect into a durable dependence, mimicking a form of learning. After recruiting cAMP-response element binding protein (CREB)-binding protein, the resultant phosphorylated CREB (pCREB) favors the expression of some genes (FosB, ΔFosB, and CART: cocaine- and amphetamine-regulated transcript) to the detriment of others (methyltransferase G9a of histone), from where come changes in neuron morphology. Serotonin (5-HT, 5-hydroxytryptamine) volume transmission trough many receptors act on cAMP signaling and thus modulate the activity of the reward neural pathways. Our previous studies show that stimulation of Gs-coupled serotonin 4 receptors (5-HT_4Rs) triggers activation of cAMP/PKA/CART/FosB/ΔFosB signaling pathway, which serve to induce anorexia-like behavior. Here, we examine how cAMP in the NAc impacts food intake. We found

that elevated levels in cAMP induced by local infusion of BIMU8, a 5-HT_4Rs agonist, into the NAc were more prominent when BIMU8 was co-infused with St-Ht31 peptide that blocks AKAP (A-kinase anchoring protein) / PKA binding. Results includes that the levels of CART peptide, known to promote anorexia and addiction, were more elevated following St-Ht31/BIMU8 co-treatment than in mice infused only with BIMU8 into the NAc. Finally, mice with highest increased levels of cAMP and CART induced by the blockade of AKAP/PKA binding in the NAc display the highest restrictive food intake following food deprivation, supporting the view that anorexia becomes persistent through similar mechanisms underlying habituation towards learning and memory.

Title: Impact of nutrition on risk decision making

Authors: *L. LIU[1], S. STRANG[1], S. O. ARTIGAS[1], A. ULRICH[2], J. TARDU[2], O. UHL[3], B. KOLETZKO[3], S. M. SCHMID[2,4], S. Q. PARK[1]

Center, Ludwig-Maximilians-Universität Munich, Munich, Germany; [4]German Ctr. for Diabetes Res. (DZD), Neuherberg, Germany

Abstract: Abstract: Previous research has provided evidence for nutrition-driven modulation on social decision-making processes. Macronutrient composition of a food modulates different biochemical processes, leading to dissociable influence on decision making. Specifically, a higher protein-carbohydrate ratio food alters blood tyrosine levels, presumably leading to an elevation in neurotransmitter dopamine. This is crucial, since many studies using pharmacological or genetic approaches have shown that an enhancement in brain dopamine leads to risk-proneness. In this study, we investigate whether a balanced one-shot Western-style meal with different protein-carbohydrate ratio is sufficient to impact risk decision making. **Methods** Thirty-five male subjects (mean age = 23.40 y, SD = 3.31; mean BMI = 22.96, SD = 1.75) were

investigated in two different days with a gap of 7-9 days. In each session, they received either a high- (25%/50%) or a low- (10%/80%) protein/carbohydrate ratio breakfast. We monitored plasma tyrosine and the individual monetary risk decision making behavior. Also, individual differences in the behavioral inhibition system and the behavioral approach system (the BIS/BAS scale) were assessed. **Results** The plasma tyrosine level was significantly enhanced, whereas the plasma tryptophan level was decreased in the high protein/carbohydrate session when compared with the low protein/carbohydrate session. Furthermore, participants showed significantly more risk-seeking behavior in the high vs. low protein/carbohydrate session. Strikingly, this session difference in risk-seeking behavior was significantly correlated with the individual differences in the BAS-fun seeking scale, suggesting that the risk decision making behaviors in individuals with high level of behavioral approach may be more susceptible to the balance between protein and carbohydrate intake. **Conclusions** Our results demonstrate how risk decisions can be impacted by the macronutrient composition of a daily meal, by unveiling its underlying metabolic processes.

Title: Involvement of transient receptor potential vanilloid (trpv) type channels in olanzapine-induced hyperphagia and weight gain

Authors: *R. SINGH[1], Y. BANSAL[1], T. SOGA[2], I. PARHAR[2], A. KUHAD[1]
[1]UIPS, Pharmacol., Panjab Univ., Chandigarh, India; [2]BRIMS, Monash Univ., Selangor, Malaysia

Abstract: Background: Despite the clinical benefits, atypical antipsychotics (AAPs) exerts troublesome adverse effects particularly hyperphagia, weight gain, dyslipidemia, insulin resistance, metabolic and cardiac complications. Recent evidence shows the role of TRPV channels in reward-seeking and feeding behavior through modulation of mesolimbic dopaminergic pathways. **Aim**: With this background present study was designed to investigate the role TRPV channels on hyperphagia and weight gain induced by olanzapine in mice. **Material and methods:** Induction of schizophrenia-like behaviors in mice (n=10) was done with MK-801 (0.1 mg/kg, i.p.) for five days. 6th day onwards animals were being treated with

olanzapine (6 mg/kg p.o.) and control (CMC 0.25%, p.o.) for 4 weeks. Weekly assessment of feed, water intake, body weight was done and on last day of fourth week fasting glucose and oral glucose tolerance test was done. Quantification of TRPV1 and TRPV3 gene expression in nucleus accumbens (NAc), hypothalamus and ventral tegmental area (VTA) were done. **Results**: MK-801 induced a schizophrenia-like behavioral alteration in mice which were significantly reversed by olanzapine treatment. Acute treatment of olanzapine-induced hyperphagia and while significant weight gain was observed as compared to control. A significant increase in TRPV3 gene expression in NAc and hypothalamus were observed while TRPV1 expressions were significantly in hypothalamus and VTA. These results indicate the role of TRPV channels in mesolimbic system (NAc and VTA) which may contribute to active reward circuitry leading to hyperphagia and weight gain. **Conclusion**: Our primary results indicated that TRPV1 and TRPV3 channels may involve in antipsychotics induced hyperphagia, weight gain and their modulators could be a therapeutic alternative in the management of hyperphagia, weight gain, food addiction, and eating disorders.

Abstract: Energy balance is finely regulated by the central nervous system: it integrates peripheral signals reflecting the energy status of the organism and in turn adapts food intake and energy expenditure in order to maintain a stable weight throughout adult life. The hypothalamus

(HT) is one of the cerebral structures having a major role in the integration of those signals. Several studies show that obesity induced by a high fat diet (HFD) leads to inflammation at the level of HT which could cause obesity. Moreover, lipids contained in HFD might be directly responsible for the onset of the inflammatory response. At cellular level, this inflammation is in part characterized by an activation of microglia cells and astrocytes in the HT. In rodent, recent studies show that hypothalamic proliferation of microglia cells and astrocytes is observed in the first 24 hours of consumption of HFD, well before the development of obesity, and seems to be reversible. We therefore assume that early glial activation would be an adaptive mechanism involved in the physiological regulation of energy balance and that overexposure to nutritional lipids could deregulate this inflammatory response and lead to obesity. In our study we observed an increase in the expression of the astrocytes and microglial cells markers (GFAP and Iba1 respectively) in the HT after 1 h of HFD consumption. Moreover we observed morphological modifications of microglial cells in the HT after 3h of HFD consumption. This remodeling is associated with differential activation of specific inflammatory markers and hypothalamic peptides involved in energy balance regulation. Our results suggest that inflammation induced by HFD consumption is a very early phenomenon which might be involved in the central regulation of energy balance. In the future, this glial remodeling will modulate using pharmacogenetic tools in order to establish the cascade of molecular and cellular events at the origin of CNS perturbations associated with obesity.

Title: The effect of naloxone in the consumption of a high carbohydrate diet at weaning and its repercussion on the intake of hypercaloric diet in adult male rats

Authors: *J. A. MATA-LUÉVANOS, JR[1], J. JUAREZ[2]
[1]Lab. de Farmacología y Conducta, Inst. De Neurociencias, Univ. De Guadalajara, Guadalajara, Mexico; [2]Univ. Guadalajara, Guadalajara, Jalisco, Mexico

Abstract: Evidence suggests that infancy may be a critical period for the exposure to hypercaloric food (rich in both fat and carbs). The hypercaloric food tends to have high palatability, which make it highly preferred. The overconsumption of this food may produce aberrant patterns of eating resulting in health problems.

At preadolescence, some of the neurotransmission systems are maturing (such as the opioid system), and due to the implication of opioids in the hedonic perception of stimuli, alterations of this pathway may affect the appetitive and consummatory aspects of alimentary behavior. On this basis, the effects of the opioid antagonist, Naloxone (NA) on the consumption of high-carbohydrates food during preadolescence and its repercussion on the consumption of hypercaloric food in adulthood were studied.
Four groups of male Wistar rats were exposed to different pharmacologic treatments on infancy during 18 days, starting at 23 postnatal day (PND); 15 min after injection the rats were exposed to a food rich in carbohydrates (CHO).
Groups:
NALCHO: NA prior CHO exposure.
CHONAL: NA after CHO exposure.
VEHCHO: Vehicle (VA) Administration prior CHO exposure.
CHOVEH: VA after CHO exposure.
At 70 days, as adults, base line (BL) of only standard food (STD) was measured, and at 75 PND, all groups (n=11) received a hypercaloric diet (HCD, rich in carbs and fat) during 4 weeks. At 103-108 PND a post-treatment (PT) period with only standard food (STD) was measured and then re-exposed (RE) to the HCD at 108-113. Food intake and body weight were registered.
At weaning, NALCHO show higher intake of calories from STD than VEHCHO and CHOVEH, and ate fewer calories from CHO than the other 3 groups. The overall (STD+CHO) calories consumed weren't affected.
At adulthood, after the hypercaloric diet was removed, we found a negative contrast effect. Intake of STD significantly decreased in PT respect of BL. The CHOVEH ate fewer STD calories than all the other 3 groups in PT. The NALCHO ate more calories than the vehicle groups, and CHONAL more than VEHCHO in RE. CHONAL gained more body weight than VEHCHO and CHOVEH, and NALCHO more than VEHCHO in BL and RE. Overall body weight gain was less in PT than in the HCD exposure. The NAL groups gained more weight than Vehicle groups in RE.
Results suggest that the blockade of the opioid system at weaning can alter the consumption of a high-in-carbohydrates food, depending on the administration occurs either, before or after having this food. Besides, this condition at infancy has repercussion in adulthood, regardless of the opioid blockade contingencies.

Title: An animal model of binge-like eating using short vs long access self-administration

Authors: *G. R. CURTIS, L. SANZALONE, N. MACK, J. R. BARSON
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Binge eating is a defining feature of binge-eating disorder and can lead to the development of obesity, which itself can cause numerous health problems. This behavior is characterized by the consumption in a discrete time period of an abnormally large amount of food, particularly palatable food high in sugar and fat, even in the absence of hunger. As few animal studies have successfully modeled this behavior, the goal of the present experiment was to develop a paradigm for reliably inducing binge-like eating. Adolescent female Long-Evans rats (N = 16), with *ad libitum* access to chow and water in the home cage, were trained 5 days per week in operant chambers to lever-press on a fixed ratio 1 (FR1) schedule of reinforcement for the highly caloric and palatable Chocolate Ensure Plus®. Half of these animals self-administered Ensure in short-access sessions of 30 minutes per day, while the other half were given long-access sessions of 6 hours per day (n = 8/group). Once their responding was stable, the short-access group consumed significantly more calories of Ensure than the long-access group during the initial 30-minute period of daily access, eating as much as 15% vs 8% of their total daily calories during this time. Notably, despite their greater overall Ensure intake, the long-access group had a similar body weight to the short-access groups, with both groups weighing significantly more than home cage control animals consuming only chow and water (N = 12). This indicates that excessive weight gain may be induced by binge-like intake of palatable food as well as general overconsumption of palatable food. In a separate cohort of adolescent female Long-Evans rats (N = 16), given short-access sessions for Ensure, we found that intake was statistically indistinguishable whether access was given for 3, 5, or 7 days per week. These results demonstrate that short, 30-minute access to Ensure leads to over-eating of palatable food, over-eating not driven by hunger, over-eating that occurs in a discrete period of time, and excessive weight gain. As such, we believe that this model reflects critical aspects of binge eating and can be thus used to identify underlying neural substrates of this behavior.

[1]Fac. of Life Sci. and the Gonda Brain Res. Ctr., Bar-Ilan Univ., Ramat-Gan, Israel; [2]Psychology, [3]Bar-Ilan Univ., Ramat Gan, Israel; [4]Inst. of Animal Science, ARO, The Volcani Ctr., Bet-Dagan, Israel

Abstract: **Background**: The hypothalamic arcuate nucleus (ARC) has an important role in energy regulation, including body weight regulation. This occurs by a balance between anorexigenic (proopiomelanocortin [POMC] and Cocaine and amphetamine-regulated transcript [CART]) and orexigenic (NPY, AgRP) neuropeptides. The cleaved product of Pomc αMSH is secreted and binds to receptors such as the Melanocortin 4 receptor (Mc4r) in hypothalamic nuclei such as the paraventricular nucleus (PVN). Binding of neuropeptides to this receptor transmits a signal of hunger/satiety in accordance to the binding peptide. Our goal is to investigate whether obesity caused by consuming a diet rich in calories and fat can be reversed by caloric restriction and what are the epigenetic mechanisms related to this process. **Results**: Both high fat diet (HFD) and caloric restriction (CR) affected body weight in rats. HFD fed rats weighed more than chow fed rats on postnatal day (PND) 90. 40% caloric restriction (HF-CR40), applied from PND 90-120 reduced their body weight only by 10-15%. The CR did not correct the weight to the level of the control group. Mc4R mRNA pattern was opposite to the body weight - the chow-chow group showed the highest expression while Mc4R expression in HF-CR40 group remained similar to that of the HF group. We found that the promoter of Mc4R is completely unmethylated whereas the coding sequence is hypermethylated. Analysis of CpG methylation at the Mc4R coding regions revealed a difference in the methylation state between the groups; the HF-HF and the chow-chow groups showed a similar methylation profile while the CR group showed higher methylation levels. Examination of the CREB transcription factor binding levels showed negative correlation with the methylation levels - higher binding levels were found in the HF-HF and chow-chow groups. Additionally, we found differences in the DNMT expression levels between the groups. **Conclusion**: We suggest that the methylation profile in a constant diet keeps to a lower level compared to a state of an attempt to reduce body weight via caloric restriction - in this case, the body will counteract this process and try to keep to a weight set point by increasing the methylation levels, thus reducing CREB transcription factor the binding levels and diminishing Mc4R expression.

Title: Effects of neonatal limited nesting stress on anxiety-like behavior and impulsivity in adult rats

Authors: *A. C. TALK, C. JEREMY, J. SHERREY, S. FISHER, A. HAMLIN, E. KYONKA
Univ. of New England, Armidale, Australia

Abstract: Growing up within a deprived childhood has been linked to impulsive decision making. However, it is not clear that a causal relationship between early life deprivation and later impulsivity exists. A third factor, such as genetics, could account for impulsivity as well as material deprivation in offspring. We conducted a series of experiments in which stress in the form of limited nesting material was randomly assigned to neonatal rats. We then assessed impulsivity, as well as anxiety-like behaviors, of the male rats after they grew into adulthood. Our goal was to establish whether a causal relationship exists between early life limited nesting stress and later impulsivity. In a series of three experiments, male Wistar rats were cross-fostered and randomly assigned to either a control condition or to being reared with limited access to nesting material during postnatal days (PND) 2-9. The rats were weaned on PND 22. From PND 60 to 150, the rats were tested on an elevated plus maze and an operant delay-discounting procedure (experiment 1), an elevated plus maze and an operant probability-discounting procedure (experiment 2), or an elevated plus maze and a dark-light box procedure (experiment 3). Across the three experiments, the deprived rats spent more time in the open arms of the plus maze than controls. Similarly, in the light-dark box, the deprived rats had a reduced latency to enter the lit side of the box, and spent more time in the light than controls. There were no statistically reliable differences between deprived and control rats on impulsivity measures during the delay-discounting procedure or the probability-discounting procedure. We are currently conducting histological analysis of the rats in these studies to determine whether changes in dendritic arborization or spine density has occurred in the frontal cortex of the deprived rats. Our results thus do not support a causal link between depriving rat pups of nesting material and later impulsivity. However, the results do support a causal link between early life deprivation and later anxiety. In our study, limited nesting material stress reduced anxiety-like behaviors in adulthood.

Title: Activation of leptin receptor-expressing neurons in lateral hypothalamus enhances food-seeking without altering food intake in mice

Authors: *Y. LEE, D.-S. HA, M. KIM, H. SONG, C. NAMKOONG, D. CHUN, H. CHOI
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The symptom of eating disorders that is difficult to treat is a dissociation between food-seeking behavior and metabolic needs. The lateral hypothalamus (LHA) regulates various motivated behaviors including food intake, and among many neuronal populations inside, LHA GABAergic neurons are known to be involved in modulation of food reward and consumption. Previous studies showed that activation of LHA GABAergic neurons enhance food intake and compulsive behaviors in mice. However, specified behavioral phenotypes and functions of the subset of LHA GABAergic neurons are unclear. Thus, our research aimed to identify the food-related behavioral phenotypes that are regulated by leptin receptor-expressing neurons in LHA. We performed food-seeking test, operant chamber test, overall chow/sucrose/saccharin consumption, preference test and marble burying test. Interestingly, through behavior assays, we found that chemogenetic activation of LHA leptin receptor neurons only increased ‘food-seeking’ behavior without altering food intake. However, activation of LHA GABAergic neurons increased both food intake and compulsive behaviors without affecting food-seeking. These results suggest that food-seeking is independent from food intake, and LHA leptin receptor neurons are specifically involved in food-seeking behavior that can be targeted to treat eating disorders.

Title: The effects of novelty on food consumption in male and female rats

Authors: *E. GREINER[1], G. D. PETROVICH[2]
[2]Psychology, [1]Boston Col., Chestnut Hill, MA

Abstract: Novel foods and novel environments impact consumption, but research into how the two interact, and whether there are sex differences, is lacking. Here, we sought to determine if exposure to a novel context enhances food neophobia—defined as a lower intake of a novel food compared to familiar—and whether the effect is sex dependent. We also wanted to establish whether the effects of novelty on food consumption in either sex were mediated by anxiety and thus could be attenuated by administration of sub-anesthetic doses of ketamine. Male and female Long Evans rats were tested for consumption in either their home cage or in a novel context (n=8 per group) and were given two foods, one familiar (rat chow) and one novel (Test Diet pellets; TD). They received 8 testing sessions on separate days and were acutely deprived of food for 20 hours prior to each. During Test 1 and 2, males and females tested at home had a significant preference for the familiar (rat chow) over novel (TD) food ($p=0.001$, both), while rats tested in a novel context ate similar, small amounts of each food. Total consumption was lower in the novel context groups compared to home cage tested groups for both sexes ($p=0.002$) but females tested in the novel context ate the least. In Test 3, male and female rats tested at home consumed equal amounts of the two foods and by Test 8 were showing a significant preference for TD (males, $p=0.03$; females, $p=0.016$). Males tested in the novel context showed higher consumption of TD by Test 4 ($p=0.014$) whereas females showed equal consumption of both foods during all tests. Further analysis of total consumption in Test 6, 7, and 8 showed that males tested in a novel context ate significantly more than females (T6, $p=0.009$; T7, $p=0.008$; T8, $p=0.003$). These results indicate that rats in a familiar context, regardless of sex, and males in a novel context habituate to novelty faster than females in a novel context. On-going experiments are examining if the sustained, suppressed consumption that females tested in the novel context show throughout testing is mediated by heightened anxiety and could be alleviated by anxiolytic ketamine.

Title: Context-induced renewal of responding to food cues: The effect of context pre-exposure in male and female rats

Authors: *D. LAFFERTY, G. D. PETROVICH
Psychology, Boston Col., Chestnut Hill, MA

Abstract: The environments in which we consume food can later influence eating behavior. Environmental food cues can stimulate food seeking, but how we respond depends on context. Context-mediated renewal is a well-suited paradigm to investigate environmental control of responding to food cues. Recent work found that males demonstrate robust context-mediated renewal of responding to a food cue after extinction but females do not. These results were established in rats with an "ABA renewal" paradigm in which a cue-food association is acquired in one context, extinction of the conditioned responding occurs in a different context, and the renewal of responding is induced by the acquisition context. The goal of the current study was to determine if context-mediated renewal could be strengthened, particularly in females, by pre-exposure to both contexts prior to training. First, food restricted adult male and female rats (N=32) experienced pre-exposure to the behavioral contexts (experimental groups) or remained in their homecage (control groups). Then all rats underwent Pavlovian conditioning in which they were presented with a tone cue (conditioned stimulus, CS) followed by delivery of palatable food pellets (unconditioned stimulus, US). Acquisition of the CS-US association occurred in a distinct context that varied in olfactory, visual, and tactile features from the context used for extinction training. By the end of acquisition training (5 sessions, each with 8 CS-US pairings) all groups showed similar robust conditioned responding (approach to the foodcup) during the CS. After extinction training (2 sessions, each with 8 CSs) all groups decreased responding during the CS. Rats were tested for renewal of responding with CS-only presentations in each context, on separate days counterbalanced for order. Here we compared responding during the CS (elevation above baseline) in the acquisition vs. extinction contexts. Analyses revealed the only group to demonstrate robust renewal were males that did not receive pre-exposure, as indicated by their higher responding during CSs when tested in the acquisition compared to extinction contexts ($t(1,14)=2.69$, $p<.01$). Additionally, the groups that had pre-exposure had higher baseline (preCS) responding in the extinction context ($t(1,30)=2.38$, $p<.05$) while all groups had similar preCS responding in the acquisition context ($p>.05$). These results

demonstrated sex differences similar to the patterns found in previous research and that pre-exposure to behavioral contexts did not improve renewal in either sex. Current work is investigating whether US delivery during pre-exposure is important for the lack of effect on renewal.

Title: The pharmacological stressor yohimbine, but not U50,488, increases responding for conditioned reinforcers previously paired with alcohol or sucrose

Authors: *R. I. TABBARA[1,4], A. RAHBARNIA[1,4], A. D. LÊ[2,3,5], P. J. FLETCHER[1,4,3]
[1]Psychology, [2]Pharmacol. and Toxicology, [3]Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [4]Biopsychology, [5]Neurobio. of alcohol, Campbell Family Mental Hlth. Res. Institute, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Stressful life events can induce craving and relapse to alcohol. In laboratory animal models, pharmacological stressors, such as the alpha-2 adrenoreceptor antagonist yohimbine and the kappa-opioid receptor agonist U50,488, can impact ethanol (EtOH) consumption and reinstate extinguished EtOH-seeking. Although alcohol has primary reinforcing properties, environmental stimuli repeatedly associated with alcohol can acquire incentive value and motivate non-abstinent and abstinent alcoholics to drink. It is unknown whether stress can potentiate these motivational properties of alcohol-paired stimuli. This work examined the effects of the pharmacological stressors yohimbine (alpha-2 adrenoreceptor antagonist) and U50,488 (kappa-opioid receptor agonist) on responding for conditioned reinforcement; a test that assesses the reinforcing properties of reward-related cues in animal models. This work also examined whether their effects on responding interact with the nature of the reward delivered (alcohol vs. sucrose). Male Long-Evans rats were mildly-food deprived and received access to EtOH solutions for 1 hr/day at increasing concentrations (3% w/v for 6 days, 6% w/v for 6 days, 12% w/v for 12 days) or a sucrose solution (21.7% for 2 days) in drinking cages. Next, they underwent 35 sessions of Pavlovian conditioning consisting of 12 trials, where a 5-sec tone-light conditioned stimulus (CS) was paired with 0.15 ml of 12% EtOH (w/v) or 21.7% sucrose. Tests of responding for conditioned reinforcement were then conducted, during which presentation of the CS alone (now acting as a conditioned reinforcer; CRf) was contingent upon pressing one of

two levers (CRf lever). Pressing the other lever had no programmed consequences (NCRf lever). To determine the effects of yohimbine and U50,488 on responding for conditioned reinforcement, rats received an injection of yohimbine (1.25, 2.5 mg/kg i.p.) or U50,488 (1.25, 2.5 mg/kg s.c.) 30 min prior to testing. Both doses of yohimbine selectively potentiated responding for a CRf previously paired with EtOH or sucrose; an effect that was maintained over several tests. However, neither doses of U50,488 affected responding. Results suggest that the ability of yohimbine to potentiate responding for a reward-related cue is not unique to alcohol-paired stimuli, and is probably not related to its stress-like effects.

Title: Cannabinoid agonist effects on pavlovian conditioned approach behavior

Authors: *A. GHEIDI[1], B. N. FROELICH[2], C. J. FITZPATRICK[2], R. L. ATKINSON[2], C. N. BARCELO[2], J. D. MORROW[1]
[1]Dept. of Psychiatry, [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Pavlovian conditioned approach (PCA) can be used to measure motivational salience attribution by repeatedly pairing a neutral conditioned cue (e.g. a retractable lever) with the response-independent delivery of a reinforcer (e.g. a food pellet). Under these conditions, animals will begin to either sign-track, i.e. approach and contact the neutral cue, or goal-track, i.e. approach the location of impending reinforcer delivery. Sign-tracking indicates an attribution of motivational salience to the cue, and is correlated with vulnerability to both addiction- and PTSD-like behaviors in rats. Sign-tracking is highly dopamine-dependent, and cannabinoids are known to regulate dopaminergic neurotransmission. We therefore investigated the effects of a cannabinoid agonist on acquisition of sign- and goal-tracking behavior. Rats received vehicle or the nonselective cannabinoid agonist CP 55,940 in a dose of 10 μg/kg, 50 μg/kg, or 100 μg/kg followed by PCA training for 7 days. Training sessions consisted of a retractable lever presentation followed immediately by food delivery into a magazine, repeated 25 times. Then 5 days of crossover training was conducted with drug rats switched to receiving vehicle and vehicle rats receiving 100 μg/kg of drug. CP 55,940 dose-dependently reduced sign-tracking and increased goal-tracking. During the crossover phase, the drug rats showed decreased goal tracking while the vehicle rats showed deceased sign tracking. To determine whether sign and

goal trackers have constitutive differences in the cannabinoid system, a different group of rats (previously characterized as sign or goal trackers) were sacrificed and their brains prepared for in *situ* hybridization using radioactive S^{35}. Riboprobes complementary to the mRNA of cannabinoid receptor 1 (CB1) and fatty acid amide hydrolase (FAAH) were visualized with Kodak film. Quantification of mRNA expression is ongoing. We conclude that cannabinoid agonism decreases acquisition of sign tracking and promotes acquisition of goal tracking behavior. This was the opposite of our original hypothesis and may be due to disrupted timing of dopaminergic activity, which in turn would interfere with sign-tracking behavior.

Title: Are cues pursued for their own sake, or because they lead to rewards?

Authors: *C. E. MARÍA-RÍOS[1], C. J. FITZPATRICK[1], T. GEARY[2], J. D. MORROW[1,2]
[1]Neurosci., [2]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: When a neutral stimulus is repeatedly paired with an appetitive reward, two different types of conditioned approach responses may develop: a sign-tracking response directed toward the neutral cue, or a goal-tracking response directed toward the location of impending reward delivery. Sign-tracking responses have been postulated to result from habitual processes that are insensitive to outcome devaluation, while goal-tracking may develop from a more explicit cognitive representation of the associated outcome. However, Pavlovian responses are typically sensitive to outcome devaluation, and the published literature has been inconsistent on the sensitivity of sign-tracking to devaluation. We therefore tested sign- and goal-tracking before and after devaluation of a food reward using lithium chloride and found that sign-tracking was sensitive to outcome devaluation, while goal-tracking was not. We also confirmed that both responses are Pavlovian because they can be learned under negative contingency conditions. Although both sign- and goal-tracking responses are likely dependent on the acquired incentive

and predictive values of the cues, the increased motivational value sign-trackers attribute to the cue, suggests that sign-tracking behavior is mostly guided by the incentive value, while goal-tracking relies more on the predictive value. This interpretation is supported by the findings for outcome devaluation where only the incentive value of the reward was altered, and only sign-tracking behavior was affected. To further explore this idea, we sought to test the effects of a blocking paradigm on sign- and goal-trackers. Blocking is thought to occur because learning is driven by prediction errors. Accordingly, once an unconditioned stimulus is completely predicted by a cue, no further learning will occur. If a second cue is then added simultaneously with the pre-trained cue but does not give any new information about the outcome, the pre-trained cue should block learning about the second cue. Under these training conditions, we found that goal-trackers showed complete blocking of the new added cue, while sign-trackers blocked, but to a lesser extent. This supports the previously stated hypothesis that sign- and goal-tracking follow different rules of reinforcement learning.

Title: Incentive salience attribution predicts task-irrelevant attention biases in human sign- and goal- trackers

Authors: *M. DIBARTOLO[1], K. M. FRASER[1], V. NICHOLAS[2], P. H. JANAK[1,2], S. M. COURTNEY[1,2,3]
[1]Psychological & Brain Sci., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Kirby Res. Ctr., Kennedy Krieger Inst., Baltimore, MD

Abstract: Individuals differ in their attribution of motivational value, also referred to as incentive salience, to reward-paired cues. In rats, individuals that are prone to attribute high levels of incentive salience to cues are more impulsive and more prone to cue-driven reinstatement of drug self-administration. However, little to no evidence to date has been found indicating whether humans demonstrate individual differences in incentive salience attribution comparable to that found in animal models. To investigate this, we developed a novel paradigm to examine sign- and goal-tracking behavior in humans. We tested healthy young adults (N = 45, 34 female) on an eye-tracking-based autoshaping task. In this task, one continuously present stimulus served as a "goal," and after a varying amount of time a separate "sign" stimulus appeared for five seconds at a different location, followed immediately by delivery of monetary

reward at the goal location. Both stimuli were interactable - movement of the gaze into the cue location produced both auditory and visual feedback, whereas goal gaze interactions only produced visual feedback. Autoshaping occurred over 4 blocks of 10 trials, immediately followed by a centralized discrimination task (CDT) implemented to assess attentional biases. During CDT trials, previous sign and goal stimuli were occasionally presented as distractors for a brief period of time (125 ms) immediately prior to responses. Eye movements were tracked throughout both tasks. We used a standard Pavlovian conditioned approach index to classify individuals as sign-trackers and goal-trackers based on their behavior during autoshaping. Upon sign stimulus presentations, sign-trackers rapidly interacted with this cue and fixated in the region of the cue for the duration of its presentation, whereas goal-trackers instead spent the duration fixated in the goal region. We found that sign-tracking behavior predicted subsequent attentional biases, even when the sign-cue was task-irrelevant. Interestingly, the phenotype into which people were sorted was well matched with self-report of enjoyment of interacting with the sign or goal. These data indicate that humans differ in their propensity to attribute reward-paired cues with incentive salience and that the degree to which they do so has implications for the capture of attention by previously rewarded cues, providing a framework for the investigation of these neural processes in humans.

Title: Insular cortex and sympathetic nervous system responses to motivational salience

Authors: *K. G. WARTHEN[1], A. BOYSE-PEACOR[2], B. SANFORD[3], B. J. MICKEY[2]
[1]Bioengineering, Univ. of Utah, Salt Lake City, UT; [2]Dept. of Psychiatry, Univ. of Utah Sch. of Med., Salt Lake City, UT; [3]Univ. of Michigan, Ann Arbor, MI

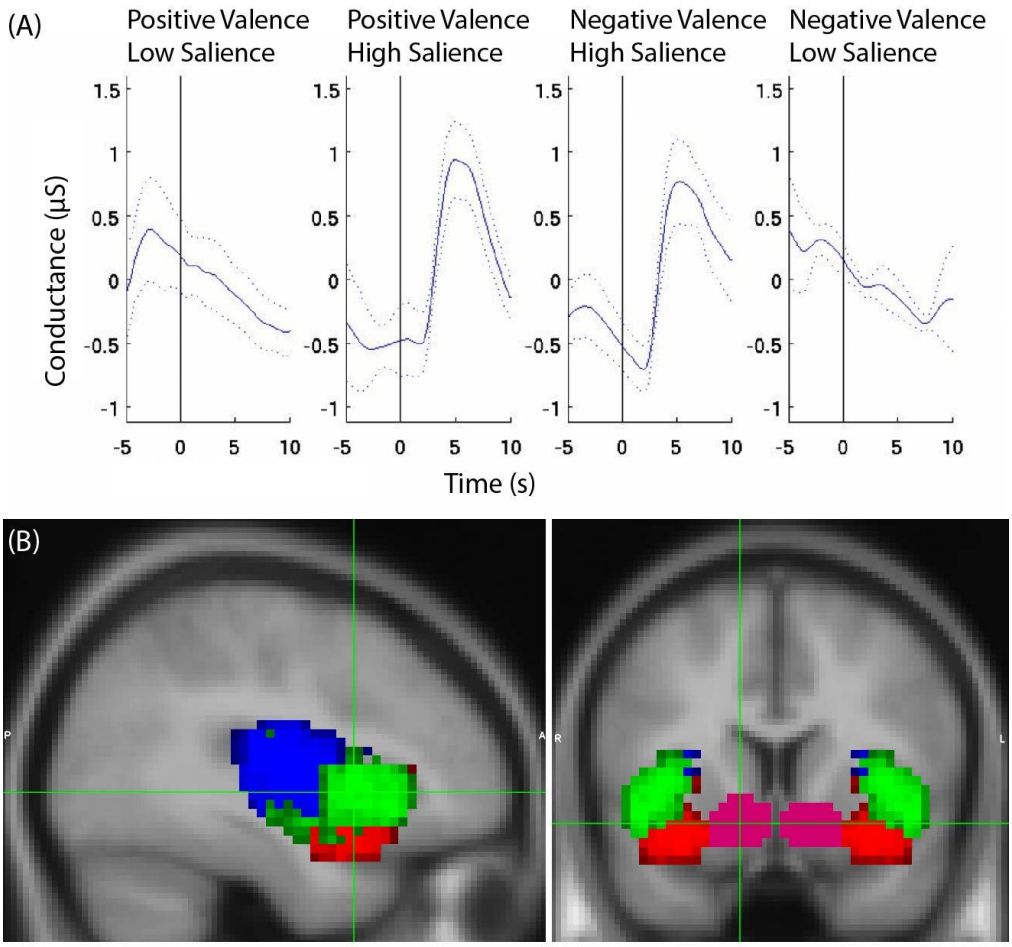
Abstract: Peripheral sympathetic nervous system (SNS) activity has been widely used in psychological research as a proxy for central nervous system activation, but how the peripheral SNS is controlled centrally is not well understood in humans. Furthermore, individual differences in SNS activity, which are thought to influence risk for a variety of health problems,

have not been well described. We hypothesized that SNS activity would be associated with neural responses in nucleus accumbens (NAc) and anterior insula (AI).

We characterized phasic SNS activation by measuring electrodermal responses (Fig. 1A) from 212 young adults (both sexes) as they performed a monetary incentive task. Forty-two of these subjects performed the same task during functional magnetic resonance imaging (fMRI). Stimuli presented during the task varied by salience (high versus low) and valence (win versus loss). Linear mixed models were used to identify associations of SNS activity with responses in four regions of interest: NAc, ventral AI, dorsal AI, and posterior insula (Fig. 1B).

Task performance and subjective arousal ratings predicted SNS activation, while subjective affect ratings did not. SNS responses to high-salience stimuli were positively associated with fMRI responses in the NAc and the ventral and dorsal AI, but not the posterior insula, after controlling for performance, subjective ratings, age, and sex.

These findings suggest that individual variation in human NAc and AI function underlie individual differences in SNS activation during motivated behavior. These effects appear to be specific to anterior versus posterior insula, and specific to salience versus valence. Modulation of excessive SNS activity might be achievable by targeting NAc and AI function in humans.



Panel (A) shows electrodermal responses by condition for an individual subject. Panel (B) shows parasagittal and coronal sections of the regions of interest used in analysis, where purple is the nucleus accumbens, blue is the posterior insula, red is the anterior ventral insula, and green is the anterior dorsal insula.

Title: Individual differences in the effects of chronic nicotine on autoshaping learning

Authors: *L. A. ORTEGA MURILLO[1], M. LAMPREA[2], J. CIFUENTES[1], E. OCAMPO[1], L. GARCIA[1], C. NOVOA[2], J. SOLANO[2]
[1]Fundacion Universitaria Konrad Lorenz, Bogota, Colombia; [2]Univ. Nacional de Colombia, Bogota, Colombia

Abstract: Current research has focused on learning and motivational processes for nicotine that are proposed to be critical for the development and maintenance of tobacco addiction. In particular, nicotine administration has been associated with the enhancement of nonassociative incentive and reinforcing properties of naturally rewarding stimuli. In the present study, the role of chronic nicotine was assessed on the acquisition phase of an autoshaping task with a natural unconditioned stimulus (food pellets). Chronic nicotine (3.6 mg/kg/day; dose reported as free base), or vehicle, were administered using mini-osmotic pumps that were inserted subcutaneously under anesthesia. Parallel to previous literature, chronic nicotine transiently enhanced lever-pressing performance. However, such effects were primarily found for rats with higher levels of lever pressing responses. Chronic nicotine also modulated goal-tracking behavior, although following differential profiles for rats with high or low levels of lever pressing behavior. In addition, chronic nicotine resulted in differential response bias profiles between rats with high or low levels of lever pressing. Together, these findings suggests a differential effect of chronic nicotine on autoshaping acquisition depending upon individual differences in the levels of acquisition of the autoshaping task. Future studies on such individual differences may help understand to the mechanisms underlying the complex and varied incentive and reinforcing effects of nicotine on natural stimuli.

Title: Systemic and intracerebroventricular nicotine administration increases goal-tracking during Pavlovian conditioned approach paradigms in Long-Evans rats

Authors: *H. A. PEARSON, P. J. MEYER
Psychology, Univ. at Buffalo - The State Univ. of Ne, Buffalo, NY

Abstract: There is substantial individual variability in the response to reward-predictive stimuli ("cues"). For example, when a discrete cue (e.g. a lever) is presented during a Pavlovian conditioned approach (PavCA) paradigm, Sprague-Dawley rats will either approach the discrete cue ("sign-tracking") or the reward delivery location ("goal-tracking"), and sign- or goal-tracking phenotypes are associated with relapse to drug-seeking in the presence of discrete drug-cues or drug-paired contexts, respectively. Previously, nicotine has been shown to increase sign-tracking but not goal-tracking to a food cue in these Sprague-Dawley rats. However, because PavCA phenotypes are influenced by genetic structure (Fitzpatrick et al., 2013), the effect of nicotine on these phenotypes may be as well. In order to investigate this hypothesis, we administered a nicotine or saline injection to Long-Evans rats prior to testing in PavCA paradigms during which a lever predicted either a food or ethanol reward. In experiment 1, male (n = 16) and female (n = 16) Long-Evans rats were administered a nicotine (0.4 mg/kg S.C.) or saline injection 15 minutes prior to testing in a PavCA paradigm during which a lever predicted the delivery of a banana pellet (25 presentations per session for 11 sessions). In experiment 2, male, Long-Evans rats (n = 40) with or without prior chronic intermittent access to ethanol were administered a nicotine (0.4 mg/kg S.C.) or saline injection 15 minutes prior to testing in a PavCA paradigm during which a lever predicted the receipt of 0.2 ml ethanol (15% v/v; 12 presentations per session for 27 sessions). Finally, in experiment 3, in order to determine whether central administration of nicotine would affect goal-tracking similarly to systemic administration, male, Long-Evans rats (n = 15) were administered bilateral, intracerebroventricular injections of nicotine (8ug/ml; 1ul per side) or saline into the lateral ventricles directly prior testing in the PavCA paradigm described in experiment 1 (9 sessions). Surprisingly, nicotine-treated rats increased goal-tracking, but not sign-tracking, relative to saline-treated controls in all three experiments. Our findings indicate that nicotine enhances goal-directed behavior for both food and ethanol cues, and that this effect is centrally mediated. Therefore, nicotine can increase both sign- and goal- tracking, and this likely depends on genetic background. Thus, nicotine may be able to promote relapse differently among individuals and effective relapse prevention may require individualized treatments.

Title: Acid sensing ion channel-1a in pavlovian reward conditioning

Authors: *A. GHOBBEH[1], R. J. TAUGHER[1], R. FAN[1], R. T. LALUMIERE[2], J. A. WEMMIE[1]

Abstract: Pavlovian fear conditioning has been shown to depend on acid-sensing ion channel 1A (ASIC1A), however it is unknown whether conditioning to rewarding stimuli also depends on ASIC1A. Here we sought to test the hypothesis that ASIC1A contributes to Pavlovian conditioning to a non-drug reward by assessing several conditioning paradigms in which the relationship between the conditional stimulus (CS) and the unconditional stimulus (US) was varied. We found significant effects of ASIC1A disruption which depended on the paradigm. When the CS preceded the US, and signaled an upcoming food reward, *Asic1a*$^{-/-}$ mice exhibited striking deficits in conditioned responses compared to *Asic1a*$^{+/+}$ mice. Alternatively, when the CS was co-initiated with the US and signaled immediate reward availability, the *Asic1a*$^{-/-}$ mice exhibited an increase in conditioned responses compared to *Asic1a*$^{+/+}$ mice, which contrasted sharply with the deficits in the first experiment. The altered behaviors associated with ASIC1A disruption in these paradigms were likely due to differences in conditioning because neither the *Asic1a*$^{-/-}$ nor *Asic1a*$^{+/+}$ mice acquired conditioned responses when the CS and US were explicitly unpaired. Furthermore, the *Asic1a*$^{-/-}$ mice exhibited normal conditioned responding when the amount of overlap between the CS and US was altered. Taken together, these results suggest that ASIC1A plays a critical, yet complex role in Pavlovian reward conditioning. Moreover, these results suggest that the effects of ASIC1A disruption depend on the temporal relationship between the CS and US. More research will be needed to deconstruct the roles of ASIC1A in these fundamental forms of learning and memory.

Title: Transient activation of VTA afferent input from the parabrachial nucleus disengages reward seeking

Authors: *H.-J. YAU[1], J.-H. TSOU[2], F.-Y. GUO[1], A. BONCI[2]
[1]Natl. Taiwan Univ., Grad. Inst. of Brain and Mind Sci., Taipei, Taiwan; [2]NIDA/NIH, Baltimore, MD

Abstract: Animals rely on gustatory stimuli to differentiate preferred food for survival from the food that causes illness. Taste helps establish food preference or aversion by associating postingestional effects of food through classical conditioning process and the neural processing of taste aspect of food starts from the gustatory system. Accumulated studies have shown that the parabrachial nucleus (PBN) is an important interface between the taste system and the feeding system. Despite that the PBN sends projections to the ventral tegmental area (VTA), a heterogeneous brain region that plays a key role in processing reward or aversion-related stimuli, it is not clear whether the gustatory/visceral system interacts with the reward/aversion pathways to regulate food-seeking or -avoiding behaviors. The research aims to investigate the functional roles of an afferent input from the PBN to the VTA. Given that PBN is an important relay of gustatory pathway, we first combined excitatory optogenetic approach with an operant food self-administration paradigm to examine the behavioral roles of PBN-to-VTA connection. The histology results show that PBN sends substantial glutamatergic projections to the VTA. Surprisingly, we found that the optical activation of PBN-to-VTA glutamatergic inputs dampens food self-administration behaviors. In addition, we found activating PBN-to-VTA input drives aversion. We propose to investigate further the regulatory mechanism of PBN regulation onto VTA circuits and explore possible application of in controlling food cravings, which leads to eating disorders and obesity.

Title: Decoding neuroanatomy and behavioral roles of distinct subpopulations in the ventral tegmental area (VTA) to advance potential for selective treatment in substance use disorder, mood disorders and Parkinson´s disease

Authors: *Z. BIMPISIDIS, N. KÖNIG, B. VLCEK, Å. WALLÉN-MACKENZIE
Uppsala Univ., Uppsala, Sweden

Abstract: The VTA is involved in reward processing and related behaviors. Consequently, VTA dysfunction is correlated with neuropsychiatric disorders such as substance use disorder and depression as well as non-motor complications occurring after dopamine replacement therapy in Parkinson's Disease (PD). Common for VTA disorders is the lack of cure and severe side effects upon treatment. Traditionally considered mainly dopaminergic, the VTA has been exposed as a strongly heterogeneous brain area comprising of several subpopulations of dopaminergic, glutamatergic and GABAergic cells, as well as of co-releasing neurons. We propose that the neurocircuitry and functional role of distinct VTA subpopulations should be decoded in order to further understand VTA function and to achieve selective treatment of VTA disorders. We recently identified unique molecular markers that characterize distinct neuronal subpopulations within the VTA and have demonstrated that cells surviving in PD express one such specific molecular marker, the gastrin releasing peptide (GRP). We have also shown that the promoters of these markers can be experimentally exploited as drivers of Cre recombinase which is useful for circuitry- and functional analysis implementing mouse transgenics and optogenetics. To specifically target neuronal subpopulations in the VTA, we currently utilize transgenic mouse lines expressing Cre recombinase under the promotor activity of previously defined markers. Using fluorescent optogenetic constructs, we selectively tag these neurons to map their distribution within the VTA, characterize their neurotransmitter phenotypes and identify their target areas. Additionally, by behavioral optogenetics and conditional knockout strategies, we investigate the role of these cells in reward-related behaviors. So far, we have characterized two distinct subpopulations within the VTA (subVTA): subVTA1 and subVTA2, that both show distinct distribution within the VTA as well as specific projection patterns. Behavioral optogenetics show that stimulation of the subVTA2 subpopulation induces approach behavior while stimulation of the subVTA1 subpopulation has no observable behavioral effects. Eliminating the ability of subVTA1 and subVTA2 to release dopamine causes distinct behavioral responses to drugs of abuse and natural rewards. Our current findings add valuable insight in the heterogeneity and functional neuroanatomy of the VTA and provide knowledge that could potentiate the search for more selective therapeutic approaches in disorders where the VTA function is compromised, including substance use disorder, mood disorders and non-motor symptoms of PD

Title: Activation of GABA projection neurons from the ventral tegmental area to the nucleus accumbens enhances adaptive reward learning without affecting motivation in rats

Authors: *M. FEJA[1], K. T. WAKABAYASHI[1,2], M. P. K. LEIGH[1], K. A. HAUSKNECHT[2], R.-Y. SHEN[2], S. HAJ-DAHMANE[2], C. E. BASS[1,2]

Abstract: Mesolimbic dopamine projections from the ventral tegmental area (VTA) to the nucleus accumbens (NAc) are critical for cue-motivated responding. However, the VTA also contains GABA interneurons, and approximately one third of mesoaccumbal projecting neurons are GABAergic. Recently we used a novel combinatorial viral approach to target activating designer receptors exclusively activated by designer drugs (DREADDs) to VTA glutamate decarboxylase 1 (GAD1)-positive neurons in rats. We demonstrated that chemogenetic activation of VTA GABA neurons decreases motivation for reward-predictive cues. Yet activation of the dense VTA GABA projections to the NAc alone, by CNO microinfusion into the NAc, does not influence motivation for the cue. Thus, the role of mesoaccumbal GABA projections in reward-seeking processes remains unclear. In this study, we hypothesized that VTA GABA neurons projecting to the NAc are necessary for reward learning. We therefore examined the effects of VTA GABA activation under conditions of changing reward value, using a cue-dependent operant task in which the magnitude of an appetitive natural reward (i.e. sucrose) is unexpectedly altered within session. We then chemogenetically activated all VTA GABA neurons by giving the CNO systemically (0.3 mg/kg i.p.), or just the VTA GABA neuron terminals in the NAc by microinfusion of CNO. Our results show that systemic CNO, which simultaneously activates VTA GABA interneurons and GABAergic projection neurons, decreased cue responding uniformly across lower and higher than expected reward sizes. However, microinfusion of CNO into the NAc, which activates accumbal terminals of VTA GABA projection neurons, enhanced learning when the reward value was less than expected. CNO had no effect in GFP control rats. These results clearly establish that mesoaccumbal GABA neurotransmission causally contributes to reward learning independently from reward-seeking mediated by cue salience.

Title: Altered reinforcement learning dynamics in heterozygous DAT-Cre KI mice

Authors: *K. M. COSTA[1,2], J. ROEPER[1]
[1]Inst. for Neurophysiol., Goethe Univ., Frankfurt am Main, Germany; [2]Natl. Inst. for Drug Abuse, Baltimore, MD

Abstract: Transgenic mouse lines that express Cre-recombinase under the control of endogenous promoters are ubiquitous tools for the genetic manipulation of specific cell-types. However, the insertion of the Cre gene can result in aberrant gene expression and affect cell function independently of the experimental goal. This occurs in the DAT-IRES-Cre line, where Cre is expressed under the control of the dopamine transporter (DAT) gene to target midbrain dopamine neurons. Homozygotic animals of this DAT-Cre KI line have a 50% reduction in DAT protein levels in the striatum (Bäckman et al, 2006). In contrast, heterozygous DAT-Cre KI mice have only a non-significant reduction in DAT expression and thus are widely used, with the implicit assumption that they have no potential behavioral phenotype. However, we discovered that heterozygous DAT-Cre KI does affect behavior in a reinforcement learning task. DAT-cre KI (N = 20) and WT littermate (N= 17) water-restricted mice learned that an auditory cue signaled the availability of a sucrose water solution in a delivery port. Reinforced cues were presented in 10 trials in daily sessions for 11 days, after which animals underwent 6 daily extinction sessions. We found that DAT-cre KI mice showed a higher probability of responding to cues (≈12%), and shorter response latencies (≈15%) than WT controls already in the first acquisition session. Two-way ANOVA also showed significant interactions between the genotypes and the temporal progression of learning in both latency ($F_{10, 350} = 2.3$, $P < 0.05$) and response probability ($F_{10, 350} = 2.4$, $P < 0.01$). Furthermore, during extinction we observed a significant interaction between genotype and session progression for response latency ($F_{5, 175} = 2.8$, $P < 0.05$) and the time the mice spent in port during cue presentation ($F_{5, 175} = 3.18$, $P < 0.01$). We also tested these animals in open field exploration, novel object preference test, hole-board exploration and spontaneous alternation in the plus maze. These tasks are sensitive to effects in a variety of cognitive processes, including locomotor control, exploratory drive and working memory. Interestingly, we did not observe any difference between the genotypes in any of these tasks.Our results demonstrate that the DAT-cre KI alters the dynamics of reinforcement

learning, in particular by increasing responding during early acquisition. Importantly, as far as we have tested, only reinforcement learning was affected. Currently, we are investigating whether DAT-cre KI mice also respond differently to drugs of abuse.

Title: Influence of stress on decision-making behavior in mice

Authors: *R. G. WILLIAMS, S. SANDBERG, P. E. M. PHILLIPS
Neurosci., Univ. of Washington, Seattle, Seattle, WA

Abstract: We have previously shown that, in the core of the nucleus accumbens, corticotropin-releasing factor (CRF) increases evoked dopamine release and produces conditioned place preference in stress-naïve animals. However, following two-day, repeated forced swim stress (rFSS), neither of these effects are present. This work demonstrates an interaction between CRF and some aspect of reward processing, at the level of the nucleus accumbens, that is sensitive to stress. To ascertain the degree to which this mechanism influences integrated reward behavior and, specifically, reward-based decision making, we used an operant concurrent-choice task where male mice could choose between [concentrarion] sucrose solution or water delivery. Following initial training, α-helical CRF (9-41) [50ng/200nL] or vehicle (1% acetic acid in saline) was administered intracranially to the nucleus accumbens core, counterbalanced over two sessions (separated by one baseline session). Next, the animals underwent rFSS, were reintroduced to the task, and were retested with α-helical CRF (9-41) and vehicle. Prior to stress, mice exhibited a significant preference for sucrose over water ($P < 0.05$), made more total nose pokes into the sucrose receptacle than the water receptacle throughout the session ($P < 0.05$), and had shorter latencies for choosing sucrose on choice trials ($P < 0.05$), although latencies were equivalent between sucrose and water trials when only one option was available ($P > 0.05$). Following administration of α-helical CRF into the nucleus accumbens core, there was a trend towards decreased sucrose preference and number of head entries into the sucrose receptacle compared to vehicle administration. Moreover, there was a significant increase in latency to choose sucrose on choice trials following α-helical CRF ($P < 0.05$) administration. These data

suggest that, in stress-naïve animals, endogenous CRF signaling potentiate decisions for more palatable rewards. Following stress, there was a decrease in sucrose preference during baseline sessions ($P < 0.05$), but α-helical CRF no longer weakened the preference.

Title: Effect of blood pressure reduction on working memory performance in spontaneously hypertensive rats: Characteristics of response latency in the delayed-matching-to-place task

Authors: *T. SATO
Social Welfare, Nagano Univ., Ueda, Japan

Abstract: Spontaneously hypertensive rats (SHRs) were originally developed as an animal model for human hypertension. It is well known that SHRs have certain behavioral characteristics, such as increased locomotor activity; however, the locomotor activity declines with decreased blood pressure (BP) induced by intravenous administration of hypotensive drugs. This study aimed to determine the effects of BP reduction on memory function in SHRs. Our previous study revealed no differences in the number of correct responses, an index of performance accuracy in a delayed-matching-to-place (DMTP) task, between the SHR group and the Wistar-Kyoto (WKY) rat group (the normotensive control group). In this study, we further examined lever-pressing latency, an index of performance speed, in these two groups. We used the DMTP task to compare the latency to selective lever-pressing responses between 8 well-trained SHRs and 8 WKY rats. After pre-training, all rats were repeatedly tested in the DMTP task for four sessions. In each session, rats were intravenously administered hydralazine, a direct acting vasodilator, at one of the four different doses (0, 0.1, 0.3, and 0.6 mg/kg) in a randomized order. During the DMTP task, rats were reinforced with food when they made a matching response, such as pressing the same lever as the sample extended at the beginning of each trial, but a press on the other lever (an incorrect response) ended the trial without reinforcement. Each task session consisted of 100 trials. At the beginning of each trial, one lever was randomly selected as the sample lever and extended in the chamber. When a rat pressed the sample lever, the lever retracted, and the food-cup light in the rear wall illuminated. After the rat made a nose poke to the food cup twice, both levers were extended. Both levers retracted when one of them was pressed. To obtain a retention gradient, the time interval between the first nose-poke and the

end of delay interval, during which the nose-poke was not effective for the presentation of both levers, varied in five different time lengths (0, 2, 5, 10, and 20 s) in a randomized order. A three-factor analysis of variance indicated that the SHR group showed a significantly longer latency to choice responses than did the control group at different delay interval of retention and dosage of hydralazine, excluding when receiving the 0.6-mg/kg dosage. In conclusion, the results indicate that the SHRs take longer time to correctly respond (choice response latency) than do the WKY rats, although no differences were observed in the number of correct responses between these two groups. Notably, decreased BP does not improve working memory performance in SHRs.

Title: Amygdala and thalamic inputs to the nucleus accumbens similarly regulate feeding and reinforcement

Authors: *C. LAFFERTY[1], S. REED[2], J. MENDOZA[1], A. YANG[2], J. P. BRITT[1]
[1]Psychology, [2]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: Excitatory inputs to the nucleus accumbens (NAc) encode features of reward-associated cues and motivational state. The specific information encoded in amygdala and thalamic inputs is unclear, but recent studies suggest these pathways have opposing influences on behaviour. To better understand NAc information processing and input-specific function, here we compare manipulations of these two pathways on behaviours highly sensitive to NAc activity. We report that amygdala and thalamic input-specific manipulations in mice produce comparable changes in behaviour on a range of tasks. Photo-inhibition of either input increases free food consumption as well as effortful reward seeking, particularly during periods of cued reward unavailability. Activation of either input abruptly terminates consummatory behaviour, and both inputs robustly support intracranial self-stimulation. These data suggest that glutamatergic drive, irrespective of source, is a main determinant of NAc behavioural control. Disruptions in NAc glutamate input both motivate unproductive reward seeking and increase feeding.

Title: Elevated dorsal striatal brain response when satiated during delay discounting in women remitted from bulimia nervosa

Authors: *A. BISCHOFF-GRETHE, C. E. WIERENGA, U. F. BAILER, W. H. KAYE
UCSD, La Jolla, CA

Abstract: Introduction: Bulimia nervosa (BN) is characterized by cycles of binge-eating and compensatory (e.g., self-induced vomiting) behavior, as well as periods of dietary restraint, suggesting variable under- and over-control that may be homeostatic-state related. To examine the influence of hunger and satiety on impulsivity in BN, the current study examined limbic (habit-based) and cognitive (goal-based) frontostriatal circuitry during temporal discounting when fasted and fed.
Methods: We compared 25 remitted BN (RBN) to 23 demographically matched healthy comparison women (CW) performing a delay discounting task when hungry (after a 16 hour fast) and when satiated (after being fed 30% of daily caloric needs) using functional magnetic resonance imaging. To determine whether choice behavior differed between groups, a Group (RBN, CW) × Visit (Hungry, Satiated) × Percent Monetary Difference linear mixed effects (LME) analysis was computed in R. A similar LME examined reaction time. To model individual brain reward valuation response, a general linear model included only decision trials in which the early reward option was available immediately (i.e., “Today”). The beta regressors were then fit to a Group x Visit LME. Regions of interest included the bilateral dorsal caudate and ventral striatum.
Results: No significant group differences were found in choice behavior. While both groups responded more quickly when hungry than when fed ($p=0.004$), RBN responded more slowly overall relative to CW, $p=0.045$. There was a group x visit interaction in the bilateral dorsal caudate and left ventral striatum. In all three clusters, RBN exhibited a lower BOLD response than CW when hungry, and a greater response compared to CW when fed. CW also responded more robustly when hungry than when fed. In contrast, RBN had a higher BOLD response when fed than when hungry in the bilateral dorsal caudate but did not show significant BOLD response

differences based on hunger levels in the left ventral striatum.
Conclusion: CW used greater neural resources within the dorsal and ventral striatum when hungry than when fed, suggesting that immediate rewards were more appetitive in the hungry state, and that greater goal-directed processing was needed to for consideration of distal rewards. In contrast, RBN did not distinguish immediate rewards based upon homeostatic state in the ventral striatum and showed greater goal-directed processing when fed than when hungry. Similar to our prior findings with taste, our results suggest RBN may not sufficiently devalue immediate monetary rewards after eating, and that greater cognitive resources may be necessary to maintain control following a meal.

Title: Projections from the nucleus accumbens shell to the ventral pallidum are involved in the control of palatable food intake in adult female rats

Authors: *S. CHOMETTON[1], G. GUÈVREMONT[1], J. SEIGNEUR[2], E. TIMOFEEVA[1], I. V. TIMOFEEV[2]
[1]CRIUCPQ, Quebec, QC, Canada; [2]CERVO, Quebec, QC, Canada

Abstract: Introduction: Palatable food is very appealing and can be consumed even when there is no metabolic need. In our modern society, palatable food is ubiquitous and easily accessible, leading to eating disorders such as binge eating, which is more prevalent in women. In the brain, the nucleus accumbens shell (AcbSh) is part of the reward system and contains mostly inhibitory GABAergic neurons. Inhibition of this brain region in male rodents induces an increase in food intake, and activation via its projection to the lateral hypothalamus (LH) attenuates food intake. However, the main target of the AcbSh is the ventral pallidum (VP), and this structure is sensitive to the hedonic aspect of food. **Objectives**: In the present study, we examined the effects of direct stimulation of the AcbSh on sucrose intake in adult female rats, and the involvement of the VP in this response. **Methods**: The consumption of 10% sucrose and lick microstructure of adult female rats were analyzed following (1) direct stimulation of the AcbSh using optogenetics, (2) pharmacological inhibition of the VP, and (3) stimulation of projections from the AcbSh to

the VP using optogenetics. The expression of *c-fos* mRNA after stimulation of the AcbSh directly, and after stimulation of axonal terminals from the AcbSh to the VP were also studied. **Results**: Direct stimulation of the AcbSh results in a decrease in sucrose intake, meal duration, and total number of licks. In these rats, the expression of *c-fos* mRNA increased in the AcbSh and decreased in the LH and VP. Similarly, a decrease in sucrose intake, meal duration, and total number of licks, was observed upon inhibition of the VP with muscimol, and also upon stimulation of axonal terminals from the AcbSh to the VP. In this last experiment, the expression of *c-fos* mRNA increased in the AcbSh and decreased in the VP, but no variation was observed in the LH compared to the control group. **Conclusion**: This study shows that, not only stimulation of the AcbSh, but also stimulation of projections from the AcbSh to the VP, results in a reduction in sucrose intake in adult female rats. These projections play a role in the regulation of palatable food intake, regardless of the already known role of the AcbSh projections to the LH.

Title: Optogenetic stimulation of the orbitofrontal cortex enhances food 'liking' vs 'wanting'

Authors: *I. MORALES[1], K. C. BERRIDGE[2]
[1]Dept. of Psychology, [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Optogenetic stimulation of the orbitofrontal cortex enhances food 'liking' to palatable tastes
Research in our lab has identified a number of cortical and subcortical hedonic hotspots that generate increases in hedonic impact or ‘liking’ for a sensory pleasure in brain limbic structures. These pleasure generators are small subregions (1 to 10 mm^3) in insula and orbitofrontal cortex, as well as subcortical nucleus accumbens and ventral pallidum (VP) where pharmacological microinjections of mu-opioid or orexin receptor agonists enhance by 200-300% hedonic ‘liking’ facial expressions elicited by sucrose. Here we more directly study neuronal causation of liking reactions by controlling activity of neurons in the hedonic ‘hotspot’ located in anterior-medial orbitofrontal cortex (OFC). We infected neurons with either channelrhodopsin (ChR2) or an

inactive control virus into the OFC and recorded affective orofacial reactions elicited by oral infusions of sucrose, quinine, or water. Rats were also tested on food intake (palatable and regular chow), self-stimulation, and conditioned taste aversion discrimination tasks. Our results so far suggest that optogenetic stimulation of the OFC site dependently increases 'liking' reactions to sucrose solutions without affective negative reactions to bitter quinine or neutral water. Similar hedonic enhancements have not been observed in our control virus animals. Our tests so far suggest the newly identified hedonic hotspots in cortical brain structures may amplify 'liking' of taste sensation via neuronal activation in these regions.

Title: Optogenetic stimulation of the paraventricular nucleus reduces motivation to self-administer sucrose

Authors: *C. MITCHELL[1], J. YEOH[1], C. ADAMS[1], E. CAMPBELL[2], J. BAINS[3], G. MCNALLY[4], B. GRAHAM[1], C. DAYAS[1]

Abstract: Corticotrophin-releasing factor (CRF) neurons of the hypothalamic paraventricular nucleus (PVN) are the principal mediators of the neuroendocrine stress response. Interestingly, recent work has shown that acute PVN CRF cell activation evokes a complex repertoire of behavioural responses that occur independent of the neuroendocrine axis. These behavioural effects appear to be mediated through the lateral hypothalamus (LH) - a central site responsible for orchestrating motivated behaviour. Here, we asked whether repeated optogenetic stimulation of PVN CRF cells could evoke a long lasting impact on behaviour reflective of a change in motivated state. To achieve this aim, male and female *CRF-Cre* mice (n=19) received stereotaxic injections of AAV5-DIO-ChR2-EYFP or EYFP control virus into the PVN followed by a unilateral fibre optic probe positioned just dorsal to the viral injection site. Mice were then trained to self-administer 10% sucrose from a FR1, FR3 and then a progressive ratio (PR) schedule of reinforcement. All mice then received optogenetic stimulation (473nm, 10Hz, 10ms pulse width, 15mW, 30s on, 30s off) for 1 hour daily for 5 consecutive days. After two days rest

mice were re-tested for motivated responding under PR conditions. Compared to controls, CRF-ChR2 animals displayed a significant decrease in PR responding for sucrose (p=0.004). One week later a subgroup of sucrose trained animals (n=8) received the same optogenetic stimulation as above and two hours later were then processed for Fos immunohistochemistry. This approach revealed a significant increase in Fos-positive cells within the PVN (p=0.0342) and the LH (p=0.0308). Together these studies demonstrate that chronic optogenetic stimulation of PVN CRF cells can produce a change in motivated responding for sucrose and we identify the LH as a likely substrate for these effects.

Title: Activation of glucagone-like peptide-1 receptors reduces the motivation to consume sucrose pellets during skilled reach foraging via neurotransmission in nucleus accumbens shell

Authors: *J. VESTLUND[1], F. BERGQUIST[1], V. LICHERI[2], L. ADERMARK[2], E. JERLHAG[1]
[1]Dept. of Pharmacol., [2]Dept. of Psychiatry and Neurochemistry, Inst. of Neurosci. and Physiol., Gothenburg, Sweden

Abstract: The appetite-reducing gut-brain peptide glucagon-like peptide -1 (GLP-1) has in addition to food intake reduction been attributed to a variety of physiological functions including reward modulation. The findings that local infusion of GLP-1 analogues into the nucleus accumbens (NAc) shell, an area essential for motivation regulation, reduces the intake of high fat diet and cocaine self-administration lead us to speculate that activation of accumbal GLP-1 receptors (GLP-1R) reduces the motivation to work for reward. In order to further explore this hypothesis we evaluated the effect of GLP-1 analogues on skilled reach foraging in the Montoya staircase test. Electrophysiological field potential recordings and whole cell recordings were performed in the NAc ex vivo to further link behavioural performance with neurophysiological responses. We found that in rats with acquired skilled reach performance the GLP-1 analogues exendin-4 (Ex4) and liraglutide, but not dulaglutide, reduced the consumption of sucrose pellets compared with vehicle. Furthermore local bilateral infusion of Ex4 into NAc reduced the

consumption of sucrose pellets in rats with acquired skilled reach performance. Supporting our behavioural data, ex vivo electrophysiology revealed a suppression of evoked field potentials following administration of Ex4 and liraglutide, while dulaglutide did not affect accumbal neurotransmission. In addition, whole cell recordings showed no effect by Ex4 on the frequency or amplitude on inhibitory inputs, indicating that the effect is primarily mediated via modulation of glutamatergic neurotransmission. Furthermore previous studies report that GLP-1 analogues enhance learning, we investigated if GLP-1 analogues administered throughout the entire training period would increase skilled reach foraging in the Montoya staircase test designed to reflect consumption driven by learning. In this design, Ex4 and dulaglutide, but not liraglutide, increased the consumption of sucrose as well as the success rate compared with vehicle. This suggest that activation of GLP-1R enhances learning of motivated behaviours in this context. Collectively these data suggest that activation of accumbal GLP-1R reduces the motivation to work for a sucrose reward in rats with acquired skilled reach performance. Given that motivation is intimately associated with addiction we speculate that accumbal GLP-1R signalling may be an important regulator throughout the addiction processes, not only in regards to food but also with respect to drugs of abuse.

Title: Mapping behaviors elicited by optogenetic stimulation of lateral hypothalamic and lateral preoptic subregions

Authors: *K. URSTADT[1], N. KAPILA[2], E. KOKOSZKA[2], K. C. BERRIDGE[3]
[1]Dept. of Cognitive Sci., Occidental Col., Los Angeles, CA; [2]Neurosci., [3]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Electrical stimulation of the lateral hypothalamus (LH) and lateral preoptic area (LPO) in rats is known to elicit a variety of behaviors including eating, drinking, self-stimulation, and general locomotion. However, two issues with electric stimulation are the recruitment of both cell bodies and fibers of passage near the electrode and that the neural volume recruited is

unclear. We build upon this research foundation by probing various LPO and LH subregions with optogenetic excitation in conjunction with assays measuring food intake, self stimulation, and general behaviors, followed by immunohistochemical measures of immediate early gene (IEG) "plumes" that reflect stimulated neural volumes. Laser stimulation (1-3 mW/mm^2) of LH subregions elicited intense eating in some subjects and intense self-stimulation in others, whereas LPO stimulation did not produce changes in these behaviors. IEG plume mapping of functional effects revealed that, along the rostrocaudal axis, the middle LH region is associated with eating and the posterior LH region is associated with self-stimulation. Increasing laser intensity can convert these behaviors into escape responses in middle and posterior LH subjects, and can increase locomotion in dorsal LH subjects. These data collectively provide a new LH map of behaviors with defined regions of activation in stereotaxic space.

Title: Optogenetic excitation of limbic corticotropin releasing factor neurons modulates motivation

Authors: *H. M. BAUMGARTNER[1], J. SCHULKIN[2], K. C. BERRIDGE[1]
[1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Neurosci., Georgetown Univ., Washington, D.C., DC

Abstract: Corticotropin releasing factor (CRF) is known as the brain's master stress molecule, but also plays a role in reward seeking. Previous pilot work from our lab suggested that optogenetic stimulation of CRF neurons in either nucleus accumbens (NAc) or central nucleus of amygdala (CeA) of CRH-Cre rats supported laser self-stimulation. Here we show that optogenetic CRF neuron stimulation can also amplify incentive motivation to earn and consume natural sucrose rewards, and narrowly focus intense motivation specifically on the particular sucrose-earning option that has been associatively paired with CRF laser stimulation. In a two-choice sucrose experiment, stimulation of CRF neurons in either CeA or NAc biased rats to specifically earn and consume laser-paired sucrose, while ignoring an alternative option to earn identical sucrose pellets delivered without laser. Additionally, CRF stimulation in NAc or CeA

enhanced motivation breakpoint or effort to work for sucrose in a progressive ratio task. By contrast, we found that stimulation of CRF neurons in bed nucleus of stria terminalis (BNST) caused rats to avoid the laser-paired sucrose option and instead choose the alternative sucrose-alone option, and suppressed motivation to work for sucrose rewards in a progressive ratio task. Together, these data suggest that stimulation of NAc or CeA CRF neurons can focus and enhance incentive motivation for natural rewards, whereas BNST CRF stimulation may suppress incentive motivation or have aversive effects.

Title: Medial preoptic circuit induces hunting-like actions to target objects and prey

Authors: *Y. JEONG, S.-G. PARK, D. KIM
Dept. of Biol. Sci., KAIST, Daejeon, Korea, Republic of

Abstract: As animals forage, they must obtain useful targets by orchestrating appropriate actions that range from searching to chasing, biting and carrying. Here, we reveal that neurons positive for the α subunit of Ca2+/calmodulin-dependent kinase II (CaMKIIα) in the medial preoptic area (MPA) that send projections to the ventral periaqueductal gray (vPAG) mediate these target-directed actions in mice. During photostimulation of the MPA-vPAG circuit, mice vigorously engaged with 3D objects and chased moving objects. When exposed to a cricket, they hunted down the prey and bit it to kill. Our study explains how the brain yields a strong motivation to acquire a target object along the continuum of hunting behavior.

Title: Chemogenetic stimulation of posterior ventral tegmental area-nucleus accumbens shell circuitry prolongs novelty response in rats

Authors: *J. M. ILLENBERGER, H. LI, M. N. CRANSTON, C. F. MACTUTUS, K. A. MCLAURIN, R. M. BOOZE
Dept. of Psychology, Univ. of South Carolina, Columbia, SC

Abstract: Dopamine release to the nucleus accumbens from neurons of the ventral tegmental area (VTA) is critical for orientation and response to novel stimuli. It is unclear which specific cell populations modulate responses to novelty, as there is considerable heterogeneity between cells of the anterior and posterior VTA. The current experiment used a retroDREADDs technique to stimulate neurons of the VTA which project to the nucleus accumbens shell (AcbSh) prior to testing under habituated or novel conditions. AAV-CMV-GFP/Cre was injected into the AcbSh and AAV-hSyn-DIO-hM3D(Gq)-mCherry (a presynaptic enhancer in the presence of its cognate ligand clozapine-N-oxide (CNO)) was injected into the VTA of Fisher 344/N rats to trigger human M3 muscarinic (hM3D(Gq)) receptor production specifically in neurons of the VTA projecting to the AcbSh. Following three days of habituation, animals that received viral infusions (n=10) and animals that received sham surgeries (n=2) were administered 1 mg/kg intraperitoneal saline (1 day) or CNO (4 days) and then repeatedly tested in locomotor activity chambers for 1 hour until well-habituated. To test the locomotor response to novelty without impeding the animals' ability to move freely, the white background noise present throughout habituated conditions was discontinued for a 10-minute period at the 30-minute timepoint during the 1-hour test session. Saline (1 day) or CNO (4 days) was administered again prior to testing under novel conditions to determine if stimulating hM3D(Gq) receptors increased the locomotor response. Stimulating hM3D(Gq) receptors in the VTA enhanced the locomotor response to novelty (e.g. removal of white background noise) without altering activity under habituated conditions or ability to detect a gap in white noise ($p \leq 0.04$). Confocal imaging confirmed hM3D(Gq)-mCherry production in the posterior limb of the VTA (pVTA). The current results support evidence of anterior-posterior heterogeneity in cells of the VTA and identify the pVTA-AcbSh as a circuit likely involved in the etiology of psychopathy in which responses to novel stimuli may be diminished, such as depression or drug addiction.

Title: Low frequency stimulation has a bidirectional effect on plasticity in periaqueductal gray and rostromedial tegmental nucleus GABAergic synapses in the ventral tegmental area

Authors: *R. ST. LAURENT[1], J. A. KAUER[2]
[1]Neurosci. Grad. Program, [2]Departments of Mol. Pharmacology, Physiology, and Biotech. & Neurosci., Brown Univ., Providence, RI

Abstract: Persistent opioid-induced changes in components of the reward pathway, such as the dopamine-rich ventral tegmental area (VTA), may precede the transition to addiction. Spontaneous activity of dopamine cells in the VTA is tightly regulated by inhibitory inputs. Opioids depress inhibitory synapses on VTA dopamine cells, increasing their excitability, and morphine exposure can affect plasticity at these synapses. However, the VTA is a heterogeneous region with different subsets of neurons having distinct functional effects on behavior, and therefore, opioid-induced adaptations may also depend on the precise circuit involved. Here, we use optogenetic strategies to investigate the plastic properties, sensitivity to opioids, and relevance to behaviors associated with reward and aversion of two different presynaptic GABAergic afferents to the VTA. The periaqueductal gray (PAG) and the rostromedial tegmental nucleus (RMTg) both have dense expression of mu opioid receptors. Like the PAG, the RMTg seems to be a key region activated by aversive stimuli (Jhou et al, Neuron 2009 61:5). $RMTg_{GABA}$ to VTA synapses are strongly depressed by opioids and influence VTA firing rates. In contrast, the opioid sensitivity of PAG GABAergic inputs to the VTA and their behavioral relevance has not yet been explored. We first compared synaptic plasticity and opioid-sensitivity of PAG_{GABA} to VTA and $RMTg_{GABA}$ to VTA synapses *in vitro*. In acute midbrain slices we performed whole-cell recordings from VTA dopamine cells and measured optically-evoked inhibitory postsynaptic currents (oIPSCs). We discovered that low frequency stimulation, 1 Hz for 6 minutes, had opposite effects on these populations: PAG oIPSCs potentiated (134±13% of baseline, $p<0.05$, $n = 17$) whereas RMTg oIPSCs depressed (79.6±7.3% of baseline, $p<0.05$, $n = 15$). Furthermore, both PAG and RMTg oIPSCs were strongly depressed by bath application of 1 μM DAMGO, a mu opioid receptor agonist (PAG: 22.9±11.2% of baseline, $p<0.05$, $n = 6$; RMTg: 32.2±6.5% of baseline, $p<0.05$, $n = 5$), with PAG oIPSCs trending towards stronger

depression. In conclusion, we are the first to report that 1) low frequency stimulation induces long-term potentiation at PAG_{GABA} to VTA synapses and conversely long-term depression at $RMTg_{GABA}$ to VTA synapses, and 2) opioids profoundly depress PAG_{GABA} to VTA synapses. Future experiments will measure the behavioral output of activating PAG_{GABA} to VTA or $RMTg_{GABA}$ to VTA synapses *in vivo* using a real-time place preference procedure.

Title: Activation of a hypothalamic-ventral tegmental circuit gates motivation

Authors: *J. N. SIEMIAN, F. L. SCHIFFINO, M. PETRELLA, J. E. SLOCOMB, S. SARSFIELD, M. L. ZUCCOLI, M. SLOMP, Y. APONTE
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Across species, motivated states such as food seeking and consumption are essential for survival. Optimal performance of these behaviors is mediated by neuronal circuits that modulate energy balance and feeding. The lateral hypothalamus (LH) has been known for decades to play a fundamental role in regulating feeding and reward-related behaviors. However, the contribution of the diverse neuronal populations in the LH have not been thoroughly identified. Here we examine how lateral hypothalamic leptin receptor-expressing (LH^{LEPR}) neurons, a subset of GABAergic cell types in the LH, regulate motivation to obtain food as measured by responding on a progressive ratio (PR) schedule of reinforcement, a widely-used behavioral task to assess motivation. We found that chemogenetic activation of LH^{LEPR} neurons significantly increased PR performance, while inhibition of these neurons decreased PR behavioral responses. We then mapped LH^{LEPR} axonal projections and demonstrated that these neurons target the ventral tegmental area (VTA). Moreover, Channelrhodopsin (ChR2)-assisted circuit mapping (CRACM) revealed that LH^{LEPR} neurons form functional inhibitory synapses with non-dopaminergic neurons in the VTA. Furthermore, activation of these projections promotes motivation for food reward. Finally, we found that neurons expressing agouti-related peptide (AGRP) in the arcuate nucleus of the hypothalamus (ARC^{AGRP}) likely act as upstream inputs to the LH^{LEPR}-VTA pathway as activation of ARC^{AGRP}-LH projections also strengthens PR performance. Together, these results identify LH^{LEPR} neurons as a new integrator of the hypothalamic-ventral tegmental circuitry that gates motivation.

Title: Exploring the neural mechanism by which optogenetic stimulation of ventral tegmental area dopamine neurons prevents extinction of cued approach behavior

Authors: *C. M. REYES[1], S. M. NICOLA[2]
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Dept. Neurosci., Albert Einstein Coll Med., Bronx, NY

Abstract: The nucleus accumbens (NAc) and its dopaminergic (DA) innervation from the ventral tegmental area (VTA) are involved in promoting reward-seeking behavior as well as strengthening cue-reward associations. Many NAc neurons exhibit cue-evoked excitations that are required for approach behavior elicited by a reward predictive cue. Additionally, a large body of literature suggests that DA neurons encode reward prediction errors (RPE), which serve to update the current state and alter the strength of cue-reward associations depending on the valence of the RPE. While RPEs presumably lead to changes in response probability, the downstream neural mechanisms from the VTA to NAc mediating this behavior remain unknown. We hypothesized that DA neuronal activity at the predicted time of reward delivery is sufficient to reinforce cued approach behavior by maintaining the magnitude of cue-evoked excitation of NAc neurons on subsequent trials, blocking the transference of a negative RPE. To test this hypothesis we recorded from neurons in the NAc of *Th::Cre* rats expressing channelrhodopsin (ChR2) or eYFP only in VTA DA neurons. Animals were trained on a conditioned stimulus (CS) task in which two distinct auditory tones were presented. One tone predicted availability of a liquid sucrose reward while the other was a non-rewarded. After training, rats were subjected to an *omission* session followed by an *omission + stimulation* session. During *omission* sessions there was a 30 min baseline in the CS task followed by omission of the reward. *Omission + stimulation* sessions introduced a 20 Hz, 1s photostimulation at the predicted time of reward. We found that the decline in behavioral responding during *omission* was prevented by photostimulation in ChR2 but not eYFP rats. Recording from NAc neurons during *omission +*

stimulation sessions revealed short latency firing of NAc neurons during stimulation. This was not seen in recordings of eYFP only animals. In addition, the reduction in cue-evoked excitations during omission was attenuated by stimulation at the time of predicted reward. These results suggest a mechanism by which VTA DA neuronal firing influences subsequent cue-evoked excitations and thus the probability of behavioral response to the cue. Stimulation of VTA DA neurons prevents the extinction of approach behavior and our results suggest that this effect is due to a reduction in the decline in cue-evoked excitations that drive the approach response. Further experiments are underway to investigate if short latency firing is required for the maintenance of approach behavior.

Title: Effort-related choice behavior is regulated by cholinergic signaling in the ventral tegmental area

Authors: *J. L. HAIGHT, E. J. NUNES, D. J. RATHI, N. A. ADDY
Psychiatry, Yale Univ., New Haven, CT

Abstract: Motivation to work for and obtain rewards in the environment is critically important for an individual's survival, and a lack of motivation (anhedonia) is considered a core component of the pathology of major depressive disorder. The choice to expend effort to pursue preferred rewards over other less preferred, but more easily available options is regulated by dopamine signaling in the nucleus accumbens (NAc). While the role of NAc dopamine signaling in motivational behaviors has been identified, our understanding of the regulation of the source of this signal, the dopamine cell bodies in the ventral tegmental area (VTA), is limited. It has been hypothesized that cholinergic tone in the VTA is a critical mediator of dopamine neuronal activity, and thus motivational activation. Recently, our lab and others have shown that cholinergic signaling in the VTA regulates downstream dopamine release in the NAc. In addition, our lab has demonstrated that cholinergic signaling in the VTA can regulate the ability of sucrose- and cocaine-paired cues to drive reward-seeking behaviors which are dependent on NAc dopamine signaling. Here, we examine the role of cholinergic signaling in the VTA in an effort-based decision making task. In this task, subjects have a choice between performing an operant response for a preferred food (lever presses for 45mg sucrose pellets) on a fixed-ratio 5

schedule, or consuming freely available but less-preferred rat chow. Previous work has demonstrated that the willingness to work for sucrose pellets in this task is dependent on dopamine transmission in the NAc, and blocking dopamine transmission in the NAc results in a reduced willingness to work. In this study, we assessed the effort-related choice effects of increasing cholinergic tone through systemic or VTA-specific administration of the acetylcholinesterase inhibitor, physostigmine. We found that systemic administration of physostigmine (0.125 mg/kg) resulted in a ≥25% reduction of lever responding in male and female rats, with no effect on chow consumption. Preliminary data also indicates that bilateral physostigmine infusion (2 ug per side) directly into the VTA had similar effects to systemic administration in male rats, reducing lever contacts while leaving chow consumption intact. These results show that cholinergic signaling, potentially in the VTA, regulates the motivation to work for a desirable reward. Further studies are currently underway to assess whether this motivational control is due to cholinergic signaling at specific nicotinic or muscarinic receptors in the VTA.

Title: Role of reward expectation on dopaminergic signals and medium spiny neurons in the dorsal striatum

Authors: *C. H. DONAHUE[1], J. A. NADEL[2], A. C. KREITZER[3]
[1]Neurosci., The Gladstone Inst., San Francisco, CA; [2]Oberlin Col., Oberlin, OH; [3]Gladstone Inst. of Neurolog. Dis., San Francisco, CA

Abstract: Dopamine is thought to play a central role in motivated behavior through its influence on striatal circuits, but how this occurs is still unclear. To investigate this, we trained mice to perform two complementary tasks where we systematically manipulated the amount of effort required to obtain reward. In a fixed-ratio task, animals were required to complete 1, 3, or 5 nose poke sequences to receive a reward. The number of required nose pokes was fixed in blocks of 40 trials to encourage the animals to build an expectation of the amount of effort required in each trial. The same mice were also trained on a variable ratio task, where an average of either 1, 3, or

5 nose poke sequences was required in each block, but the precise number could not be predicted on any given trial. The animals gradually became faster as they progressed through a nose poke sequence only in the fixed ratio task, suggesting that knowledge about their proximity to upcoming reward invigorated their movements.
We expressed a genetically-encoded calcium indicator (gCaMP6f) in the dorsal striatum and imaged single cell activity of direct- and indirect-pathway medium spiny neurons (dMSNs and iMSNs) with a head-mounted microscope as animals performed each task. In the fixed ratio task, both dMSNs and iMSNs were significantly more active when animals executed nose pokes early in the sequence when they were furthest from reward, and their responses progressively decreased as they got closer to reward**.** This effect was significantly more pronounced in the iMSN population. In the variable ratio task, where the number of required movements could not be predicted, activity did not modulate throughout the nose poke sequence, suggesting that knowledge about proximity to reward drove these responses. Next, we used fiber photometry to image dopaminergic projections to the dorsal striatum and found the opposite relationship: the magnitude of phasic responses associated with each movement progressively increased as the animals got closer to reward, and this occurred only in the fixed ratio task. Together, these results suggest that reward expectation modulates movement-related dopaminergic signals in the dorsal striatum, which could play a potential role in modulating ongoing striatal activity.

Title: Pramipexole enhances disadvantageous probabilisticdecision-making via D_3, but not D_2, dopamine receptors

Authors: *R. CADEDDU, M. ORRU´, H. STRATHMAN, M. BORTOLATO
Univ. of Utah, Salt Lake City, UT

Abstract: Pramipexole (PPX) is a D_2 and D_3 dopamine receptor agonist, used in the treatment of Parkinson's disease (PD) and restless leg syndrome. PPX increases the risk of problem gambling and impulse-control disorders in vulnerable patients; the neurochemical bases of this effect, however, remain unclear. To study the effects of PPX on risky probabilistic decision-making, we recently designed a probability-discounting task to capture the effects of this drug in response to disadvantageous options. We found that PPX (0.3 mg/kg/day, SC) led to mild probability-discounting deficits, which were significantly exacerbated by a concurrent treatment with the monoamine-depleting agent reserpine (RES; 1 mg/kg/day, SC), at low doses that did not affect

baseline locomotor and operant responses. Building on this evidence, in this study we aimed at assessing the neurochemical mechanisms that facilitate and mediate the behavioral effects of PPX. First, we found that the same regimen of RES that facilitated the effects of PPX increased the binding of D_3, but not D_2 dopamine receptors, in the nucleus accumbens. Then, we verified that the effects of PPX were not affected by concurrent treatment with the highly selective D_2 dopamine receptor antagonist L,741-626 (0.1-1 mg/kg, IP); but they were partially reduced by the highly selective D_3 dopamine receptor antagonist SB277011-A (1-10 mg/kg, IP), at doses that did not significantly increase omissions (3 mg/kg, IP). Finally, we documented that the association of RES and PPX did not increase the proclivity to cross a suspended bridge, suggesting that the effects of RES and PPX on probability discounting do not reflect a generalized increase in risk taking.

Title: MPA-induced drive-assisted steering (MIDAS) system for behavior experiment

Authors: *D.-G. KIM[1], Y.-C. JEONG[1], S.-G. PARK[1], P.-S. LEE[2], D. KIM[1]
[1]Biol. Sci., [2]Mechanical Engin., KAIST, Taejon-City, Korea, Republic of

Abstract: We devised the MPA-induced drive-assisted steering (MIDAS) system, in which a head-mounted bait object swings (servo-motor) within the visual field and CaMKIIα+ MPA-vPAG photostimulation (LED) is remotely induced the hunting-like behavior. This closed-loop system can detect the mouse head positions and angles in real time through the CMOS camera and control the movement of mouse using head-mounted device by navigation algorithm. Using the system, we successfully guided mice to navigate specified routes in our 3D maze. Considering that the mice were able to pass through the various obstacles using appropriate behaviors under MIDAS control, we suggest that the MIDAS system could prove useful in behavioral experiments and other application.

Title: Single cell transcriptomic profiling reveals distinct subtypes of serotonergic neurons in the mouse dorsal raphe nucleus

Authors: *K. HUANG[1], N. E. OCHANDARENA[1], A. C. PHILSON[1], M. HYUN[2], B. L. SABATINI[3]

Abstract: The dorsal raphe nucleus (DRN) is an important source of neuromodulatory inputs that innervates a wide range of forebrain regions to regulate many physiological and behavioral processes. While most studied as a major source of serotonergic (5-HT) inputs, DRN neurons exhibit a large degree of heterogeneity at the anatomical and molecular level. Although this heterogeneity likely accounts for the DRN's diverse functions, efforts to establish clear relationships between the molecular identity and function of DRN cell types have been impeded by the lack of a well-annotated map between their molecular and anatomical features. In this study, we used high-throughput single cell RNA sequencing (scRNA-Seq) and profiled approximately 50,000 cells from the mouse DRN and surrounding ventrolateral periaqueductal gray. Through this unbiased survey of DRN cell types, we have identified several neuronal cell types and at least four distinct subtypes of 5-HT neurons. Using multiplexed fluorescence *in situ* hybridization, we have mapped these 5-HT neuron subtypes to different spatial domains within the DRN. Analysis of differentially expressed genes between DRN 5-HT neuron subtypes suggests that they co-release different neurotransmitters and peptides, potentially exerting distinct and competing effects both locally and on downstream circuits. Additionally, retrograde tracing studies have found that DRN neurons innervating functionally distinct target regions are also spatially segregated. By combining viral retrograde genetic tagging with both scRNA-Seq and fluorescence *in situ* hybridization, we are mapping 5-HT neuron subtypes defined by their spatial location and anatomical projection to their molecular profiles. Based on our findings, we

are also exploring intersectional and spatially resolved approaches towards investigating functional differences between 5-HT neuron subtypes.

Title: Glutamate and GABA neurons of the ventral pallidum: Opponent roles in motivated behavior

Authors: *L. FAGET, V. ZELL, E. SOUTER, A. MCPHERSON, R. RESSLER, D. DULCIS, T. S. HNASKO
UCSD, LA Jolla, CA

Abstract: The ventral pallidum (VP) is a structure central to reward pathways and the control of motivated behaviors. The VP is predominantly GABAergic but is neurochemically heterogeneous containing various distinct cell types including cells expressing the glutamatergic marker vesicular glutamate transporter (VGLUT2). Using reporter lines we find that VP glutamate neurons are concentrated in the rostro-central ventro-medial VP and are mostly distinct from other VP cell types - rarely coexpressing GABAergic and cholinergic markers. Using cell-type-specific tracing approaches we find that VP glutamate and GABA neurons share similar projection targets, distinct from those made by cholinergic neurons in VP. Using optogenetic manipulation, we observe that activation of VP GABA cell bodies elicit behaviors indicative of positive reinforcement and enhanced appetitive drive mainly through projections to VTA, while their inhibition produces avoidance behaviors. On the other hand, activation of VP glutamate neurons led to behavioral avoidance, particularly via their projections to the LHb. These findings highlight a potent role for bidirectional control of motivated behaviors by VP inhibitory and excitatory neurons, dysregulation of which could contribute to the emergence of deficits in reward functions associated with drug addiction and other neuropsychiatric disease.

Title: The anterior caudate nucleus supports impulsive choices triggered by pramipexole

Authors: *L. TREMBLAY[1], E. MARTINEZ[2], B. PASQUEREAU[3], Y. SAGA[4], V. SGAMBATO-FAURE[5]
[1]CNRS UMR-5229, Bron, France; [2]Univ. of Lyon 1, Lyon, France; [3]CNRS, Lyon, France; [4]Ctr. de Neurosci. Cognitive, Bron Cedex, France; [5]Neurosci. Cognitive Ctr. - CNRS UMR 5229, BRON, France

Abstract: Excessive impulsive behaviors are associated with various psychiatric and neurological disorders. In Parkinson's disease, Pramipexole (PPX, D2/D3 agonist) is known to reduce motor symptoms but often leads to impulse control disorders. Three well-categorized types of impulsive behaviors are described: action impulsivity, choice impulsivity and waiting impulsivity (Dalley and Robbins, 2017). Based primarily on the heterogeneity of cortico-striatal projections and the fact that the striatum is massively innervated by dopamine (DA) inputs, we hypothesize that those impulsive behaviors triggered by DA treatments may be supported by distinct striatal territories. The Caudate nucleus (CdN), dedicated to decision-making processes, could be related to the emergence of impulsive choices. The Putamen (Put) that is involved in motor processes could be related to action impulsivity. And, the Ventral Striatum (VS), well known to be involved in motivation and outcome expectation could be related to waiting impulsivity. Here, we compared systemic (0.1 mg/kg) and local (6µl) injections of PPX in monkeys trained to execute a delay discounting task. This behavioral paradigm allows detecting impulsive choices by measuring the tendency to choose small immediate rewards over large delayed ones. Local microinjections were alternatively performed inside the three striatal territories to determine the selective contribution of those subregions in DA-induced impulsive behaviors. First, we found that systemic injections of PPX induced impulsive choices in three monkeys by increasing their temporal discounting factors. Then, we reproduced those impulsive behaviors when PPX was directly injected into the CdN, while injections into the VS or the Put had no effect on monkeys' choices.
Together, our results confirm the involvement of the CdN in decisional processes and highlight the importance of this striatal sub-region in impulsive choices. These results are consistent with

clinical studies using PPX and allow us to emphasize the importance of dopamine modulation inside the Caudate nucleus in the neurobiological processes of impulsive behaviors.

Title: Separate neural mechanisms underlie mean reward and reward variance in risky decision making

Authors: *S. SUN[1], R. YU[2]
[1]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Psychology, Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Value-based choices are influenced both by potential gains and by the risk of potential gains or losses. How our brain represents expected value and potential risks, integrates such information, and leads to a decision is largely unexplored. Using an incentivized reaction time task in which mean reward and reward variance were parametrically manipulated and orthogonalized, we found that participants respond faster with increasing mean reward and reward variance. Besides, the faster reaction time is indicated by smaller pupil size and more gaze transitions between two rewards, suggesting more alertness, motivation, and efforts are involved in higher reward anticipation. Neuronally, the striatum encodes mean reward, whereas insula encodes reward variance with different neural circuits to integrate both motivational (e.g. amygdala and vmPFC, respectively) and cognitive (e.g. SFG and dACC, respectively) information. With a computational modeling, we further suggested that the putamen is involved in subjective (vs. objective) risk preference by integrating both expected rewards and risks. Taken together, our findings suggested that both rewards and risk work as positive agents which initiate actions with an engagement of cortical-striatal, cortical-limbic and salience networks, and thus modulate subsequent behaviors. Our findings provide new insights into the neural process of decisions under uncertainty.

Title: GABAergic ventral pallidum neuron roles in risky decision making

Authors: *M. R. FARRELL, C. RUIZ, J. HEYER, S. MAHLER
Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Drug addiction is fundamentally a disorder of decision making, in which addicts choose drugs despite mounting negative consequences of their use. However, the neural circuitry underpinning this maladaptive decision making remains poorly characterized. The ventral pallidum (VP), which lies at an anatomical nexus of reward and aversion neural circuits, is ideally positioned for influencing action selection during decisions made under motivational conflict. VP is highly heterogenous, with diverse neuronal subtypes that contribute differently to motivated behavior. For example, VP GABA neurons promote approach and reward seeking, while glutamate neurons instead mediate aversion and avoidance (Faget et al., 2018, *Nat. Commun.*; Tooley et al., 2018, *Biol. Psychiatry*). Interestingly, both populations of VP neurons innervate both reward- and aversion-related brain regions (ventral tegmental area, lateral habenula), opening the possibility for both playing roles in reward as well as aversion. Therefore, we here asked how manipulating activity of VP GABA neurons modulates behavior when both opportunity for reward and potential for punishment are present. Employing a modified version of the risky decision task in rats (Simon et al., 2009, *Neuropsychopharmacology*), we ask whether inhibitory (hM4Di) or excitatory (hM3Dq) DREADD stimulation or inhibition of VP GABA neurons alters risky decision-making behavior. Mildly food-deprived GAD1-Cre rats with hM3/4D DREADDs expressed exclusively in VP GABA neurons were trained to choose between two levers: pressing one delivers a “small” food reward (1 pellet) while the other delivers a “large” food reward (2 pellets). Over the course of a 1 hr session, the large reward lever also delivered an increasingly probable co-delivered footshock, such that the risk of footshock increased as the session progressed (0% for 20 trials, 25%, 50%, 75%, 100%). The “small” food reward lever never delivered footshock and always delivered 1 pellet. In addition to examining effects of stimulating or inhibiting VP GABA neurons on risky decision making, we will also explore effects of manipulating VP GABA projections to reward (VTA) and aversion (LHb)-related output regions. Our results will elucidate roles for VP GABA neurons in

controlling reward-seeking behavior under threat of harm, as often occurs in drug abuse and addiction.

Title: Neural mechanism of valence control in the Brainstem

Authors: *W. SHIN, J. KIM
Ctr. for Neurosci., Korea Inst. of Sci. and Technol. (KIST), Seoul, Korea, Republic of

Abstract: Balancing emotion and motivation is an important process to make appropriate actions for survival. This function exists in all animals from lower vertebrates to higher primates. The brainstem, called as primitive brain, is evolutionary conserved and essential region for survival. However, its causal role for valence control are largely unknown, due to their dense and complex nuclei compartments and various cell types. Our goal is to unravel the neural circuits and novel cell types in the brainstem that participate in valence control. Here we are going to introduce and discuss a novel circuit recently discovered using optogenetics, imaging and circuit specific cell characterization.

Title: Chemogenetic inhibition of neurons in the paraventricular thalamus that project to the nucleus accumbens has no effect on the expression of morphine conditional place preference

Authors: *X. DONG[1], S. LI[1], Y. LI[2,3], G. J. KIROUAC[1,4]
[1]Dept. of Oral Biology, Col. of Dent., Univ. of Manitoba, Winnipeg, MB, Canada; [2]Key Lab. of Mental Health, Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [3]Dept. of Psychology, Univ. of Chinese Acad. of Sci., Beijing, China; [4]Dept. of Psychiatry, Col. of Med., Winnipeg, MB, Canada

Abstract: The paraventricular nucleus of the thalamus (PVT) is anatomically positioned to mediate addiction behaviors because it projects to multiple brain areas involved in appetitive motivation and drug-seeking. Indeed, experimental evidence shows that the PVT contributes to cocaine- and alcohol-seeking and that a projection from the PVT to the nucleus accumbens (NAc) may be involved in cocaine-seeking. In the present study, we examined the role of PVT-NAc projecting neurons in the expression of morphine conditioned place preference (CPP) in mice. We expressed Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) in the form of the inhibitory hM4Di in PVT neurons that project to the NAc using an intersectional dual-virus approach. This approach involved injections of AAVrg-Syn1-EBFP-Cre bilaterally in NAc and injections of the Cre-dependent AAV8-hSyn-DIO-hM4Di-mCherry or AAV8-hSyn-DIO-mCherry in the PVT. Following a recovery of 2-3 weeks, mice were trained using an unbiased CPP task in which mice received either morphine (10 mg/kg) or saline immediately before a 30-min training session. After four rounds of pairing, mice showed preference to the morphine paired side and clozapine (0.1 mg/kg, i.p.) had no effect on morphine CPP expression in mice expressing hM4Di. In a separate experiment, mice expressing hM4Di that were treated with clozapine showed a lower level of anxiety-like behavior in an open field compared to mice expressing hM4Di treated with saline or in mice expressing mCherry alone treated with clozapine. The number of PVT neurons with both mCherry and c-Fos was reduced specifically in hM4Di-expressing mice treated with clozapine validating that clozapine induced inhibition of neural activity specifically in hM4Di-expressing neurons. In summary, our results do not support a role of the PVT-NAc pathway in the expression of morphine CPP. This study also points to a potential role of the PVT-NAc projection in anxiety-like behavior.

Title: Dissociable effects of M4 and M3 muscarinic cholinergic receptor antagonism in the rostromedial tegmental nucleus on reward and locomotor activation

Authors: *S. STEIDL, R. HARB, L. RIEDY, S. SCHEINMAN
Psychology, Loyola Univ. Chicago, Chicago, IL

Abstract: GABAergic neurons of the rostromedial tegmental nucleus (RMTg), also known as the "tail" of the ventral tegmental area (VTA), project to and inhibit VTA dopamine neurons. The laterodorsal tegmental nucleus (LDTg) and the pedunculopontine tegmental nucleus (PPTg), two principle brainstem acetylcholine (ACh) cell groups, each provide cholinergic as well as non-cholinergic projections to the VTA that regulate VTA dopamine neuron activity. The RMTg also receives projections from each of the LDTg and the PPTg. We have recently shown that RMTg infusions of the M3 muscarinic ACh receptor antagonist 4-DAMP, but not of the M4 muscarinic ACh receptor antagonist Tropicamide, strongly increase open-field locomotion (Steidl et al., 2017). We now show that RMTg infusions of Tropicamide, but not of 4-DAMP, result in the acquisition of conditioned place preference (CPP). Taken together it appears that cholinergic inputs to the RMTg differentially contribute to rewarding and locomotor effects via M4 and M3 muscarinic ACh receptors, respectively. Current studies are focused on testing the rewarding effects of selective optogenetic inhibition of LDTg or PPTg cholinergic projections to the RMTg.

Bordeaux, QC, Canada; [6]Inst. of Nutr. and Functional Foods - Laval Univ., Quebec, QC, Canada; [7]LETIAM - IUT d'Orsay, Univ. Paris Sud, Paris, France; [8]CNRS UMR 5287, Bordeaux cedex, France

Abstract: Inflammation can affect mesodopaminergic system and mediates depressive symptoms related to motivation and locomotion. Precisely, pro-inflammatory cytokines can alter dopamine synthesis and thus availability. Tetrahydrobiopterin (BH4) is the mandatory co-factor for phenylalanine and tyrosine hydroxylase activities and therefore essential for dopamine synthesis. Interestingly, inflammation can decrease BH4 by acting on its synthesis and degradation. So, lower BH4 level could participate to the dopaminergic and motivational deficits that occur frequently in chronic inflammatory conditions. Despite its importance, the effects of BH4 administration on dopamine synthesis and related behaviors have been poorly characterized. We hypothesized that BH4 administration can improve dopaminergic function and motivational processes and could be used to counteract inflammation-induced alterations. We first demonstrated that peripheral administration of BH4 (50mg/kg;intraperitoneally) was sufficient to double BH4 brain content within 3h. Using in-situ brain perfusion, we found that the brain uptake clearance (Clup) of BH4 was approximately 0.08µl/g/sec, consistent with a modest transfer across the blood brain barrier. BH4 injection neither changed the expression of main enzymes involved in BH4 and DA synthesis nor total striatal dopamine content. However, using *in vivo* microdialysis in freely moving mice, we showed that BH4 administration induced a slight increase in dopamine release in the nucleus accumbens during food presentation and a higher amphetamine-induced DA release (3mg/kg). Furthermore, BH4 injection increased motivation in a progressive ratio task in operant conditioning without affecting sucrose consumption and anhedonia. Surprisingly, BH4 injection led to a moderate decrease in spontaneous locomotion and to a blunted locomotor sensitization after second exposure to amphetamine. Last, BH4 injection reduced brain pro-inflammatory cytokines expression in an acute inflammation model induced by lLipopolysaccharide injection (830µg/kg). Here, we showed that increased BH4 content leads to increased dopamine release and motivation, and reduces the proinflammatory response to an acute inflammatory challenge. This suggests that BH4 could be a promising treatment for behavioral deficits related to dopaminergic disturbances related to inflammatory condition.

Title: Releasing motivation: Direct inhibition of nucleus accumbens shell neurons promotes motivated behaviors

Authors: *J. J. OLNEY[1], K. C. BERRIDGE[2]
[1]Dept. of Psychology, [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: The nucleus accumbens shell (NAcSh) is a critical node in the mesolimbic reward circuit. A popular hypothesis proposes that it is primarily inhibition of NAcSh GABAergic neurons that promotes motivated behaviors. Such inhibition of GABAergic activity interrupts the inhibitory input onto downstream targets, which, in turn, generate intense motivation. In support of this theory, previous pharmacological studies from our lab have demonstrated that suppression of neuronal activity within the NAcSh via microinjections of the AMPA antagonist, DNQX, or the GABA agonist, muscimol, are capable of eliciting motivated behaviors such as feeding or defensive treading. What is more, depolarization of these neurons via the excitatory optogenetic construct, channelrhodopsin, blocks these DNQX-induced effects, indicating that hyperpolarization of the NAcSh is necessary to produce motivation. The purpose of the present study was to provide direct evidence regarding whether neuronal inhibition in NAcSh is sufficient to generate increases in motivated behaviors. Here, we used pharmacogenetics and optogenetic tools to directly inhibit NAcSh neurons. Preliminary findings suggest that food intake more than doubled following treatment with CNO to trigger DREADD inhibition of NAcSh neurons, indicating that neuronal inhibition produces appetitive motivation. Additionally, although the total amount of food eaten was not altered as a function of optogenetic inhibition, closer examination indicates that animals spent more than twice the amount of time eating or treading while the laser was on relative to when the laser was off, suggesting that laser inhibition of NAcSh neurons temporally organized motivated behaviors to mostly coincide with laser illumination rather than during the intervening laser-off periods. Taken together, preliminary data from these experiments suggest that neuronal inhibition in NAcSh is sufficient to generate increases in motivated behaviors. As a whole, these findings indicate that neuropsychiatric disorders characterized by pathologically high levels of motivation, such as addiction, may be a consequence of hypoactivity within the NAcSh. Title: Optogenetic stimulation of the medial amygdala may focus pursuit for a cocaine reward

Authors: *E. E. NAFFZIGER, K. C. BERRIDGE
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: *Optogenetic stimulation of the medial amygdala may focus pursuit for a cocaine reward* E. E. Naffziger and K. C. Berridge Previous research on the medial amygdala (MeA) has highlighted a crucial role of orchestrating sociosexual behaviors based-off incoming pheromone signals. Recent work from our lab suggests MeA may be contributing to the motivation for rewards outside of the realm of sociosexual behaviors, such that pairing MeA channelrhodopsin (ChR2) stimulation with an external sucrose reward was capable of increasing the motivation for the MeA ChR2-paired sucrose reward. Importantly, MeA belongs to the medial component of the extended amygdala system (EAS). The lateral counterpart of EAS (including the central amygdala) has been well-documented to play a role in motivation for drug rewards. However, the extent to which MeA may be involved in processing motivation for a drug reward has yet to be explored. In this study, rats received bilateral infusions of ChR2 into MeA before later receiving intra-jugular catheter implants. After recovery, animals underwent self-administration and had the choice to earn an infusion of cocaine or an infusion of cocaine paired with MeA ChR2 photostimulation. Preliminary data from self-administration suggests that pairing MeA ChR2 with one of two available cocaine infusions is capable of driving desire towards the MeA ChR2-paired infusion. This data could indicate that while historically the lateral EAS has been examined in addiction, there may be a role for the medial EAS as well. Importantly, this data helps inform our understanding of neuropsychiatric disorders that are characterized by abnormal motivation.

Title: Dissecting the addiction-like preference created by optogenetic stimulation of the central amygdala

Authors: C. L. POISSON[1], M. MIAN[2], D. VAAMONDE[2], J. M. CHABOT[2], H. XU[2], C. FREELAND[3], *M. J. ROBINSON[4]
[1]Neurosci. and Behavior, [3]Biol. Dept., [4]Psychology, [2]Wesleyan Univ., Middletown, CT

Abstract: Substance use disorders involve compulsive preference for drugs of abuse over better alternatives, and despite adverse consequences. We have recently shown that optogenetic stimulation of the Central Amygdala (CeA) creates an addiction-like preference for a stimulation-paired reward (Tom et al., 2018). However, little is known about the psychological mechanisms that help generate this persistent and compulsive preference. The present study evaluates the relative role of three theories of addiction in generating CeA-induced compulsive preference: 1) accelerated learning, 2) habit formation, and 3) increased incentive value of reward-associated stimuli. Rats were injected with Channelrhodopsin or a control virus into the CeA, which was optogenetically stimulated using laser light. The first experiment employed a novel decision-making task, where auditory cues signaled which of two levers would deliver a reward. The ability of CeA stimulation to enhance acquisition (1) of the task was examined by pairing laser stimulation only with correct responses, whereas habit formation (2) was tested by repeatedly pairing laser stimulation with responses on one of the two levers, whether responses were correct or incorrect. The ability of CeA stimulation to promote habit formation of a particular instrumental response was further examined in a task where laser stimulation accompanied an 8 sec timeout period following reward delivery, during which animals were either allowed or not to repetitively respond on the reward-paired lever. Finally, the ability of CeA stimulation to ascribe incentive value to reward-paired stimuli (3) and not just rewards, was examined by pairing laser stimulation with a particular response and its reward-paired cues, either only in the presence of reward delivery or when reward was omitted. Our results suggest that laser stimulation of the CeA does not create a compulsive preference by enhancing learning, promoting habit formation or increasing the incentive value or reward-associated choices and cues. Instead the CeA appears to create a narrow preference for one particular reward by enhancing the motivational value of reward outcomes. However this preference appears to display compulsive-like traits, and shows resistance to devaluation, only after the preference is initially acquired free of challenges. These results suggest that the CeA may play a role in the transition from casual use to the persistent and compulsive pursuit of a particular reward.

Title: Alcohol dependence and withdrawal alter serotonergic modulation of GABA transmission in the CeA

Authors: S. KHOM, R. R. PATEL, D. HEDGES, F. P. VARODAYAN, *M. BAJO, M. Q. STEINMANN, R. VLKOLINSKY, D. KIRSON, M. ROBERTO
Dept. of Neurosci., The Scripps Res. Inst., La Jolla, CA

Abstract: Increased serotonergic neurotransmission plays a critical role in the etiology of alcoholism regulating both reward and stress circuits in the brain. Studies in humans and animal models have shown that modulating the serotonergic signaling can both increase and decrease ethanol consumption. Chronic ethanol intake enhances the activity of serotonergic neurons in the dorsal raphe nucleus, and in addition altered 5-HT_{2C} signaling in the extended amygdala contributes to anxiety-like behaviors during ethanol withdrawal.
The central nucleus of the amygdala (CeA) is the major output region of the amygdalar complex and a major player in the development of alcoholism. Our overall hypothesis is that ethanol dependence and withdrawal dysregulate 5-HT signaling in central amygdala. Our electrophysiological data show that 5-HT dose-dependently (0.5-50 μM) increases spontaneous GABA release in the CeA of naïve rats. Specifically, we found that 50 μM 5-HT significantly ($p<0.001$) increased (to 402±63% of control) the frequency but decreased (to 76±9% of control) the amplitude of spontaneous inhibitory postsynaptic currents (sIPSCs), indicating that 5-HT increases action-potential dependent GABA release and decreases $GABA_A$ receptor functions in the CeA of naïve rats. Interestingly, 50 μM 5-HT significantly increased frequency of sIPSCs in both CeA neurons of ethanol-dependent (153±24% of control) and 14 days withdrawn rats (219±49% of control), however this increase was significantly less pronounced compared to naive rats. In addition, the 5-HT-induced decrease in the amplitude of sIPSCs observed in naive

CeA neurons was lost in ethanol-dependent and withdrawn rats. Moreover, 50 μM 5-HTabolished spontaneous firing of CeA neurons in both naïve and ethanol-dependent rats. The selective 5-HT_{2C} agonist WAY161503 significantly increased sIPSC frequency in ethanol-naïve CeA neurons (217±44%, $p<0.05$), but had mixed effects on sIPSC frequency on CeA neurons from ethanol-dependent and ethanol-withdrawn rats. Overall, we find that 5-HT signaling profoundly modulates GABA transmission in the CeA of naïve rats and that ethanol dependence and withdrawal produces adaptive changes in the 5-HT system.

Title: Ethanol enhancement of dopamine release in the nucleus accumbens and ethanol reward are mediated by peripheral neuroimmune interactions

Authors: *J. D. OBRAY[1], E. Y. JANG[3], T. J. CLARKE[2], A. KLOMP[1], A. P. RICHARDSON[2], M. PARSONS[2], C. H. YANG[3], J. T. YORGASON[2], S. C. STEFFENSEN[1]
[1]Dept. of Psychology, [2]Neurosci. Ctr., Brigham Young Univ., Provo, UT; [3]Daegu Haany Univ., Daegu, Korea, Republic of

Abstract: The prevailing view is that enhancement of dopamine (DA) transmission in the mesolimbic DA system originating in the midbrain ventral tegmental area (VTA) and projecting to the nucleus accumbens (NAc) underlies the rewarding properties of alcohol. Despite the fact that many labs have shown that DA release is enhanced by acute ethanol in vivo, the story is mixed ex vivo, with some labs showing enhancement, while others inhibition, of DA release in the NAc. Further complicating this story is that ethanol injected directly into the VTA has no effects on DA release in the NAc. The aim of this study was to determine the role of peripheral neuroimmune responses in mediating ethanol enhancement of DA release in the NAc and ethanol reward. Using microdialysis and HPLC, systemic administration of ethanol (0.5-4.0 g/kg) markedly enhanced DA release in the NAc in male subjects. Ethanol (IP) or IV DA enhancement of DA release in the NAc was abolished by administration of the peripheral-only acting D2 receptor (D2R) antagonist domperidone. A place conditioning paradigm was used to

test rats for ethanol preference. Domperidone (1 mg/kg, IP) administered before ethanol conditioning trials was found to prevent acquisition of ethanol conditioned place preference. Locomotor activity and motor coordination were tested using open field and rotarod paradigms, respectively. Domperidone (1 mg/kg, IP) was found to attenuate ethanol suppression of locomotor activity at large doses of ethanol (2.0 - 4.0 g/kg, IP) while not affecting ethanol impairment of motor coordination. These findings suggest that ethanol enhancement of DA release and ethanol reward is in part mediated by a peripheral mechanism involving D2Rs. These results challenge the dogma regarding direct ethanol actions on mesolimbic DA transmission. Experiments are ongoing to evaluate ethanol mediated changes in plasma catecholamine concentrations, ethanol effects on DA release in animal models of monocyte/macrophage/microglia depletion, and domperidone effects on ethanol mediated enhancement of DA neuron firing rate in vivo.

Title: Effects of low-dose embryonic ethanol on the early development of hypocretin/orexin neurons and behavior in larval zebrafish

Authors: *A. COLLIER, V. HALKINA, S. MIN, O. KARATAYEV, G. Q. CHANG, S. F. LEIBOWITZ

Abstract: Embryonic exposure to ethanol is known to increase alcohol drinking and have long-term effects on neurochemical systems in the brain. With zebrafish (ZF) emerging as an advantageous model for elucidating neural mechanisms of numerous brain disorders, we recently established (Sterling et al., 2015) a model of voluntary ethanol-gelatin consumption in adult ZF and demonstrated that consumption of ethanol significantly stimulates the neuropeptide, hypocretin/orexin (hcrt/ox), in the anterior hypothalamus. We also showed (Sterling et al., 2016) that embryonic ethanol exposure stimulates the proliferation and expression of hcrt/ox and increases voluntary consumption of ethanol-gelatin in adult ZF as well as locomotor activity, anxiety, and aggression. In the present study, we utilized live imaging confocal microscopy and

Imaris software to investigate how low-dose embryonic ethanol (0.5%) affects the early development of hcrt/ox neurons and how this effect relates to behavior in larval ZF. In control animals examined from 24-28 hpf, we found hcrt/ox neurons to exist primarily in tight clusters, which from their original position in the medial/anterior/ventral region of developing hypothalamus migrated in a lateral/posterior/dorsal direction. Embryonic ethanol exposure increased the proliferation of hcrt/ox neurons and significantly disrupted their migratory path, reducing the straightness of their movement and disrupting their migration in medial-lateral and anterior-posterior directions. Interestingly, these effects occurred mostly on the right side of the brain. The ethanol-induced changes in migration ultimately altered the anatomical distribution of hcrt/ox neurons in lateral hypothalamus from 6-12 dpf, causing the hcrt/ox neurons to be more dispersed and located more medial and posterior again on the right side. Ethanol also affected hcrt/ox neuronal projections, increasing their number and arborization on the right. These neuronal changes induced by embryonic ethanol were closely associated with changes in behavior at 6-12 dpf. Using a new model for measuring voluntary ethanol-gelatin consumption in larval ZF, we found that, similar to our results with adult ZF, embryonic ethanol stimulated voluntary ethanol consumption at 12 dpf and increased locomotor activity and anxiety-like behavior. These results demonstrate that low-dose ethanol markedly affects migration, morphology and anatomical distribution of hcrt/ox neurons and behavior in the same fish, suggesting a causal relationship and demonstrating the importance of hcrt/ox developmental asymmetry in normal neuronal and behavioral functioning.

Title: Effects of systemic and intra-ventral tegmental area administration of 5-HT1B receptor agonist CP94253 on oral self-administration of ethanol in rats

Authors: *J. C. JIMÉNEZ, F. CORTES-SALAZAR, L. N. CEDILLO, R. I. RUÍZ-GARCÍA, C. E. MÉNDEZ-CORONEL, A. I. BARRIENTOS-NORIEGA, F. MIRANDA-HERRERA*
Facultad de Estudios Superiores Iztacala, Mexico, Mexico

Abstract: GABAA receptors are expressed in cell body of ventral tegmental area (VTA) GABA interneurons, and other sites, in the reward system and play a key role in the addictive actions of

ethanol (EtOH). Activity of VTA GABA interneurons is regulated by postsynaptic 5-HT1B (hetero) and presynaptic 5-HT1B (auto) receptors. Activation of 5-HT1B heteroreceptors in the VTA reduces GABA release onto VTA dopamine (DA) neurons resulting in their desinhibition and consequently increasing DA release in nucleus accumbens. On the other hand, activation of 5-HT1B autoreceptors has opposite effects on GABA and DA release. One strategy to find out if the 5-HT1B receptor agonist administration produces its behavioral effects activating 5-HT1B auto or heteroreceptors is to observe the behavioral effects after systemic or intra-VTA injection of 5-HT1B receptor agonist. Here we evaluate the effects of the systemic and intra-VTA injection of the 5-HT1B receptor agonist CP94253 on oral self-administration of EtOH in rats. Male Wistar rats (250-300 g) were used. Rats were water deprived for 24 h, and then trained to lever-press for water reinforcement on a FR1 schedule (30-min session) by 3 days. Then, rats were trained to lever-press for EtOH (0.01 ml of EtOH in water at 12%) on a FR1 schedule (30-min session) by 3 days. After this training, the reinforcement contingency was changed to FR3 for EtOH access (30-min session) until response rate remained stable at 80% by 3 consecutive days. Then rats were randomly assigned to one of the 6 groups (n=10). Three groups of rats received a systemic injection of 5-HT1B receptor agonist CP94253 (2.0, 4.0 and 8.0 mg/kg, one dose per group) before rats were under FR3 schedule of reinforcement for EtOH access by one session. Other three groups of rats received intra-VTA injection of CP94253 (0.625, 1.25 and 2.5 µg, one dose per group, cannulae were implanted 2 mm dorsal to the VTA at AP -5.1 mm of Bregma, ML ± 0.9 mm, DV -7.8 mm). The data showed that both systemic and intra-VTA injections reduces oral self-administration of EtOH. These findings suggest that 5-HT1B autoreceptors may modulate the reduction of oral self-administration of EtOH in rats.This study was supported by PAPIIT IN301717 (UNAM, Mexico)

Title: Acute stress and alcohol exposure produce a common alteration in ventral tegmental area inhibitory signaling

Authors: *B. A. KIMMEY, A. OSTROUMOV, R. WITTENBERG, J. A. DANI
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Drugs of abuse, including alcohol, produce robust synaptic plasticity adaptations in the mesolimbic reward pathway that are paralleled by stress exposure. We recently found that acute stress in rats leads to long-lasting alterations in inhibitory signaling in the ventral tegmental area (VTA), which is mediated by a deficit in the function of the potassium-chloride cotransporter 2 (KCC2) in VTA GABA neurons. Impairment of KCC2-mediated chloride extrusion shifts ethanol-induced VTA GABAergic signaling from inhibitory toward excitatory via a depolarized GABA reversal potential (E_{GABA}) in GABA neurons. Here, we replicate our stress findings in mice and show that after four weeks of ethanol drinking experience under the intermittent two-bottle choice paradigm in unstressed mice, E_{GABA} in VTA GABA neurons is depolarized relative to mice which drank saccharin for the same duration. This depolarizing shift in E_{GABA} following ethanol consumption mirrors the effect of acute stress. Moreover, western blot analysis revealed that functional KCC2 phosphorylation was decreased in ethanol-drinking mice when compared to saccharin drinking mice, as we have found following acute stress. These data suggest that VTA KCC2 is a common molecular adaptation arising from acute stress and alcohol exposure, which may contribute to subsequent alcohol abuse. Targeting KCC2, therefore, may provide a novel therapeutic avenue for limiting the progression to alcohol use disorder.

Title: Plasticity of cingulate cortex intrinsic excitability following voluntary ethanol consumption

Authors: *R. D. CANNADY[1], P. J. MULHOLLAND[2]
[1]Med. Univ. of South Carolina, Charleston, SC; [2]Neurosciences, MUSC, Charleston, SC

Abstract: Exposure to ethanol promotes plasticity of intrinsic excitability in several brain regions and is implicated in the dysregulation of learning processes and effective integration of

synaptic signaling. Several studies have examined how passive ethanol exposure and ethanol withdrawal alter intrinsic excitability. However, few studies have examined how voluntary ethanol consumption alters neuronal firing. The anterior cingulate cortex (ACC) is a key region that integrates input from several reward-related brain regions, but the mechanisms that promote sensitivity to ethanol exposure and withdrawal have not been fully investigated. Moreover, it is not known if voluntary ethanol consumption alters intrinsic excitability of ACC neurons. To address this gap in understanding, male C57BL/6J mice were given access to 20% ethanol and water using a chronic intermittent two-bottle choice drinking procedure. The brains of these mice were extracted for patch-clamp electrophysiology recordings after 1 day, 1 week, 4 weeks, or 7 weeks of voluntary intermittent access to ethanol. Current pulses were injected into deep layer ACC pyramidal cells to evoke action potentials and to examine excitability following voluntary consumption. A single day of ethanol consumption significantly increased evoked action potentials relative to water-drinking control mice. Mice that consumed ethanol for 1 week exhibited reduced spiking in the ACC relative to controls. The changes in spiking were transient and dependent on drinking history as mice that consumed ethanol for 4 or 7 weeks showed no significant alterations in action potential firing between ethanol and water consuming mice. These data indicate that voluntary ethanol consumption produces unique and transient alterations in ACC intrinsic excitability. Thus, the ACC may be involved in encoding ethanol-specific information after early consumption with implications as a predictive indicator of responsiveness to consumed ethanol.

Title: Effect of voluntary binge drinking on microglial cells in the medial prefrontal cortex and hippocampus of male and female adolescent rats

Authors: *A. SILVA-GOTAY[1], W. VARGAS RIAD[2], E. TAVARES[1], A. LIN[1], M. K. HOLDER[3], H. N. RICHARDSON[1]
[1]Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA; [2]BGB Group, New York, NY; [3]Georgia State Univ., Atlanta, GA

Abstract: Adolescence is a period of development when teenagers are engaging in risky behaviors including binge drinking. Heavy alcohol use may be particularly hazardous at this time because brain circuits in the frontal lobes are undergoing maturational processes important for higher cognitive function and behavioral control in adulthood. Alcohol has been shown to induce inflammation in the brain. Microglia, the brain immune cells, not only mediate inflammation but also play a role in neural development. The goal of the present study was to test the hypothesis that voluntary alcohol activates microglia in the medial prefrontal cortex (mPFC) and dorsal hippocampus early in adolescence, as this could alter the trajectory of neural circuit development and function. Adolescent male and female Wistar rats underwent two weeks of operant binge alcohol self-administration of sweetened alcohol or sweetened water (PD 28-42). Brains were collected one day after the last drinking session and microglia were labeled using an ionized calcium-binding adapter molecule 1 (Iba1) antibody. We found that higher levels of binge drinking were associated with increased Iba1 immunoreactivity in the mPFC of males and females. There was also a trend of increased Iba1 immunoreactivity in the dentate gyrus and CA1 field of the hippocampus in alcohol males. These findings suggest voluntary binge drinking may elicit an inflammatory state in the brain. Future studies will determine whether higher immunoreactivity is due to increased cell number, cell size, and/or thicker proximal processes, as well as elevated neuroinflammatory cytokines. Overall, these findings highlight the potential risk moderate to high voluntary intake could have on the developing brain.

Title: Better insights with ISC when using a multi-sensory fMRI paradigm

Authors: *D. SINGLA[1], J. KAUR[2], A. DHAWAN[3], V. MAHAJAN[4], R. GARG[2]
[1]Electrical Engin., [2]Computer Sci. & Engin., Indian Inst. of Technology, Delhi, New Delhi, India; [3]All India Inst. of Med. Sci., Delhi, India; [4]Mahajan Imaging Pvt. Ltd., Delhi, India

Abstract: Cue reactivity tasks have been widely employed in fMRI studies. Due to ease of use and compatibility with General Linear Model (GLM), visual cues are predominantly adopted despite their limitation in terms of replicating real life scenario. We propose using Intersubject Correlation Analysis **(ISC)** to analyse multi sensory paradigms over GLM based analysis and

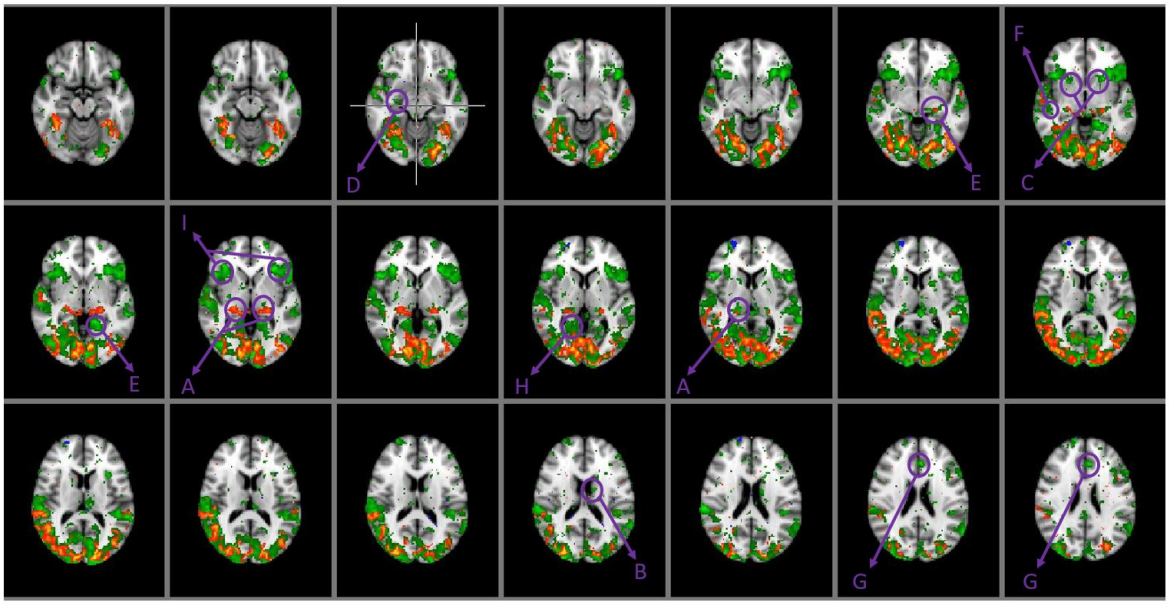
demonstrate advantages of ISC in a multi sensory paradigm using a case study of craving for alcohol in subjects with heavy alcohol use.

Four male young adults (mean age of 24) with heavy alcohol use whose score on Alcohol Use Disorder Identification Test (AUDIT) was greater than 8, were scanned using a 3T GE MRI Scanner while undergoing a multi sensory craving paradigm. The paradigm included 20 blocks with short videos with fixation cross after every block. Ten videos contained alcohol which were matched with neutral videos based on colour, background, presence of faces, emotions, etc. The order of blocks was randomized once and then kept same across all subjects.

Preprocessing of fMRI data included BET extraction, slice timing correction (ascending interleaved), spatial smoothing (FWHM of 5mm) and temporal filtering of 0.01Hz using FSL. Contrast between alcohol cues and fixation was computed using GLM analysis and compared with statistical maps obtained using ISC analysis. Both the statistical maps were corrected for multiple comparisons using False Discovery Rate (FDR) of 0.05.

With GLM analysis, both visual and auditory regions were observed to be activated along with thalamus. With ISC analysis, regions previously known to be involved in craving such as insula, amygdala, hippocampus, caudate, putamen, anterior cingulate cortex (ACC), posterior cingulate cortex (PCC), orbitofrontal cortex (OFC) were also activated. Refer to the attached figure for the two statistical maps and the activated areas.

We hypothesize that craving is nonlinear in nature. Linear Time Invariant (LTI) assumption of GLM makes it harder to capture craving regions when applied to multi-sensory cues. ISC analysis is a better option in this case.



Red-Yellow represent regions activated by General Linear Model (GLM) analysis while Blue represent regions deactivated by GLM analysis. The Green color represent regions given by Inter-Subject Correlation (ISC)

Title: Liver alcohol metabolism directly fuels histone acetylation in the brain

Authors: *P. MEWS[1], G. EGERVARI[1], S. SIDOLI[1], R. NATIVIO[1], G. DONAHUE[1], D. C. ALEXANDER[1], E. J. NESTLER[2], B. A. GARCIA[1], S. L. BERGER[1]
[1]Epigenetics Inst., Univ. of Pennsylvania, Philadelphia, PA; [2]Icahn Sch. Med. At Mount Sinai, New York, NY

Abstract: In the adult brain, epigenetic control of gene expression has important roles in the processing of neural activity. Emerging evidence suggests that epigenetic regulation is dependent on metabolic state, implicating specific metabolic factors in neural functions that drive behavior. In neurons, histone acetylation is dependent on the metabolite acetyl-CoA that is produced from acetate by chromatin-bound ACSS2. Here, using in vivo stable isotope labeling, we show that liver alcohol metabolism rapidly fuels histone acetylation in the brain by direct deposition of alcohol-derived acetyl groups onto histones in an ACSS2-dependent manner. A similar induction was also observed with heavy labeled acetate injection in vivo. In addition, injection of labeled alcohol into a pregnant mouse results in incorporation of labeled acetyl groups into the brains of the gestating fetuses. In isolated primary hippocampal neurons in vitro, extracellular acetate induced learning and memory-related transcriptional programs that were sensitive to ACSS2 inhibition. These findings establish a novel and direct link between hepatic alcohol metabolism and neuronal histone acetylation, providing the first evidence for dynamic signaling from liver metabolism directly to epigenetic regulation in neurons.

Title: D2 dopamine receptor in ethanol-induced behaviors

Authors: *N. M. DELGADO, A. CEBALLOS, P. R. SABANDAL, K.-A. HAN
Univ. of Texas At El Paso, El Paso, TX

Abstract: Alcohol is one of the most widely used drugs worldwide. Alcohol consumption has many effects including euphoria and sedation. Excessive alcohol intake causes motor impairment and possibly risky sexual behavior and substance use disorder. Numerous studies have identified dopamine as a critical neuromodulator mediating several effects of ethanol. In the fruit fly *Drosophila melanogaster*, exposure to ethanol causes changes in behavior such as alterations in locomotor activity, tolerance and behavioral disinhibition similar to other animals and humans. The goal of this study is to uncover the role of the D2 dopamine receptor in alcohol-induced behaviors. We exposed wild-type *Canton-S* and D2 receptor mutant *d2r* flies to ethanol and monitored behavioral changes. *d2r* mutant flies exhibited initial sensitivity to the sedative effect of ethanol comparable with that of *Canton-S* but showed abnormal locomotor activities, sedation, tolerance and behavioral sensitization to disinhibited courtship. Our findings suggest that D2 receptor plays multiple roles in alcohol-induced behaviors. We are currently investigating the underlying mechanism. Our research may provide novel insights into the neurobiological mechanisms underlying alcohol use and addiction. This work was supported by the NIH grants NIMHD 2G12MD007592 and NIAAA R15AA020996.

Title: Optogenetic modulation of dopamine release in the nucleus accumbens and ethanol self-administration

Authors: *W. M. DOYON, JR[1], S. VILLATORO[2], D. A. CONNOR[1], J. A. DANI[1]
[1]Neurosci., [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Our previous studies have correlated increased ethanol self-administration, following nicotine or stress exposure, with blunted dopamine signaling in the medial nucleus accumbens (NAc). However, a causal role for dopamine signaling and increased ethanol self-administration has not been confirmed. To examine the functional consequences of dopamine release in the medial NAc, we are using optogenetics in male and female Long-Evans rats that express Cre-recombinase to modulate release at specific target areas. Viral vectors were injected into the midbrain to express channelrhodopsin (ChR2-YFP), halorhodopsin (NpHR3.0-YFP), and YFP alone in a Cre-dependent manner. In ChR2-expressing rats, blue light stimulation in the medial NAc shell (20 Hz/5 sec for 5 min) transiently increased extracellular dopamine levels as measured by in vivo microdialysis (n = 3 rats). By contrast, in NpHR-expressing rats, green light stimulation attenuated dopamine levels (n = 2 rats). To determine the impact of light stimulation on ethanol intake, rats were trained for operant self-administration of 4% ethanol (+0.1 % saccharin). In ChR2-expressing rats, light stimulation during self-administration caused a decrease in daily ethanol/saccharin consumption (n = 4 rats), but did not alter intake of saccharin alone. Ethanol/saccharin intake was unaffected by light stimulation in one YFP-expressing control rat. These preliminary results and ongoing experiments could reveal a causal role of specific dopamine neural projections in ethanol reinforcement and motivated behavior.

Title: Excessive ethanol consumption elevates GABAergic inputs onto cholinergic interneuron in the dorsomedial striatum

Authors: *H. GANGAL, J. LU, X. WANG, J. WANG
Texas A&M Univ., Bryan, TX

Abstract: The dorsomedial striatum (DMS) and the cholinergic system are known to play a critical role in behavior flexibility, the ability to adjust to salient stimuli in the environment. This flexibility is impaired under the influence of excessive ethanol consumption. This study is aimed to investigate the neural mechanism underlying this impairment. Chat-eGFP transgenic mice were used to allow the fluorescent visualization of cholinergic interneurons (CINs) in the DMS. Excessive ethanol consumption was established using the intermittent-access to 20% ethanol two-bottle choice drinking procedure, and whole-cell patch-clamp electrophysiology was used to record in the DMS CINs. We discovered that the average spontaneous firing frequency of the DMS CINs was reduced in the alcohol mice as compared to their water controls. We also found that there was a significant increase in the frequency of spontaneous inhibitory post synaptic currents (sIPSCs) to the DMS CIN. Given our previous finding that activity of dopamine D1 receptor-expressing medium spiny neurons (MSNs) in the DMS were elevated following excessive alcohol intake (Cheng et al., Biological Psychiatry, 2017) and that these neurons are GABAergic, we hypothesize that the DMS CINs receives inhibitory inputs from these D1R-MSNs; these inputs are strengthened by excessive ethanol intake. Using triple transgenic mice, D1Cre;Ai32;Chat-GFP, which allows optical stimulation of D1R-MSNs and recording from DMS CINs at the same time, we discovered that a series of light stimulation of D1R-MSNs with increasing intensities caused increased amplitudes of IPSCs. These IPSCs were blocked by a $GABA_A$ receptor antagonist, suggesting that DMS D1-MSNs form GABAergic connections with striatal CINs. We are currently examining whether the IPSCs are enhanced by excessive alcohol consumption. These results indicate that ethanol-mediated potentiation of D1R-MSN activity may down-regulate DMS CIN activity, which may contribute to impaired flexibility in alcohol use disorder.

Title: Effects of different modes of alcohol administration on hypothalamic synaptic plasticity and HPA axis hormonal and behavioral responses to stress

Authors: *V. N. MARTY, Y. MULPURI, J. MUNIER, S. LELE, R. H. VO, I. YENOKIAN, I. SPIGELMAN
UCLA, Los Angeles, CA

Abstract: Alcohol use disorder is associated with a persistently dysregulated hypothalamic-pituitary-adrenal (HPA) axis and corticotropin-releasing factor (CRF) signaling that leads to inappropriate stress responses, thereby increasing relapse susceptibility in abstinent alcoholics. Here we investigated the effects of two different modes of ethanol (EtOH) administration inducing neuroadaptive changes responsible for the dysregulation of the HPA axis. Using whole-cell patch-clamp recordings, we showed that stress induces a CRF-dependent depression of NMDAR function in parvocellular neurosecretory cells (PNCs) in the paraventricular nucleus of the hypothalamus (PVN), which allows for short-term potentiation (STP) of AMPAR-mediated currents following high-frequency stimulation (HFS, 100Hz for 1sec, x4). This stress-induced STP can be evoked for several days and provides a mechanism by which the HPA axis responds adaptively to subsequent stressors. Chronic intermittent EtOH (CIE) was administered either by oral gavage (30 doses, 5g/kg of EtOH once every other day for the first five doses, and 6g/kg of EtOH once every day for the following 25 doses), or by EtOH vapor (12h daily for 6 weeks). All experiments were performed after at least 40 days of withdrawal. We found that HFS-induced STP was impaired in PNCs of stressed CIE-gavage and -vapor rats. NMDAR inhibition by intracellular MK-801 restored stress-induced STP suggesting that the loss of CRFR1-mediated NMDAR blockade in CIE rats may prevent stress-induced STP. To relate the expression of STP to the HPA axis hormonal response, we examined ACTH and CORT plasma levels in response to repeated (at 72hr-intervals) restraint stress. In both CIE-gavage and -vapor rats, the ACTH response to the 3rd stress was blunted independent of plasma CORT levels, indicative of enhanced negative feedback. Stress-induced increases in self-grooming behavior, an adaptive response to stress involving CRF-expressing PNCs, were impaired in CIE-gavage, but not in CIE-vapor rats. These data indicate that CIE-induced alteration of stress-induced PNC synaptic plasticity could be responsible for the HPA axis maladaptive hormonal responses to stress, and that the mode of EtOH administration remains a key variable in studying the effects of chronic alcohol on brain function. Title: Individual differences in alcohol consumption in relation to instrumental extinction learning and dorsomedial striatal parvalbumin expressing neurons

Authors: *A. LENSING, A. PAJSER, H. FISHER, R. BOERGER, S. GILBERT, H. LIN, C. PICKENS
Kansas State Univ., Manhattan, KS

Abstract: In humans, there is a relationship between levels of alcohol use and response inhibition abilities. Relationships between alcohol consumption and response inhibition have also been found in rodent models. We have previously found that, in outbred Long-Evans rats given chronic intermittent access to alcohol (CIA) during adolescence and early adulthood, rats that consume high levels of alcohol also exhibit lower conditioned fear, faster instrumental extinction and lower errors in a reversal learning task. These findings suggest a generalized behavioral phenotype, which we have termed the HALF-FIELDER rat (Pajser et al., 2018). However, the neurobiological substrates of the HALF-FIELDER rat are unknown. Here, we determined whether alcohol consumption would correlate with instrumental extinction in a task specifically designed to assess operant extinction. We also determined whether striatal parvalbumin-positive (PV+) neurons would correlate with alcohol consumption and instrumental extinction, as preliminary data from our lab suggested a possible association.
Rats received CIA (n = 21) or water-only (n = 15) access for 6 weeks (PND 26-66). Ten days after completion of the CIA paradigm, rats began behavioral training. Once free-operant lever pressing had been established, the rats received 2 once-daily sessions of cued instrumental training, in which a lever-light compound was presented during 40-sec cues and lever-presses could earn 2 food pellets/trial on an intermittent reinforcement schedule. Then, rats underwent extinction training in which no food was earned. The rats were then euthanized and their brains were processed to stain for PV+ neurons in the dorsomedial striatum (DMS) and dorsolateral striatum (DLS)using immunohistochemistry.
Contrary to prior results, we found that rats with prior alcohol access exhibited faster instrumental extinction than rats only given water. We also found that alcohol consumption and extinction correlated, such that higher drinking rats showed a faster rate of extinction. Preliminary data suggest that PV+ neurons in the DMS, but not DLS, are correlated both with alcohol consumption and the rate of instrumental extinction. These results suggest that rats that consume more alcohol show a faster rate of extinction, and both of these behavioral traits correlate with the number of PV+ neurons in DMS. Our findings support the reliability of associations between behavioral traits in the HALF-FIELDER phenotype, and suggest a possible neuronal substrate for these traits.

Title: Amino acid neurotransmitter release in the nucleus accumbens differs between mice exhibiting low and high sensitization to ethanol

Authors: *M. G. NASHED, D. CHATTERJEE, D. NGUYEN, M. DIWAN, J. N. NOBREGA
Res. Imaging Ctr., Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Ethanol-induced behavioural sensitization (EBS) is a neurobehavioral model of the adaptive neurochemical changes that occur following repeated exposure to the same dose of ethanol (EtOH). Interestingly, EBS does not occur uniformly in all mice exposed to the sensitization paradigm, even among animals from the same strain and cohort. Indeed, low-sensitized (LS) mice can readily be differentiated from high-sensitized (HS) mice, suggesting innate differential responses to EtOH in the reward circuitry of individual animals. Although this phenomenon remains poorly understood, we have recently reported that glutamate is variably regulated in the nucleus accumbens (NAc) of LS and HS mice during the expression phase of EBS. Here, we expand on these findings by examining both excitatory amino acid (EAA) and inhibitory amino acid (IAA) neurotransmitter release in the NAc during the expression phase of EBS. Male DBA mice (N = 32) received 5 EtOH (2.2 g/kg; n = 24) or saline (n = 8) injections twice per week, and 15-minute locomotor activity (LMA) was assessed immediately following injections 1, 3, and 5. Of the 24 EtOH mice, eight were classified as LS and eight were classified as HS on the basis of injection 5 LMA. Two weeks following injection 5, mice were challenged with EtOH (1.8 g/kg), and either their LMA was evaluated (n = 12) or in vivo microdialysis samples were periodically collected via implanted cannulae targeting the NAc core (n = 12). In response to EtOH, LS mice did not exhibit increased LMA, while HS mice exhibited a 110% increase in LMA compared to saline mice. Analysis of the microdialysis samples revealed that EAAs and IAAs were differentially elevated in the NAc of mice predominantly in the first 20 minutes following EtOH challenge. In LS mice, post-EtOH glutamate and aspartate (EAAs) peaked at 140% and 141% of baseline, respectively. The IAAs GABA, glycine, and taurine peaked at 423%, 553%, and 676% of baseline, respectively. In HS mice, post-EtOH glutamate and aspartate peaked at 184% and 170% of baseline, respectively. GABA, glycine, and Taurine peaked at 277%, 168%, and 212% of baseline, respectively. Interestingly, while LS mice exhibited similar levels EAAs compared to saline mice, they exhibited higher levels of IAAs, particularly taurine. By contrast, HS mice exhibited higher levels of EAAs and lower levels of

IAAs compared to both saline and LS mice. These results suggest that differential amino acid neurotransmitter regulation in the NAc may underline the innate neurobehavioral differences observed in LS and HS animals. In particular, the role of glycine receptors in mediating resistance to EBS should be further investigated.

Title: Pituitary adenylate cyclase-activating polypeptide in the nucleus accumbens shell reduces ethanol drinking

Authors: *A. T. GARGIULO[1], L. SANZALONE[1], P. S. SHAH[2], J. R. BARSON[1]
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Drexel Univ., Philadelphia, PA

Abstract: Alcohol use disorder is pervasive and multifaceted, but currently available pharmacotherapies are not widely effective. Thus, a better understanding of the neurobiological mechanisms underlying alcohol use disorder may help in identifying novel targets for the development of efficacious treatments. Very limited evidence suggests that one neuropeptide that may play a role in ethanol drinking is pituitary adenylate cyclase-activating polypeptide (PACAP), and recent results from our laboratory suggest that the PACAP protein isoform, PACAP-27, could be involved. Notably, while PACAP-38 is more ubiquitously expressed in the brain and has been associated with a number of stress-related behaviors, PACAP-27 is more selectively expressed and has not been associated with such behaviors. In the present study, we examined the effects of the PACAP isoforms on ethanol drinking, testing both the nucleus accumbens shell (NAcSh) and core (NAcC), which have both been implicated in motivated behavior. Notably, the NAcSh shows some of the strongest binding of PACAP-27 in the brain. Therefore, we trained male, Long-Evans rats to drink 20% ethanol using the intermittent-access two-bottle choice paradigm. Once they established pharmacologically-relevant drinking, we implanted the rats with bilateral cannulae into either NAcSh (n = 10) or NAcC (n = 7) and bilaterally injected them prior to their daily ethanol access with PACAP-27 or PACAP-38 (25 pmol, 50 pmol), compared to saline vehicle (0.3 ul). For the NAcSh, we found that PACAP-27 significantly reduced ethanol drinking without affecting intake of simultaneously-available

chow. In contrast, drinking was not significantly affected by PACAP-38 when injected into the NAcSh or by either PACAP isoform when injected into the NAcC. Ongoing experiments are examining the effects of these isoforms on ethanol drinking in female rats and on sucrose drinking. Thus far, the results demonstrate that PACAP-27, acting in the NAcSh but not NAcC, can significantly inhibit pharmacologically-relevant ethanol drinking. We propose that this peptide should be further investigated for its utility as a novel pharmacological target for the treatment of alcohol use disorder.

Title: Identifying neural ensembles that mediate EtOH seeking by stimuli conditioned to withdrawal alleviation by EtOH in dependent subjects using pharmacogenetic inactivation in transgenic rats

Authors: *O. O. KOZANIAN[1], F. WEISS[2]
[1]Neurosci. Dept., The Scripps Res. Inst., San Diego, CA; [2]Dept. of Mol. and Cell. Neurosci., The Scripps Res. Inst., La Jolla, CA

Abstract: Alcoholism is a chronically relapsing disorder characterized by compulsive ethanol (EtOH) seeking and use. One major factor implicated in vulnerability to relapse includes learned responses induced by contextual stimuli that have become associated with the subjective actions of EtOH. In alcoholics, the severity of EtOH craving evoked by environmental cues is highly correlated with the degree and history of EtOH dependence. This is hypothesized to result from repeated experiences of EtOH consumption during withdrawal, which modifies the individual's reinforcement history to include the subjective effects of EtOH during this state, thereby enhancing EtOH's reinforcing actions. We have previously shown that environmental stimuli conditioned to EtOH availability during withdrawal produces significant reinstatement and that stimuli conditioned to EtOH availability in the same rats during the nondependent state lose their efficacy to elicit EtOH seeking. We have also shown that stimuli conditioned to EtOH availably during withdrawal, unlike in nondependent rats without this history, elicit compulsive-like EtOH seeking as revealed by resistance to suppression of cue-induced responding despite adverse consequences and rats' willingness to expend greater effort to obtain EtOH. Here, we extend our

previous findings by examining the neural regulation of withdrawal-related conditioning on EtOH seeking and vulnerability to relapse using Daun02 pharmacogenetic inactivation of key sites within the incentive motive circuit in cfos-LacZ transgenic rats. At the present time, the data suggest that inactivation of EtOH stimuli-responsive neural ensembles in the mPFC eliminates EtOH seeking associated with relief from withdrawal in dependent rats, but not EtOH seeking induced by stimuli conditioned to EtOH availability in the nondependent state in the same rats. Title: Interleukin 10 increases dopamine neuron activity in the ventral tegmental area and increases dopamine release in the nucleus accumbens via reduction of GABA inhibition

Authors: *A. J. PAYNE, S. D. WILLIAMS, T. J. CLARKE, J. D. OBRAY, E. EISINGER, N. LEWIS, M. C. WOODBURY, S. C. STEFFENSEN
Neurosci., Brigham Young Univ., Provo, UT

Abstract: Dopamine (DA) transmission is a key player in the rewarding aspects of ethanol as well as ethanol dependence. The current dogma is that DA transmission is increased during ethanol exposure via the inhibition of ventral tegmental area (VTA) GABA neurons and that excitation of VTA GABA neurons during withdrawal results in decreased DA transmission. Microglia, the major neuroimmune effector in the brain, may be a key mediator in this process by releasing cytokines following activation. It is also thought that BDNF may mediate this effect. We evaluated the effect of ethanol on cytokine concentrations in the VTA and nucleus accumbens (NAc), and found that low dose ethanol (1.0 g/kg) decreased interleukin (IL)-10 levels, but high dose ethanol (4.0 g/kg) increased IL-10 levels. We also used standard cell-attached mode electrophysiological techniques to evaluate the effects of select cytokines and BDNF on VTA neuron firing rate *in vitro*. We found no change in firing rate in response to IL-6 and BDNF, but an increase in firing rate in VTA DA neurons in response to IL-10. Consistent with the changes in firing rate, optically-evoked IPSCs were also found to be decreased in response to IL-10. *Ex vivo* voltammetry and *in vivo* microdialysis were done to determine whether IL-10 can directly result in an increase in DA release. Although *ex vivo* voltammetry showed no change in DA release, IL-10 increased DA release *in vivo*. These findings suggest

that the rewarding and/or addictive effects of ethanol may be mediated by cytokines, specifically the anti-inflammatory cytokine IL-10.

Title: Acute ethanol increases monocyte infiltration of the cns and influences microglia activation

Authors: *S. C. STEFFENSEN[1], T. J. CLARKE[2], J. D. OBRAY[3], J. BRUNDAGE[1], D. RUTTER[1], S. B. WILLIAMS[1], J. T. YORGASON[1], S. HOPE[1]
[2]Psychology, [3]Dept. of Psychology, [1]Brigham Young Univ., Provo, UT

Abstract: Microglia are the primary immune cell in the central nervous system (CNS) and are known as “resident” macrophages, although their role has more recently been shown to extend far beyond immunity. The effects of ethanol on the brain are closely linked to neuroimmune responses mediated by microglia that are present in the healthy brain from the time of development. For example, post-mortem studies of alcoholic brains show increases in microglial markers, and high dose ethanol has been shown to cause the activation of CNS microglia. Normally, the blood-brain barrier (BBB) prevents the infiltration of cells and foreign pathogens from crossing from the periphery into the CNS. However, peripheral monocytes are known to infiltrate the CNS in response to seizures, traumatic brain injury, infection, and multiple sclerosis. Whether or not these cells engraft and become microglia is still a topic of debate. The aim of this study was to determine the effect of acute ethanol on microglia activation and monocyte infiltration into the CNS. Using the MaFIA mouse model (GFP+ on Csf1r promoter), fluorescent microscopy, and flow cytometry, we assessed the presence and phenotype of microglia and infiltrating monocytes following 1, 2, and 4 g/kg ethanol at 0.5, 1, and 2 hours post injection. We found that acute ethanol significantly increased ventral tegmental area and nucleus accumbens microglia volume/surface area by up to 30%, suggesting activation. We also found that GFP+ MaFIA macrophages injected into C57BL6/J mice will cross the BBB in response to acute doses of ethanol. These findings suggest a neuroimmune interaction with acute, low doses of ethanol, and challenge the dogma that ethanol has exclusively central effects, and

neuroimmune effects only at high doses. Further research is being performed to examine the implications of this effect, and what effects a conditional knockdown of monocytes in MaFia mice has on ethanol intoxication and reward.

Title: Effects of chronic ethanol and stress on spontaneous and sensory-evoked responses of locus coeruleus noradrenergic neurons

Authors: *C. R. DEN HARTOG[1], D. E. MOORMAN[2], E. M. VAZEY[3]
[1]Biol. Dept, Univ. of Massachusetts at Amherst, Amherst, MA; [2]Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA; [3]Dept. of Biol., Univ. of Massachusetts, Amherst, MA

Abstract: The locus coeruleus NE (LC-NE) system regulates various brain processes including cognitive control and stress responses through ascending projections to regions including mPFC and BLA. Dysregulation of LC-NE transmission by chronic ethanol is thought to play a critical component in the addiction cycle by driving reward-seeking behavior and withdrawal-induced stress responses. Exposure to repeated chronic stress also can alter CRF-mediated LC tone and dysregulate LC-NE function. LC noradrenergic function is critical for regulating alcohol consumption and stress responses, yet the effects of chronic ethanol and stress interactions on LC-NE circuits remain to be elucidated.In this study, we looked at the effects of chronic intermittent ethanol (CIE) and repeated forced swim stress (FSS) exposure on spontaneous and footshock-evoked (FS-evoked) sensory responses of LC neurons before and after acute ethanol. We recorded LC neurons from both male and female mice 3-7 days following the completion of 4-5 cycles of intermittent CIE vapor and stress exposure across four exposure groups - Air/No stress (NS), Air/FSS, CIE/NS, and CIE/FSS. As we have seen previously, after repeated CIE and/or FSS animals robustly escalated volitional drinking. LC neurons were identified by their firing rate and waveform characteristics. Baseline LC activity was collected before and after FS-evoked sensory responses to increasing stimulation intensities (1, 3, and 10 mA). Mice were then injected with a dose of ethanol equal to their last weekly average intake during 1hr access to 15% ethanol before repeating baseline LC activity and sensory-evoked activity collection. A main

effect of vapor and stress exposure was observed on sensory evoked LC activity in which CIE mice had enhanced FS-response magnitudes compared to Air/NS controls. Acute ethanol blunted sensory evoked magnitudes across all stimulus intensities and normalized CIE exposed response magnitudes to levels seen in air controls. We also saw changes in evoked response latencies and durations between air and CIE or stress exposed animals. These data demonstrate that chronic ethanol and stress can lead to persistent changes in LC function that are sensitive to acute ethanol. These findings provide important insight into the mechanism by which ethanol and stress can alter LC circuitry.

Title: Voluntary binge drinking disrupts myelin-associated proteins in the medial prefrontal cortex and hippocampus of adolescent rats

Authors: *S. AKLI[1], E. R. TAVARES[1], A. SILVA-GOTAY[1], R. WYROFKSKY[2], W. M. VARGAS RIAD[3], E. VAN BOCKSTAELE[2], H. N. RICHARDSON[1]

Abstract: Myelination of axons during adolescence is thought to lead to efficient neural communication between prefrontal and subcortical brain regions, thus improving cognitive abilities and emotional regulation in adulthood. We have previously found in male rats that adolescent binge drinking decreased myelin fiber density in the medial prefrontal cortex (mPFC). High alcohol intake also predicted poor performance on a working memory task in adulthood. The goal of the current study was to determine the effect of alcohol on proteins important for the structure and maintenance of myelin sheaths. Adolescent male and female Wistar rats underwent two weeks of operant self-administration of alcohol (postnatal days 28-42). Brains were then processed for Western blot analysis of myelin-related protein levels or for immunofluorescent labeling and confocal analysis of proteins in specialized axonal domains at the node of Ranvier. Our findings suggest that myelin basic protein is reduced by alcohol in regions undergoing plasticity during adolescence (mPFC and hippocampus), but not in the striatum. This effect was

greater in males compared to females. Alcohol also impacted the nodal domains of myelinated axons in the mPFC in both males and females. These molecular and microstructural changes in myelinated axons could have lasting effects on neural transmission, which may explain some of the cognitive and emotional deficits linked to binge drinking.

Title: Ethanol and migration of immature gabaergic interneurons: From chloride to calcium

Authors: *S. M. LEE, P. W. L. YEH, H. H. YEH
Dept. of Mol. and Systems Biol., Geisel Sch. of Med. at Dartmouth Col., Hanover, NH

Abstract: Prenatal exposure to ethanol disrupts the normal pattern of tangential migration of cortex-bound primordial GABAergic interneurons, and this has been postulated to contribute to the etiology of fetal alcohol spectrum disorder (FASD). There is evidence that ethanol interacts with $GABA_A$ receptors that are tonically activated by ambient GABA to exert this effect but, beyond this, the cellular and subcellular mechanisms are largely unexplored. Here we initiated a project to establish the experimental premise for investigating the mechanisms linking ethanol, $GABA_A$ receptor activation and aberrant migration.
First, we asked whether ethanol exposure enhances $GABA_A$ receptor-induced depolarization. Perforated patch clamp recordings were performed on tdTomato-positive GABAergic interneurons from acute E14.5 Nkx2.1Cre/tdTomato slices to measure $GABA_A$ receptor reversal potential (E_{GABA}) before and during 6.5mM ethanol (30mg/dl or 0.03% equivalent) exposure. Ethanol exposure shifted E_{GABA} to being more depolarized compared to control. Ethanol also potentiated the amplitude of current responses to 50μM GABA. Pre-treatment of slices to 20μM bumetanide blocked the degree of ethanol-enhanced GABA depolarization.
Second, we asked whether the ethanol-enhanced GABA chloride flux is linked to a rise in intracellular calcium via voltage-gated calcium channels, since calcium is implicated in regulating neuronal migration and cytoskeletal dynamics. To this end, organotypic slice cultures were prepared from E14.5 Nkx2.1Cre/tdTomato embryos and assigned to four groups: Control, 20μM Nifedipine, 20μM Nifedipine+6.5mM Ethanol and 6.5mM Ethanol. The slice cultures

were maintained for 27 hours, fixed and tdTomato-fluorescent cells were counted to provide an index for the extent of tangential migration. The addition of the calcium channel blocker nifedipine prevented the ethanol-induced aberrant tangential migration. Ongoing experiments are employing the ratiometric calcium indicator Fura-2 to monitor ethanol-induced changes in intracellular calcium and correlate this with changes in growth cone dynamics.
The present study sets the stage for filling mechanistic gaps that link chloride homeostasis to calcium dynamics in regulating the migration of immature GABAergic cortical interneurons.

Title: Adolescent intermittent binge ethanol alters the expression of GABAergic interneurons in the prelimbic cortex of adult rat brain

Authors: *W. LIU, F. T. CREWS
Bowles Ctr. for Alcohol Studies, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: The maturation of adolescent brain is a vulnerable to repeated exposure to alcohol, particularly for prefrontal cortex (PFC) that play critical roles in inhibitory control and executive functions. Studies have shown that alcohol has significant effects on the structure and function of the PFC, but it is not clear about the role of GABAergic interneurons in the PFC. The current study examined the effect of adolescent intermittent binge ethanol on GABAergic interneurons in the adult PFC. Male Wistar rats were bred and reared in our vivarium, on postnatal day 1 (P1) litters were culled to 10 pups. At weaning on P21, male offspring were weight matched, pair-housed and assigned into control water or adolescent intermittent ethanol (AIE, 5g/kg/day, i.g., P25-P55; 2 days alcohol, 2 days off) groups. Animals were sacrificed at P80 in young adulthood. The impacts of adolescent intermittent binge ethanol (AIE) on the interneurons was determined using immunohistochemistry in the PFC (including the prelimbic, PrL and infralimbic cortex, IL). The interneuron markers, parvalbumin (PV), somatostain (SST), 5-hydroxytryptamine 3a receptor (5HT3aR), vasoactive intestinal peptide (VIP), calretinin (CR), Calbindin (CB), neuropeptide cholecystokinin (CCK), neuropeptide Y (NPY), reelin (Rln), Nitric oxide synthase (NOS), and Glutamate decarboxylase 67 (GAD67) have been used. Results showed that the PrL have a greater number than the IL in controls compared with AIE group. AIE exposure significantly affected PrL, reducing SST+ (28%, $p<0.05$), PV+ (21%, $p=0.05$), CCK+ (49%

$p<0.001$), Rln+ (37%, $p<0.01$) and NOS+IR expression (35%, $p<0.05$), but not 5HT3aR+, VIP+, CB+ and CR+IR expression at P80. Interestingly, AIE exposure increased NPY+ (51%, $p<0.05$), GAD67+, (69%, $p<0.05$) and pCaMKII+IR expression (293%, $p<0.001$). There is a correlation between the increase of NPY+ and GAD67+IR expression in AIE group. Only the decrease in Rln+IR (42%, $p<0.01$) and the increase in pCAMKII+IR expression (461%, $p<0.01$) by AIE exposure were found in IL. These findings suggest that adolescent intermittent binge ethanol exposure alters the neuronal phenotypes of the adult PFC, particularly the PrL (Funded by the NADIA from NIAAA).

Title: Altered pyramidal neuron function persists in the somatosensory cortex following prenatal ethanol exposure

Authors: *L. C. DELATOUR, H. H. YEH
Dept. of Mol. and Systems Biol., The Geisel Sch. of Med. At Dartmouth, Hanover, NH

Abstract: Exposure to ethanol during gestation can lead to a broad range of brain and behavioral abnormalities which constitute Fetal Alcohol Spectrum Disorder (FASD), a leading cause of preventable intellectual disability. We previously reported that binge-type prenatal ethanol exposure disrupts the radial migration of primordial pyramidal neurons during embryonic corticogenesis. This exposure also leads to aberrances in pyramidal neuron form and function. Specifically, there is an imbalance of GABA and glutamate-mediated neurotransmission, favoring glutamate. This was found in the somatosensory cortex during the early postnatal period, which is a critical time in synapse development. However, the underlying mechanisms for these changes and whether neurotransmission remains altered later in development, are unknown. We therefore asked whether prenatal ethanol exposure affects the excitatory/inhibitory balance, apical dendritic spines, synaptic efficacy, and synaptic strength in somatosensory cortex pyramidal neurons in early adolescent mice (postnatal day 28-32).
We employed a binge-drinking paradigm in which pregnant mice were exposed to ethanol (5% in liquid food) from embryonic day (E) 13.5 through E16.5, spanning the height of cortical

neurogenesis and migration. Using whole cell patch clamp electrophysiology, pharmacologically isolated spontaneous inhibitory and excitatory postsynaptic currents were recorded in layer V/VI somatosensory cortex pyramidal neurons in male and female mice. Our results indicate a shift in the excitatory/inhibitory balance, favoring excitation, in ethanol-exposed mice. Ongoing studies are also examining changes in action potential-independent miniature inhibitory and excitatory postsynaptic currents.
To investigate synaptic strength and efficacy, optogenetically-evoked excitatory and inhibitory synaptic currents are recorded in transgenic mice which express channelrhodopsin in either pyramidal neurons or GABAergic interneurons, respectively. Thus far, our studies reveal a change in the paired-pulse ratio of excitatory postsynaptic currents in ethanol-exposed mice compared to controls, indicative of diminished presynaptic release probability and a weaker synapse. Given this change in excitatory synaptic strength, ongoing experiments are investigating the AMPA/NMDA ratio as well as spine density and morphology.
Our findings to date indicate that prenatal ethanol exposure has persistent effects on neurotransmission and alters synaptic strength. These data strongly implicate the somatosensory cortex as an important area of study to understand the sensory deficits that hallmark FASD.

Title: Adolescent exposure to cuprizone leads to demyelination and increased microglia cell number in the corpus callosum of male rats

Authors: *E. TAVARES[1], A. SILVA-GOTAY[2], A. LIN[1], G. MOLICA[1], S. HURWITZ[3], H. N. RICHARDSON[3]
[1]Psychological and Brain Sci., Univ. of Massachusetts - Amherst, Amherst, MA; [3]Dept. of Psychological and Brain Sci., [2]Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Adolescence is an active period of brain plasticity where axonal pathways in the frontal lobes are undergoing myelination. We have found that exposure to toxic substances such as alcohol during early adolescence can lead to reduced myelin in the prefrontal cortex in male rats. To gain a better understanding of the mechanisms by which myelin can be altered during this developmental period, we tested how these axons are impacted by exposure to a

demyelinating agent. From postnatal day 28-42, male adolescent rats were fed a diet containing cuprizone, a copper chelator, or a control diet (n=6/group). Brains were then processed for analysis of demyelination in white and grey matter regions of the frontal lobes. Cuprizone exposure elicited a substantial decrease in myelin in frontal white matter fiber tracts such as the anterior branches of the corpus callosum (visualized by Luxol Fast Blue). We then used immunofluorescence and confocal microscopy to test for evidence of neuroinflammation. Microglia, the resident immune cells of the brain, activate in response to toxic substances and signal the release of pro-inflammatory cytokines. Microglia were visualized using an antibody against ionized calcium binding adaptor molecule 1 (iba1). There was almost a four-fold increase in the number of microglia within the corpus callosum of cuprizone-treated animals compared to controls. Although microglia cell number was also increased in the cortex, this change was modest compared to white matter structures. We are currently exploring whether the degree of myelin loss and microglial infiltration relates to expression of estrogen receptor alpha (ERα). Estradiol has been shown to decrease expression of pro-inflammatory factors and protect against cuprizone-induced demyelination. In addition, we have recently found ERα is expressed in microglia in the prefrontal cortex; thus, estradiol could act directly on microglia to mediate sensitivity to cuprizone.

Title: Cnr1 polymorphism, adverse childhood experience and their interaction on cannabis use and resilience abilities

Authors: *E. I. ORTEGA MORA[1], U. CABALLERO-SÁNCHEZ[1], T. V. ROMÁN-LÓPEZ[1], J. A. GONZALEZ-BARRIOS[2], M. MÉNDEZ-DÍAZ[3], O. PROSPÉRO-GARCÍA[3], A. E. RUIZ-CONTRERAS[1]

Abstract: Adolescents who had experienced childhood trauma are almost five times more likely to use cannabis than those who had not and can adversely affect resilience abilities (i.e., the ability to cope with stressful or disturbing events). A significant prevalence of childhood trauma and lower resilience levels have been observed in cannabis users, compared to healthy controls. Previous studies indicate that *CNR1*, the gene that codes for the cannabinoid receptor 1, is associated with drug dependence, but it is unknown if this gene is involved in expressing resilience abilities. The aim of the present study was to evaluate if the genotypes of the rs2180619 of CNR1 gene, childhood trauma and their interaction would influence cannabis consumption vulnerability and resilience abilities among Mexican young adults. Cannabis users and healthy controls were interviewed and were asked to answer a computerized Childhood Trauma Questionnaire (CTQ) and a Resilience Scale; finally, participants provided a saliva sample for genotyping. The exposure to childhood trauma was associated with cannabis consumption; there were not differences associated with the rs2180619 (AA, AG, GG). However, a subsequent analysis only with cannabis users showed that GG who presented higher frequency of episodes of cannabis consumption also presented higher cannabis abuse and lower resilience scores. Our results suggest that the rs2180619 of CNR1 gene as well as childhood trauma play a role in resilience and cannabis consumption. The exposure to at least one type of trauma during childhood confers a differential vulnerability for cannabis consumption and reduce the ability to cope with stressful or disturbing events, depending on the rs2180619 genotype of the CNR1 gene.

Title: Testing the role of the posterior cingulate cortex in processing salient stimuli in cannabis users: An rTMS study

Authors: *S. PRASHAD, E. S. DEDRICK, W. TO, S. VANNESTE, F. FILBEY
Univ. of Texas at Dallas, Dallas, TX

Abstract: The posterior cingulate cortex (PCC) and precuneus are hubs in the default mode network and play a role in processing external salient stimuli. Accordingly, activation in these

regions has been associated with response to salient stimuli using drug cue-reactivity paradigms in substance using populations. These studies suggest that the PCC and precuneus may underlie deficits in processing salient stimuli that contribute towards the development of substance use disorders. The goal of this study was to directly test this hypothesis using repetitive transcranial magnetic stimulation (rTMS). Using a double-blind, placebo-controlled design, we used rTMS to target the PCC and precuneus with a double-cone coil at 10 Hz (high frequency; HF) and 1 Hz (low frequency; LF) in 10 adult cannabis users and 10 age- and sex-matched non-using controls. EEG data were collected before and after rTMS during a modified oddball paradigm with neutral, oddball, self-relevant, and cannabis-related stimuli. We hypothesized greater ERP response (P2, N2, and P3 components) to self-relevant stimuli in both groups as well as greater response to cannabis-related stimuli in users only during baseline compared to after HF rTMS. Cannabis users exhibited increased amplitude in P3 (p = 0.04) and faster latencies in the P3 (p = 0.02), N2 (p = 0.02), and P2 (p = 0.04) components in response to self-relevant stimuli compared to controls during baseline that normalized after rTMS. Cannabis users also exhibited greater N2 amplitude (p = 0.02) after LF rTMS and faster N2 (p = 0.04) and P2 (p = 0.003) latencies during baseline to cannabis-related stimuli. These results suggest that cannabis users exhibited heightened salience to external stimuli that were modulated after rTMS. PCC dysfunction in cannabis users may be related to abnormalities in processing salient stimuli, such those during cue-reactivity, and provides a potential target for cannabis use disorder intervention.

Title: (Un)like two peas in a pod? Unexpected results from a preliminary study on the persistent depressive-like phenotype induced by chronic exposure to HU-210 during adolescence in female rats

Authors: *M. FERREIRA[1,2], F. M. MOURO[1,2], A. M. SEBASTIÃO[1,2]
[1]Inst. de Medicina Mol. João Lobo Antunes, [2]Insitituto de Farmacologia e Neurociências, Faculdade de Medicina, Univ. de Lisboa, Lisboa, Portugal

Abstract: Cannabis is the most widely consumed illegal drug in the world, especially amongst adolescents. Because adolescence is a period of heightened vulnerability to the impact of external influences on brain development, the persistent consequences of chronic cannabinoid use during this period are of high relevance. Animal studies have shown that chronic adolescent exposure to cannabinoid receptor (CBR) agonists induces impairments in both the cognitive (e.g. recognition memory) and affective (e.g. depressive-like phenotypes) domains, that persist into adulthood, even after drug exposure has ceased, suggesting a long lasting impact. Moreover, the affective deficits have been predominantly reported in female animals, highlighting a possible sex-specific vulnerability to effects of adolescent CBR exposure.
This work reports the results of an attempt to replicate the findings relating to the affective impact of chronic cannabinoid exposure, using a CBR agonist (HU-210) yet untested for this purpose. To that end, adolescent female Wistar rats were administered daily intraperitoneal injections for 15 days, in an escalating dosing schedule, of either HU-210 (N=10; PND35-39: 25μg/kg; PND42-46: 50μg/kg; PND49-53: 100μg/kg) or vehicle (N=10). Behavioral testing occurred after a 26-day washout (PND80) and consisted of the Elevated Plus Maze (EPM), Open Field (OFT), Social Interaction (SIT), Forced Swimming (FST), Sucrose Preference (SPT) and Marble Burying (MBT) tests.
Results showed that HU-210 decreased weight gain during the administration period, but this effect did not persist into adulthood. There were no differences between groups in either EPM, OFT or MBT performance, suggesting no changes in anxiety. Similarly, social anxiety, as indexed by the SIT, was not altered by HU-210. In the FST, HU-210 exposed animals showed diminished climbing time, but no differences in either swimming or immobility times – suggesting some alterations at the level of stress coping. During the SPT, HU-210 treated animals consumed less food than controls, but no differences were found for either sucrose preference or consumption – indicating absence of impact on the reward system.
In summary, we could observe signs of impaired stress-coping but no marked signs of a depressive-like state. While the discrepancies with previous reports might result from differences in the experimental protocol, it is also possible that HU-210 might be qualitatively different from other CBR agonists. If so, our data may raise questions as to the comparability of studies using different CBR agonists, and as to why this compound differs from others in its effects.

Title: Effects of parasympathetic activation on large-scale brain networks in adolescents with cannabis use disorder in withdrawal

Authors: *D. G. GHAHREMANI[1], L. KESSLER[2], N. AZZIZI[2], D. SARRAF[3], A. C. DEAN[2], E. D. LONDON[1]
[1]Dept. of Psychiatry and Biobehavioral Sci., [2]UCLA, Los Angeles, CA; [3]Marlborough Sch., Los Angeles, CA

Abstract: Heavy adolescent cannabis use is often associated with withdrawal symptoms during periods of cessation. These symptoms arise from activation of neural mechanisms of stress during this allostatic state (Koob & Le Moal, 2001) and are linked with resumption of drug use. We sought to determine whether parasympathetic activation during this period would relieve withdrawal symptoms and alter connectivity of large-scale resting state brain networks. Adolescents (age 17-19, Mean=18) with severe cannabis-use disorder (CUD, N=18, 5 female) completed fMRI scans on two separate days after 48-hours of abstinence from cannabis use. Withdrawal symptoms were measured via self-report questionnaires; parasympathetic activation was induced through controlled breathing techniques and was measured via heart rate variability (HRV). On each of the two testing days, withdrawal symptoms and HRV were measured before and after either undergoing controlled breathing or a guided relaxation exercise (control), directly prior to fMRI scanning. Participants showed changes in HRV after controlled breathing and reduced withdrawal symptoms. Analysis of RSFC showed decreased thalamocortical connectivity after controlled breathing vs. guided relaxation. These preliminary results suggest that strategies for parasympathetic activation during withdrawal states reduce withdrawal symptoms and connectivity of large-scale networks. They hold promise for helping to maintain abstinence during initial periods of cessation from drug use when allostatic load and potential for relapse is high.

Title: Impaired segregation between cognitive and emotional processes in cannabis dependence

Authors: *P. MANZA[1], E. SHOKRI-KOJORI[2], N. D. VOLKOW[3]
[2]Natl. Inst. on Alcohol Abuse and Alcoholism, [1]NIH, Bethesda, MD; [3]NIH/NIDA, Bethesda, MD

Abstract: Addiction is characterized by an erosion of cognitive control towards drug taking that is accentuated by negative emotional states. Here we tested the hypothesis that the enhanced interference on cognitive control reflects a loss of segregation between cognition and emotion in addiction. We analyzed Human Connectome Project data from 1204 adults aged 22-35, of whom 89 had cannabis dependence (CD). Two composite factors, one for cognition and one for emotion, that accounted for close to 50% of the variance on a large battery of neuropsychological tests, were derived using principal component (PC) analyses. Component scores for these two PCs in the CD group were significantly correlated, such that negative emotionality was associated with poor cognition. However, the corresponding component scores were uncorrelated in matched controls and in non-dependent recreational cannabis users. In CD, but not in controls or recreational users, fMRI brain activations to emotional stimuli (angry/fearful faces > shapes) correlated with the activations to cognitive demand (working memory; 2-back > 0-back). Canonical correlation analyses linked the individual differences in the cognitive and emotional component scores with the brain activations. In CD there was a substantial overlap between cognitive and emotional brain-behavior associations, but in the controls the associations were more restricted to the cognitive domain. These findings support our hypothesis of an impaired segregation between cognitive and emotional processes in CD that might contribute to impaired cognitive control under conditions of increased emotional demand. Interventions aimed at buffering negative emotionality and/or strengthening cognitive control might help restitute the loss of segregation between emotional and cognitive networks in addiction.

Title: White matter alterations in heavy cannabis users

Authors: *G. P. MONTEVERDE[1,2], A. ANGULO[2], L. NAVA[2], S. ALCAUTER[2]
[1]Inst. de Neurobiología, UNAM, Corregidora, Mexico; [2]Inst. de Neurobiología, Univ. Nacional Autónoma de México, Querétaro, Mexico

Abstract: Contradictory evidence regarding which brain areas may be compromised with high levels of marijuana consumption has been reported in previous studies. We have explored tissue integrity of the main white matter (WM) tracts using the MRI Diffusion Tensor Imaging (DTI) Technique, and evaluated cognitive function using neuropsychological tests to study the effects of chronic exposure to exogenous cannabinoids by comparing brain structure of regular users to a healthy non-consuming control group. Participants comprised 31 heavy marijuana users (main

illegal substance for recreational use, at least 16 joints per month in the previous year) and 32 controls. High resolution (voxel size of 1x1x1 mm^3) T1 weighted images were acquired in addition to 64 diffusion weighted images in a 3T MR scanner. Images were anonymized and processed using FSL´s Diffusion Toolbox; the main WM fiber segments for analysis were selected using John Hopkins University Atlas, also included in FSL.
Whole-brain WM integrity was analyzed using non parametric T tests and permutations, and it showed no significant difference between groups, defined as $p<0.05$ after correction for multiple comparisons across regions using the Threshold-Free Cluster Enhancement Tools developed for Tract Based Spatial Statistics (TBSS) by FSL. However, when analyzing specific tracts individually, widespread structural differences were identified in prefrontal and thalamic fibers. In addition, significant interactions between age and performance on psychometric tests were noted across predominantly frontal tracts for WM integrity indices.
Our results extend those findings on the effects of regular marijuana use on the brain's WM, supporting the idea that exogenous cannabinoids induce microstructural differences on several tracts by altering normal neural development and maintenance processes. Also we provide evidence that WM structural integrity measures relate to cognitive performance when assessed by different neuropsychological tests.

Title: Adolescent cannabinoid exposure increases nigrostriatal dopaminergic transmission

Authors: *E. PÉREZ[1], A. A. GRACE[3], M. E. ANDRÉS[2], J. A. FUENTEALBA[1]
[1]Ctr. interdisciplinario de Neurociencia, [2]Pontificia Univ. Católica De Chile, Santiago, Chile; [3]Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA

Abstract: Adolescence is a period characterized by gradual behavioral and physiological transition from childhood to adulthood. During adolescence, critical neuronal circuits changes to respond to physiological changes and to adapt to environmental stimuli (Sturman and Moghaddam 2011). In particular, nigrostriatal dopaminergic (DA) pathways are in constant change during the development of animals (McCutcheon and Marinelli 2009). In early

adolescence, the DA activity is lower compared to adulthood, but during the middle and late adolescence, the DA activity is higher than in adults (McCutcheon and Marinelli 2009; Naneix et al 2012). The dynamic changes observed in DA circuits suggest that adolescence is a period of high vulnerability to the long-term effects associated to drugs of abuse (Schneider 2008). The most common illegal drug of abuse used in Chile by teenagers is cannabis (Servicio Nacional para la Prevención y Rehabilitación del Consumo de Drogas y Alcohol, http://www.senda.gov.cl/observatorio/estadisticas). Evidence suggest a relationship between an early use of cannabinoids and psychiatric disorders with abnormal DA system, such as schizophrenia, depression and addiction (Renard, Rushlow, and Laviolette 2016). However, it remains unclear the impact of adolescent exposure to cannabinoids on nigrostriatal DA pathways in adulthood. We hypothesize that repeated treatment with the CB1/2 agonist, WIN55212-2, during adolescence produces a long-lasting increase in the DA activity of nigrostriatal pathways mediated by changes of neurotransmitter in DA somatodendritic region. Male rats were treated with 1.2 mg/kg WIN 55212-2 daily during the adolescence period (postnatal day 40 - 65, 25 injections), then DA electrophysiological activity in Substantia Nigra (SN), microdialysis of GABA and glutamate in SN, and microdialysis No-Net flux of DA in Dorsolateral Striatum (DLS) were carried out during adulthood (Postnatal day 72 - 78). The results show an increase in extracellular levels and releases of DA accompanied by an increases of population activity of DA neurons and a decrease of GABA extracellular levels without changes in the firing burst pattern nor extracellular levels of glutamate. These results suggest that adolescent treatment with WIN55212-2 produce a long-lasting increase of DA transmission by changes on GABAergic input, that modulate the population activity, without modify glutamatergic input, that modulate firing burst pattern (Floresco et al. 2003; Gomes, Rincón-Cortés, and Grace 2016; Steiner and Tseng 2017).

Title: Effects of exogenous cannabinoids on vagal afferent signaling

Authors: *C. W. KOWALSKI[1], F. J. SHAFFER[2], J. E. M. LINDBERG[2], B. PETERSON[2], J. H. PETERS[2]
[2]IPN, [1]Washington State Univ., Pullman, WA

Abstract: Following legalization of cannabis in some U.S. states, its use among adults over 50 years of age has increased more than twice as fast as any other age group. This population frequently suffers chronic diseases including type-II diabetes, metabolic syndrome, and cardiovascular disease; conditions influenced by both vagal afferent signaling and cannabis. Although the majority of cannabis research has focused on cannabinoid receptor 1 and 2 signaling due to its ubiquity, TRP channels have recently emerged as an excitatory target of cannabinoids. Since transient receptor potential (TRP) channels are abundantly expressed in vagal afferents where they robustly influence glutamate release, they constitute a novel and direct excitatory mechanism for cannabis to influence autonomic function. We have investigated the direct effects of the primary cannabinoids Δ-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) acutely and after chronic cannabis vapor exposure in cultured dissociated nodose ganglia and brainstem slices containing the NTS and vagal afferent terminals. With calcium imaging, we found that CBD and THC increased intracellular calcium primarily in cultured nodose neurons expressing TRPA1. This effect was blocked by removal of extracellular calcium, the nonspecific TRP channel blocker ruthenium red, the TRPA1 antagonist A967079, and genetic knockout of TRPA1. Using patch-clamp electrophysiology, we recorded CBD provoked currents in dissociated nodose ganglia consistent with a TRP-channel mediated conductance, in afferents expressing TRPA1. Both CBD and THC inhibited potassium conductance, while CBD also inhibited voltage-activated sodium channels selectively in A-fibers but not C-fibers. Using patch-clamp recordings in brainstem slices, we found that CBD approximately doubled spontaneous release frequency from NTS neurons containing TRPA1; genetic deletion of TRPA1 prevented this effect, with CBD instead slightly reducing spontaneous release frequency. The acute and chronic autonomic effects of cannabis are biphasic and generally opposed, but an explanation for this change is lacking. We investigated the effects of chronic cannabis vapor exposure on CBD and THC provoked calcium and current responses in dissociated nodose ganglia, on glutamate release in brainstem slices, and on expression of TRPA1, TRPV1, and CB1 in nodose ganglia and the NTS. Our findings demonstrate that CBD and THC effects on vagal neurotransmission are pleiotropic yet generally excitatory, putatively contributing to the autonomic effects of cannabis.

Title: Differential adaptive properties of mesolimbic and mesocortical dopamine transmission to taste stimuli after repeated exposure to the synthetic cannabinoid JWH-018

Authors: *M. A. DE LUCA[1], N. PINTORI[2], C. MILIANO[2], M. DE FELICE[2], C. SAGHEDDU[2], G. MARGIANI[2], M. ENNAS[2], M. PISTIS[2], G. DI CHIARA[2], M. CASTELLI[2]

Abstract: Since 2004, herbal mixtures broadly known as Spice/K2, containing synthetic cannabinoids (SC) such as JWH-018, have been marketed as a legal marijuana surrogate. Previous studies of our group showed that JWH-018 has CB1-receptor dependent reinforcing properties and increases dopamine (DA) transmission in the shell of the nucleus accumbens (NAc). Other studied showed that taste stimuli increase extracellular DA in the NAc and in the medial prefrontal cortex (mPFC) of rats. This effect shows single-trial habituation in NAc shell but not in core or in mPFC. However, mPFC 6-OHDA lesions, abolishes habituation of DA responsiveness to taste stimuli in NAc shell but induces it in mPFC. Such findings support the hypothesis of an inhibitory influence of mPFC on NAc DA, and its putative role in the loss of control of the motivational value of stimuli and in impulsivity. In order to test if the repeated administration of JWH-018 is able to modulate the activity of DA terminal areas and is associated to changes in the responsiveness to taste stimuli, rats were administered once a day for 14 consecutive days with JWH-018 (0.25 mg/kg i.p.) or with vehicle. After a week of washout, the DA extracellular levels were measured by *in vivo* brain microdialysis in the NAc shell and core and mPFC of rats either naive or pre-exposed to chocolate (1ml/5min i.o.); behavioral taste reactions were also recorded. JWH-018 administration inhibits the increase of DA in the NAc shell of animals naive to chocolate, abolished habituation of DA responsiveness to repeated chocolate exposure in the same area while induced it in the mPFC. In the NAc core, the treatment with JWH-018 potentiated, delayed and prolonged the stimulatory DA response to taste stimuli of animals pre-exposed to chocolate. No differences in behavioral taste reactivity were observed. Parallel studies of *in vivo* electrophysiology showed that JWH-018 treatment reduces the number of spontaneously active DA neurons of the ventral tegmental area (VTA) and increases their bursting activity. Further studies on neurodegeneration (TH in the VTA; DAT in the mPFC/NAc) produced by repeated JWH-018 administrations are in progress. These data show that JWH-018 is able to change the activity of DA neurons and to induce differential adaptive changes of the responsiveness of DA transmission to taste stimuli in DA terminal areas, similarly to previous results obtained in mPFC 6-OHDA lesioned rats. This study may be useful

to understand if such dysfunctions of cortical-limbic-striatal DAergic circuit can lead to specific detrimental effects of recurring use of Spice/K2 drugs.

Title: Tetrahydrocannabinol-induced hypernausea assessed in the conditioned gaping model in rats

Authors: *M. DEVUONO[1], K. M. HERLJA[1], E. M. ROCK[1], L. SABAZIOTIS[1], A. RAJNA[2], C. L. LIMEBEER[1], D. M. MUTCH[2], L. A. PARKER[1]

Abstract: The psychoactive component of cannabis, Δ9-tetrahydrocannabinol (THC), is known to produce several aversive effects in human users and experimental animals. THC is a partial agonist of the cannabinoid 1 (CB_1) receptor of the endocannabinoid (eCB) system. Findings in animal, as well as the characterization of "Cannabinoid Hyperemesis Syndrome" in humans suggest that high doses of THC can produce nausea/vomiting. These findings are paradoxical, however, because low doses of THC are known to reduce nausea/vomiting in humans undergoing chemotherapy treatment, and animal models of toxin induced nausea/vomiting. The mechanism responsible for the nauseating effects of THC remains unclear. It is hypothesized that a dysregulation of the eCB system is involved in the nauseating effects of THC.
The conditioned gaping model, a rat model of nausea, was used to examine the nauseating effects of high dose THC. In experiment 1, male Sprague Dawley rats underwent 3 daily conditioning trials where they received an intraperitoneal (i.p.) injection of 0.5, 5, or 10 mg/kg THC, or vehicle (VEH) following an intraoral infusion of a novel saccharin solution for 2 min at a rate of 1 ml/min. The day following the final conditioning trial, rats underwent a drug-free test where they were only exposed to intraoral saccharin. Experiment 2 evaluated the ability of the CB_1 antagonist/inverse agonist, rimonabant (SR141716A; 1 mg/kg i.p.) or VEH 30 min prior to each conditioning trial to interfere with the establishment of conditioned gaping produced by 10 mg/kg THC.

Doses of 5 and 10 mg/kg THC produced conditioned gaping reactions, whereas 0.5 mg/kg THC, a dose known to prevent lithium chloride induced conditioned gaping, and VEH did not. Pre-treatment with 1 mg/kg rimonabant prior to conditioning prevented the establishment of conditioned gaping produced by 10 mg/kg THC. These results suggest that high doses of THC can produce nausea through activation of the CB_1 receptor.
Current experiments are implementing polymerase chain reaction to investigate changes in CB_1 receptor, and eCB related enzymes (fatty acid amide hydrolase, monoacylgycerol lipase, and diacylglycerol lipase) gene expression in nausea related brain regions (interoceptive insular cortex and dorsal vagal complex), thermoregulatory regions (hypothalamus), and control regions following administration of 10 mg/kg THC.

Title: Cannabinoid/Serotonin interactions in the interoceptive insular cortex in the regulation of LiCl-induced nausea in rats

Authors: *L. A. PARKER, C. L. LIMEBEER, E. M. ROCK
Dept. of Psychology and Collabortive Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada

Abstract: Nausea and vomiting are distressing side effects of chemotherapy treatment for cancer. Currently available first-line anti-emetic therapies (in particular 5-HT3 antagonists) have been critical in reducing these side effects, however, nausea in particular is more resistant to treatment than is vomiting. Considerable recent evidence indicates that cannabinoids and manipulations that enhance the functioning of the natural endocannabinoid system may be promising treatments for nausea. Although the neurobiology of vomiting is well understood, much less is understood about that of nausea, because of the lack of selective and reliable animal models of nausea. Rats do not vomit, but they display conditioned gaping reactions (Grill & Norgren, 1978) to flavors previously paired with a nauseating treatment, such as lithium chloride (LiCl). Conditioned gaping is a more selective and specific model of nausea than is that of conditioned taste avoidance learning in rats, as anti-emetic drugs prevent gaping, but not conditioned taste avoidance. Reduced forebrain 5-HT availability, as well as enhanced

endocannabinoid availability interfere with the establishment of LiCl-induced conditioning gaping in rats, without interfering with conditioned taste avoidance. Endocannabinoids act on presynaptic cannabinoid-1 (CB_1) receptors to reduce neurotransmitter release, including that of 5-HT. Using the conditioned gaping model, we have identified the interoceptive insular cortex as a central site of action of the nausea-inducing effects of 5-HT and the anti-nausea effects of endocannabinoid manipulations. At this site, recent evidence suggests that selective depletion of 5-HT prevents the establishment of LiCl-induced conditioned gaping reactions, but not taste avoidance. As well, elevation of the endocannabinoid 2-arachidonyl glycerol (2-AG) by inhibition of its degradative enzyme, monoacylglycerol lipase (MAGL), reduces LiCl-induced conditioned gaping reactions. Using in-vivo microdialysis, we found that LiCl triggers the release of 5-HT in this region and elevation of 2-AG prevents this LiCl-induced elevation of 5-HT, presumably by its action on the CB_1 receptor. As well, the phytocannabinoid, cannabidiol, reduces LiCl-induced elevation of 5-HT, most likely by its action on somatodendritic $5\text{-}HT_{1A}$ autoreceptors in the dorsal raphe nucleus. Finally, intraoral exposure to LiCl-paired saccharin also conditionally elevates 5-HT in the interoceptive insular cortex. Understanding the neural mechanisms regulating nausea may result in the development of better treatments to control this distressing disorder.

Title: THC and stress exposure during adolescence alters behaviour in adult male Wistar rats

Authors: *A. C. WEEKS, H. QUIGLEY, B. PULYK, T. MCCHARLES, H. DOMSY, S.-L. KILBY, T. BENT, B. REIMER, A. STILLAR

Abstract: The legalization and increased use of cannabis has enhanced research interest related to the potential interactions of cannabis use and other psychological conditions. Adults and adolescents often report using cannabis as a way of coping with stress and anxiety. While the effects of cannabis use on the adult brain are fairly well understood, less is known about chronic use during adolescence. This study assessed anxiety levels, spatial memory and social interactions in adult rats after chronic stress and Δ9-tetrahydrocannabinol (THC; the main psychoactive constituent in cannabis) during the adolescent phase of development. Four

experimental groups included: stress/THC, no stress/THC, stress/vehicle, and no stress/vehicle. Following 15 days in the housing condition (stress or no stress; PND 30 to 45), daily THC or vehicle injections were carried out for 10 days (PND 45 to 55). An open field test was completed after the stress housing period to assess pre-THC anxiety levels. Following the injections, animals were allowed to age to adulthood or PND 63. An elevated zero maze task, a water maze and a social interaction task were then used to assess anxiety/fear, spatial memory, and social behavioral changes between the groups. The behavioral results suggest that chronic adolescent THC administration following stress caused adult rats to become emotionally dysregulated but not more fearful. Specifically, the elevated zero maze showed changes in the initial phases of the task. No significant changes were found in the acquisition of the water maze task but differences were observed in the probe trial where the stress/THC rats spent less time in the established location of the escape platform. The social interaction results indicated that the stress/THC rats groomed and mounted other rats less frequently. Following the behavioral tests, the rat were also perfused for synaptic analysis using electron microscopy. Pilot data from this analysis related to changes in synaptic ultrastructure in the amygdala will be presented.

Title: Cannabinoid pre-exposure does not induce sensitization or conditioned activity in adolescent rats

Authors: M. J. STONE, B. C. ADAME, B. L. OLIVER, D. O. SANCHEZ, *C. A. CRAWFORD
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Cannabis use during adolescence has increased due to enhanced availability and greater societal acceptance. This increased usage is problematic because individuals who experiment with cannabis during adolescence, when compared to adulthood, are more likely to become chronic cannabis users and experiment with other drugs. The reason why early cannabis exposure increases the susceptibility to later drug use is unclear, but it may result from altered drug sensitivity. To assess this issue, we examined the behavioral response of early adolescent rats to CP-55,490 (a cannabinoid agonist) or cocaine (a psychomotor stimulant) two days after

repeated CP-55,490 administration. In the first experiment, 137 male and female adolescent rats were given vehicle (50% DMSO/H_2O) or CP-55,490 (4, 16.5, or 40 µg/kg, IP) once daily for five consecutive days (PD 30-PD 34). On each day, locomotor activity was measured for 1 h after drug injection. After a 48 h abstinence period (i.e., on PD 36), rats were injected with CP-55,490 (4 or 16.5 µg/kg, IP) and locomotor activity was monitored for 2 h. In the second experiment, 146 male and female adolescent rats were tested using the same protocol as in Experiment 1, except rats were given vehicle (saline or 50% DMSO/H_2O), CP-55,490 (16.5 or 40 µg/kg) or cocaine (20 mg/kg) for five days and then challenged with saline or cocaine (10 mg/kg) after 48 h. In Experiment 1, CP-55,490 did not alter locomotor activity on the five pre-exposure days or cause enhanced locomotor activity on the test day (i.e., behavioral sensitization was not evident). In Experiment 2, cocaine pretreatment led to both behavioral sensitization and conditioned activity when rats were challenged with cocaine or saline, respectively, on the test day. In contrast, CP-55,490-treated rats did not show enhanced locomotor activity when injected with cocaine or saline on the test day, thus indicating that CP-55,940 did not induce behavioral sensitization or conditioned activity. These data show that repeated CP-55,490 exposure does not cause a change in drug sensitivity nor does this cannabinoid agonist act similarly to a psychostimulant drug. The failure to detect cannabinoid-induced behavioral sensitization, cross-sensitization, or conditioned activity during adolescence suggests that cannabinoid exposure may not alter drug sensitivity in a way that causes an increase in later cannabinoid or cocaine use.

Title: Working memory training reduces drug-seeking for the cannabinoid WIN 55,212-2

Authors: *S. J. STRINGFIELD[1,2], E. K. KIRSCHMANN[4], M. M. TORREGROSSA[1,2,3]
[1]Dept. of Psychiatry, [2]Ctr. for the Neural Basis of Cognition, [3]Ctr. for Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [4]Psychology & Counseling, Immaculata Univ., Immaculata, PA

Abstract: Evidence from clinical and preclinical studies suggests that cognitive training may promote resistance to the development of problem drug use or dependence. Cognitive training

may also serve as a treatment option to promote continued abstinence in individuals with several substance use disorders and is the subject of ongoing research. In rodent models of drug self-administration, rats will self-administer the synthetic cannabinoid WIN 55,212-2 (WIN), show cue-induced reinstatement of WIN-seeking, and show incubation of WIN craving after 30 days of abstinence. We hypothesized that cognitive training on a working memory task prior to WIN exposure would blunt this elevation of drug-seeking during abstinence. To test this hypothesis, adult male Sprague-Dawley rats (n=42) were trained on a delayed-match-to-sample working memory task. During this task, rats learn to nose poke into one of 5 illuminated sample ports to receive a sucrose pellet reward. After the rat nosepokes into a specific sample port, 3 adjacent ports are presented and the rat must choose the originally sampled port. Rats in the experimental group (WM) completed a cognitively taxing version of the task that engaged their working memory during a 0 - 24s delay period before the choice phase. Animals in the control (CON) group did not experience a delay before the choice phase. Next, all rats were trained to self-administer WIN (12.5µg/kg/infusion) during 2-hour sessions for 14 days. Rats were then tested in abstinence for working memory performance and WIN-seeking over 35 days. Rats were classified into high- and low-drug taking groups for further analysis based on WIN intake during self-administration. We found that CON rats took significantly more WIN than WM animals, and showed increased WIN seeking in abstinence. This effect was most pronounced in CON animals that stably self-administered higher amounts of WIN throughout self-administration. Both WM and CON animals showed decreases in working memory or control task accuracy when tested in abstinence after WIN self-administration. Thus, cognitive training on a working memory task prior to WIN self-administration has a protective effect against the subsequent expression of high levels of drug-seeking. Ongoing studies will continue to investigate the involvement of the prefrontal cortex in mediating this effect.

Title: Cocaine-induced increases in motivation require CB1 receptor activation

Authors: *V. M. AYVAZIAN[1], J. M. WENZEL[2], N. E. ZLEBNIK[2], A. BOWS[2], J. F. CHEER[2]

Abstract: A large body of evidence supports an integral role for mesolimbic dopamine in motivation. Indeed, drugs that increase dopaminergic transmission, such as cocaine, increase motivation for a number of reinforcers as measured by increased breakpoints in a progressive

ratio (PR) schedule of reinforcement. Conversely, dopamine receptor antagonism decreases PR breakpoints. Our laboratory and others have shown that phasic mesolimbic dopamine is under the control of midbrain endocannabinoids (eCBs). Relatedly, antagonism of cannabinoid type-1 (CB1) receptors decreases PR breakpoints for food reinforcers, likely through downstream effects on dopaminergic function. However, it remains unclear if drugs that increase dopamine effectively increase motivation through eCB-dependent processes. To test this, we trained female rats on a PR task for food. Once breakpoints stabilized, each rat underwent a series of test days in which they were pretreated with either cocaine (10mg/kg, IP), one of two doses of the CB1 receptor antagonist rimonabant (1, 3mg/kg, IP), or both cocaine and rimonabant. Each test session was interleaved with non-drug baseline sessions until breakpoints re-stabilized. As expected, acute cocaine increased breakpoints, while rimonabant dose-dependently decreased breakpoints. Importantly, rimonabant, at a dose that on its own did not decrease breakpoints, blocked the ability of cocaine administration to increase breakpoints. These data suggest that cocaine-induced gains in motivation are dependent upon eCB signaling, and add to a growing body of evidence supporting the eCB system as a key modulator of dopaminergic function. We are currently utilizing fast-scan cyclic voltammetry to further understand the neurobiological mechanisms underlying our behavioral observations.

Title: Cell type and pathway-specific imaging of cannabinoid receptor modulation at cholinergic terminals

Authors: *E. HERNANDEZ, D. P. COVEY, J. F. CHEER
Dept. of Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The hippocampus is well-known as a center for memory consolidation and spatial navigation, as it receives input from and is connected to a wide array of neuronal circuits. Acetylcholine input to the hippocampus is critical during memory formation, with abnormal cholinergic activity exhibiting major implications in memory-related disorders, such as Alzheimer's disease. The endocannabinoid (eCB) system, known for its modulation of marijuana's psychoactive and reinforcing aspects in the brain, is a wide neurochemical network that also plays a major role in memory consolidation. Indeed, we have recently found dense expression of the cannabinoid type 1 (CB1) receptor on medial septal cholinergic neurons that

innervate the hippocampus, suggesting an important role of this pathway in mnemonic processes. In order to harness this anatomical framework, we used our recently-published transgenic mouse line bearing a selective deletion of CB1 receptors on cholinergic neurons. We tested short-term memory in these animals and showed an increase in function in a delayed non-match to sample task. Additionally, we monitored short-term spatial memory consolidation in a novel object recognition task. This particular test allows for habituation to the environment and familiarization to a set of objects before the introduction of a novel object. Spatial memory capacity was quantified by measuring the rodents' innate tendency to recognize novel objects familiar objects within an open field. To further understand cholinergic signaling in the hippocampus, we employed *in vivo* calcium imaging through miniature endoscopes to visualize longitudinal patterns of activity at CA1 pyramidal neurons, which were contrasted between experimental and control animal cohorts of both sexes. These results will help elucidate the extent to which the eCB system regulates memory function within the hippocampus and may offer insight into abnormal cholinergic activity associated with memory-related symptoms during cannabis use, as well as in disorders such as dementia.

Title: Chronic D9-tetrahydrocannabinol (THC) causes pathway-specific synaptic plasticity in the nucleus accumbens

Authors: *E.-K. HWANG, C. R. LUPICA
Electrophysiology Res. Section, Cell. Neurobio. Res. Br., NIDA IRP, NIH, Baltimore, MD

Abstract: Cannabis is the most widely used illicit drug and its chronic use is associated with cannabis use disorder (CUD). THC is an agonist of CB1, and CB2 cannabinoid receptors that are found throughout the brain. The nucleus accumbens shell (NAcs) is important for reward and motivated behavior, receives glutamate inputs from a wide array of brain regions, including the ventromedial prefrontal cortex (vmPFC), the ventral hippocampus (vHipp) and the basolateral amygdala (BLA). These divergent glutamatergic inputs are integrated in the NAcs to regulate the activity of medium spiny neurons, and dysfunction of these pathways contribute to drug reward and addiction. The axons of dopamine (DA) neurons originating in the ventral tegmental area (VTA) also densely project to neurons in the NAcs. Many VTA DA neurons projecting to NAcs

also co-release glutamate, and the consequences of this are not fully understood. Brain imaging studies in CUD subjects show that corticolimbic circuits, including the NAcs, are altered, and this is associated with dysregulated cognition, learning, and emotion. However, our understanding of the mechanisms underlying these neuronal changes is limited. Here, we examine functional consequences of chronic exposure to the psychoactive constituent of cannabis (THC) on glutamatergic afferents to the NAcs arising in the vmPFC, vHipp, BLA and VTA using optogenetics. We find that chronic THC weakens glutamatergic vmPFC-NAcs synapses via diminished glutamate release probability. In contrast, synaptic strength in vHipp-NAcs synapses is strengthened by chronic THC, and this is mediated by AMPA receptor subunit changes. Moreover, BLA-NAcs synapses are strengthened by chronic THC, and, although overall glutamate synaptic strength is not altered by chronic THC in the VTA-NAcs pathway, both the proportion of AMPA receptors lacking GluR2 subunits and the probability of glutamate release increase, suggesting homeostatic reorganization. We also find that group I mGluR-dependent long-term depression is prevented by chronic THC at both vmPFC-NAcs and vHipp-NAcs synapses. In conclusion, chronic THC exposure results in altered glutamate synapse function in several corticolimbic pathways impinging on the NAcs, and we suggest that this relates to the pattern of cognitive and emotional changes observed in chronic cannabis users.

Title: Acute THC impairs voluntary locomotor activity through both CNR1 and non- CNR1 ammonia-mediated mechanisms

Authors: *M. ZUCCOLI[1,2], S. SARSFIELD[1], L. WHITAKER[1], O. A. ABULSEOUD[1], Y. APONTE[1]
[1]NIDA IRP, Baltimore, MD; [2]Intrnl. Med., Univ. of Genoa, Genoa, Italy

Abstract: Substantial evidence indicates inhibitory effects of THC on locomotor activity. The dorsolateral striatum (DLS) has been broadly studied for its role in mediating these locomotor effects. It is widely accepted that these effects occur through presynaptic inhibition of neurotransmitter release of striatal outputs mediated by cannabinoid type 1 receptor (CNR1). However, we previously demonstrated that a single administration of THC to naive mice induced

a 10-fold increase in striatal ammonia concentration, suggesting its potential role in locomotor activity suppression. Excess ammonia decreases spontaneous locomotor activity in mice and alters neuronal firing patterns, glutamatergic signaling, and production of nitric oxide (NO). Moreover, a recent study showed a decrease in exploratory activity and reduced magnitude of long-term potentiation in corticostriatal synaptic transmission under hyperammonemia. These findings suggest that THC might alter the excitability of neuronal circuits in the striatum, not only through the activation of CNR1, but also by inducing a transient increase in ammonia concentration. Here we report the effects of single administration of THC or ammonium acetate (NH_4Ac) on locomotor activity tested by open field (OF) and running wheel (RW), neuronal activity within the DLS using *in vivo* two-photon endomicroscopy, and glutamatergic transmission using brain slice electrophysiology. Moreover, we tested the efficacy of sildenafil citrate (SILD), a phosphodiesterase inhibitor involved in the NO pathway, to reduce THC-induced hypolocomotion. Our results show that both THC and NH_4Ac cause significant reduction in OF (THC: $p<0.0001$; NH_4Ac: $p<0.0001$, $n=8$/group) and RW (THC: $p<0.0001$; NH_4Ac: $p<0.0001$, $n=4$/group). These behavioral changes correlate with a significant attenuation in DLS neuronal activity. In addition, electrophysiological recordings reveal fluctuations in NMDAR function following THC and NH_4Ac administration. Neutral CNR1 antagonist NESS 0327 successfully reversed the overall locomotor effects of THC ($p<0.0001$, $n=7$). However, NESS 0327 did not reverse the THC effect within the first 5 minutes post-injection, suggesting that during this early time window hypolocomotion is not mediated by CNR1. Remarkably, pretreatment with SILD blocked the overall effect of THC on locomotor activity ($p<0.0001$, $n=8$), and unlike NESS 0327, SILD blocked this activity within the first 5 minutes ($p=0.003$). In summary, these results are the first to report effects of THC mediated by ammonia and indicate sildenafil citrate as a potential treatment for some cannabis-related side effects.

Title: The cognitive effects of delta-9-tetrahydrocannabinol and cannabidiol in the ventral hippocampus are mediated through differential modulation of the c-jun-n-terminal kinase pathway and prefrontal cortex neuronal activity

Authors: *R. M. HUDSON[1], W. RUSHLOW[2], S. R. LAVIOLETTE[2]
[1]Neurosci., [2]Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: Adaptive behaviours and cognition require accurate processing of the endless barrage of sensory information entering the brain. In particular, the brain must appropriately discern this information to engage in contextually appropriate and adaptive memory formation that enables ongoing environmental interactions. Evidence suggests that the phytocannabinoids delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) induce distinct actions on attention, memory acquisition, and psychiatric risk. In fact, chronic cannabis users exhibit volumetric reductions in cortical and subcortical brain regions, and large doses of THC induce neuronal apoptosis via activation of the c-Jun N-terminal kinase (JNK) signaling cascade. However, the contributions of specific neurocircuitry to THC-induced cognitive disturbances, and whether CBD co-administration can counteract these processes remain unknown. Given that direct projections between the ventral hippocampus (VHipp) and medial prelimbic prefrontal cortex (mPFC) facilitate contextually-relevant attentional processing and subsequent memory formation, we explored the hypothesis that VHipp THC and CBD elicit opposing effects on mPFC neuronal activity to influence attention and memory processing via distinct actions on the JNK signal transduction pathway. We examined the effects of VHipp THC, CBD and their combination on attentional processing and memory formation, VHipp JNK phosphorylation, and mPFC neuronal and oscillatory activity. VHipp THC induced deficits in social interaction, exploratory behaviours, and spatial memory assays that were rescued by CBD co-administration, or inhibition of VHipp JNK phosphorylation. Although THC considerably increased startle responses during pre-pulse facilitation, this effect was inverted into startle inhibition by CBD co-administration, or JNK inhibition. Sensorimotor gating was enhanced by the THC+CBD combination. Whereas intra-VHipp THC increased mPFC gamma oscillations and decreased mPFC phasic bursting activity via activation of VHipp JNK phosphorylation, CBD increased mPFC bursting activity via decreased VHipp JNK phosphorylation. In contrast, combined THC+CBD inhibited the actions of either drug on mPFC single unit and oscillatory activity. Our findings indicate the VHipp JNK signaling pathway as a critical molecular signaling mechanism by which THC dysregulates attention and memory processing, and suggest important implications for specific cannabis compounds in psychiatric disorders.

Title: Measuring 2-arachidonoylglycerol hydrolyzing activity by ABHD6

Authors: *S. SINGH[1], N. STELLA[2]
[1]Univ. of Washington, Seattle, WA; [2]Pharmacology/Joint Psychiatry & Behavioral Sci., Univ. Washington, Seattle, WA

Abstract: α/β Hydrolase domain containing 6 (ABHD6) is a serine hydrolase that cleaves 2-arachidonoylglycerol (2-AG), the most abundant endocannabinoid (eCB) in the brain, into arachidonic acid and glycerol. Inhibition of ABHD6 may produce potential therapeutic benefits, including reducing the severity and frequency of seizures that are triggered by various devastating neurological diseases. To date, we have a very limited understanding of the molecular mechanism behind ABHD6 function in neurons and how it controls 2-AG levels and eCB signaling.

To study the molecular mechanism involved in 2-AG hydrolysis by ABHD6, we implemented and validated an enzyme-linked fluorescent assay that measures the production of glycerol resulting from 2-AG hydrolysis. In this assay, glycerol enters a series of enzymatic reactions that produces the fluorescent product resorufin, which is excited at 530 nm to detect a 590 nm emission. To validate this assay, we selected a cell line that expressed high levels of ABHD6 mRNA (SK-MEL-2, a melanoma cell line) and low levels of ABHD6 mRNA (U251 cells, a glioblastoma cell line). We found that SK-MEL-2 exhibits higher 2-AG hydrolyzing activity than U251 (rate of glycerol production over the course of 60 minutes was 0.75 pmol/min and 0.53 pmol/min, respectively, for 30 µg of lysate; n = 2) and that 2-AG hydrolysis in SK-MEL-2 cells showed greater inhibition following treatment with an ABHD6 inhibitor compared to U251 cells (KT-182, 10 µM, 41% and 8.3% inhibition, respectively), confirming a higher ABHD6 activity in the SK-MEL-2 cells. This result was further validated with quantitative-reverse transcriptase PCR of ABHD6 mRNA that showed that SK-MEL-2 cells had on average about five times more ABHD6 mRNA expression than U251 cells.

Our results show that this fluorescent-based assay allows for reliable, precise and relatively cheap measurements of 2-AG hydrolysis in cell lysates. This assay gives us a platform to measure 2-AG hydrolysis by ABHD6 as well as study the molecular mechanism underlying ABHD6 hydrolysis activity and the mechanism of action of ABHD6 inhibitors. Pharmacological

inhibition of ABHD6 activity in the brain represents a promising therapeutic approach to modulate the eCB signaling for the treatment of various diseases, including epilepsy.

Title: Sex differences in the potentiation of intermittent self-administration on incubation of cocaine craving: Effect of estrous cycle

Authors: *C. NICOLAS, T. I. RUSSELL[1], A. PIERCE[1], A. HOLLEY[2], Z.-B. YOU[1], M. M. MCCARTHY[2], Y. SHAHAM[1], S. IKEMOTO[1]

Abstract: Cocaine seeking progressively increases during abstinence, a phenomenon termed 'incubation of cocaine craving'. Incubation of craving has been demonstrated using a continuous cocaine self-administration procedure. Recently, Zimmer et al. (2011) introduced an intermittent self-administration procedure in which the rats have access to cocaine for 5 min followed by 25 min of time out, and found that this procedure increases motivation to self-administer cocaine. Additionally, studies report sex differences and a role of ovarian hormone in cocaine relapse. Here, we studied whether intermittent cocaine self-administration would increase incubation of craving in male and female rats, and then we investigated the role of ovarian hormones in this effect. First, we trained male and female rats to self-administer cocaine (0.75 mg/kg/infusion) continuously or intermittently for 12 days (8 h/day). We found, in both sexes and under both training conditions, an escalation of cocaine intake and a higher cocaine seeking in the relapse test after 29 days than 2 days (incubation of craving). Importantly, in both training conditions, female rats showed an increase of drug seeking on both day 2 and 29 compared to males. However, potentiation of incubation of craving was observed exclusively in females after intermittent self-administration. Next, by monitoring the estrous cycle in females, we found that only the rats in estrus showed an incubation of cocaine craving. Our results demonstrate that intermittent cocaine access potentiates the incubation of craving and suggest a critical role of ovarian hormones in this effect in female rats, highlighting the importance of the therapeutic window in the treatment of addiction in women.

Title: Neural encoding of reward seeking in the medial prefrontal cortex

Authors: *Y. ZHANG, G. BARBERA, L. ZHANG, B. LIANG, Y. LI, Y. SHAHAM, D.-T. LIN
NIH, Baltimore, MD

Abstract: The search for better therapeutic strategies for drug addiction raises the challenge to diminish motivation for drug without decreasing that for natural rewards. While the medial prefrontal cortex (mPFC) is important for reward seeking, how prefrontal neural activities code reward seeking remains unknown. Here, we employed miniScope, a custom miniature fluorescence imaging system, together with detailed computational analysis, to simultaneously track calcium activities from hundreds of neurons longitudinally, at the single cell resolution in the mPFC during mice food and cocaine self-administration. We found that different subgroups of neurons showed increased activity around distinct behavioral events (i.e. house light on, lever extend into behavior chamber, lever press/cue presentation, and food retrieval). More neurons were active during lever press/cue presentation and food retrieval. We further observed that distinct subsets of neurons were active during lever press/cue presentation for food and cocaine, respectively. Our results suggest distinct and dynamic neural population codes for natural reward and drug reward seeking in the mPFC and pave the way for future efforts in targeting specific neural codes for drug reward seeking as novel therapeutic strategies for drug addiction.

Title: Reward- and context-specific ensembles following sucrose or cocaine self-administration in mice

Authors: *M. SLAKER[1], N. N. NAWARAWONG[1], C. M. OLSEN[2]
[1]Pharmacol. and Toxicology, [2]Neurosci. Res. Ctr., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Neuronal ensembles are small sets of neurons whose activity is required for manifestation of a behavior. Previous studies have identified ensembles in fear and reward memory that are sufficient to drive behavior. The TetTag mouse model is a unique reporter line that allows the study of neuronal ensembles over time. The TetTag mouse model is a Tet-Off reporter mouse that uses the c-Fos promoter to drive expression of a long-lasting EGFP-histone-2B fusion protein tag. Our lab has previously identified an ensemble within the medial prefrontal cortex (mPFC) whose reactivation correlated to the persistence of cocaine seeking across two drug seeking sessions separated by 2 weeks abstinence. We found that the greater proportion of an ensemble activated during a seeking session on abstinence day 7 that was reactivated on day 21 was correlated to a higher degree of cocaine-seeking behavior. Most human drug use, however, does not occur in one environment, but instead spans multiple settings. Contextual cues can reinstate drug seeking even when operant responding has been extinguished in a different environment, and a 2014 study identified a specific ensemble within the nucleus accumbens shell that mediated context-induced reinstatement of cocaine seeking. Therefore, in this study, we examined the association between cocaine-seeking ensembles and contexts within the mPFC and nucleus accumbens. TetTag mice were trained to self-administer cocaine (0.5mg/kg/infusion) in two distinct contexts. Seeking on abstinence day 7 was tested in one context and tagged with EGFP, while seeking on abstinence day 21 was tested in the other context and assessed for c-Fos. In both contexts, mice were able to learn self-administration and show elevated levels of seeking. We also examined the specificity of the context ensemble to an additional rewarding modality, 10% sucrose. TetTag mice learned to self-administer a sucrose solution in two contexts with robust responding during seeking tests. Future analysis will examine the similarities and differences between populations of ensemble cells identified in each context, as well as those

labeled by both contexts. These studies provide insight into the ability of contextual cues to trigger seeking behaviors at a neuronal level.

Title: Conditioned gaping produced by delayed, but not immediate, exposure to cocaine in rats

Authors: *K. GUENTHER, C. E. WIDEMAN, E. M. ROCK, C. L. LIMEBEER, L. A. PARKER
Univ. of Guelph, Guelph, ON, Canada

Abstract: Wheeler (2008) reported that following several daily pairings of multiple exposures to a saccharin cue with the delayed (30 min) opportunity to self-administer cocaine, rats eventually display conditioned gaping reactions (Grill & Norgren, 1978) during the waiting period, suggesting a conditioned withdrawal effect. In contrast, Parker (1993) demonstrated that following several spaced (72 hr apart) conditioning trials with a 2-min exposure to a saccharin cue immediately followed by a subcutaneous (sc) injection of cocaine, rats did not display conditioned gaping reactions. Here we determined if both effects could be reproduced under similar conditioning protocols (daily conditioning trials) that differed by short single exposure and delayed multiple exposures to saccharin. In Experiment 1, rats were given daily conditioning trials with a 2-min exposure to saccharin which was immediately followed by 5, 10 or 20 mg/kg cocaine sc (1a), cocaine ip (1b) or 50 mg/kg LiCl (1c). In Experiment 2, rats were given daily multiple brief (10 sec) exposures to saccharin over a 30-min period prior to cocaine (20 mg/kg, both sc and ip) or LiCl (50 mg/kg, ip) injections. Experiment 3 evaluated the potential of a context which signals delayed access to cocaine to produce aversive response. Experiment 4 evaluated the potential of another rewarding drug, morphine (10 mg/kg sc) to produce aversive reactions following pairings of delayed access (10 min). Finally, Experiment 5 evaluated the potential of sc cocaine to produce aversive aftereffects (Ettenberg, 1999) using a conditioned floor preference paradigm, with different groups receiving 20 mg/kg, sc cocaine 0, 15, 30 and 60 min prior to placement in the chamber with a distinctive floor. Conditioned gaping reactions and chin rubbing reactions were elicited by saccharin (but not a context) paired with delayed cocaine (sc stronger than ip), but not by immediate exposure to cocaine; however, neither immediate nor

delayed cocaine produced the aversive reactions paw treading. Both cocaine and LiCl produced the ingestion related effects of suppressed tongue protrusions and enhanced passive drips consistent with previous reports (Parker 1993). When injected sc, but not ip, cocaine also elicited the potential withdrawal reactions of yawning. When administered sc, 20 mg/kg cocaine did not produce a conditioned floor preference or aversion (as reported by Mayer & Parker, 1993) at any post-cocaine interval. The results are consistent with Wheeler et al (2008) that when paired with delayed access to cocaine, the flavour triggers an negative affective state that is revealed by gaping.

Title: Alpha$_{2a}$-adrenergic hetero-receptors are necessary for stress and agonist regulation of BNST activity and stress-induced reinstatement of cocaine-associated behaviors

Authors: *R. PEREZ[1], N. HARRIS[2], B. NABIT[3], S. FLAVIN[1], K. MERKEL[2], R. GILSBACH[4], L. HEIN[4], D. WINDER[2]
[2]Mol. Physiol. and Biophysics, [3]Pharmacol., [1]Vanderbilt Univ., Nashville, TN; [4]Pharmacol., Univ. of Friedburg, Friedburg, Germany

Abstract: Stress is often cited as a precipitating factor for relapse of cocaine use. Therefore, clinically available alpha$_{2a}$-adrenergic receptor (A_{2a}-AR) agonists, have been investigated as potential treatments for stress-induced craving and relapse. While A_{2a}-AR agonists decrease stress-induced craving, they have not reduced relapse rates. It has been postulated that A_{2a}-AR agonists reduce craving by engaging auto-receptors and blunting norepinephrine (NE) release in brain regions critical for stress-induced drug seeking, such as the bed nucleus of the stria terminalis (BNST). However, using a genetic strategy in which A_{2a}-ARs are re-expressed in NE-producing cells of A_{2a}-ARs knockout mice (hetero-receptor KOs), many of the pharmacological functions originally ascribed to A_{2a}-AR auto-receptors, such as analgesia and sedation, have been suggested to be mediated by hetero-receptors. The relative role of these receptor pools in the regulation of drug seeking behavior has not been investigated. Thus, we aimed to determine the role of A_{2a}-AR hetero-receptors in stress induced reinstatement of cocaine-associated behaviors and in regulation of BNST activity. We evaluated the role of hetero-receptors in stress-induced

reinstatement using the cocaine conditioned place preference (CPP) paradigm. We found that in wild-type, 6 minutes of forced swim stress reinstates previously extinguished cocaine CPP. However, stress failed to reinstate CPP in full or hetero-receptor KO mice. We also evaluated changes in BNST activity following stress by measuring levels of cFOS, a neuronal activity marker, following 30 minutes of restraint stress in wild type, full and hetero-receptor A_{2a}-AR KO mice. We found that stress significantly increases the number of cFOS positive neurons in wild-type mice but not in full or hetero-receptor KO mice. We also evaluated whether A_{2a}-AR hetero-receptors are necessary for agonist regulation of excitatory transmission within the BNST using an *ex vivo* patch-clamp electrophysiology approach combined with application of the A_{2a}-AR agonist guanfacine. We found that guanfacine depresses excitatory transmission within the BNST of wild-type mice, however, this suppression does not occur in full or hetero-receptor KO mice. These findings suggest that following stressful stimuli, A_{2a}-AR hetero-receptors regulate the activity of the BNST to induce reinstatement of cocaine seeking.

Title: Novelty place preference predicts addiction-like behavior in C57BL/6J mice self-administering cocaine

Authors: *D. GUZMAN, K. LINDQUIST, S. G. BIRNBAUM, D. W. SELF
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Identification of premorbid genetic vulnerability to drug addiction has been hindered by an absence of large scale human genetic data to specific drug classes (e.g., opiates, psychostimulants). One approach is to focus on intermediate phenotypes related to vulnerability to drug addiction in both pre-clinical and clinical studies. For example, novelty-seeking traits have been associated with drug abuse disorders in humans and have been found to predict initiation of drug use. In rats, a high Novelty Place Preference (NPP) predicts the development of an addictive-like phenotype with prolonged cocaine self-administration. The aim of the current study is to confirm that NPP also predicts cocaine addictive-like behaviors in mice, which would allow for high throughput screens of NPP in mutagenesis studies to identify genes involved in novelty seeking and vulnerability to addiction. We measured the preference for novel versus

familiar side of a 3-compartment test chamber in male C57BL/6J mice. The mice were first confined to one side for a 20-min period (i.e., becomes the “familiar” side). The mice were then removed and placed in a holding cage for 2-min, and then placed into a center compartment and given free access to both the familiar and novel sides for a 10-min test period. As expected, animals averaged over 60% of the time in the novel side during the test. We also measured the difference in time spent between the novel and familiar side as a “novelty score”. 24 mice were grouped by a median split and upper and lower quartiles and designated as “HIGH” or “LOW” NPP responders and were subsequently trained to self-administer cocaine (CSA). Once animals reached acquisition criteria, we tested them using two measures of addictive-like self-administration and relapse behaviors. We found that the HIGH NPP group (n = 6/upper quartile) exhibited a vertical shift in the dose-response for CSA (fixed ratio schedule) compared to the LOW group (n = 6/ lower quartile). Second, following a 7-10 day withdrawal period and 5-hr extinction session, the HIGH group also exhibited a significantly higher level of cue-induced reinstatement compared to the LOW group. Finally, in a separate group of 6 mice, HIGH NPP responders (n=3/upper median) worked harder to self-administer cocaine compared to the LOW NPP responders (n=3/lower median) when tested using the progressive ratio reinforcement schedule. These data validate the association between a high NPP phenotype and cocaine addiction-like behaviors, and support the use of NPP as a screen in mutagenesis studies to identify genes that convey vulnerability to cocaine addiction.

Title: Effects of chronic stress exposure during withdrawal on the incubation of cocaine craving in adult female rats

Authors: C. M. CORBETT[1], E. BABENKO[2], *J. A. LOWETH[2]
[1]Grad. Sch. of Biomed. Sci., [2]Cell Biol. & Neurosci., Rowan Univ. Sch. of Osteo. Med., Stratford, NJ

Abstract: Although clinical studies indicate sex differences in both cocaine addiction and stress and anxiety disorders, the majority of preclinical studies on cue- and stress-induced relapse vulnerability have been conducted with male rats. Our own recent studies with adult male rats

indicate that chronic stress exposure during early withdrawal from extended access cocaine self-administration accelerates the time-dependent intensification or incubation of cue-induced cocaine craving that occurs during the first few weeks of withdrawal. This enhanced cue-induced seeking behavior observed following chronic stress exposure may make rats more vulnerable to cue-induced relapse during this period. We are currently conducting studies to assess whether similar effects of chronic stress exposure on incubation of cocaine craving are observed in adult female rats and to characterize the time course of these effects. Similar to our previously published studies with male rats, freely cycling female rats will self-administer cocaine under extended access conditions (6 hours per day for 10 days). During the first two weeks of withdrawal, rats will receive repeated restraint stress exposure or control conditions and changes in cue-induced seeking behavior will be assessed at different time points during withdrawal. Prior to all seeking tests, vaginal smears will be performed to determine estrous cycle stage and preliminary analyses will be conducted to determine whether estrous cycle influences stress-induced changes in cocaine seeking behavior. These findings will identify whether sex differences exist in cue- and chronic stress-induced relapse vulnerability and may pave the way for subsequent studies to study the interaction of cocaine and stress in female rats.

Title: DBS-like optogenetic stimulation of accumbens dopamine D2 receptor-containing neurons attenuates cocaine reinstatement

Authors: *P. J. HUFFMAN[1], M. C. KNOUSE[1], S. E. SWINFORD-JACKSON[1], A. U. DEUTSCHMANN[2], A. S. THOMAS[1], L. A. BRIAND[2], R. C. PIERCE[1]
[1]Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Psychology, Temple Univ., Philadelphia, PA

Abstract: Previous work indicated that deep brain stimulation (DBS) of the nucleus accumbens (NAc) shell attenuated reinstatement of cocaine-seeking in rats. However, the potential differential impact of DBS on specific populations of neurons to drive the suppression of cocaine-seeking is unknown. Medium spiny neurons in the NAc are differentiated by the expression of dopamine D1 receptors (D1DRs) or dopamine D2 receptors (D2DRs), activation of

which promotes or inhibits cocaine-seeking behavior, respectively. We used recently-developed transgenic rat lines that express Cre recombinase selectively in D1DR-containing or D2DR-containing neurons in combination with a Cre-dependent adeno-associated viral vector expressing channelrhodopsin (ChR2) to deliver high frequency optogenetic stimulation selectively to each population of neurons in the NAc shell. Rats were trained to self-administer cocaine, and this behavior was extinguished prior to the cocaine-primed reinstatement sessions. Intra-NAc shell DBS-like optogenetic stimulation or no stimulation was administered throughout the reinstatement session. DBS-like optogenetic stimulation of D2DR-containing neurons attenuated reinstatement of cocaine seeking, whereas DBS-like optogenetic stimulation of D1DR-containing neurons did not alter cocaine-primed reinstatement. Electrophysiology experiments to further explore the effect of DBS-like optogenetic stimulation on cell firing indicate that high frequency stimulation of D2DR-containing accumbens MSNs results in virtually instantaneous neural silencing. Collectively, these results suggest that DBS of the NAc attenuates cocaine-primed reinstatement through the selective inactivation of D2DR-containing neurons.

Title: Stress-induced reinstatement requires PAC1 receptor endosomal MEK signaling

Authors: *O. MILES[1], S. BRAINARD[1], V. MAY[2], M. E. BOUTON[1], S. E. HAMMACK[1]
[2]Dept. of Neurolog. Sci., [1]Univ. of Vermont, Burlington, VT

Abstract: A primary challenge in the treatment of substance abuse is the tendency of users to relapse following acute or extended periods of abstinence; on average, over 60% of substance abusers will return to drug use within a year of receiving treatment, many relapsing following stressful life events. Central to the successful treatment of drug addiction is understanding the cellular mechanisms by which relapse episodes occur. We have previously demonstrated that in rats that learned to lever press for intravenous cocaine, and subsequently had that behavior

extinguished, a bilateral intra-bed nucleus of the stria terminalis (BNST) infusion of pituitary adenylate cyclase-activating peptide (PACAP) caused robust reinstatement of drug seeking on the lever previously associated with cocaine delivery. Furthermore, the bilateral intra-BNST infusion of PACAP type 1 receptor (PAC1-R)/vasoactive intestinal peptide type 2 receptor (VPAC2) antagonist PACAP6-38 blocked reinstatement of cocaine seeking following stressor exposure. In the current studies, we used immunohistochemical procedures, pharmacological treatments, and a behavioral model of stress-induced relapse to evaluate PACAP and PAC1-R signaling in stress-induced reinstatement to cocaine seeking. BNST infusions of PAC1-R selective agonist, maxadilan, reinstated drug-seeking on the lever previously associated with cocaine delivery, specifically implicating PAC1-Rs (rather than VPAC2-Rs) in reinstatement to drug-seeking. Moreover, footshock stress increased BNST phosphorylated extracellular signal-related kinase (pERK) expression in cocaine-experienced rats, and this increase was blocked by BNST PACAP receptor antagonism. Recent studies have suggested that PAC1-R activation may lead to endosomal signaling and MEK activation that influence intracellular events. Here, we show that footshock-induced reinstatement and subsequent PACAP receptor-dependent pERK signaling is abrogated by BNST pretreatment with mitogen activated protein kinase-ERK (MEK) inhibitor, PD98059, or an endocytosis inhibitor, Pitstop2, that blocks extracellular signal-related kinase (ERK) signaling. These data suggest that the activation of PAC1-R endosomal MEK/ERK signaling is a key event underlying stress-induced reinstatement. Furthermore, this data suggest that there may be long term changes in the BNST PACAPergic system (i.e. sensitization) following cocaine exposure.

Title: Impact of endogenous ghrelin on the maintenance and reinstatement of cocaine addiction-like behaviors in self-administration trained rats

Authors: *Z.-B. YOU[1], B. WANG[2], G.-H. BI[1], F. ALEN[1], Z.-X. XI[1], R. A. WISE[2], E. L. GARDNER[1]
[1]Mol. Targets and Medications Discovery Br., [2]Behavioral Neurosci. Br., NIDA-IRP/NIH/DHHS, Baltimore, MD

Abstract: Appetitive hormones are well recognized as important modulators of body mass, food intake and energy homeostasis primarily via their actions on hypothalamus neurons. Most such

hormones also regulate the functions of mesolimbic dopamine system, a brain system critical for the rewarding effects of food and abused drugs. Ghrelin, an orexigenic hormone secreted primarily from stomach and gut, has been recently found not only to stimulate mesolimbic dopamine transmission and modulate food reward, also to be involved in the regulation of the rewarding effects of most abused drugs-including nicotine, amphetamine and cocaine as tested using classical place conditioning. The roles of ghrelin in drug self-administration (S-Ad) remain largely to be investigated. In this study, we systemically investigated the responses of ghrelin in bloodstream to cocaine S-Ad and S-Ad related behaviors, and the effects of ghrelin antagonism on such behaviors using the selective ghrelin receptor antagonist JMV2959 in rats. We found that cocaine S-Ad (1 mg/kg /infusion) is associated with dramatic elevations in plasma ghrelin levels. These elevations are also seen when rats (either cocaine-trained or cocaine-naïve) receive yoked cocaine infusions (cocaine infusions triggered via lever-presses of other trained rats). The elevations of ghrelin by yoked cocaine are significantly less in cocaine-naïve than in cocaine S-Ad trained rats. S-Ad of saline (first saline substitution session in trained rats) also caused significant elevations of ghrelin levels, but these elevations are less prominent than those seen under cocaine S-Ad and are no longer evident during the 14^{th} extinction session. Pretreatment of cocaine trained rats with JMV2959 (0-6mg/kg, i.p.) dose-dependently inhibits animals' responding on the active lever tested either for S-Ad or during extinction. Pretreatment with JMV2959 inhibits reinstatement of cocaine-seeking induced by cocaine (10 mg/kg, i.p.) in cocaine S-Ad trained and subsequently behaviorally extinguished rats. Our findings indicate a significant stimulatory effect of cocaine on ghrelin secretion and that this effect is strengthened in rats following repeated cocaine S-Ad training and can be conditioned to the stimuli associated with cocaine S-Ad. The inhibitory effects of JMV2959 on cocaine S-Ad, non-reinforced extinction "burst" responding and on cocaine-induced reinstatement suggest a contributory role of ghrelin signaling in the maintenance of and in provoking motivation for cocaine. Thus, manipulations of ghrelin systems may represent a feasible approach for psychostimulant addiction treatment. Supported by funds from NIDA-IRP

Title: Inhibition of glycogen synthase kinase 3 disrupts cocaine-associated memories in the rat self-administration model

Authors: *J. L. BARR, X. SHI, E. M. UNTERWALD
Dept Pharmacol & Ctr. Sub Abuse Res., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Addictive drugs stimulate associative learning processes, and subsequent exposure to drug-related contexts or cues previously associated with drug elicit conditioned responses that can trigger drug-seeking behaviors that can promote relapse after prolonged periods of abstinence. Therefore, learning and memory processes play an important role in the maintenance of addiction and disruption of the maladaptive associations between environmental cues and the memory of cocaine-induced reward may diminish cue-induced drug seeking behaviors and ameliorate relapse vulnerability. Glycogen Synthase Kinase 3 (GSK3) signaling is critical for the maintenance of cocaine contextual memories. Exposure to an environment previously paired with cocaine activates GSK3, and administration of the selective GSK3 inhibitor SB216763 after exposure to a cocaine-paired environment abolished a previously established place preference. We hypothesized that GSK3 inhibition after recall of cocaine self-administration memories will reduce subsequent cue reactivity. Adult Sprague Dawley rats were trained over 10 days to intravenously self-administer cocaine. After acquisition of stable self-administration behavior, rats underwent cue-induced reactivation followed by GSK3 inhibition (SB216763, 5 mg/kg, ip.). Inhibition of GSK3 immediately following reactivation attenuated previously acquired operant drug-seeking behaviors when tested 24 hours later. Furthermore, reactivation of cocaine cue memory resulted in the stimulation of GSK3 in the nucleus accumbens. These findings indicate that memory for a cocaine-paired stimulus depends critically on GSK3 activity in part within the nucleus accumbens. Current studies are determining the effect of GSK3 inhibition after cue exposure on subsequent cue-induced reinstatement as well as further anatomical substrates for GSK3 signaling important for cocaine cue memory reconsolidation.

Title: Impact of intra-nucleus accumbens administration of MS-275, a class I HDAC inhibitor, on cocaine-seeking behavior

Authors: *D. K. FISCHER, A. S. THOMAS, S. E. SWINFORD-JACKSON, M. C. KNOUSE, R. C. PIERCE
Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Recent evidence suggests that histone post translational modifications (PTMs), which can be modified by cocaine use, contribute to the relapse to cocaine addiction. Thus, pan-histone deacetylase (HDAC) inhibitors have been found to attenuate cocaine-seeking behavior in rodent models (Romieu et al. 2008; Romieu et al. 2011), which suggests that histone PTMs are a potential target for pharmacological intervention of cocaine addiction. However, whether specific classes of HDACs differentially influence cocaine-seeking is not fully understood. Class I HDACs are the most abundant HDACs in the brain and the most catalytically active HDAC class. Previous research has suggested that Class I HDACs may regulate histone PTMs which influence cocaine-related behaviors. When paired with repeated administration of non-contingent cocaine, chronic intra-NAc infusion of MS-275, a Class I HDAC inhibitor, altered both acetylation and methylation patterns in the NAc, suggesting that Class I HDACs broadly alter histone PTMs (Kennedy et al., 2013). Here, we expand upon prior studies to explore the role of Class I HDACs in cocaine-seeking behavior. We hypothesized that that MS-275, cocaine, and their combination will differentially alter histone PTMs in the NAc shell, and that repeated intra-nucleus accumbens administration of MS-275 would attenuate reinstatement of cocaine-seeking behavior. In rats that received repeated administration of non-contingent cocaine or saline, bilateral infusions of MS-275 (500 µM) or vehicle (1% DMSO) into the NAc shell differentially altered histone acetylation and methylation at specific histone residues in the NAc, suggesting that cocaine and MS-275 interact to alter histone PTMs. Following cocaine self-administration and extinction training, rats received bilateral infusions (2 µl/side) of MS-275 (500 µM) or vehicle (1% DMSO) into the NAc shell for three consecutive days. Three hours after the last intracranial infusion, rats were pretreated with cocaine (10 mg/kg, i.p.) and reinstatement of cocaine-seeking was assessed. This study advances our understanding of how particular classes of HDACs, specifically Class I HDACs, play a role in cocaine-relapse. Future studies will continue to explore the different epigenetic targets that are modified by cocaine use, such as different classes of HDACs, which may provide insight for future pharmacological intervention for cocaine relapse.

Title: Silence is golden: A “quieter” brain response to 6 sec cocaine video cues is linked to better drug use outcomes

Authors: *A. R. CHILDRESS, K. JAGANNATHAN, P. REGIER, J. J. SUH, Z. MONGE, K. A. YOUNG, S. DARNLEY, E. BERKOWITZ-STURGIS, M. TAYLOR, M. GAWRYSIAK, T. FRANKLIN, R. WETHERILL, D. LANGLEBEN, K. KAMPMAN, C. P. O'BRIEN
Psychiatry, Univ. PENN Perelman Sch. Med., Philadelphia, PA

Abstract: Aims: Addicted individuals who are less “triggered” by drug reminder cues may be less vulnerable to relapse. We hypothesized that this advantage might be reflected in a brain that is “quieter”, less reactive, in response to cocaine video cues.
Methods: Prior to outpatient treatment, stabilized cocaine inpatients were scanned with BOLD fMRI during exposure to a quasi-random alternation of 6 sec (Cocaine and NEUTRAL) videos, with instructions to either “WATCH” or try to reduce (“DOWN”) their response to the cocaine videos. The SPM 12 pipeline was used for pre-planned contrasts (e.g., WATCH vs. NEUTRAL, DOWN vs. NEUTRAL, thresholded $2<t<5$) for two clinical outcome subgroups: GOOD (< 30% cocaine urines pos/missing across 12 outpt. weeks; n=9); vs. POOR (>90% cocaine urines pos/missing; n=12). We divided the task trials in half, allowing us to examine “early” and “later” reactivity patterns in the task, as well as any *changes* in reactivity from the first to the second half of the task.
Results: Cocaine inpatients who would proceed to GOOD clinical outcome had low cue reactivity (a “quieter” brain response) to the cocaine video, for both the WATCH and DOWN conditions, and for both “early” and “late” trials. In contrast, patients who would go on to POOR outcome evidenced dramatic brain activations -- including classical motivational circuitry – to the cocaine cues. Interestingly, POOR patients demonstrated increased reactivity (in ventral striatum) to the neutral cues from the first half to the second half of the task (a potential indicator of new learning supported by the cues).
Conclusions: Cocaine patients with a "quieter" brain response to the brief cocaine videos had GOOD drug use outcomes; these patients were a small subgroup. A heightened brain response to the cocaine cues was common in the POOR outcome patients. These results highlight the potential of brain cue-reactivity paradigms for predicting clinical outcome, for screening anti-relapse interventions, and for identifying patients in greatest need of interventions to target their cue-vulnerability.

Abstract: Cocaine addiction is a growing problem, but there are currently no approved medications for the treatment of cocaine addiction, and current treatment options, such as rehabilitation, are not successful at preventing relapse. In fact, relapse rates for cocaine addiction are estimated to be around 40-60%, within the range of other chronic illness. Stress can be triggered by a variety of factors, including exposure to stressful life events as well as re-exposure to cocaine itself. Understanding the mechanisms by which these factors elicit relapse is critical in developing better treatment options. In addition to environmental factors, genetic factors can predispose to addiction risk. The gene *CACNA1C*, which codes for the L-type calcium channel $Ca_v1.2$, has been strongly associated with numerous neuropsychiatric conditions, such as bipolar disorder and schizophrenia, which show high comorbidity with addiction. *CACNA1C* has also been shown to influence reward-related behaviors and neural activity in humans, as well as addiction-related phenotypes in rodent models. Additionally, *cacna1c* has been shown to mediate the effects of stress on the brain, suggesting it could be a key mediator of stress-induced addiction-related behaviors like relapse. In the current study, we find that global heterozygous knockout of $Ca_v1.2$, as well as focal deletion of $Ca_v1.2$ within the prelimbic cortex, attenuates stress- and cocaine-induced reinstatement of cocaine conditioned place preference. We are utilizing techniques such as chemogenetics and fiber photometry to explore the $Ca_v1.2$-dependent circuitry downstream of the prelimbic cortex that mediates these behavioral phenotypes.

Title: Chromatin remodeler INO80 mediates cocaine craving during prolonged withdrawal

Authors: *C. T. WERNER[1], J. A. MARTIN[1], A. F. STEWART[1], A. LEPACK[2], Z.-J. WANG[1], S. MITRA[1], P. N. GOBIRA[1], A. CACCAMISE[1], R. L. NEVE[3], I. S. MAZE[2], D. M. DIETZ[1]

Abstract: While it is challenging for individuals with cocaine use disorder to achieve abstinence, the greatest challenge is avoiding relapse, which is triggered by drug-associated cues. Cue-evoked cocaine craving intensifies (or "incubates") during abstinence in human cocaine abusers and pre-clinical substance use models that is believed to contribute to persistent relapse vulnerability. Incubated cocaine craving is mediated in part by neuroadaptations in brain regions associated with reward and motivation, including the nucleus accumbens (NAc). While chromatin remodeling regulates drug-induced epigenetic plasticity, the role of multimeric chromatin remodeling complexes is unknown. Following extended-access cocaine self-administration, we found that INO80, a chromatin remodeling complex ATPase subunit, was increased in the NAc of cocaine-treated rats compared to saline controls on withdrawal day (WD)30 but not WD1. Using viral-mediated gene transfer, we determined that INO80 bidirectionally mediates the expression of incubated cocaine craving during prolonged withdrawal. To determine INO80 interactions with DNA, we performed chromatin immunoprecipitation followed by massively parallel DNA sequencing (ChIP-seq). Predicted pathways regulated by INO80 based on enrichment in cocaine-treated rats included cAMP response element binding (CREB) signaling and glutamate receptor signaling, suggesting that INO80 mediates gene expression of pathways that mediate cocaine plasticity. To determine how INO80 is regulated, we examined tripartite motif-containing protein 3 (Trim3), an E3 ubiquitin ligase (E3) in the ubiquitin-proteasome system (UPS) that regulates degradation of INO80. We

also found that Trim3 and polyubiquitinated INO80 were decreased on WD30 in cocaine-treated rats compared with saline controls, indicating that degradation of INO80 is reduced during prolonged withdrawal. Furthermore, viral-mediated gene transfer of Trim3 also bidirectionally mediated incubated cocaine craving. Together, these results demonstrate that INO80-dependent gene expression mediates cocaine-induced behavioral and cellular plasticity during prolonged withdrawal and E3 Trim3 regulates INO80 expression.

Title: Epigenetic priming in the nucleus accumbens underlies relapse of cocaine-associated behaviors

Authors: *A. J. LOPEZ[1,2], M. KUTLU[2], A. R. JOHNSON[2], L. J. BRADY[2], K. C. THIBEAULT[2], E. S. CALIPARI[2]
[1]Dept. of Neurobio & Behavior; Ctr. for the Neurobio. of Learning & Memory, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA; [2]Pharmacol., Vanderbilt Univ., Nashville, TN

Abstract: Substance use disorder, a chronic relapsing neuropsychiatric disease, is characterized by the resilience of drug-seeking even following long periods of abstinence. Drugs of abuse, such as cocaine, are known to cause persistent changes in neuronal function throughout the circuitry regulating motivation, memory, and reward. Underlying these changes in circuit function are maladaptive changes in gene expression and synaptic plasticity caused by repeated drug exposure. Due to the persistence of both drug-seeking behaviors and drug-induced plasticity, the addiction field has implicated various epigenetic mechanisms as targets for drugs of abuse. Of note are the changes in the nucleus accumbens (NAc), a key regulator of cocaine-associated and cocaine-seeking behaviors. Recent work has demonstrated a critical role for histone acetylation in the NAc and has identified key genes critical in the acute and chronic effects of cocaine exposure. Yet, while the role of the NAc in cocaine self-administration has

been extensively studied, few studies have evaluated the long-lasting changes within this region contributing to reinstatement of cocaine-seeking. Recent studies in the Calipari lab have identified a unique gene expression profile in the NAc during cocaine-primed reinstatement, including dysregulation of genes with known roles in synaptic function such as *Oprk1*, *Scn4b*, and *Homer3*. We hypothesize that cocaine self-administration generates a long-lasting epigenetic environment which alters the integration of neural circuit activity within genetically defined cell types in the NAc and, ultimately, driving relapse. To test this, 8-week old c57BL/6J mice were trained to self-administer cocaine or saline for 10d. Following a 30d withdrawal period, animals received an acute saline or cocaine re-exposure (I.P.) and were sacrificed 1 hr later. In the NAc of cocaine re-exposed animals, we identified a subset of genes enriched for epigenetic marks previously shown to be dysregulated during reinstatement of cocaine-associated behaviors, including H3S10 phosphorylation, H3K9 acetylation, and H3K14 acetylation. Moreover, this subset of phosphoacetylation rich genes coincides with genes dysregulated in the NAc during cocaine-primed reinstatement. The results of this study provide evidence for epigenetic alterations leading to gene expression changes that make animals vulnerable to relapse. Future studies will identify a causal link between changes to epigenetic gene regulation and NAc circuit function during relapse-like behaviors.

Title: Pairing extinction of cocaine-seeking with vagus nerve stimulation reduces contextual reinstatement and modulates plasticity in extinction networks

Authors: *J. CHILDS[1], S. KROENER[2], C. DRISKILL[3], S. KIM[4]
[2]Sch. of Behavioral and Brain Sci., [1]Univ. of Texas at Dallas Sch. of Behavioral and Brain Sci., Richardson, TX; [3]Univ. of Texas at Dallas, Dallas, TX; [4]Univ. of Texas at Dallas, Richardson, TX

Abstract: Cocaine addiction can cause maladaptive neuroplasticity that persists long after cessation of drug taking. The relative permanence of cue associations formed during drug taking contributes to relapse. These cues and drug-associated environments can trigger relapse to drug use. Breaking the cue/drug association via extinction learning is one approach to preventing

relapse. We use vagus nerve stimulation (VNS) to enhance extinction from drug-seeking, and describe studies which examine the underlying mechanisms. We previously found that giving VNS during extinction of operant drug-seeking reduced the drug-seeking response during extinction and during cued reinstatement. Because we found facilitated extinction learning regardless if VNS was delivered contingently (with the non-reinforced operant response) or non-contingently (at fixed intervals throughout the extinction session), this raised a question: is VNS is also effective for extinguishing context in addition to extinguishing operant response? To answer this question, we used conditioned place preference (CPP) to examine the effect of VNS on contextual extinction in the absence of operant response. Animals which received VNS during extinction showed reduced preference for the cocaine-associated side compared to Sham animals. Additionally, animals that received homecage VNS immediately following drug side extinction sessions also showed reduced drug side preference. These findings suggest that VNS can facilitate the extinction of a drug-paired context. Next, we isolated the effect of VNS on extinction of an operant response by performing self-administration and extinction in two ABA experiments. First, animals were allowed to self-administer in context A, extinguish in context B, and reinstate in context A. Animals that got VNS during extinction in context B showed reduced reinstatement compared to Sham animals, suggesting a generalization of extinction from one context to another, or a strong extinction of the operant response. To further isolate the effect of VNS on extinction of the operant response, a second ABA experiment was conducted in which, in contrast to the first experiment, the levers were absent during extinction and animals were unable to operantly respond. The reciprocal pathways between the basolateral amygdala (BLA) and prefontal cortex (PFC) are involved in consolidating drug reward and expressing extinction learning. We used in-vivo recordings of evoked field potentials to examine changes in the connectivity between the BLA and mPFC, and then used high frequency stimulation to induce LTP. Pairing extinction with VNS altered the synaptic plasticity in this pathway.

Title: Cholinergic receptors in the ventral tegmental area mediate both cue-induced cocaine-seeking and anxiety-related behaviors during cocaine abstinence

Authors: *E. J. NUNES, L. BITNER, S. WALTON, S. HUGHLEY, K. SMALL, L. E. RUPPRECHT, N. A. `. ADDY
Psychiatry Ribicoff Res., Yale Univ., New Haven, CT

Abstract: Psychiatric co-morbidities, such as anxiety and depression, often accompany symptoms of cocaine craving and cocaine-paired cues to support resumed drug taking. The ventral tegmental area (VTA) to the nucleus accumbens core (NAc) pathway is necessary and sufficient for cue-induced cocaine craving. Furthermore, VTA dopamine (DA) neuron activity has been shown to contribute to depressive and anxiogenic-like behaviors in procedures such as the elevated plus maze (EPM). Cholinergic receptors in the VTA mediate DA neuron activity and phasic DA release in the NAc. We have previously shown that VTA cholinergic receptor blockade decreases cue-induced cocaine seeking on day 3 of abstinence. However, the role of VTA cholinergic receptors following longer cocaine abstinence periods is unknown. Thus, we trained male Sprague-Dawley rats to self-administer cocaine for 10 days followed by a forced abstinence period of 14 days. We show that VTA nicotinic and muscarinic receptor blockade with the non-selective nicotinic receptor antagonists, mecamylamine (10 ug, and 30 ug per side), or the non-selective muscarinic receptor antagonist, scopolamine (2.4 ug, 24 ug per side), decreased cue-induced cocaine seeking after 14 days of forced cocaine abstinence. Next, we sought to determine the role of VTA cholinergic receptor blockade on behavioral responses in the EPM in cocaine naïve rats. VTA blockade of nicotinic and muscarinic receptors was effective to reduce anxiogenic behavior in cocaine-naïve rats at the highest dose only tested on the cue-seeking test. A separate cohort of rats self-administered cocaine or saline for 10 days, followed by 14 days of forced abstinence On the 14^{th} day of abstinence, rats were tested using the EPM. Rats undergoing cocaine abstinence had increased anxiogenic-like responses on the EPM compared to rats that only received saline. Blockade of VTA cholinergic receptors, at the same doses tested above, attenuated this anxiogenic effect of cocaine on the EPM in a separate group of rats. Taken together, VTA nicotinic and muscarinic receptor blockade decreases cue-induced cocaine seeking and the anxiogenic effects of cocaine abstinence. These data point to overlapping roles of VTA cholinergic receptors and the ability to regulate multiple symptoms experienced during periods of cocaine abstinence. This suggests that targeting of VTA cholinergic receptors during periods of cocaine abstinence can reduce both cocaine craving and the anxiety associated with cocaine withdrawal. Future experiments will begin to identify what specific VTA muscarinic acetylcholine receptor subtypes mediate one or multiple symptoms observed during cocaine abstinence.

Title: Item-location representations in the medial temporal lobe of non-human primates during a short-term-retention task

Authors: *H. CHEN[1,2,3], Y. NAYA[1,2,4,5,6]
[1]Peking Univ., Beijing, China; [2]Ctr. for Life Sciences, Peking Univ., Beijing, China; [3]Acad. for Advanced Interdisciplinary Studies, Peking Univ., Beijing, China; [4]Sch. of Psychology and Cognitive Sciences, Peking Univ., Beijing, China; [5]IDG/McGovern Inst. for Brain Research, Peking Univ., Beijing, China; [6]Interdisciplinary Inst. of Neurosci. and Technology, Zhejiang Univ., Hangzhou, China

Abstract: The conventional insight regarding item-location integration processes in the medial temporal lobe (MTL) describes a convergence of ventral and dorsal pathways into the hippocampus (HPC) via the perirhinal cortex (PRC) and the parahippocampal cortex (PHC). However, recent visual neuroscience studies suggest that integration proceeds along the ventral pathway prior to reaching the HPC. In this study, we investigated neuronal process encoding item-location information from the ventral pathway to the MTL. For this, we devised an item-location-retention (ILR) task requiring the subject to retain the identity and location information of a sample stimulus. A trial of the ILR task consisted of an encoding phase and a response phase with an interphasic interval (0.7-1.4 sec). In encoding phase, after presentation of a fixation dot at one of the quadrants on a display, one out of six objects was presented at the same quadrant (i.e., foveal view condition) for 0.3 seconds as a sample stimulus. Following the interphasic interval, the response phase was initiated with a fixation dot presented at the center. Subsequently, one of the six objects was presented in the center for 0.3 seconds as a cue stimulus. After another 0.5 seconds of delay period, five discs were presented as choice: one green disc at center, and four blue discs in the quadrants respectively. When the cue was same as the sample, the subject was required to choose a blue disc in the same quadrant as the sample located. Otherwise, the subject was required to choose the green disc. We recorded single-cell activities from the HPC (n=636), PRC (n= 436), PHC (n=245) in the MTL as well as TE (n =357) of two macaques. We examined item and location selective responses for individual cells during the encoding phase using two-way ANOVA. We found that a substantial number of neurons exhibited significant ($P < 0.01$) item-selective responses in the HPC (25%) as well as in the PRC and TE (18% and 20%), in contrast with the small proportion in the PHC (3%).

Interestingly, both PRC and TE showed as large a proportion of location-selective ($P < 0.01$) neurons (30% and 31%) as the HPC (22%) and PHC (20%) did. The proportion of location-selective neurons decreased in both MTL and TE (HPC:8%, PHC:6%, PRC:10%, TE:7%) when a sample stimulus was presented at a quadrant while the subject fixated at the center of display (i.e., peripheral view condition), though the percentage of item-selective neurons were similar (HPC:27%, PHC:3%, PRC:21%, TE:21%). These results suggest that when a subject encodes an item at a particular location on a background, both the PRC and TE as well as the HPC represent the identity of the item and its location, as viewed by a subject.

Title: Spatial view cells in the primate hippocampus: Properties demonstrated during active locomotion

Authors: *E. T. ROLLS
Oxford Ctr. For Computat. Neurosci., Coventry, United Kingdom

Abstract: Video animations will be presented to illustrate the properties of hippocampal spatial view cells recorded in macaques during active locomotion in a 2.7x2.7 m open field foraging environment located in the middle of a laboratory which provided a rich scene. The place, head direction, eye position, and location being fixated on the walls of the room are displayed every 25 ms during the playback of the neuronal spikes in these new analyses. These neurons recorded in CA3, CA1 and the parahippocampal gyrus (1) respond primarily to a view of space 'out there', with much less information about the place where the monkey is located; (2) have responses that depend on where the monkey is looking, as shown by measuring eye position; (3) can still occur (especially for CA1 neurons) if the view details are obscured with curtains; (4) retain part of their 'space' tuning even in complete darkness, for several minutes (especially in CA1); (5) have an allocentric spatial representation; and (6) utilize independent encoding in that the information about spatial view increases linearly with the number of cells in the representation. A computational model shows that the spatial representation may be different from that of place cells in rats because of the smaller field of view of primates due to the primate fovea. It has also been shown that some hippocampal neurons encode for objects, others for spatial view in a room, and others for a combination of objects and spatial view, while a monkey is performing an object-place memory task in which the place is 'out there' in the room. This task and the one-trial object-place associations formed by these neurons is prototypical of

episodic memory, and provides evidence that the primate hippocampus does associatively link information about objects and allocentric information about places 'out-there'. Recordings were made sufficiently long from 40 of the 708 neurons (5.6%) to provide evidence that they were spatial view neurons in this single environment, and in addition some neurons had place field responses.

Title: Reference frames for encoding of eye movements: A comparison between lateral prefrontal cortex and hippocampus in non-human primates

Authors: *B. W. CORRIGAN[1], R. A. GULLI[4], G. DOUCET[5], M. ROUSSY[2], R. LUNA[1], J. C. MARTINEZ-TRUJILLO[3]
[1]Neurosci., [3]Physiol. and Pharmacol., [2]Univ. of Western Ontario, London, ON, Canada; [4]Dept. of Pharmacol. and Physiol., Western Univ., London, ON, Canada; [5]McGill Univ., Montreal, QC, Canada

Abstract: Primate vision processing is highly developed, with very high acuity at the fovea which requires saccades to explore the visual world in detail. Saccade encoding has been measured area 8A of lateral prefrontal cortex, where neurons also encode several other visual features during attention and working memory (Bichot, Heard, DeGennaro, & Desimone, 2015; Boulay, Pieper, Leavitt, Martinez-Trujillo, & Sachs, 2016). The hippocampus (Hc) has also been reported to encode saccade target locations, and is involved in forming episodic memories(Rolls & Xiang, 2006). We set out to investigate presaccadic tuning for spontaneous saccades in these areas. We had four male macaques (macaca mulatta) perform a cued saccade task, but analysed spontaneous saccades in the intertrial intervals. Two subjects had Utah arrays (Blackrock Microsystems, Utah) in area 8A, and recorded from 520 neurons over six sessions. We used

single electrodes to record from the Hc of the other two NHPs and recorded from 80 neurons over 20 sessions. To analyze spatial selectivity, we binned screen space into 8°x8° bins and calculated firing rates for 200ms before the saccade onset for all saccades that landed in a bin while nothing was on the screen during inter-trial-intervals. And we also calculated this using bins centred at the point of fixation to get retinal coordinates. Using permutation testing on the Hc neurons, we found that 7 (9%) were selective for space in screen coordinates while 2 (3%) were selective for retinal coordinates. We found that of the PFC neurons, 125 (24%) were selective for space in screen coordinates while 191(37%) were selective for space in retinal coordinates. The high percentage of retinal centric target selective neurons in the PFC is expected from previous findings of saccade target encoding (Boulay et al., 2016). Finding more screen coordinate selective neurons might be predicted from the previous results from Rolls and results from the entorhinal cortex (Killian, Potter, & Buffalo, 2015), but the low numbers of neurons encoding spontaneous saccade targets suggests that encoding during active vision may be also encoding target information.

Title: Spatial information encoding across multiple neocortical regions

Authors: *I. ESTEVES[1], H. CHANG[4], A. R. NEUMANN[2], S. JIANJUN[2], M. H. MOHAJERANI[3], B. L. MCNAUGHTON[5,6]

Abstract: Hippocampal-cortical interactions are essential to spatial contextual learning processes. Hippocampal place cells (PC) have sparse coding characteristics and, when combined with 'rate remapping' produce experience-unique outputs from the hippocampus to the neocortex. Such patterns are hypothesized to provide an ‘index’ code to link distributed representations of specific experiences over the cortex and may coordinate memory retrieval. Recently it has been shown that superficial Retrosplenial cortex, a major target of hippocampal output, exhibits place-

cell like activity and that this phenomenon depends on an intact hippocampus. We enquire here whether such 'place-cells' can be found more broadly distributed in the cortex. Thy-GCamP6s mice were head-fixed and trained to move a treadmill belt with tactile cues. Cellular calcium imaging was conducted across different cortex regions and hippocampal CA1 region. In five mice a 5 mm craniotomy was made above the dorsal cortex (+1 mm to -4 mm AP and -2.5 mm to 2.5 mm ML) and a coverslip was attached to the skull. For hippocampus imaging, a cranial hippocampal window was performed in one mouse. This window was composed of a 1.5 mm glass cylinder with a 3 mm coverslip attached to one end. Combining the two-photon calcium imaging and the treadmill apparatus, we studied how the neural activity encodes spatial information in different cortical areas. With a systematic survey over the cranial window, we found neurons in multiple neocortical regions that exhibit spatially-localized activity with firing field that are robustly correlated with the animal position on the belt, similar to hippocampal place cells (PC) and Retrosplenial cells measured in the same task. Motor Area and Somatosensory cortex presented greater PC fractions than associational areas such as the Posterior Parietal Cortex and Retrosplenial Cortex in 4/5 of the animals recorded. Thus, there is a substantial population of neurons distributed widely over the cortex whose activity resembles hippocampal place cells. Our results provide support for the hypothesis that the HPF generates a spatiotemporal contextual ‘index’ code to link information distributed across the entire cortex. Furthermore, this study will help to shed light on how the hippocampus and neocortex interaction support both spatial navigation and memory.

Title: Imaging long-term population dynamics of rat hippocampal place cells

Authors: *G. BLAIR[1], A. G. HOWE[2], P. GOLSHANI[4], H. T. BLAIR[3]
[1]Psychology, [2]NSIDP/Psychology, [3]Dept Psychology, UCLA, Los Angeles, CA; [4]UCLA Dept. of Neurol., Los Angeles, CA

Abstract: Populations of hippocampal place cells are thought to encode spatial memories—or “cognitive maps”—of familiar environments. To implement this population code for space,

individual place cells fire at their own preferred firing locations in a given environment[1]. It was previously assumed that a place cell's spatial tuning function does not change (or changes very slowly on a time scale of many days) across repeated visits to the same familiar environment[2]. But recently, single-unit recording studies in rats[3,4] and calcium imaging studies in mice[5] have suggested that hippocampal place cells exhibit rapid changes in their firing properties across repeated visits to the same familiar environment. This raises new questions about the long-term stability of the hippocampal place code. To address these questions, it is important to understand how place cell stability varies across species (e.g., rats versus mice), and how it might be influenced by methodological confounds (e.g., tissue damage arising from lens implantation in calcium imaging studies). Prior calcium imaging studies of long-term place cell dynamics have been carried out in mice[5], so here, we used the UCLA miniscope to obtain long-term population recordings of hippocampal place cells in freely behaving rats. Rats were injected with 1.0 uL of AAV9-Syn-GCaMP6f into the CA1 pyramidal layer, followed by implantation of a 1.8 mm diameter GRIN lens above the stratum oriens. Four weeks after virus injection, rats were imaged for more than a month, alternating every other day between open-field and linear track environments. Similar to results from mice, population participation within each environment was highly transient across the experimental timeframe. However, place field locations were relatively stable, consistent with the proposed function of rate remapping across time, with relatively little global remapping within the same environment[6]. In future work, we will carry out electrophysiological recording and calcium imaging of place cells from the same rats, to assess how place cell stability depends upon recording methods.

Title: Probing neurophysiological substrates of LSD-induced hallucinations in freely behaving rats

Authors: *C. DOMENICO, D. C. HAGGERTY, X. MOU, D. JI
Baylor Col. of Med., Houston, TX

Abstract: The compound lysergic acid diethylamide (LSD) produces visual hallucinations, which are subjective perceptions that occur disjoint from external stimuli. Mounting evidence supports that visual hallucinations arise from activation of 5-hydroxytryptamine-2-A receptor (5-HT2AR) and are behaviorally correlated with the head twitch response (HTR) in rats. By studying disorganized states of consciousness like that induced by LSD, we can better understand how the brain orchestrates the transduction of external inputs and internal signaling to culminate in our subjective experience. To examine the neural substrates of hallucinations, we employed tetrode recordings in the CA1 of hippocampus and the primary visual cortex V1 of freely moving Long-Evans rats as they ran laps on a familiar track. Each rat is recorded twice on the track in the same day with a three-hour rest between: In the first track session, rats are administered saline, and in the second track session they are administered a high or low dose of LSD (.24 mg/kg or .06 mg/kg) or a 5HT2AR antagonist (M10097) prior to LSD administration. Rats demonstrate a significant HTR with LSD administration that is not observed in the LSD and antagonist condition. Further, rats in the LSD conditions have poor lap running behavior and pause often throughout the second track session. Consequently, we observe high voltage spike (HVS) events during immobility in rats in the LSD condition. HVS are high amplitude population activity associated with wake-to-sleep transitioning in rodents. We also see changes in neural population firing rates just prior to the HTR in CA1 and V1 that may correspond to a decoupling of CA1 from the primary sensory area that precedes behavioral expression of hallucination. Further analyses aim to answer whether these false percepts are linked to neural activity associated functionally with a sleep state alongside otherwise wakeful behavior.

Title: Changes in synchronous spike patterns of hippocampal neurons associated with learning of an optimal route in a spatial detour task

Authors: *H. IGATA[1], T. SASAKI[1,2], Y. IKEGAYA[1]
[1]Lab. of Chem. Pharmacology, Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo,

Japan; [2]Precursory Res. for Embryonic Sci. and Technol., Japan Sci. and Technol. Agency, Kawaguchi, Saitama, Japan

Abstract: Animals learn the best spatial navigation strategy to a goal through experiencing multiple possible strategies. During this learning process, activity patterns of brain circuits gradually converge into the most optimal ones by evaluating outcomes resulting from exploratory behavior. Accumulated evidence has shown that the hippocampus plays an important role in spatial learning by representing current and future episodes. Especially, awake hippocampal replay, in which temporally compressed sequential patterns of place cells are reactivated corresponding with running trajectories, have been considered to support memory consolidation and future planning. In this study, we designed a spatial task in which rats learn to take a specific route point to a fixed goal in a two-dimensional task field. In this task, a trial began when the animals performed an active nose poke in a start box where sucrose water was presented for 10 seconds. A start door was then opened so that the rats entered into the field. The rats could obtain reward at a goal box if they correctly stopped at a specific point where a small amount of chocolate milk was placed on the way to the goal box. After the rats continuously performed the same task for 3-4 days, a reward point was changed to a different point. The rats first showed exploratory behavior throughout the field after the rewarding rule was changed but could learn a new optimal route through the trial-and-error exploration. During this learning process, a multiunit recording was performed from hippocampal CA1 neurons. Especially, we focused on synchronous events of neurons, in which instantaneous firing rates were increased to 3 standard deviations above the baseline or more than 4 neurons showed co-firing. The number of synchronous events was increased and event-to-event correlation of synchronous events was increased after the rewarding rule was changed, demonstrating that the frequency of recruiting specific sets of neuronal ensembles within synchronous events was pronouncedly increased associating with a change in behavioral strategy. These results suggest that the contents of hippocampal neuronal reactivation might be prioritized by learning, supporting reinforcement of a specific behavior pattern.

Title: Serial cells track the global temporal ordering of discrete episodic events

Authors: *C. SUN[1], W. YANG[2], J. MARTIN[1], S. TONEGAWA[1]
[1]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [2]The Univesity of Edinburgh, Edinburgh, United Kingdom

Abstract: Daily episodic experience occurs as a sequence of events. Hippocampal neurons, essential for episodic memory, have spatial codes, but whether they code the pure temporal order of events in an episode is unknown. Here, we report hippocampal "serial cells" that track the discrete and successive serial order of events, as mice experience a series of materially indistinguishable yet temporally distinguishable events. The serial order code is degraded when the temporal relations between events are disrupted, and the code is remapped when temporal relations between events are globally altered, suggesting that serial cells track the pure temporal order structure of episodic events. Serial cells have place fields but the serial order code is preserved even when place fields globally remap, showing that the serial code is conjunctive with the spatial code but is independent of it. The serial code, tracking the pure serial ordering of events, may be one of the fundamental ingredients by which our brain represents episodic events.

Title: Activity-regulated cytoskeleton-associated protein, Arc, is required for the broad tuning of neuronal firing in the hippocampal CA1 area

Authors: L. YUAN, M. FALLAHNEZHAD, Y. WANG, I. ÅMELLEM, C. CHANG, *A. TASHIRO
Nanyang Technological Univ., Singapore, Singapore

Abstract: Tuning of neuronal response is a basic element underlying neural information coding. Two examples of such neuronal tuning are found in principal neurons in the hippocampal CA1 area. First, these neurons are tuned to specific areas in an environment and therefore called place cells. Second, they are tuned to a specific phase of theta oscillations, which is referred to as phase locking. Narrow tuning is beneficial for individual neurons to code specific information while broad tuning allows a group of neurons to function together. Therefore, the breadth of tuning is important for neural circuit functions. However the molecular mechanism by which

neurons achieve a proper breadth of tuning is unknown. Here, we focused on an immediate early gene encoding activity-regulated cytoskeleton-associated protein (Arc, also known as Arg 3.1), which is expressed in response to neuronal activation and regulates synaptic functions. We knocked down Arc gene using virus-mediated RNA interference in a portion of hippocampal CA1 area in rats, and monitored the activity of principal cells in the manipulated area. We found place cell activity both in control and Arc knockdown groups. However, Arc knockdown group showed more specific spatial firing patterns. Further, while firing rate was reduced all over the environment in Arc knockdown group, this reduction was more extensive outside of place fields than inside. This biased reduction outside of place fields resulted in narrower spatial tuning. In addition, we found that higher proportion of firing occurs around a specific phase of theta oscillations in Arc knockdown principal cells, indicating that Arc knockdown principal cells show stronger phase locking to theta oscillations or, in other words, narrower tuning to the specific phase. Next we examined the consequence of Arc knockdown in neuronal network functions. We found that Arc knockdown principal cells cofire less frequently than control. Further, using a computational modeling approach to estimate the animal's position based on the experimental data from groups of neurons, Arc knockdown groups exhibited higher extent of errors. These results support impaired network functions in Arc knockdown group. These effects of Arc knockdown on single-cell and network functions suggest that, under normal conditions, Arc plays a role in establishing the broad tuning of individual neurons. This broad tuning in individual neurons may, in turn, increase the functional interaction among neuronal populations and maximize its information processing capability.

Title: Long term characterisation of pyramidal cell activity in the hippocampal CA1 area using microendoscopic calcium imaging

Authors: *C. P. KOH[1], L. F. COBAR ZELAYA[2], A. TASHIRO[2]
[1]Nanyang Technological Univ. (NTU), Singapore, Singapore; [2]Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore

Abstract: Through the use of electrophysiological techniques, it has been shown that pyramidal cells in the hippocampal CA1 area exhibit place cell activity, having place fields that can be stable up to months. However, more recent work using calcium imaging demonstrated that pyramidal cells shift between being active and inactive across days, although they tend to show place cell activity with constant place fields when they are active. Thus, place cell activity seems to be less stable between days than initially thought, but how their activity varies between days and over months is still unclear. Therefore, we performed long-term characterisation of place cell activity to elucidate the day-to-day changes over the course of three months. We injected adeno-associated viral vectors expressing a calcium indicator, GCaMP6s, under the control of the CaMKIIα promoter into the hippocampal CA1 region of mice to express GCaMP6s specifically in pyramidal cells. While these mice ran back and forth in a 1-m long linear track, we carried out calcium imaging using a microendoscope to monitor CA1 pyramidal cell activity. With this method, we performed long-term imaging from the same mice and were able to identify the same set of pyramidal cells over three months. We found that some cells were active on all the days analysed, but others were active only on some days and remained inactive on the other days. For cells that were always active, we observed that their frequency of calcium events differed between imaging days, and a majority of the calcium events occurred when the mouse was stationary at one, but not the other, end of the linear track. In addition, on some of the imaging days analysed, some cells displayed calcium events while the mouse was running. Most of those calcium events began at one end of the track when the mouse started running. These events continued for 0.8-3 sec, over 25-80 cm of the track, and can be regarded as place cell activity. Furthermore, on some imaging days, calcium events occurred at both ends of the track when the mouse started running in both directions. In conclusion, it appears that the activity of CA1 pyramidal cells in freely moving mice, as measured by intracellular calcium levels, shows substantial fluctuations over time.

Title: Place cells represent three-dimensional, volumetric space anisotropically

Authors: *R. GRIEVES, S. JEDIDI-AYOUB, K. MISHCHANCHUK, K. J. JEFFERY
Univ. Col. London, London, United Kingdom

Abstract: Place cells in the hippocampus represent places by increasing their firing rate when an animal visits specific regions of its environment, these regions of high firing are known as 'place fields'. In flat mazes place fields are typically small and round. However, animals must often navigate complex three dimensional environments. Do place cells represent three-dimensional volumetric space and if so, how?

In freely flying bats place fields have been observed to form spheres, suggesting that these animals can localise themselves equally well in all dimensions. In contrast, fields recorded in rats exploring vertical climbing walls form vertical columns, suggesting that they are less able to localise themselves vertically. Thus, we propose that rats have an anisotropic representation of space; they are less able to localise themselves vertically and their place fields will form elongated vertical columns in three-dimensions. To investigate this we wirelessly recorded the activity of place cells in a three-dimensional volumetric space; a cubic lattice composed of horizontal and vertical climbing bars.

Over the course of 34 sessions (each 60 minutes long) we recorded a total of 428 place cells in this maze from 8 rats. Rats exhibited a strong bias in their style of locomotion; they navigated significantly more frequently and at a faster rate along the horizontal dimensions. Place fields had normal horizontal characteristics but many were elongated vertically. Decoding the position of animals in this maze using only the activity of place cells revealed lower spatial information in the vertical dimension. These results suggest that place cells represent three-dimensional volumetric space anisotropically.

To determine if this is related to the rats' bias in locomotion or the geometry of the maze we also recorded a further 225 place cells from 3 rats in the same lattice maze, rotated to stand on one vertex, so that all horizontal and vertical climbing bars were instead diagonally sloped. Results thus far suggest that in this environment no place fields form vertical columns, they are more likely to form spheres and those that are elongated do so along one diagonal axis of the lattice maze.

Place cells recorded in freely flying bats have been shown to exhibit near spherical place fields,

why might this differ in rats? Our results suggest that the place fields of rats are vertically elongated in a cubic lattice, but that this is dependent on the structure of the lattice and the locomotor constraints on the rat rather than allocentric dimension. Thus, in rats, the representation of volumetric space is shaped by the affordances of the environment for locomotion.

Title: All-optical manipulation of place cells drives spatially associated behaviour

Authors: *N. T. ROBINSON[1], L. A. L. DESCAMPS[1], L. E. RUSSELL[1], C. SCHMIDT-HIEBER[2,1], M. HAUSSER[1]
[1]Univ. Col. London, London, United Kingdom; [2]Inst. Pasteur, Paris, France

Abstract: Hippocampal place cells fire when an animal occupies a specific location in an environment and are thought to play an important role in memory formation and spatial navigation. However, the causal role of place cell firing in driving decision making during spatial navigation has remained elusive. Addressing this question requires targeted manipulation of specific place cells in navigating animals. Here we have used an “all-optical” approach for targeted manipulation of place cell activity in head-fixed mice navigating a virtual reality environment. Using simultaneous two-photon calcium imaging and two-photon optogenetic holographic stimulation, we functionally define and manipulate the activity of populations of place cells with a specific firing field location and examine the impact on behaviour. Mice were trained to stop and lick for reward at a location on a linear track. Place cells were identified and grouped into neurons which fired either at the rewarded zone or an equivalent area near the start of the track. We then selectively activated either the reward zone or non-reward zone place cells at a separate equidistant location on the virtual track to test whether the behavioural output associated with the originally encoded location can be retrieved. Our preliminary results suggest that activation of appropriate place cells can drive reward-associated behaviour. This approach

enables us to probe the causal relationship between hippocampal neural activity patterns and memory retrieval to guide behaviour.

Title: Investigating multisensory integration by place cells in visual + olfactory virtual reality

Authors: *B. A. RADVANSKY[1], D. A. DOMBECK[2]
[1]Neurobio., Northwestern Univ., Chicago, IL; [2]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Mammals are believed to discern their locations in their environments using a cognitive map - a stored internal representation of space. Yet, the brain has no mechanism to directly detect “space.” Rather, it draws upon sensory perceptions of sights, sounds, smells, etc. to *construct* the cognitive map of space. Therefore, the mapping of space must ultimately be rooted in the senses. The overwhelming sensory complexity of the real world, however, has made it difficult to investigate how individual senses, or combinations of senses, contribute to and are represented by the cognitive map. Here, we address this challenge by using virtual reality to control a multisensory visual + olfactory landscape. We trained head-fixed mice on a spherical treadmill to navigate a multisensory linear track comprised of numerous proximal and distal visual cues overlaid with two olfactory gradients. The sensory cues making up the linear track were designed such that each location was uniquely defined using either visual or olfactory cues (or both). We established a multisensory-guided spatial behavior in which mice attended to both visual and olfactory spatial features during virtual navigation. To determine the sensory composition of the cognitive map engaged during this behavior, we systematically manipulated visual vs. olfactory features while recording from “place cells” in hippocampal region CA1 using 2-photon calcium imaging. We deconstructed the spatial tuning of each neuron into visuospatial and olfacto-spatial components based on responses to each sensory feature manipulation. From the population responses of these neurons, we determined how the different sensory sub-components of the environment were represented by the cognitive map.

Title: CA3 population activity during free running on a virtual circular track

Authors: *B. A. SUTER, C. BORGES-MERJANE, Y. BEN SIMON, P. JONAS
Inst. of Sci. and Technol. (IST) Austria, Klosterneuburg, Austria

Abstract: Hippocampal region CA3 is believed to implement pattern completion, in particular the CA3a region (Lee et al, 2015), which is densely innervated by the dentate gyrus (DG) via the mossy fiber tract. Recurrent connectivity between CA3 principal neurons is sparse, yet finely tuned to optimize information storage (Guzman et al, 2016). Mossy fibers from the DG form powerful synapses onto CA3 pyramidal neurons, capable of one-to-one action potential transmission in vitro (Vyleta et al, 2016), however DG granule cells exhibit very sparse activity in vivo (Danielson et al, 2016; Pilz et al, 2016). Recently, our lab found that the small fraction of active DG granule cells exhibit a diversity of activity types, from single action potentials to super-bursts during head-fixed locomotion. We are interested in determining the overall activity pattern of CA3 at the population level, and as it relates to this sparse yet diverse input from the DG, in order to understand how information is shaped along the hippocampal axis.
To this end, we aim to quantify the distribution of firing rates of CA3 pyramidal neurons in the awake, behaving animal. Extracellular recordings report high firing rates, including bursting, in individual CA3 pyramidal neurons, but may be unable to detect silent and sparsely firing neurons. We therefore use concurrent two-color, two-photon imaging in the head-fixed mouse to record neural activity while simultaneously visualizing anatomical landmarks and individual neurons in the second, structural channel. This permits us to count CA3 pyramidal neurons in an unbiased manner, and quantify their activity patterns during behavior on a circular virtual reality track.
In order to image identified CA3 pyramidal neurons, we used transgenic mice expressing a red fluorophore in the DG with the labeled mossy fiber tract as a landmark for the CA2/CA3 border. We targeted viral injections into CA3 to transfect neurons with a red fluorophore in the nucleus, to allow for unbiased detection of neurons independent of their activity, while co-expressing the most sensitive calcium indicator currently available (GCaMP6s). Using the red (structural) channel to identify a dense sample of 89 CA3 pyramidal neurons, we manually defined somatic

ROIs and extracted time-varying Calcium traces from the green channel, restricting our analysis to periods of forward locomotion (speed > 2 cm/s). We used MLSpike (Deneux et al, 2016) to estimate the underlying spike trains and found a broad range of firing rates: average 0.58 Hz, standard deviation 0.53 Hz. The highest average rate across the population was 2.4 Hz, while 2 (of 89) neurons never fired during the duration of the acquisition.

Title: Spatial and temporal stability deficits in hippocampal place cells following moderate prenatal alcohol exposure

Authors: *R. E. HARVEY[1], L. E. BERKOWITZ[2], D. D. SAVAGE[3], D. A. HAMILTON[4], B. J. CLARK[2]
[1]Dept. of Psychology, [2]Psychology, [3]Neurosci., Univ. of New Mexico, Albuquerque, NM; [4]Univ. New Mexico, Albuquerque, NM

Abstract: Spatial memory and navigation impairments are common following prenatal alcohol exposure (PAE) in humans and in animal models. Hippocampal neurons, some of which are highly modulated by environmental locations i.e. place cells, display significant synaptic and structural alterations after PAE. Each hippocampal place cell fires in a unique environmental location indicating that a large population of these cells covers the spatial layout of each environment encountered by the animal. It is currently unknown whether the spatial and temporal coding characteristics of hippocampal place cells are altered in PAE. Thus, we performed electrophysiological recordings from the hippocampus (CA1 and CA3) of adult male rats exposed to either moderate amounts of ethanol or saccharin prenatally. Hippocampal neural activity was monitored in two behavioral paradigms in which rats performed laps to each end of a narrow linear track (120 x 9cm) or while randomly foraging in a circular open field (76cm in dia). Each recording session on the track or in the cylinder was ~20 min in duration. Similar numbers of hippocampal place cells were identified in both PAE and saccharin exposed animals. However, place cells recorded in PAE animals exhibited larger field sizes in both the linear and

circular environments. Further, place cells recorded in PAE animals on the linear track displayed inconsistent firing as they progressively ran laps and often took several laps on the linear track to initiate firing. In contrast, place cells from control animals displayed stable firing throughout all laps. Finally, place cells are known to change their spike timing in such a way that cells fire at progressively earlier phases of the extracellular theta rhythm as the animal passes through their respective place fields. This phenomenon is known as theta-phase precession, and is thought to be supported by medial entorhinal cortex input. Importantly, while place cells from PAE animals had deficits in stable firing, they did not show deficits in theta-phase precession relative to control place cells. Collectively, the broader tuning and instability of hippocampal place cells provides a potential mechanism to explain spatial memory impairment after PAE.

Title: Neurobiology of learning to learn; long-lasting, input-specific synaptic circuit function changes in hippocampus

Authors: *A. CHUNG, A. A. FENTON
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Cognitive behavior therapy (CBT) improves learning and memory, such that the brain learns to learn. The dominant CBT-neuroplasticity hypothesis asserts that CBT causes neural plasticity to change brain function but predicted evidence of 1) CBT-induced 2) long-lasting, and 3) memory-independent changes in synaptic circuit function is lacking. We previously reported persistent *ex vivo* and anesthetized *in vivo* electrophysiological changes in GABAergic-sensitive hippocampus synaptic function after learning an active place avoidance task that requires intact hippocampal activity, and persistent PKMzeta-mediated long-term potentiation (LTP) of synaptic function. Here, we test the three predictions of the CBT-neuroplasticity hypothesis in freely-behaving mice. Adult mice were implanted with sets of stimulating electrodes in the perforant path entorhinal cortex (EC) input to DG and CA1 along with 32-site recording electrodes that spanned the somatodendritic axis of dorsal hippocampus. Evoked potential responses were measured in DG in response to 0-250 μA test pulses before and 2h after each

training session in either active place avoidance or control tasks with minimal cognitive demand. Initial training reduced the fEPSP slope in the molecular layer of the supra-pyramidal blade of DG (supDG); changes were minimal in the hilus population spike and at the infra-pyramidal blade (infDG). Current source density analysis showed that training reduced the sink at the inner molecular layer of supDG where medial EC axons terminate. These changes persisted at least 60 days without further training. Additional training to acquire a new place memory in the same environment, or to learn a new place avoidance in a novel environment showed that subsequent learning was improved and that the initial training-induced changes occluded further changes of synaptic function. DG expression of PKMzeta increased after training compared to the control groups. Specifically, somatostatin (SST) expressing GABAergic neurons showed increased PKMzeta expression, particularly in supDG where interneurons predominate. Optogenetic manipulations of mice expressing ChR2 in Gad2 expressing neurons were studied to localize the training-induced inhibitory synaptic function changes. These findings confirm predictions of the CBT-neuroplasticity hypothesis, demonstrating that cognitive training during which mice learn to learn, can cause persistent hippocampus synaptic circuit function changes coincident with increased plasticity-protein expression at specific post-synaptic interneuron subtypes, independent of synaptic changes that may encode memories.

Title: Remapping 2.0 : Ensemble coding in the hippocampus

Authors: *E. R. LEVY, E. PARK, A. A. FENTON
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Action potential discharge in rodent hippocampus is thought to encode spatial information using an across-cell - “ensemble” - place code, such that each environment is represented by a set of ensemble discharge patterns - “activity vectors” - each of which is characteristic for a particular environmental location. Activity vectors typically change smoothly from one location to the next, but the set of activity vectors can also change abruptly, a phenomenon called “remapping.” Remapping is most reliably observed between distinct environments as the sets of activity vectors tend to be unrelated between environments. Instead

of using activity vectors, remapping is standardly depicted as a change in cell-specific "place fields", which describe location tuning of a single cell. Place fields are quantified using firing rate maps, each of which describes the activity of a single cell as a function of location. Place field remapping necessarily implies ensemble remapping. However, because ensemble remapping can occur in a single environment, without place field remapping, the relationship between activity vectors and environments is uncertain (e.g. Kao et al., 2017, J. Neurosci. 37:12031; Fenton et al., 2010, J Neurosci. 30:4613). Here we evaluate the hippocampus ensemble place code across different environments to investigate how activity vectors differ between distinct environments. We recorded the activity of mouse CA1 neurons expressing virally-induced GCaMP6f with a bright-field miniature microscope placed above a surgically implanted GRIN lens. In a "physically distinct" paradigm, freely-behaving mice alternated between exploring two visually and geometrically distinct environments 3 days a week, for 3 weeks. In a "behaviorally distinct" paradigm, mice alternated between two similar environments: in one of them they learned to avoid an unmarked shock zone in a hippocampus-dependent active place avoidance task; in the second environment mice did not show avoidance behavior because a clear Perspex floor prevented shock. We find that although activity vectors in the same environment significantly reproduce across days, they become more distinct with longer intervals. Ensemble activity vectors are more distinct (but not independent) between different environments than across days in the same environment and these patterns maintain whether or not cells with place fields are included in the ensemble comparisons. The properties of remapping are compared as evaluated by 1) correlating single cell firing rate maps, 2) correlating ensemble activity vectors, and 3) decoding position information from ensemble activity.

Title: Linear self-motion cues contribute to hippocampal place cells: Functional implications

Authors: *R. M. YODER[1], R. E. HARVEY[2], S. A. RUTAN[3], L. C. CARSTENSEN[4], G. R. WILLEY[3], C. A. TERRY[3], J. J. SIEGEL[5], B. J. CLARK[2]

Abstract: The vestibular system contributes to the activity of hippocampal place cells and navigational performance. We tested whether the vestibular contribution to place cells includes linear self-motion signals originating in the otolith organs by recording hippocampal place cells from otoconia-deficient *tilted* mice and littermate controls, across five consecutive recording sessions [standard, 90° cue rotation, standard, darkness, and standard]. This procedure enabled evaluation of place cells' basic firing characteristics, stability within and across trials, response to cue rotation, and reliance on visual information. *Tilted* mice's place cells showed reduced coherence across all testing sessions, regardless of changes in cue position or room lighting. *Tilted* place cells also showed reduced intra-session stability, indicating impairments in the ability to represent location across short time scales. Following cue rotation, *tilted* place cells showed less accurate rotations with the cue, suggesting deficits in landmark control over place fields. *Tilted* place cells also represented locations closer to environmental boundaries, relative to control place cells, suggesting an increased reliance on tactile cues. These place cell deficits suggest that putative associated functions (e.g., place recognition) crucially rely on signals from the otolith organs. We tested this prediction by evaluating *tilted* mice's search strategy and place recognition on two versions of a Barnes maze: a 69 cm maze with 8 days of training, and a 120 cm maze with 4 days of training; for both mazes, a probe trial was conducted one day after the end of training. Control mice, but not *tilted* mice, preferentially used a directional search strategy by the 8th day of training on the small maze. Control mice also preferentially used a directional search strategy by the 2nd day of training on the large maze, whereas *tilted* mice failed to show a significant preference by the last day of training. Somewhat surprisingly, both groups clearly showed a preference for the former goal quadrant on the subsequent probe trial for both mazes, suggesting intact place recognition. Overall, our recordings suggest that otolith signals contribute to place cells' ability to represent locations distant to walls, possibly via the head direction signal or associated brain signals such as the grid cell or boundary vector cell signal. Our behavioral tests suggest that otolith signals contribute to the use of a directional search strategy, but are not required for accurate place recognition.

Title: Dentate spike modulation of hippocampal activity

Authors: *D. DVORAK[1], A. CHUNG[2], N. HUSSAIN[2], A. A. FENTON[1]
[1]Ctr. for Neural Sci., [2]New York Univ., New York, NY

Abstract: Dentate spikes (DS) are large amplitude, short duration field potentials that can be localized to the hilar region of the dentate gyrus, and may play a role in learning, memory consolidation and stabilization of the hippocampal circuit through anti-excitation. While the exact roles of DS are unknown, prior observations suggested the hypothesis that excessive DS may underlie cognitive flexibility deficits in Fmr1-null mice that model the genetic defect in Fragile X Syndrome (FXS) and express representational inflexibility of hippocampus place memory representations (Dvorak et al., PLoS Biol. 16: e2003354).We recorded local field potentials (LFPs) from freely-behaving wild-type and Fmr1-null mice during sleep and open-field exploration, as well as during aversively-motivated active place avoidance tasks, two unreinforced object spatial novelty tasks, and the three-chamber social novelty tests. LFP recordings using 32-channel linear silicon probe arrays that spanned the dentate gyrus and CA1 of dorsal hippocampus allowed current source density analysis and identification and classification of DS events.We find that Fmr1-null mice are impaired when behavior requires cognitive control to judiciously use relevant and ignore irrelevant information in memory. Although conditioned-place learning and memory of Fmr1-null mice are both normal for the initial location of an avoidable shock, the mice are impaired on conflict trials when the shock is relocated opposite to the initial location. Unlike wild-type, Fmr1-null mice fail to show the normal early preference for novelty in an object/place mismatch when the locations of two of four familiar objects are exchanged in the same environment and in an object/context mismatch when two of four objects are exchanged between environments. While Fmr1-null mice express a normal preference for mice over inanimate objects, their preference for novel mice over familiar mice is weaker than the wild-type's.We detected exaggerated rates of DS events in Fmr1-null mice. Whereas wild-type DS rates decrease dramatically during conflict trials, Fmr1-null DS rates remain high. Fmr1-null DS rates are also exaggerated compared to wild-type during exploration of place-mismatched and context-mismatched familiar objects, and during exploration of novel but not familiar mice during social discrimination.These findings point to a possible role for dentate spikes in maintaining hippocampal representations, and that the cognitive representational inflexibility of FXS-model mice is indexed by inability to attenuate DS rates in response to diverse types of environmental novelty.

Title: The effect of moderate prenatal alcohol exposure on object discrimination by adult rats

Authors: *L. M. SANCHEZ[1], S. D. BENTHEM[1], S. A. JOHNSON[3], S. M. TURNER[3], D. D. SAVAGE II[5], S. N. BURKE[4], B. J. CLARK[2]
[1]Psychology, [2]Univ. of New Mexico, Albuquerque, NM; [3]Univ. of Florida, Gainesville, FL; [4]Univ. of Florida, Ganesville, FL; [5]Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM

Abstract: Fetal Alcohol Spectrum Disorder, which includes Fetal Alcohol Syndrome (FAS), partial FAS, and Alcohol related Neurodevelopmental disorder, are a major public health concern in the United States impacting approximately 2-5% of children especially since it is an avoidable public health concern. While a great deal of research has been done to understand the effects of high dose prenatal alcohol exposure (PAE), there is increasing evidence that moderate PAE is much more common and can also have a long-lasting impact on cognition and behavior. One of the most striking behavioral abnormalities after PAE are deficits in learning and memory which can have serious repercussions for scholastic performance. While a large body of research has been focused on the effects of PAE on cognitive processes such as spatial learning and memory, the impact of PAE on high-order sensory representations such as the perception of complex objects is currently unknown. In the present study, we tested a moderate PAE rat model (Savage et al., 2010) in an object discrimination task (PAE: n = 25; Saccharin control: n = 22). In brief, the task is composed of training rats to discriminate between a pair of toy objects that differed in size, shape, and color. In Experiment 1, rats were given a total of 20 trials per day with each trial ending once the rat pushed one of two objects to uncover a piece of food. The same object was rewarded on each trial throughout training and the position of the object within the pair varied across trials. Thus, animals were required to select a particular object on the basis of its perceptual features. In Experiment 2, rats were given 10 trials per day throughout training. Overall, PAE and control rats expressed a similar rate of task acquisition in each experiment, with rats reaching criterion (two consecutive days >80% correct) within 4 days of training in Experiment 1, and within 8 days in Experiment 2. In addition, PAE and control rats exhibited similar performance as measured by the percentage of correct trials across testing ($p > 0.05$). Although these findings suggest that moderate PAE does not impair object discrimination, the objects used in these experiments were distinct. Thus, in Experiment 3, rats will be tested in a discrimination task in which the degree of feature overlap between the object pairs is systematically increased. The results of this study will be discussed in relation to the hippocampal-parahippocampal basis of object discrimination learning and the effects of moderate prenatal ethanol on this neural circuitry.

Title: Cognitive control and the dynamic grouping of spatial frame-specific hippocampus discharge in the absence and presence of task demands

Authors: *A. A. FENTON, Z. TALBOT, M. VAN DIJK
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Cognitive control describes the ability to judiciously use task-relevant information while ignoring task-irrelevant information. How can a single neural system, able to process more than one class of information selectively represent only the most currently relevant information, and how should the selection reverse when what is task-relevant changes? One solution is "dynamic functional grouping," whereby the ensemble discharge of a population of neurons transiently organizes into same-function groups of co-active cells to process one class of information at the exclusion of other classes. Dynamic functional grouping in the discharge of hippocampus place cells is observed as rats solve a two-frame active place avoidance task on a rotating arena with two concurrent goals: 1) avoid shock in a stationary location defined by static room cues, and 2) avoid shock in a rotating location defined by rotating arena cues. Every few seconds, place cells alternate between an ensemble-level preference for signaling locations in either the room frame or the arena frame, but rarely both. Here, to investigate features of cognitive control independent of overt behavior, we use this spatial-frame ensemble preference (SFEP) on a rotating arena as a neural expression of cognitive control. We ask whether 1) cognitive control is expressed in the absence of an explicit task; and 2) whether explicitly reinforcing one class of information (room places) as useful, causes preferential representation of the relevant information. Hippocampus principal cells were recorded while mice explored a continuously (1 rpm) rotating arena during pretraining (before) and (during/after) active place avoidance training to avoid a room shock zone. Ensemble discharge alternatingly represented room places and arena places, with a preference for room information during pretraining. Surprisingly, this room-dominant spatial-frame ensemble preference reduced with training to avoid the room shock zone; hippocampus discharge changes to represent room locations and arena locations with equal frequency. With training, room-preferring discharge was more likely near the shock zone and arena-preferring discharge was more likely away from it. These findings indicate that internal cognitive variables may not be accurately inferred from overt behavior or

task contingencies, and point to the hippocampus opting for greater representational flexibility than representational compression in solving this hippocampus-dependent cognitive task, more consistent with model-based than with model-free learning systems.

Title: Investigating task-adaptive position coding in MEC neurons

Authors: *K. HARDCASTLE, W. N. BUTLER, L. M. GIOCOMO
Neurobio., Stanford Univ., Stanford, CA

Abstract: Accurate navigation requires that animals maintain an internal representation of their current location. Medial entorhinal cortex (MEC) likely supports this representation, as MEC neurons have been shown to modulate their activity with the animal's position, head direction, or running speed. Further, recent work has shown that the position and head direction tuning of MEC neurons is also modulated by the running speed of the animal; a greater number of cells encode position and head direction information at fast running speeds, and the quality of encoding also increases (Hardcastle et al., 2017). However, it is unclear whether this change in navigationally-relevant information encoding is due to locomotion alone, or rather reflects an increase in attention to navigation-specific information, which has previously been shown to improve encoding in hippocampal place cells (Kentros et al., 2004). To probe this distinction, we recorded MEC neurons while rats performed two separate tasks in two distinct environments. In environment 1, animals foraged for randomly scattered food rewards. In environment 2, animals were trained to navigate to an unmarked goal location in response to an auditory cue in order to receive a large food reward. Both environments were geometrically identical and were surrounded by identical distal cues, but differed in wall color, floor scent, and the flavor of the food reward. Comparison of position-encoding medial entorhinal cells between these environments revealed grid translation and re-mapping of non-grid position-encoding cells, consistent with prior work (Jeffrey et al., 2015). In addition, the degree to which grid cells encoded position information was selectively altered during the spatial task. Further, we

observed task-specific re-mapping of position tuning, such that position decoding was improved near the unmarked reward zone. Combined, our results indicate that MEC can shift its coding properties along task-relevant dimensions to better support accurate navigation.

Title: Heterogeneous coding for position and context across hippocampal subregions

Authors: *M. PLITT, L. GIOCOMO
Stanford Univ., Stanford, CA

Abstract: The ability to generate novel associations between stimuli is a hallmark of learning and often depends critically on the hippocampus. One example of this process is context discrimination, in which animals must remember outcomes that are paired with a particular constellation of sensory cues, some of which may be overlapping with other outcomes. Here, we aim to gain insight into how the hippocampus supports the creation of distinct representations for similar sensory experiences by imaging hippocampal neurons as animals are trained animals to perform a difficult context discrimination task and are then presented with ambiguous context-related stimuli. In this study, mice performed a novel two alternative forced choice context discrimination task while we imaged calcium activity in CA1 or the dentate gyrus (DG) using two photon microscopy. Animals ran in one of two virtual reality environments and learned to report which hallway they were in by licking to a particular side. Once animals reached expert level performance, they were occasionally placed in an ambiguous environment that was a morph of the known contexts. Behaviorally, mice gradually increased their licking to a particular side as the evidence for that context increased. During this task, we found that the hippocampus formed a robust and low dimensional representation of both position and context. Coding for context was heterogeneous. Some neurons showed “engram”-like coding, in which cells were constitutively active in one context or the other, while others showed a partial reorganization of the place field map across contexts. Taken together, this data can shed light on whether

representations of contexts in the hippocampus are discrete entities like fixed point attractors or more continuous representations of the stimuli in the environment.

Title: Distinguishing grid from non-grid cells in virtual reality

Authors: *M. G. CAMPBELL, M. PLITT, C. S. MALLORY, L. M. GIOCOMO
Stanford Univ., Stanford, CA

Abstract: Head-fixed rodent behavior is now a popular experimental paradigm because it allows an ever-expanding toolkit of recording techniques, including 2P imaging, whole cell recording, and acute silicon probe recording, to be applied in awake, behaving animals. One prominent example is head-fixed virtual reality, in which animals move through a visual, tactile, or olfactory environment by running in place on a cylinder, belt, or spherical treadmill. By enabling whole cell recording and imaging, as well as near-total control of the animal's sensory environment, this tool has greatly advanced our understanding of the neural mechanisms underlying the spatial response properties of hippocampal and entorhinal neurons during navigation. In medial entorhinal cortex (MEC), one prominent cell type is the grid cell, which fires at the vertices of a triangular lattice that spans the environment. However, the MEC also contains many other spatially-responsive neurons which are not grid cells. This leads to the question of whether grid cells can be accurately identified in linear virtual environments during head-fixation. To address this issue, we recorded hundreds of medial entorhinal neurons using tetrodes while animals explored both an open field environment (OF) and virtual linear track (VR). We labeled the cells as either grid or non-grid based on the OF data and asked whether these cells could be distinguished based on their VR response properties alone. We found that our ability to distinguish grid from non-grid cells based on the VR recordings alone was limited, but could be improved by manipulating the gain between the animal's locomotion and the movement of the visual cues, which separates cells that respond differentially to these two cues.

These results provide a benchmark for future work using virtual reality to study medial entorhinal cells during navigation.

Title: Experience-dependent evolution of place cell coding during spatial learning

Authors: *Y. SUN, L. M. GIOCOMO
Neurobio., Stanford Univ., Stanford, CA

Abstract: Hippocampal place cells are thought to provide a neural substrate for spatial learning and memory. However, how place cell ensembles evolve their representation of space as a function of experience remains incompletely understood. As the progression of spatial learning can occur over long time scales (weeks), this topic has been challenging to study using conventional electrophysiological techniques, due to the inherent difficulty in tracking the same cell population for many days. Here, we used a miniaturized fluorescence microscope to investigate the dynamics of spatial learning by imaging long-term calcium dynamics of CA1 place cells in freely behaving mice. For these experiments, mice were exposed to two previously unexplored environments (square vs. circular open field) every other day for 20 days and the same group of CA1 neurons were tracked and imaged repeatedly. Consistent with previous work (Ziv et al., 2013), we found that a subset of place cells remained relatively stable after the environment became familiar. However, the number of cells that showed place fields in both environments were linearly decreased over time. More interestingly, the majority of the place cells that were present on day 1 of the experiment were unstable in subsequent early sessions (days 1-7) and did not show coherent place fields in later sessions (days 9 - 20). In parallel, another group of CA1 neurons, many of which were not classified as place cells on day 1, came online and increased in stability and information in the later sessions (days 9 - 20). Thus, our data suggest a the place cell population undergoes a major reorganization in its activity pattern during spatial learning and provide new insights on the circuit dynamics that occur as environments transition from novel to familiar.

Title: Dorsal-Ventral place cell representations in multi-scale environments

Authors: *B. HARLAND[1], M. CONTRERAS[1], P. SCLEIDOROVICH[2], A. WEITZENFELD[2], J.-M. FELLOUS[1]
[1]Psychology, Univ. of Arizona, Tucson, AZ; [2]Computer Sci. & Engin., USF, Tampa, FL

Abstract: Most of what is known about spatially-tuned cells in the brain has been learned while recording from rodents in small, highly controlled environments. Hippocampal 'place cells' generally exhibit only one 'place field' in small boxes or cylinders (typically between 40 cm and 1.5 m across), and narrow walkways. However, there is evidence that place cells possess multiple place fields in larger environments [1], perhaps indicating a fundamentally different coding mechanism in complex natural environments. We recorded wirelessly from dorsal and ventral CA1 hippocampal place cells while rats performed two different behaviors in a large open environment (530 x 350 cm) containing multiple intra- and extra-maze cues. In the majority of sessions, the rat chased a small robot baited with food [2]. The advantage of this technique is that it allows control over navigation without restricting the animal. Other sessions involved 'classical foraging' in which the rat searched for small food pellets scattered on the floor. Each session consisted of a rest/sleep period, a recording in a small enclosure (180 x 120 cm), the recording in the large environment, another recording in the small enclosure, then a final rest/sleep period. This allowed us to compare place cell coding at multiple spatial scales and to assess the stability of place cells throughout the session. We have found that dorsal place cells indeed exhibit multiple fields in the large environment. These multiple fields can greatly vary in size even within the same cell, a result similar to that shown in bats in a corridor [3] but shown here in rodents, and in an open-field environment for the first time. Ventral CA1 place cells exhibited larger place fields and increased out-of-field firing compared to their dorsal counterparts. Establishing how spatially-tuned cells operate in this larger space may be key to understanding how we form a spatial representation of complex large-scale natural environments.

Title: An empirically driven hierarchical anti-hebbian network model for the formation of spatial cells in three-dimensional space

Authors: *K. SOMAN[1], V. CHAKRAVARTHY[1], M. M. YARTSEV[2]
[1]Dept. of Biotech., Indian Inst. of Technol. Madras, Chennai, India; [2]Bioengineering, Univ. of California Berkeley, Berkeley, CA

Abstract: The discovery of spatial maps in rodents has yielded valuable insights into the brain's spatial navigation systems. However, studies of spatial navigation, both empirical and computational, are highly biased towards navigation in one or two-dimensional spaces, while three-dimensional (3D) navigation is relatively under-studied, despite the fact that most forms of navigation occur in 3D environments. The discovery of 3D spatial cells in the mammalian hippocampal formation supports the existence of 3D spatial maps; yet the underlying computations that support the formation of such maps are vastly unknown. With this motivation in mind, we propose a hierarchical oscillatory anti-hebbian network model for the formation of three-dimensional spatial cells. The proposed model is a hybrid one that incorporates both oscillatory and rate coded neurons. A virtual animal is simulated to fly freely inside a cubical enclosure. The model is driven by animal's velocity components in 3D space viz. azimuth and pitch. The model has a hierarchical architecture with two parallel neural layers representing azimuth and pitch respectively. The distribution of the directional coding neurons (azimuth and pitch) in the model is made to match experimentally observed distributions. This neural representation of flight direction is passed to the downstream low-frequency oscillatory layer (0.5 Hz) that, integrates the incoming neural velocity information into the phases of the oscillators, thereby performing path integration (PI). The final anti-hebbian neural network layer is trained on the output of the oscillatory PI layer. The anti-hebbian network is a recurrent neural network whose afferent and lateral weight connections are trained using Hebbian and anti-

Hebbian rules respectively. The model, after training, accounts for the natural emergence of place, border and grid-cells in 3D. Furthermore, it provides experimentally testable prediction for the existence of two new, previously undescribed, types of 3D spatial cells that we call 'plane cells' and 'stack cells'. Interestingly, it naturally provides a mechanistic explanation for the discrepancy between the anisotropic coding of place and grid-cell firing fields observed in rodents, and the isotropic coding reported (in the case of place-cells) and predicted (in the case of grid-cells) during 3D volumetric navigation in flying bats. Lastly, it provides evidence for the importance of unsupervised learning rules in the formation of higher dimensional spatial maps.

Title: Multiplexed continuous tracking of spatial location and navigational choice values in the posterior parietal cortex of foraging bats

Authors: *N. M. DOTSON[1], M. M. YARTSEV[2,1]
[1]Bioengineering, [2]Hellen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Real-life navigation is complex and often occurs in dynamically changing environments where an equilibrium must be struck between exploration and exploitation to guide navigational choices. Importantly, a hallmark of natural environments is a lack of certainty in both the source and reliability of reward. Yet, the neurobiological computations that support complex navigation and provide continuous monitoring of both spatial position and choice value remain largely unresolved. Here we addressed this topic utilizing wild caught Egyptian fruit bats - expert aerial navigators that are accustomed to foraging in such complex natural environments. Utilizing the development of a fully automated flight room behavioral setup in our laboratory we could effectively train these bats to perform a probabilistic navigation task. There, the animals had to choose (on each trial) between one of four navigational goals, each with a different underlying reward probability that varied on a daily basis. Importantly, the bats could only gain knowledge about the reward contingency for each target by trading-off exploration and

exploitation strategies, as no other explicit cues were available to the animal. The robustness of the behavior and controlled conditions allowed us to leverage reinforcement learning models to extract value estimates corresponding to the navigational choices on a trial-by-trial basis. To study the neural computations that might support such a complex form of spatial navigation we utilized the development of wireless electrophysiological methods in freely flying bats which we integrated with the automated flight room behavioral setup. We targeted the posterior parietal cortex region of the bat as this region has been previously shown to be involved in spatial navigation and decision-making. We find that many of the neurons in this region exhibit highly reproducible and spatially restricted firing fields in freely flying bats performing the task. Strikingly, a significant fraction of neurons exhibited value-modulated neural activity that reliably tracked the value of navigational choices on a moment-by-moment basis. Further analyses are aimed at unraveling the intriguing relationship between spatial and value coding exhibited by posterior parietal neurons to uncover their potential contribution to complex forms of spatial navigation.

Title: The automated flight room: Studying complex three-dimensional spatial navigation and its underlying neural codes in freely-flying bats

Authors: *D. GENZEL, M. M. YARTSEV
Helen Wills Inst. of Neurosci. and Dept. of Bioengineering, Univ. of California, Berkeley, CA

Abstract: Bats, as the only mammals capable of self-propelled flight, freely navigate in three-dimensional space. They are renowned for their ability to extract information about the environment through their active echolocation system (biosonar), but visual, passive auditory and often olfactory signals are often used for navigation as well. How this multitude of sensory inputs are used for navigation we are only beginning to understand. Since the discovery of

position-coding neurons, considerable progress has been made in unraveling the neural mechanisms underlying how the brain guides navigation through complex three-dimensional environments, but much remains unknown, especially with respect to the influence of sensory inputs on ongoing neural activity as well as the mechanisms that come into play when more complex and varying constraints on navigation are present. To address these challenges, we designed a sophisticated setup in which we can record flight behavior, echo-acoustic attention and neural activity in a highly controlled manner. Specifically, the design of our system facilitates fully automated training, thus reducing the great variability of manual training, eliminating the biases due to experimentalists' presence during testing and increasing the number of trainable animals. Here we describe the implementation of this approach in the design of a task in which Egyptian fruit bats (a bat species with exceptional visual capabilities) are trained to approach in flight one of four targets to obtain a food reward, where a correct target is marked by a visual cue. By varying the intensity of the light cue, we can reduce the reliability of the sensory cue used for this navigational task and ask how this is reflected in the bat's psychometric navigation performance and ongoing neural activity. As it is becoming more evident that the retrosplenial cortex plays a major role in coding spatial information, in particular during visual-guided navigation, our goal is to investigate for the first time its underlying neural codes in a freely flying bat. The study of navigating bats coupled to cellular-resolution measurements of brain activity during free flight and under ethological yet controlled conditions, will provide important insight into how the mammalian brain supports complex forms of three-dimensional navigation.

Lab., Lysaker, Norway; [2]Univ. of Oslo, Oslo, Norway; [3]Univ. of Göttingen, Göttingen, Germany; [4]Ctr. for Neural Circuits and Behavior, Neurobiol Section, Div. of Biol Sci., UCSD, La Jolla, CA; [5]Dept. of Biosci., Oslo, Norway; [6]Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: Since the discovery of place cells, stable spatial representations in the hippocampus are thought to form a cognitive map. In line with this theory, place cells in hippocampal region

CA3 have well-defined, spatial receptive fields that remain stable upon repeated exposure to the same environment. In contrast, place cells in neighboring region CA2 have very different properties. There, place cells tend to have multiple fields with changing peak firing rates and shifting positions, resulting in a gradual decorrelation of the spatial map. Integrating recent insights about synaptic plasticity in both regions, we developed a computational model to investigate the conditions under which place field instability may arise.
Pyramidal cells in CA3 form plastic recurrent connections thought to be involved in forming stable spatial representations. In contrast, in CA2 it is not yet clear whether excitatory plastic recurrent connections exist. But, it has been shown that proximal dendrites of pyramidal cells in CA2 are tightly enwrapped by dense extracellular matrix, limiting plasticity at afferent excitatory synapses from CA3.
In our model we hypothesize that recurrent excitatory synapses in CA2 exist, but that they are not plastic. In consequence, we assume that recurrent plasticity in CA3 allows the formation of a spatial attractor, but not so in CA2.
Using a rate-based model, we contrast emerging spatial representations of CA3 and CA2. Recurrent connections of CA3 are tuned to spatial input from entorhinal cortex (EC), CA2 recurrent connections are not. The spatial attractor in CA3 is able to transform multipeaked EC input to single place fields. Activity in CA2 reflects rather its input and tends to have multiple, irregularly spaced fields.
Despite the limited plasticity at proximal dendrites of CA2 pyramidal cells, it has been shown that afferent projections from EC onto distal dendrites of CA2 pyramidal cells are very plastic. Compared to the EC-CA3 synapse, LTP is much stronger at the EC-CA2 synapse.
In addition, neurotransmitters, such as vasopressin, oxytocin and substance P, selectively modulate the EC-CA2 synapse.
In our model, mimicking simple plasticity at the EC-CA2 synapse during rest is sufficient to reproduce field-specific changes in peak firing rates, position instabilities and a continuous decorrelation of the spatial map.
The proposed model provides an intuitive way of understanding the emergence of multiple, independently modulated place fields. Further, the model points to plasticity at the EC-CA2 synapse during rest as a potential source for the decorrelation of the spatial map over time.

Title: Enhanced associative competition by a latent inhibitor with a retention interval: Role of incubation

Authors: R. RICHARDSON[1], T. KILLMADE[2], D. KLAKOTSKAIA[1], P. MICHENER[1], *T. SCHACHTMAN[3]
[1]Psychological Sci., [2]Dept. of Psychological Sci., [3]Univ. of Missouri, Columbia, MO

Abstract: Published studies have shown that a latent inhibitor is poor at competing for learning with another conditioned stimulus (CS) on a compound conditioning trial. Moreover, the poor conditioned response (CR) produced to a latent inhibitor (a CS given preexposure and then paired with the US) can be reversed by a retention interval placed after conditioning and prior to testing the CR (e.g., Bakner et al., 1991). In these experiments, a CS ("A") is given CS-alone preexposures prior to a pairing of the CS with the unconditioned stimulus during pretraining phases. A compound conditioning phase then occurs in which this CS was able to compete with an added novel CS ("B"). However, prior to the AB-US compound conditioning phase, a retention interval occurred lasting either one day or many days (15 or 21 days). The lengthy retention interval enhances the competitive potential of the pretrained CS. The present experiment extended these findings in showing that the effect is not due merely to an "incubation effect" (e.g., Spear & Riccio), in which associations appear to increase in strength over time; rather, conflicting associations appear to compete for retrieval.

Title: Processing of associatively-activated representation requires PLCß1 of the left mPFC

Authors: H.-J. KIM, *H.-Y. KOH
Korea Inst. of Sci. & Technol., Seoul, Korea, Republic of

Abstract: According to associative learning theory, a conditioned stimulus (CS) evokes associatively-activated representation (AAR) of a paired unconditioned stimulus (US), and then this AAR can substitute for the actual US itself in the acquisition of new learning about US, which is called representation-mediated learning (RML). Studies with rodents showed that RML occurs only with a small number of CS-US pairings and not with extended training. It is

suggested that, with minimal CS-US pairings, CS evokes a highly realistic AAR which is not fully distinguished from the actual US so that RML can occur, and that, with extended training, AAR is replaced by a less perceptual one that is distinguishable from the actual US, so RML does not occur. Processing of AAR supporting RML sensitivity course is suggested to have implication for psychiatric conditions (synesthesia, hallucination, flashbacks in PTSD). Although the concept of AAR is used in psychology of associative learning in theoretical terms, this theory has never been addressed experimentally. In this study, (1) we observed the processing of AAR by analyzing the pattern of CS-evoked neural activation in gustatory cortex and nucleus accumbens, using cFos immunohistochemistry in wild-type mice; (2) In PLCß1 KO mice, in which RML sensitivity course is disrupted, processing of AAR was also disrupted, suggesting that PLCβ1 is required in AAR processing; (3) Local knockdown of PLCß1 in the left medial prefrontal cortex (mPFC) disrupted RML sensitivity course and processing of AAR. These results suggest that the left mPFC PLCβ1 is required in the processing of AAR.

Title: Characterizing a simple, automated active avoidance task for mice that leads to persistent avoidance behavior

Authors: *M. WEBER, A. EASTON
Dept. of Neurosci., Genentech Inc, South San Francisco, CA

Abstract: Persistent avoidance behavior is a hallmark of phobias, panic disorders and other neuropsychiatric (NP) disorders, while the extinction of avoidance behavior is a core principle of cognitive behavioral therapy. While rodent tasks of active avoidance (AA) may be useful for studying the biological basis of some of these behavioral patterns, it may also be useful for probing long-term memory (LTM). Here, we have characterized a two-way AA task for mice. C57BL6/J mice learned to avoid an unconditioned stimulus (UCS, a mild electric shock) by moving into the opposite compartment of a shuttle box during the presentation of (conditioned) visual and/or acoustic stimuli before the UCS is applied to the compartment in which the mouse was located at the beginning of the trial. We show that acquisition of AA is rapid in both sexes, reaching near maximal levels during the 2nd day of training. AA was impaired in aged mice consistent with earlier studies that were conducted with different stimulus conditions. The fact that these results lead to similar conclusions despite varying experimental conditions (# of trials, sex) supports the robustness of the task. When two separate tests were conducted under identical

conditions, but 5 years apart, virtually identical results were obtained, demonstrating high re-test reliability. The % of trials in which AA behavior was shown during acquisition depended on the number of "learning trials" previously encountered, showing that the behavior is amenable to training intensity. Once AA was stably established, AA memory was extremely long lasting, yielding near maximal % AA in tests 8 weeks post training. Mice still performed above their initial baseline % AA level 22 weeks post training. Following stable acquisition, AA behavior was resistant to complete extinction despite 9 consecutive days of AA training with 100 trials/day in the absence of the UCS. In sum, this AA task is simple, automated, highly reliable, and robust, and leads to a long-lasting memory that can be elicited when tested several months post training. This AA task could not only be useful for studying the biological basis of LTM or extinction, but also for testing the effects of compounds that may affect LTM or extinction.

Title: The ability of song recognition learning does not depend on age in male and female zebra finches

Authors: *D. LEE, K. KAI, S. KOJIMA
Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: Just as speech acquisition in humans, song learning in many oscine species strongly depends on age. In the zebra finch, male birds develop a good copy of their tutor's song only when they are exposed to the tutor song during a restricted period of development. In this sensory phase of song learning, birds form an auditory memory of tutor song that will be used as a template to guide song development in the subsequent sensorimotor learning phase. Although zebra finches do not learn to produce new song once the sensory learning phase is over, however, they maintain the ability to memorize songs for conspecific recognition even in adults: a number of previous studies have demonstrated that adult zebra finches learn to identify or discriminate conspecific songs. What is the relationship between song memorization for song learning and song memorization for conspecific recognition? One possibility is that juvenile birds learning song have a higher ability to memorize conspecific song compared to that of adult birds and that such enhanced ability of song memorization critically contributes to the age dependence of song

learning. To test this hypothesis, we trained juvenile and adult zebra finches to memorize a single conspecific song using a go/no-go operant-conditioning paradigm, and compared their learning speed and memory retention between the two age groups. Birds were trained to respond to a particular conspecific song (target song) to obtain a food reward, and to withhold their responses to 5 other conspecific songs (non-target songs) to avoid a mild punishment (a 20-sec time-out). Despite the strong age dependence of song learning, we found no significant differences between juvenile and adult male birds in either learning speed or memory retention. In addition, no significant differences were found between juvenile males and age-matched females in the same measures despite the lack of song learning ability in female birds. These results sharply contrast the strong dependence of song learning on age and gender, raising the possibility that song memory formed with operant conditioning is fundamentally different from song memory formed with tutoring. In support of this idea, we also found that the juvenile birds that have memorized a target song with our operant conditioning paradigm later developed adult song that does not resemble the memorized target song. We will discuss possible differences in neural mechanisms between these two forms of song recognition learning and mechanisms that regulate the sensory period of song learning.

Title: Effect of long term sugar consumption on insular cortex glutamate levels during new aversive learning

Authors: *D. BADILLO JUAREZ[1], M. I. MIRANDA[2]
[1]Behavioral and Cognitive Neurobio., Inst. de Neurobiología UNAM, Queretaro, Mexico; [2]Dept. de Neurobiologia Conductual y Cognitiva, Inst. de Neurobiologia, Queretaro, Mexico

Abstract: Conditioned taste aversion (CTA) is an associative learning in which subjects associate a novel taste with visceral malaise, which results in a robust aversion. However, when a familiar or pre-exposed taste is associated with a visceral malaise a delay in the ability to associate the stimuli is observed; this effect is known as latent inhibition (LI) of CTA. Glutamatergic activity in the Insular Cortex (IC) plays a crucial role in memory formation and several studies have reported that during CTA (for novel saccharin) there is a significant increase

of glutamatergic activity in the insular cortex that it is related with the aversive stimulus; however, glutamate activity during LI of CTA has been little studied. Therefore, the objective of this work was to evaluate glutamate levels in the IC during CTA acquisition for novel sugar or after 21 days of permanent sugar exposure. Adult male Wistar rats were long-term exposd to permanent access to sugar solution (10%); on day 14 they were stereotaxically implanted with one microdialysis cannula directed to the right IC. At the end of the long-term sugar consumption (21 days), rats were trained in CTA during in vivo microdialysis (MD) as well as during aversive memory retrieval. Glutamate levels in the MD samples were analyzed with a HPLC coupled to fluorescence detector. During novel sugar CTA acquisition, a significant increase on IC glutamate levels where observed immediately after LiCl i.p. injection. However, during CTA acquisition, with high familiar sugar, glutamate levels did not present changes during or after LiCl injection, in rats that also presented a strong LI of CTA. This result shows that the LI of CTA induced by long-term sugar consumption had a differential glutamate release during visceral-aversive signaling. This result confirms that glutamatergic activity in the IC during CTA acquisition is required for aversive taste association and suggests that visceral information signaling could be altered after long-term periods of sugar consumption, since highly familiar taste that induces strong LI of CTA is associated with a non-effective glutamatergic cortical activity.

Title: CA1 hippocampal ensemble neural activity reveals associative representations in mice acquiring a context-dependent learning task

Authors: *T. ROGERSON[1], J. MAXEY[1], P. JERCOG[2], T. H. KIM[1], S. EISMANN[1], B. AHANONU[1], B. F. GREWE[3], J. LI[1], M. J. SCHNITZER[1]
[1]Stanford Univ., Stanford, CA; [2]IDIBAPS & Cellex Inst., Barcelona, Spain; [3]ETH Zurich, Zurich, Switzerland

Abstract: Substantial research has shown that hippocampus has a key role in spatial cognition, but the role of hippocampus in associative learning and memory is less well understood [Wirth *et al., Science (2003)*]. Prior studies have identified hippocampal neurons that encode conjunctions

of spatial information and sensory stimuli [*Rolls et al*., J. Neurophysiol. (2005), Komorowski *et al*., J. Neurosci. (2009)], but how these conjunctive representations develop with associative learning and are evoked in contexts with conflicting information remains largely unknown. To study the role of hippocampus in associative memory, we used a miniature head-mounted fluorescence microscope to record neural calcium dynamics in hippocampal area CA1 in freely behaving mice as they learned a task requiring mastery of a bi-conditional rule. This behavioral task involved two visuo-tactile stimuli, each of which we presented to the mice in two different U-shaped running tracks with distinctive features. In each context, only one of the two stimuli signaled the presence of a reward; thus, to receive rewards successfully in both contexts the mouse had to learn two different context–stimulus associations. Mice learned to perform this task well above chance even when rapidly alternating between the two contexts. Pharmacological inhibition of dorsal hippocampus in trained mice impaired their performance of the task, consistent with a hippocampal role in context-dependent associative memory retrieval. In trained mice, we found hippocampal cells that encoded stimulus-context associations; we hypothesize that the formation of conjunctive coding features such as these underlie the ability to respond appropriately to varied stimuli in distinct contexts. We are presently analyzing the development of these coding features during learning and their dependence on the training regimen.

Title: Conditions that govern false fear memories in rats

Authors: *N. W. LINGAWI[1], V. LAURENT[2], R. F. WESTBROOK[3], N. M. HOLMES[3]
[1]Sch. of Psychology, [2]Psychology, [3]Univ. of New South Wales, Kensington, Australia

Abstract: Memories are not often faithful records of our experiences: they often contain information about events that did not happen or did not happen the way in which they are remembered. These so-called false memories can have potentially far-reaching consequences, yet we know little about the conditions under which they are formed. We recently developed a

laboratory model to study false memories (Bae, Holmes and Westbrook, 2015), and showed that rats pre-exposed to a context, A, on day 1, then given an immediate shock upon placement into a similar context, B, on day 2, show more fear to context A than context B at test, despite the fact that rats were shocked in B and not in A. These findings have been explained in terms of mediated conditioning: rats retrieve the configural representation of context A upon placement in the similar B context; the shock in B associates with the representation of context A. Implicit in this description is that the amount of fear that accrues to each context is determined by the level discriminability between the two contexts. Thus, manipulations that prevent or impair discrimination between the pre-exposed A and shocked B contexts should increase false fear conditioning of A while minimizing true fear conditioning of B; and conversely, manipulations that permit or enhance discrimination between A and B should reduce false fear conditioning of A and simultaneously increase true fear conditioning of B. We tested these predictions in a series of experiments using the protocol developed by Bae et al (2015). We found that disrupting the formation of the configural representation of context A by shocking the A context increased false memory to A, but increasing the placement-to-shock interval in context B restored the amount of true fear memory to context B. Importantly, we showed that these two factors (i.e., an immediate shock in A and the placement-to-shock interval in B) interact in determining the strength of the false and true fear memories. These findings have important implications for how false fear memories might be formed, prevented or reduced.

Title: Sustained temporal attention prevents habit formation in rats

Authors: *Z. LIN[1], H. NISHIKAWA[1], Y. IGUCHI[2], A. IWANAMI[3], Y. MINABE[1], S. TODA[1,3]
[1]Dept. of Psychiatry & Behavioral Science, Kan, Kanazawa, Japan; [2]Dept. of Mol. Genetics, Inst. of Biomed. Sciences, Fukushima Med. Univ., Fukushima, Japan; [3]Dept. of Psychiatry, Showa Univ. Sch. of Med., Tokyo, Japan

Abstract: It is well known that operant learning with distinct reinforcement schedules results in different consequences in terms of habit formation. For example, the operant learning with random interval schedule is difficult to predict action-outcome contingency, but it is prone to be a habit, whereas the one with fixed interval (FI) schedule is easy to predict action-outcome contingency, but it is resistant to be habitual. However, what promotes or interferes with habit formation has yet to be fully elucidated. We hypothesized that the sustained attention for monitoring the interval that is required for FI, but not RI, schedule during sessions could prevent habit formation. To verify this, we first prepared three cohorts of male Sprague-Dawley rats (N=13/each) for the operant learning with FI60 (i.e., a reward is given in every 60 seconds by lever pressing) schedule for 2 weeks. As previously reported, all groups gradually adjusted their lever pressing according to the FI schedule, but their goal-directed actions did not transfer to a habit. We next allocated distinct training conditions for each cohort; for the first cohort, the operant learning with the same FI schedule was continued as before. For the second cohort, the operant learning with the same FI schedule was continued just as the first group, however, the timing of lever pressing was informed to the subjects just before it by an auditory cue, thus the subjects need not pay attention to the interval. For the last cohort, the operant learning with FI schedule was continued with auditory cues just as the second group, however, the auditory cues were provided in a yoked fashion to the ones for the second group, thus were non-contingent to the timing of reward. After 2 weeks of additional FI sessions, we found that the first group remained as goal-directed as before, meanwhile, the second and third groups developed a habit. The results of outcome devaluation also revealed that habit formation was the most robust in the second group. These results implicate that habit formation requires attention-free situation rather than action-outcome contingency, therefore continuous cognitive burden such as monitoring a certain interval by oneself prevents an action from acquiring automaticity. The reason why a habit was also developed among the last cohort is not clear, however, it is possible that the non-contingent auditory cues, which were functionally irrelevant noises, may have dispersed and/or attenuated the attention by preventing focusing on the interval monitoring.

Title: All-go behavioral state with resetting cue-outcome associations in ventral striatum during reversal learning

Authors: *Y. TANISUMI, Y. SAKURAI, J. HIROKAWA, H. MANABE
Grad. Sch. of Brain Sci., Doshisha Univ., Kyoto, Japan

Abstract: In changing environments, animals must adaptively select actions based on the predictive information and their motivational state to achieve their goals. Previous studies have shown that neurons in the ventral striatum(VS) fire to predictive cues associated with outcomes and play a critical role in promoting behavioral responses required to obtain outcomes. However, little is known about how VS neurons associate cues with outcomes during learning and guide behavioral choices. We therefore investigated the firing of VS neurons during go/no-go odors discrimination and reversal learning using simultaneous multiple single-unit recordings in rats. In this task, we trained rats to associate go-cue odors at the odor port with the behavior to go to the reward port to obtain water reward (”go” responses), and to associate no-go-cue odors with staying near the odor port to wait for the next trial (”no-go” responses). Firstly, we analyzed the behavioral responses during reversal learning. After reversal of odor-outcome contingencies, rats reached the 80% correct response criterion in a mean of 89 trials in 121 sessions. In addition, during an initial phase of reversal learning, rats made go responses following both go and no-go cue odors and continued this behavioral strategy in a mean of successive 43 trials. We called this behavioral state “all-go state”. Next, we focused on neural activity correlated with behavioral choices. We found that a subset of VS neurons fired selectively to go-cue odors or no-go-cue odors when rats showed cue odor-induced behaviors. There was a strong correlation between their firing rates during sampling cue odors and the selected behaviors after sampling. However, in all-go state, the selective firing during odor cue sampling was dramatically reduced and did not correlate with behavioral choices. As rats began learning to withhold responding after sampling new no-go cue odors, these neurons tended to generate their selective firing to the new cue odors. In addition, a subset of VS neurons fired to water reward regardless of changes of cue-outcome association rule. These results indicate that during the initial reversal learning phase, VS neurons were in a preliminary state to learn the new association between cue odors and outcome without affecting behavioral choices.

Title: The effect of habit formation on reinforcer devaluation in rhesus macaques

Authors: *E. LAFLAMME[1], P. A. FORCELLI[2], L. MALKOVA[1]
[2]Dept of Pharmacol., [1]Georgetown Univ., Washington, DC

Abstract: Actions may be goal-directed, in pursuit of a specific result, or they may be driven by mechanistic habit in response to a familiar stimulus. The switch from goal-directed behavior to habitual responding is one of the major challenges in fighting addiction, making this type of research highly translational. Reinforcer devaluation is a task that probes goal-directed behavior, and has been used in rodents (Balleine & Dickinson, 1998) and non-human primates (Malkova *et al.*, 1997). Overtraining on stimulus-reward pairings (~360 pairs) impairs reinforcer devaluation in rodents: animals begin responding habitually (Dickinson & Balleine, 1995). However, the degree to which this is true in primates is unknown. Here, animals are repeatedly exposed to a set of pairs of objects (e.g. 40 per day) presented as discrimination problems (one rewarded and one non-rewarded). They learn implicitly over time which objects are associated with specific food reinforcers (peanut or fruit snack). Upon reaching criterion, they are offered a choice between the peanut-associated objects and fruit snack-associated objects to assess baseline preference. An experimental reduction of reward value by selective satiation (i.e., providing one food to satiety) produces a devaluation effect, i.e. a decrease in the proportion of objects associated with the sated food that are selected. We set out to determine how many exposures are necessary for a monkey to develop a habitual response, manifest as loss of the devaluation effect. In this task, three male rhesus macaques (ages 4-5) are being trained on the discrimination problems beyond criterion with some objects with high exposure per day and some with low exposure (< 50 total). Reinforcer devaluation is measured after 100, 260, and 430 exposures to designated high-exposure object pairs. Preliminary data demonstrate that 260 exposures are insufficient to establish a habit response, as the animals continue to display the same devaluation effect when choosing between high-trained objects as they do between low-trained objects. Whether this will be the case after further overtraining remains to be determined.

Title: The spatiotemporal profile of diffusion MRI based measures of microstructural tissue changes evoked by learning novel skills

Authors: *C. THOMAS[1], M. B. MOYER[2], B. COLEMAN[2], P. BROWNING[2], F. Q. YE[2], D. K. YU[2], A. AVRAM[3], C. I. BAKER[1], E. A. MURRAY[2]
[1]Lab. of Brain and Cognition, [2]NIMH, Bethesda, MD; [3]NIBIB, Bethesda, MD

Abstract: The ability to learn novel skills throughout our lifetime is known to be mediated by structural changes in the brain. However, the nature of the structural changes, and the spatiotemporal dynamics of such changes during the course of learning are unclear. Here, we trained naïve, adult rhesus monkeys (Macaca Mulatta; N=8) in two tasks differing in complexity. The monkeys were first trained to criterion (90%) in the "one-place" task, a visuomotor task which required the monkey to reach and touch an object on a computer screen to earn a reward. Next, the monkeys were trained in the "scenes" task, in which they learned to touch a target foreground object placed in an artificial "scene" composed of multiple geometric elements to earn a reward. The monkeys learned several unique scenes concurrently; the identity and location of the target object differed across scenes but was fixed within scenes.We acquired multishell Diffusion MRI (dMRI) images from the monkeys across two timepoints using a Bruker 4.7T MRI system. The pre-training scans were acquired before any formal training and the post-training scans were acquired when the monkeys reached criterion in the second (scenes) task or failed to reach criterion despite extensive training. Behaviorally, the monkeys showed wide individual variability in their ability to acquire the different tasks, with 2 of the 8 monkeys failing to learn the one-place task. Interestingly, monkeys that required fewer trials-to-criterion in the one-place task learned faster in the scenes task ($rho = - 0.77$ $p < 0.04$). Examination of the spatial topography of changes in dMRI measures based on a median split analysis with group (good/bad learners) and timepoint (Pre/Post) as factors in a linear mixed effects model revealed a significant main effect of group, with the good learners showing higher Fractional Anisotropy (FA) of the right internal capsule, anterior commissure and crus of the fornix. Finally, correlation analysis between the learning profile and changes in dMRI measures revealed: (a) a trend towards a positive correlation between faster learning in the scenes task and global increase in white matter (WM) volume ($p < 0.13$); (b) more trials-to-criterion in the one-place task correlated positively with an increase in FA and a decrease in Radial Diffusivity in the dorsal parieto-occipital WM. This region is considered part of the fronto-occipito fasciculus (FOF), which has been associated with reaching and grasping arm movements. Overall, the pattern of changes in the dMRI measures suggest that prolonged experience in performing the training tasks evokes changes in tissue microstructure consistent with changes in myelination.

Title: Developmental experience of food insecurity reduces cognitive flexibility in a rodent model

Authors: *W. LIN[1], L.-H. TAI[1], E. GALARCE[2], L. WILBRECHT[1]
[1]Psychology Dept., Univ. of California Berkeley, Berkeley, CA; [2]Hlth. & Society Program, Robert Wood Johnson Fndn., Berkeley, CA

Abstract: In the United States, approximately 17 percent of the households with children experience food insecurity, defined as uncertain or irregular access to food. Globally, hundreds of millions of people experience developmental food insecurity. Experience of food insecurity is positively linked to obesity and associated with poor academic performance, greater risk of developing psychological issues and substance use disorders. In human subjects, food insecurity is difficult to isolate from other factors associated with adversity that may also affect brain development. To understand what role food insecurity may play on the developing brain, we developed a mouse model of developmental food insecurity in which we delivered limited amounts of food on a variable schedule from P21, just after weaning, to P40, a late adolescent timepoint. Controls were mice fed ad libitum through this P21-40 period and mice that experienced a more stable food restriction. After P41, all groups were returned to ad libitum access to chow. We then tested mice in adulthood in odor based discrimination learning and cognitive flexibility. We found that adult male mice (P61-70) with developmental history of food insecurity performed similarly to controls in discrimination learning but were more perseverative than controls in reversal learning. Females showed no effect of developmental experience of food insecurity on discrimination learning or cognitive flexibility in adulthood. We conclude developmental feeding history in mice can have sex-specific effects on adult behavior. We are engaged in further research to determine the mechanisms underlying differences in cognitive flexibility in male mice.

Title: Renewal attenuation by extinction in multiple contexts after amphetamine-induced place preference conditioning

Authors: *R. RUÍZ GARCÍA, L. N. CEDILLO, L. D. GUTIERREZ, S. Y. NUÑEZ, J. C. JIMENEZ, F. MIRANDA-HERRERA*
FES, Iztacala, Estado de México, Mexico

Abstract: Drug craving plays an important role in turn to drug use or relapse. A high relapse rate suggests that drugs of abuse produce persistent changes in drug-induced behaviors. Some researchers have suggested experimental extinction as the basis for many therapies. Although extinction produces a reduction of the target behavior, several results indicate that this behavioral change is difficult to maintain, indicating that extinction procedure does not destroy the first learned behavior. One of the post extinction phenomena that support this notion is renewal. Several studies have suggested renewal effect as a model for relapse. Renewal effect has been reported if after acquisition, extinction takes place in a different contexts and testing in the acquisition context. Because of vulnerability of extinguished behavior to relapse, researchers have been looking for better treatments to prevent drug relapse. Bouton (1994) suggested extinction in several contexts rather than in the same context to enhance the generalization of extinction to other contexts. Learning in multiple contexts may reduce context specificity of conditioned responding. Specifically, renewal should be attenuated when behavior was extinguished in several contexts. The main goal of this study was to evaluate the effects of extinction in multiple contexts on the renewal effect after amphetamine-induced place preference conditioning (CPP). Forty male Wistar rats (250 g) were used. After establish the place of preference (PP), for training in the CPP procedure, subjects underwent drug- or saline-trials as follows: drug-trials, animals were administered AMPH (1.0 mg/kg, ip) and placed in the non-preference place (NP) for 30 min. Saline-trials, the animals were administered isotonic saline (1 ml/kg, ip) and placed in the PP for 30 min. Subjects received a total of 10 drug- and 10 saline-trials. Drug- and saline-trials alternated randomly, with the restriction that drug trials did not occur more than two consecutive occasions. In the extinction, subjects were administered isotonic saline as in the saline-trial, and were placed in the NP (Ext-A Group) or in multiple contexts (Ext-ABCD). With each group 8 sessions were carried out. For renewal test, three sessions were carried out (24-36-48 h after extinction session ended). In these sessions subjects

were put in the middle compartment. Results showed that CPP response decreased after the extinction process. However, renewal was observed when the subjects returned to the context where the AMPH was administrated. The renewal of the CPP can be attenuated by the extinction in multiple contexts. This study was supported by PAPIIT IN301717 (UNAM, Mexico).

Title: Characterization of lynx1 in sensory processing, learning and memory function

Authors: *Y. SHERAFAT, J. P. FOWLER, C. D. FOWLER
Univ. of California of Irvine, Irvine, CA

Abstract: Nicotinic acetylcholine receptors (nAChRs) have been implicated in various cognitive processes, including learning, memory and sensory processing. However, little is known about the endogenous mechanisms that modulate the function of nAChRs and their impact on behavior. Here, we examined the role of an endogenous protein modulator of nAChRs, lynx1, in a knockout mouse model. We hypothesized that the absence of lynx1 would increase operant learning and sensory gating, since its presence has been proposed to dampen nAChR signaling. To test the effects of lynx1 on sensory processing, lynx1 knockout mice and their wildtype littermates were examined in the prepulse inhibition test. To examine the effects on operant learning and cognitive flexibility, lynx1 knockout and wildtype mice were trained to press a lever to receive food reward under a fixed ratio schedule of reinforcement. After acquisition and establishing baseline levels of responding, mice were then assessed in a lever reversal task. Together, these findings further define the function of lynx1 proteins in behaviors mediated by cholinergic signaling mechanisms.

Title: A cortical reinforcement prediction error computed by VIP interneurons

Authors: *Q. CHEVY, H.-J. PI, E. T. GIBSON, A. KEPECS
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Our ability to interact with our environment strongly relies on how well we can predict the outcome of our present actions. The computation leading to such predictions can be framed using a reward prediction error (RPE) model. Neuronal correlates of RPE computation have been observed in midbrain dopamine neurons but it has been unclear whether similar prediction error signals also exist in cortical circuits. Interestingly, VIP interneurons, a subtype of cortical interneuron which drive strong cortical disinhibition, are strongly recruited by reward and punishment (Pi et al. 2013). VIP interneurons are therefore in a key position to participate in reinforcement learning by controlling cortical plasticity. We now show that VIP interneurons convey not simply the presence of reinforcers but rather a prediction error about reinforcers. To characterize the response of VIP interneurons to reinforcers, mice were trained in a range of classical conditioning tasks with auditory cues. We measured the activity of VIP interneurons either using optogenetically-identified single unit recordings with tetrodes or using fiber photometry to collect calcium-transients. After learning, we found that outcome expectations modulated the reinforcer-activation of VIP interneurons. VIP interneuron responses were also modulated at cue presentation by the predictive value of the cue. VIP interneuron responses increased both for outcome that were unexpectedly worse or better than predicted, a hallmark of an unsigned reward prediction error signal (‘surprise’). Finally, we demonstrated that the modulation of VIP interneurons by expectancy is independent of the sensory modality of the predictive cues. This suggests that cortical VIP interneurons may be the recipients of inputs conveying an unsigned RPE signal to neocortex. We propose that RPE signaling by VIP interneurons could provide a cortical teaching signal, shaping local computation.

Title: Development of a raven's progressive matrices to examine fluid intelligence in the pigeon, columba livia

Authors: *M. FLAIM[1], A. P. BLAISDELL[2]
[1]Univ. of California Los Angeles, Los Angeles, CA; [2]Psychology, UCLA, Los Angeles, CA

Abstract: Raven's progressive matrices (RPM) is a nonverbal intelligence test that examines fluid intelligence by asking subjects to correctly complete a stimulus matrix where transformations between stimuli in the matrix follow one or more rules. While this test has been used since 1936, and has been modified to accommodate a variety of humans (genius, children, dementia, etc.), it has never been adapted for testing non-human animals. Our study is an attempt to adapt the RPM-task for pigeons. Pigeons were trained on a task that could progressively increase in complexity through the addition of rules by which the matrix is completed. Pigeons were initially presented with a partially completed 2x2 matrix. Two shapes were presented in either the row or column of the matrix. The two shapes followed a rule, either size change along the rows or orientation change in the columns. Pigeons were initially trained on one rule at a time, using a go/no-go discrimination procedure with pecking reinforced when the rule was present (Go) but not when the rule was absent (NoGo). As discrimination performance reached criterion, pigeons were tested for transfer of the rule to novel stimuli. Following this, pigeons were then trained on a second rule. In the first version of this study, there were 6 subjects, 2 of which learned both rules to criterion. Both subjects were able to maintain the size change rule when presented with novel shapes. However, only one of these subjects was able to maintain the orientation change rule with novel shapes. This subject was able to maintain performance when both rules were presented in the same session and received full matrix presentation probe trials. In the second version of this study, 4 new subjects are learning the same rules, but along opposite dimensions. For these subjects, the size change occurs in the column and size change goes across the row. This was to determine if the rule learning was affected by the way information was presented or if the rules have different levels of difficulty. Two of the subjects have learned the size change to criterion, but none have learned the orientation change. Individual differences are expected in an intelligence test, but learning failures and modifications will be discussed.

Abstract: Zebrafish are rapidly emerging as a model vertebrate system for neurobiological investigations of learning and memory. The larvae of zebrafish are particularly attractive for such investigations due to their transparency, which enables robust optogenetic manipulations and *in vivo* imaging of neural activity; the relative simplicity of the neural circuitry underlying some of their behaviors; and their capacity for simple forms of learning such as habituation and classical conditioning. In the present study, we examined a form of short-term sensitization induced by application of allyl isothiocyanate, a chemical irritant, in restrained larval zebrafish. We found that allyl isothiocyanate increased heart rate and tail movements for several minutes after the chemical irritant was removed from the bath. Our results demonstrate that a noxious stimulus, allyl isothiocyanate, can reliably induce sensitization in restrained larval zebrafish, and set the stage for future investigations of this simple form of learning using optical monitoring of neural activity in the intact larva.

Abstract: The larval form of the zebrafish (*Danio rerio*) holds significant promise as a model vertebrate system for understanding the neural mechanisms of learning and memory. Zebrafish larvae possess two particularly valuable properties: translucence, which permits robust optogenetic manipulations and in vivo optical imaging; and behaviors mediated by relatively simple neural circuits, which facilitate cellular analyses of behavior. In addition, larval zebrafish have demonstrated the capacity for simple forms of learning, including habituation and classical conditioning. In the present study, we examined the effect of a known chemical irritant, allyl isothiocyanate (mustard oil), on movement in freely swimming zebrafish larvae (5 dpf). We found that mustard oil (MO, concentration = 10 μM) induced increased locomotor activity, as well as thigmotaxis, a behavioral correlate for anxiety, in the larvae. These results demonstrate sensitization of movement in the larval zebrafish. In future work we will attempt to determine the specific changes induced by MO in the behavioral circuits that mediate swimming in the zebrafish. The results of this work may contribute to an understanding of the neural basis of anxiety disorders.

Title: Understanding sensorimotor processing via a novel close-loop odor tracking task for head-fixed mice

Authors: *P. GUPTA[1], M. DUSSAUZE[2], U. LIVNEH[1], D. F. ALBEANU[1]
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Neurosci., Ecole Normale Superieure, Paris, France

Abstract: An emerging view of brain function is that of a simulator that generates predictions of sensory inputs via an internal model which maps motor actions to sensory outcomes (Craik 1943, Wolpert 1995). Sensory errors, the mismatches between observed and predicted sensory outcomes (Keller et al. 2012), in turn serve as feedback for updating the internal model. Experimental validation of this predictive coding framework necessitates close-loop behaviours where animals continually refine their motor actions based on the current and desired sensory percepts.
Here we present a novel behavioral paradigm, where water-restricted, head-fixed mice learn to control the lateral location of an odor source by maneuvering a light-weight lever with their front paws. Throughout the task, a fixed linear gain maps the 1-D movement of the lever onto left-right displacement of the odor source, such that a unit displacement of the paws (lever) generates a predictable, fixed displacement of the odor source. Each trial begins with the animal pulling the lever to a fixed start location which initializes the odor source location with a random offset with respect to the animal's snout. To obtain water rewards, animals are required to steer the lever such that the odor source is aligned to their snout and parked in place for >200 ms. Mice can learn this task within ~4 weeks, performing ~300-400 trials per session with >80% accuracy.
The close loop control enables us to flexibly manipulate the coupling between sensory feedback and motor action by delaying the sensory feedback or decoupling the sensory outcome (odor location) from reward availability. Using these feedback perturbations, we show that animals update their movements moment-by-moment based solely on the current odor location, and do not rely on either motor memory or other sensory cues (air flow, vision, whiskers etc).
Successful performance of this task requires at least two parallel processes: (i) directed movement of the paws (lever) based on the learned mapping between paw movement and odor displacement, i.e. an internal model, and (ii) continual assessment of the current versus expected odor location, i.e. sensory prediction errors. We are currently probing activity (via extracellular

recordings and activity suppression) in olfactory and motor cortex as well as olfactory striatum to understand the sensorimotor transformations that enable this behaviour.

Title: Deterministic and stochastic influences in oscillatory synchronization for information transfer: Complementary roles affecting global regulation

Authors: *D. C. LARRIVEE
Toronto, CANADA, Intl. Assn. Catholic Bioethicists, Chicago, IL

Abstract: Numerous studies now show that executive mechanisms evoke dynamic, oscillating activity by synchronization, which coordinates information transfer between global and regional circuits [1]. Shifting information content to generate novel information flow, conversely, requires oscillatory desynchronization prior to reassociation of new combinatorial variants, a mechanism likely to be employed in memory retrieval [2]. How this transfer is regulated is unknown but is likely to be broadly used, particularly for behavioral flexibility and to entail ubiquitous features of neural activity, including deterministic factors like phase resetting and stochastic activity that impact spike discharges of oscillating circuits. This paper explores how these mechanisms are likely to be used for regulating regional activity on the presupposition that oscillator associations are weakly coupled, a widely acknowledged model for cognitive information transfer. We show here that weak coupling constrains synchronization, leading to phaselocking values less than one, that is, to less than full synchronization [3]. Partial synchronization entails frequency modulation and phase precession through all phase angles, with cycling between periods of enhanced and weakened coupling within each phase cycle. By employing pulse trains for phase resetting, periodic weak coupling can be amplified, thereby favoring dissociation [4], with subsequent formation of new synchronous combinations. Conversely, stochastic events can modulate the phase range over which coupling strength is minimized, broadening phase variance and increasing susceptibility to transfer. Stochastic processes, moreover, can enhance transfer and responsivity by exposing coupled pairs to a wide variety of input firing patterns. That is, they can assess the information capacity of the neural system as a function of the total variation of spiking patterns that are elicited stochastically, that is, the maximum Shannon entropy. The selection of unique informational content, in turn, is achieved through a minimization of entropic variance, a mechanism likely to be employed in retrieval of unique engrams [5]. Subject to weak coupling constraints, therefore, the modulation of information content is likely to be regulated

complementarily by deterministic and stochastic events. References:1. Hellyer M, et al (2014). J Neurosci 34(2):451-461. 2.Almeida L, Idiart M, Lisman J (2007). Cold Spring Harbor Press 14:795-806.3. Title: Mu- and delta-opioid receptors differentially modulate thalamo-cortico-striatal pain circuitry

Authors: *W. BIRDSONG[1], B. C. JONGBLOETS[1], K. A. ENGELN[1], D. WANG[2], G. SCHERRER[2], T. MAO[1]

Abstract: Affective/ motivational pain processing involves the medial thalamus, anterior cingulate (ACC) and prefrontal (PFC) cortical regions and striatum. Opioid analgesics are known to modulate this circuitry and relieve the negative emotional effects of pain. However, the identity of the opioid receptors, their cellular locations, and their physiological effects on this affective circuitry remain uncharacterized. In the present study, synaptic connections between three brain regions; thalamus, striatum, and midline cortex (ACC and PFC), were studied in mice (both sexes, 8-12 weeks of age) to investigate the ability of opioid agonists to modulate glutamatergic transmission between these regions. Using optogenetic and electrophysiological approaches, it was determined that single medium spiny neurons (MSNs) in the dorsomedial striatum received direct input from both medial thalamic and cortical afferents. It was found that opioid receptors differentially modulated thalamic and cortical glutamate release in striatum. Additionally, μ and ∂-opioid receptors were found to play distinct roles in modulating thalamo-cortical and intracortical synaptic transmission in the ACC. Using electrophysiological and immunological approaches, it was determined that delta opioid receptors could disinhibit cortical

circuitry through inhibition of local cortical interneurons. Finally, it was demonstrated that a two-armed polysynaptic circuit involving direct thalamo-striatal projections and indirect thalamo-cortico-striatal projections could converge on single striatal MSNs with delta opioid receptor activation facilitating thalamo-cortico-striatal glutamate transmission and mu opioid receptor activation inhibiting both direct and indirect thalamo-striatal glutamate transmission. These data identify opioid receptor subtype-dependent inhibition of specific pathways within the thalmao-cortico-stiatal circuitry, using multiple approaches and across multiple medial thalamic and midline cortical brain regions providing insights into how opioid analgesics modulate affective pain at the synaptic and circuit level and more broadly affect thalamo-cortico-striatal circuit dynamics.

Title: Neuromodulatory pathways required for targeted plasticity therapy

Authors: *D. HULSEY[1], S. SADMAAN[2], S. ABE[3], S. HAYS[2], M. KILGARD[1]
[1]Behavioral and Brain Sci., [2]Erik Jonsson Sch. of Engin. and Computer Sci., [3]Sch. of Natural Sci. and Mathematics, Univ. of Texas at Dallas, Richardson, TX

Abstract: Targeted plasticity therapy (TPT) utilizes vagus nerve stimulation (VNS) paired with physical rehabilitation to direct plasticity and promote recovery after neurological injury. Precise timing of VNS is required to drive plasticity and functional recovery after injury in rodent models. VNS engages pro-plasticity neuromodulators, but there is no direct evidence that they mediate plasticity effects of VNS. We have shown that VNS drives rapid phasic activation of the noradrenergic locus coeruleus (LC). Parametric variation of VNS intensity, frequency, and duration shape LC responses. We believe this precisely timed noradrenergic activation reinforces task specific circuitry to drive reorganization of motor cortex output. Additionally, we show that VNS-directed plasticity requires cortical innervation of norepinephrine, acetylcholine, and serotonin. Pairing VNS with a lever-press task for one week reliably causes expansion of proximal forelimb representations. Depletion of each neuromodulatory input with targeted immunotoxins prevents VNS promoted reorganization. These results make substantial

contributions to elucidating the mechanisms, resoundingly confirming the neuromodulatory basis for TPT and VNS-directed plasticity. Further experiments assessing the involvement of the dopaminergic system are planned. Pharmacological interventions altering the release and reuptake levels of these key neuromodulators may also influence plasticity outcomes. These experiments can help guide clinical considerations in terms of patient selection for TPT based on pharmacological profiles.

Title: Cross-modal association learning in humans and monkeys

Authors: *T. VAN KERKOERLE[1,2], L. E. PAPE[2], M. EKRAMNIA[2], J. TASSERIE[2], M. DUPONT[2], B. JARRAYA[2], S. DEHAENE[2], G. DEHAENE-LAMBERTZ[2]

Abstract: Compared to other animals, humans have been suggested to have a unique capacity for symbolic representations, as exemplified in their ability for language and mathematics. However, direct evidence for this hypothesis remains sparse. One element of symbolic representation is that an association is bidirectional, a symbol can be presented either before or after the associated object for them to be paired. Behavioral studies have indicated that non-human primates do not spontaneously reverse learned associations. Here, we directly compared humans with macaque monkeys in their ability to reverse a cross-modal association, and if so, which cortical areas were involved. Different views of four objects (for example a chair or a purple prolate ellipsoid) were associated with speech sounds (such as 'mush', or 'bugnunu'). The sound was always presented before the image for 2 of the 4 objects (sound-image order), or after the image for the other 2 (image-sound order). Three days of training with 2-4 minutes long videos presenting the 4 pairs were followed by one day of scanning (3T Siemens Tim Trio), both in human adults (31 subjects) and in monkeys (32 sessions in 2 macaque monkeys). To test learning, incongruent pairs were presented during the scanner sessions either keeping the same pairing order than during learning (canonical pairs) or reversing it (reversed pairs). Crucially,

when the pairing order was reversed, the same number of congruent and incongruent pairs were presented to prevent any associative leaning in that direction. Furthermore, as the training comprised both orders (sound-image and image-sound pairs), it should prevent surprise effect for the mere reversal of the order and also facilitate generalization in monkeys. In humans, a network of areas, including the inferior frontal gyrus and the superior temporal gyrus reacted to incongruent pairs independently of the direction of the pairing (canonical or reversed), indicating that humans store the association in a reversible manner, at a symbolic level. In contrast, monkeys only showed an effect of incongruency in the canonical (i.e. learned) direction, without generalization to the reversed pairs. The network was limited in monkeys to the early sensory areas and the inferior frontal gyrus. These results demonstrate a fundamental difference between humans and monkeys, using the exact same paradigm in both species. Humans, but not macaque monkeys, can spontaneously access to a symbolic format, going beyond simple associative learning. This study confirms animal difficulties for symbolic representations as indicated in previous studies.

Title: Reward associations do not explain performance on transitive inference tasks in monkeys

Authors: *V. P. FERRERA[1], G. G. JENSEN[2], Y. ALKAN[1], H. TERRACE[2]
[1]Neurosci., [2]Psychology, Columbia Univ., New York, NY

Abstract: The observation that monkeys appear to make transitive inferences about the stimuli in ordered lists has been taken as evidence of their ability to form mental representations of those lists and to manipulate their contents. However, alternative explanations have been proposed, which argue instead that transitive inference performance can be explained entirely by "model-free" mechanisms (i.e. by expected or experienced reward value). To test the contribution of reward value to monkeys' behavior in TI paradigms, we performed two experiments in which we manipulated the amount of reward associated with each item in an ordered list. In these experiments, monkeys were presented with pairs of items drawn from the list, and rewards were delivered if subjects selected the item with the earlier list rank. In one condition, stimuli that

were correct more often were paired with lower rewards, whereas those correct less often were paired with larger rewards (creating a "reversed gradient" of reward magnitude). This created a scenario in which the reward magnitude associated with the correct item in any pair of stimuli was smaller overall than that associated with the incorrect item. When subjects were presented with a reversed reward gradient, correct responding was reduced, but nevertheless remained above chance. Over time, monkeys eventually learned to make correct rule-based choices despite countervailing incentives to select incorrect stimuli. In the second experiment, monkeys were trained with a subset of pairs and tested with the remaining pairs. Despite experiencing reversed reward magnitudes during training, they were still able to perform above chance when tested on novel pairs, a strong indication of the transfer of ordinal knowledge. In another condition, the opposite gradient was used, such that larger rewards were paired with stimuli that were correct more often (a "concordant gradient" of reward magnitude); this did not result in disrupted performance. These results demonstrate that monkeys' performance in TI paradigms is not driven solely by expected reward, but that they are able to make appropriate inferences in spite of competing reward associations.

Title: Theta phase-coupled gamma power in human memory structures strongly correlates with memory performance

Authors: *Y. SALIMPOUR[1], W. S. ANDERSON[2]
[1]Johns Hopkins Sch. of Med., Baltimore, MD; [2]Dept. of Neurosurg., The Johns Hopkins Hosp., Baltimore, MD

Abstract: The cross-frequency coupling (CFC) between neural oscillations at different frequency bands is a currently investigated neuronal mechanism for complex information processing in the central nervous system. Phase-amplitude coupling (PAC) is a commonly implemented form of CFC. PAC reflects the coupling of the phase of oscillations in a specific lower frequency band to the amplitude of oscillations in another higher frequency band. In a healthy brain, PAC occurs in mesial temporal structures, and changes in PAC have been associated with neurological disorders such as Parkinson's disease and Alzheimer disease (AD). The purpose of this study is to investigate the neurophysiological function of CFC across memory-related structures in the human brain during multi-item working memory tasks. the electrocorticographic (ECoG) activity from the intracranial grid, strip, and depth electrodes was

analyzed in fifteen epilepsy subjects while they performed image sequence encoding and recall tasks. Subjects were involved in remembering (encoding phase) and also reporting (recall phase) the temporal order of sequentially presented images and ECoG was recorded while subjects performed the task. After preprocessing the recorded signals, the frequency spectrum and also the phase-amplitude coupling between the phase of the theta band rhythms (4-9 Hz) and the amplitude of the gamma band oscillations (50-250 Hz) on each trial were estimated. CFC analysis of ECoG signals recorded from the parahippocampal gyrus of epilepsy patients is demonstrated by the strong correlation between levels of PAC and memory performance. Additionally, the portion of gamma activity coupled to the phase of the theta oscillations shows a higher correlation with memory performance in comparison to total gamma band power. These results point toward the possible role of cross-frequency coupling (specifically theta phase-coupled gamma power) in memory related activities in the human brain and demonstrate its crucial function in memory formation and retrieval.

Title: The primacy of processing speed: Distributed neural activity during digit-symbol performance discriminates individual differences in working memory

Authors: *Y. ZHAO[1], M. MOTES[1], N. HUBBARD[2], M. TURNER[1], B. RYPMA[1]
[1]Univ. of Texas at Dallas, Richardson, TX; [2]MIT, Cambridge, MA

Abstract: The neural and cognitive bases of individual differences in working memory (WM) performance remain unknown. One hypothesis is that processing speed underlies WM performance differences. In this view, WM performance differences arise from differences in the speed of fundamental operations. Such speed would afford faster individuals additional mental resources for succeeding WM and higher-level processes (e.g., rehearsal), to benefit their performance. Consistent correlations between processing speed and WM capacity make it difficult to adjudicate the primacy of processing speed or WM from behavioral data. Neuroimaging data provide additional leverage on this question by providing information about the extent to which variability accompanying one task (e.g., a processing speed task) mediates the performance on another task (e.g., a WM task). Similar to the behavioral studies, fMRI studies reveal similar neural mechanism for the two cognitive processes. However, activation pattern characteristics across the brain could be more informative about the fundamental substrate of WM. In this study, we tested the hypothesis that individual differences in processing

speed underlie WM utilizing a multivariate barycentric discriminant analysis (BADA) method, that permits us to predict individuals' WM performance from the patterns of multi-regional fMRI data. 25 healthy younger adults (Mage = 24.3 years, 15 females) completed a digit symbol verification task (DSVT) and a Sternberg WM task (SWMT) during fMRI scanning. In DSVT trials, participants saw an array of nine digit-symbol pairs and a digit-symbol probe pair below it. They indicating whether the probe-pair was present in the key or not by button-press. In the SWMT, participants encoded 2, 4, or 6 letters, maintained them over a delay, and then decided whether a probe letter was present in the encoded set. Average β values from eight frontal and parietal regions were used in the BADA analysis. There was a strong correlation between composite DSVT scores and composite SWMT Cowan's K ($r = .67$, $p < .001$). Consistent with behavioral findings, BADA analysis indicated that, with .95 bootstrap confidence interval, the DSVT task-related fMRI pattern differences could successfully separate the SWMT poor performers from the moderate and the best performers. SWMT could not discriminate those performance differences on SWMT. Our findings support the hypothesis that individual differences in processing speed and the neural substrate underlying processing-speed tasks account for WM performance differences.

Title: Event segmentation reveals working memory forgetting rate

Authors: *A. JAFARPOUR[1], E. A. BUFFALO[2], R. T. KNIGHT[3], A. G. COLLINS[4]
[1]Univ. Of Washington, Seattle, WA; [2]Physiol. and Biophysics, Univ. of Washington, Seattle, WA; [3]Univ. of California Berkeley, Berkeley, CA; [4]UC Berkeley, Psychology Dept., Helen Wills Neurosci. Inst., Berkeley, CA

Abstract: We perceive the world as series of segmented sequence of events. People generally agree with segmenting when salient events occur but there is inter-individual variation in the number of perceived segments. According to a prominent theory of event perception (Event

Segmentation Theory; Zacks et al 2007), the working memory system plays a key role in tracking and segmenting a sequence of events; however, data linking individuals' event segmentation to their working memory system is missing. Here, we tested if individuals' event segmentation rates predict their working memory capacities and forgetting rates. Forgetting rate reflects how fast working memory system forgets an encountered event. Healthy adults (n=36) segmented three movies that had different storylines (movie 1 had an overarching story with recurrent events, movie 2 had no overarching story but with recurrent events, and movie 3 had a linear overarching story) and performed a source memory test about the movies. These individuals also participated in an image-action association learning task that was used to extract the individual's working memory capacity and forgetting rate (Collins et al, 2017). Model-free and model-based analyses of the association learning task both showed that memory decay rate is linked to event segmentation. We found an inverted U-shape relationship between the number of reported segments in the movies and working memory forgetting rates in that people who perceived either a very low or a very high number of events had a higher forgetting rate. The working memory forgetting rate did not correlate with source memory performance. The results were robust to the storylines. Working memory forgetting rate is a less studied parameter of working memory system because of the high computational effort for extracting the parameter. The results suggest using individuals' event segmentation performance to infer working memory forgetting rate.

Title: Recovery of working memories after delay-period interference

Authors: *R. MALLETT, J. A. LEWIS-PEACOCK
Psychology, The Univ. of Texas At Austin, Austin, TX

Abstract: Distractors presented during the delay period of a working memory task can have a negative impact on performance. However, some memory items can be protected from this interference if a retro-cue informs subjects that only a subset of items will be tested (Makovski & Pertzov, 2015). This retro-cue is theorized to bring one of multiple memory items into the "focus of attention" (FoA) within working memory (Oberauer, 2002). Discussions about the protective effects on items inside the FoA have only been made relative to items that are no longer task-relevant, and therefore not only outside the FoA, but also outside of working memory altogether. Here we sought to understand whether it is the FoA specifically that provides interference protection to working memories, or if this protection is provided to all items in working memory regardless of their attentional state. Participants performed a double retro-cue paradigm (Oberauer, 2005) in which after the encoding of two memoranda (face and scene), a first retro-cue indicated which item would be probed after the first delay, and a second retro-cue indicated which item would be tested after the second. On half of trials, participants maintained the same memorandum throughout both delays (repeat trials), and on the other half participants switched to the previously uncued memorandum for the second probe (switch trials). Crucially, half of trials included interference during the first delay period on which participants made a sub-category judgement for an otherwise task-irrelevant picture of an animal. This paradigm allows us to, during the second delay period, investigate the "recovery" of a memorandum that was either inside the FoA (repeat trials) or outside the FoA (switch trials) during interference. Behavioral memory performance on the second memory probe was degraded by interference more on switch trials than on repeat trials, indicating that memoranda outside the FoA are impacted more by delay interference than those inside the FoA. Preliminary fMRI results (tracking category-level pattern instatement via MVPA) show that during the second delay, classifier evidence was greater for the cued item compared to the uncued item after interference, but only on repeat trials. On switch trials, when participants were asked to recover an item from outside the FoA after interference, classifier evidence was not differentiable between cued and uncued items. Both behavioral and fMRI results indicate that delay interference has a down-stream effect on the recovery of memory representations, and that this effect preferentially impacts memoranda outside the FoA.

Title: Predicting memory formation using theta oscillations and temporal-frontal oscillatory coupling

Authors: *T. TRAN[1], B. VOYTEK[2]
[1]UCSD, San Diego, CA; [2]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA

Abstract: Successful memory formation is associated with dynamic changes in temporofrontal cortical activity. These changes are apparent when examining 4 - 8 Hz theta oscillations and population-level spiking activity as well as when measuring the degree of oscillatory coupling between them. However, it is unclear which changes are most predictive of memory encoding as well as how consistently these changes predict encoding across individuals. To investigate this, we analyzed previously collected electrocorticographic (ECoG) recordings from 17 patients undergoing treatment for drug-resistant epilepsy (Solomon et al., 2017). These patients performed a free recall task in which they were serially and visually presented multiple lists of words, from which they were asked to memorize as many words as possible. From these recordings, we measured temporal and frontal cortical theta amplitude, high-frequency activity (HFA), phase-amplitude coupling (PAC), and aperiodic (1/f) slope, as well as interregional, temporofrontal PAC. We used these features to train individualized logistic regression models to correctly classify whether a word would be recalled, on a within-subjects basis, using neural activity during the presentation of subsequently remembered versus forgotten words. With these models, we achieved above-chance classification performance in 13/17 patients. To determine which features most accounted for prediction of memory formation, we used algorithmic feature selection and found that similar classification performance was achievable with a smaller subset of features. Moreover, comparison of model coefficients indicated that this feature subset was relatively consistent across patients. Using this approach, we identify reliable predictive patterns of neural activity that ultimately suggest crucial neural mechanisms underlying memory formation.

Title: Maintenance and manipulation components of working memory and associated structural brain regions in bipolar disorder

Authors: *I. CHO[1], M. K. SHAKEEL[2], V. GOGHARI[1]
[1]Psychological Clin. Sci., Univ. of Toronto Scarborough, Scarborough, ON, Canada; [2]Psychiatry, Univ. of Calgary, Calgary, AB, Canada

Abstract: BACKGROUND Cognitive deficits are thought to play an important role in the functional impairments seen in patients with bipolar disorder (BD). A domain of cognition that has been found to be impaired even during euthymic periods is working memory (WM). Based on Alan Baddeley's model, WM can be divided into separate *maintenance* and *manipulation* components. Despite the separation of WM into these two components, no study to date has investigated both components separately in BD and associated them with underlying structural brain regions.
OBJECTIVE To investigate differences in maintenance and manipulation components of WM and prefrontal and parietal cortex regions between controls and patients with bipolar disorder.
METHODS Forty-nine participants (24 controls) between 18-60 completed a visuospatial WM task and underwent neuroimaging. For the maintenance condition, participants determined if the position of the initial objects were the same as the newly presented objects, following a delay. The manipulation condition required the mental flip of objects along a horizontal line. Participants determined if the flipped positions of the previous objects matched the position of the new objects. Both accuracy and reaction time (RT) were measured. Structural neuroimaging data of regions generated by using FreeSurfer will be analyzed.
RESULTS 2 group x 2 WM condition ANOVAs examined accuracy and RT data. For accuracy, a significant main effect of WM condition was found across groups ($F(1,47) = 10.249$, $p = 0.002$), with the manipulation condition being more difficult; this did not significantly interact with group. However, the main effect of group approached significance ($F(1,47) = 3.69$, $p = 0.061$), with controls being more accurate than patients. A similar ANOVA for RT found a significant main effect of WM condition ($F(1,47) = 62.35$, $p < 0.001$), with the manipulation component having longer response times. There was no main effect of group ($F(1,47) = 0.142$, $p = 0.708$) or interaction between condition and group ($F(1,47) = 1.69$, $p = 0.199$). These results will be presented alongside findings from the structural neuroimaging data.
DISCUSSION Although both groups found manipulation to be more difficult, only the main effect of group approached significance for accuracy (with controls having higher accuracy). However, these results will be augmented by structural integrity indexes (i.e., gray matter volume, cortical thickness, and surface area) within the prefrontal and parietal cortex. Structural integrity measures may provide alternative information regarding the underpinning of WM dysfunction and brain-behaviour associations in bipolar disorder.

Title: Evidence for domain-specific working memory buffers from human single-neuron recordings

Authors: *J. KAMINSKI[1], A. BRZEZICKA[1], J. M. CHUNG[2], C. M. REED[2], A. N. MAMELAK[1], U. RUTISHAUSER[1,2,3]
[1]Neurosurg., [2]Neurol., Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: There are two main views on the nature of working memory (WM) buffers. One proposes that information is stored in a central capacity-limited modality-free buffer; the other suggests that domain-specific buffers exist for different modalities. In the Medial Temporal Lobe (MTL) of humans, cells represent multimodal concepts and they also exhibit persistent activity during WM maintenance. To explore the nature of WM storage in MTL, we performed single-neuron recordings in Medial Temporal Lobe in neurosurgical patients as they performed a working memory task. We asked subjects to maintain in WM images. These images were preselected for each of them individually using a screening task to ensure image-specific neuronal activation with image presentation. In addition to keeping in mind these images, subjects performed a verbal or a spatial distractor task in the middle of the maintenance period. Here, we investigated the properties of neurons that showed visual selectivity for one of the images. These neurons remained persistently active and tuned during maintenance. We found that this image selective persistent activity was significantly disrupted by the spatial but not verbal distractor task. We also found that persistent activity recovered after completion of the spatial task. This result shows two aspects of the specific nature of the neuronal representation of WM information in the MTL. First, the observation that only the spatial task disrupted the persistent activity demonstrates existence of domain-specific buffers independently from those used in other tasks operating in different modality. Second, the observation that persistent activity recovers after the spatial distractor could be an evidence of a distributed system holding multiple copies of the same information in different brain areas. These copies might be used to recover information in the MTL.

Title: Sex differences in electroencephalographic activity in default mode related with processof attention and memory

Authors: *Y. M. SERRATO
Neuropsychology, Univ. Nacional Autonoma de Mexico, Ciudad de Mexico, Mexico

Abstract: ABSTRACT
Cognition results from the synchronic interaction of bioelectric activity of the glio-neuronal assemblies that construct the brain circuits. However, to identify these circuits it is essential to describe absolute power (PA) profiles of the spectrum with its topography in default mode network (DMN) and its modifications in simple learning processes. The purpose of the present study is to simultaneously analyze four frequencies of the EEG (δ, θ, α and β) in DMN, habituation to the repeated photostimulation (FR) and visual-motor association (asso-vm) describing possible differences between genders and correlating the PA of the DMN with performance in neuropsychological evaluations. A total of 40 undergraduate students (20 ± 2 years) were divided into a group of women (GM) and a group of men (GH). The EEG was recorded in DMN and before (pre-FR) and during FR of 20 series from 2 s to 5 Hz (condition of habituation). A similar FR was performed with the indication that upon sensing it, a switch (aso-vm condition) would be pressed with the dominant hand. The analysis of EEGc revealed differences between genders in the power spectrum: GH showed higher PA of δ with respect to GM, while in the other bands (θ, α and β) the opposite phenomenon occurred. In the habituation, synchronization activity was predominant (understood as greater inhibitory activity), while during the asso-vm greater desynchronization was observed (greater activation). Finally, a correlation of the PA of θ in DMN with the total memory score was found. These duly identified data could be established as quantitative electroencephalography biomarkers for the support of neurological diagnoses and follow-up of cognitive neuro-rehabilitation interventions.

Title: EEG Neurofeedback training for memory enhancement and rehabilitation

Authors: *G. B. PATRUDU
Andhra Med. Col. & King George Hosp., Visakhapatnam, India

Abstract: Several studies show that EEG Neurofeedback training of selective bands has a positive effect on memory and several other cognitive functions. This review summarizes the studies investigating the effect of EEG neurofeedback training of different rhythms like Upper Alpha , Sensory Motor Rhythm , Gamma , Beta and Theta bands on various aspects of memory. EEG Neurofeedback training has been shown to be beneficial to both healthy subjects and patients with cognitive impairment. A study by Alekseeva etal (2017) showed that Alpha based Neurofeedback training enhanced memory in stroke patients. Other studies on Alpha Neurofeedback training had shown specific improvements in Episodic memory (Wei etal, 2017 , Hsench etal 2016), Working memory (Wei etal, 2017; Hsench etal, 2016; Kober etal , 2015; Escolano etal, 2011) , Mental rotation abilities(Escolano etal, 2011; Hanslmayr etal,2005) and Strategic and controlled recollection (Guez etal, 2015) . Sensory motor rhythm NFT improved Visuospatial short term memory (Gomez-Pilar etal, 2016; Kober etal, 2015), Automatic item specific and Familiarity based processes in memory (Guez etal, 2015) and Semantic working memory (Vernon etal, 2003). Both Upper alpha NFT and Sensory motor rhythm NFT nonspecifically improved Short and Long term memory(Kober etal, 2015). Frontal mid line theta up training improved performance on Working memory along with other cognitive functions in aging adults(Wang & Hsieh, 2013).Similarly, up regulating the theta to alpha power ratio in the anterior parietal region improved Working memory performance(Xiong etal, 2014).In a study by Keiser etal (2010), Gamma band activity targeted NFT improved Recollection and Beta band targeted NFT improved Familiarity memory.These findings show that EEG neurofeedback training has a potential to play a promising role in enhancement and rehabilitation of specific aspects of memory

Title: Perceptually-matched images that are meaningful are remembered better and result in increased CDA in visual working memory

Authors: *I. E. ASP, V. S. STÖRMER, T. F. BRADY
Psychology, Univ. of California San Diego, La Jolla, CA

Abstract: People are able to hold more items in visual working memory (VWM) when asked to remember meaningful stimuli (e.g., umbrella) than abstract stimuli (e.g., blue square) (e.g., Brady et al. 2016). However, in previous work, real-world objects and abstract stimuli were not controlled for perceptual equivalency. It is therefore possible that differences in VWM capacity were driven by perceptual properties (e.g., visual information load) rather than representational meaning. Here we address this concern by using perceptually-matched stimuli and manipulating only their meaningfulness. We used two-tone images (Mooney faces) that can be perceived as meaningful faces when upright, but meaningless blobs when inverted or shuffled. In particular, we measured VWM capacity for faces vs. non-face stimuli and recognized vs. unrecognized faces while simultaneously measuring the contralateral delay activity (CDA) using EEG. The CDA is believed to be a neural marker sensitive to the number of items being actively held in mind (e.g., its amplitude increases as the number of items held in VWM increases). By combining behavior and CDA we can assess the effect of meaningfulness on VWM capacity.In Experiment 1, we found that participants had higher VWM capacity for trials with more faces present compared to perceptually-matched non-faces ($t(11)=3.23$, $p=0.008$), and on trials where participants recognized more of the faces compared to trials with the same stimuli where they recognized fewer faces ($t(11)=3.99$, $p=0.002$). In Experiment 2, we found that in addition, CDA amplitudes were larger when the memory sets consisted of more faces than when they consisted of fewer faces ($t(18)=2.94$, $p=0.001$). We also found that the CDA tended to be larger on trials where participants recognized more of the faces compared to trials where they recognized fewer faces ($t(14)=2.11$, $p=0.053$), suggesting that VWM capacity depends on whether an object is perceived (subjectively) as meaningful by an individual or not. Together these results indicate that meaningfulness plays an important role in enabling more items to be held in VWM, independent of perceptual properties. Broadly, this suggests that VWM capacity is not fixed but critically depends on what type of information is being remembered.

Title: Glutamatergic modulation of working memory precision and serial biases

Authors: *H. STEIN[1], D. LOZANO-SOLDEVILLA[1], J. DALMAU[2,3], A. COMPTE[1]
[1]Theoretical Neurobio., [2]Neuroimmunology, IDIBAPS, Barcelona, Spain; [3]ICREA, Barcelona, Spain

Abstract: Continuity of mnemonic contents in time contributes to integrating information into coherent memory representations. Recently, attractive response biases towards previously memorized locations in visuospatial delayed response tasks have been reported as evidence for continuous integration of memory contents between trials. These serial attractive biases emerge specifically during working memory (WM) delay. Assuming a beneficial role of attractive biases for the coherence of memory representations, psychiatric and neurological disorders could be characterized by atypical serial memory biases, along with impairments in memory maintenance and precision. We tested a unique population of patients recovering from anti-NMDAR encephalitis to study possible synaptic mechanisms of memory maintenance and continuous memory integration. These patients still have a decreased NMDAR mediated neurotransmission and reportedly suffer from long-term and WM deficits. We collected behavioral and electroencephalography (EEG) data from anti-NMDAR encephalitis patients and healthy control subjects performing a visuospatial delayed response task. While healthy controls' responses were significantly biased towards previous memoranda, serial attractive biases were absent in patients with reduced glutamatergic synaptic transmission. Moreover, encephalitis patients reported memorized spatial positions with lower precision than healthy controls. Both serial biases and WM precision normalized with recovery from the synaptopathy. In EEG data, we analyzed task-related changes in alpha-band power during WM delay and prior to stimulus onset. Both during WM encoding and delay, encephalitis patients showed reduced decodability of the stimulus, compared to healthy controls. Similarly, past stimulus locations could be decoded just before the onset of the new stimulus in healthy controls, but not in encephalitis patients. Persisting target-

specific neural activity during delay and in the inter-trial interval might play a role in explaining behavioral differences between anti-NMDAR encephalitis patients and controls. Taken together, our findings suggest a fundamental role of the NMDAR in the within- and between-trial maintenance of short-term memory traces, potentially leading to deficits in the continuous integration of memory contents in NMDAR synaptopathies.

Title: Structural support for brain state transitions that contribute to working memory

Authors: *E. J. CORNBLATH[1,2], R. CIRIC[3], G. L. BAUM[3], K. RUPAREL[3], T. M. MOORE[3], R. C. GUR[3], R. E. GUR[3], D. R. ROALF[3], T. D. SATTERTHWAITE[3], D. S. BASSETT[2]

Abstract: In the healthy brain, large-scale white matter architecture and local neuronal membrane properties facilitate seamless transitions between cognitive states. However, the manner in which white matter supports the brain's recurrent spatial patterns of activity, or states, remains unknown. Here, we ask whether structural connectivity predicts trajectories of brain states in the resting state, and whether those predictions are conserved as participants engage in a cognitively demanding task. Using a large (n = 690) community-based sample of healthy youths from the Philadelphia Neurodevelopmental Cohort, we identify common brain states by applying unsupervised clustering to functional neuroimaging data acquired during the resting state and during the performance of an n-back working memory task to classify each time point as a discrete state. Highly active regions in the cluster centroids closely mirror resting state functional networks, with larger dwell times in visual and frontoparietal states during task and default mode network (DMN) states during rest. Furthermore, state transition probabilities differ between rest

and n-back and change over the course of normative neurodevelopment. Using diffusion-weighted imaging acquired from the same subjects, we show that increasing structural connectivity between highly active regions in each state positively correlates with the probability of transitioning between the respective states. These trends are similar for resting state and n-back task data, persist when accounting for spatial distance, and are robust to the choice of cluster number. State probabilities and state transition probabilities also predict working memory performance: increased DMN dwell times and transitions into DMN states at rest positively predict working memory performance. These results challenge the notion that the default mode network is a task negative system, suggesting that frequent, simultaneous activation of the entire DMN at rest and during the n-back task represents brain activity favorable for working memory. Overall, these findings shed new light on the relationship between brain structure and brain activity, as well as the role of regional coactivation in cognition.

Title: An fMRI study of cognition in early post-treatment Lyme disease

Authors: *C. L. MARVEL[1], J. A. CREIGHTON[1], O. P. MORGAN[1], M. B. SLAPIK[1], E. A. MIHM[2], A. W. REBMAN[2], C. B. NOVAK[2], J. N. AUCOTT[2]
[1]Dept. of Neurol., [2]Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Background: Lyme Disease (LD) is caused by the bacterium Borrelia burgdorferi, which is transmitted by infected deer ticks. Symptoms of LD typically include a variety of physical symptoms and cognitive complaints. Specifically, cognitive complaints include difficulty with concentration, executive function, and working memory, despite antibiotic treatment. Contrasting patient reports, however, neuropsychological tests describe normal cognitive function in early post-treatment LD patients. This can be frustrating news for patients who feel their cognitive symptoms are not being adequately addressed in the clinic. We hypothesized that people with LD are able to function at a cognitively normal level, but do so at a physiological cost, which could be measured as hyperactive brain activity. That is, their brains need to work harder than before LD to achieve normal performance. Methods: We administered

a functional MRI (fMRI) paradigm of working memory to 7 patients and 10 healthy controls at three weeks post LD diagnosis and again at six months (N=7 both groups). The working memory paradigm followed a Sternberg design which presented 1 or 2 letters at encoding and consisted of two rehearsal conditions: 1) passive storage of those letters, or 2) manipulation of those letters, such that the subject counted two alphabetical letters forward of each and held those new letters in mind. When a probe was presented, subjects indicated by button press whether the probe matched the original letters (storage) or the newly created letters (manipulation). Event-related fMRI analyses focused on the rehearsal phase that involved storage/manipulation processes only. Contrasts were conducted on the manipulation minus control conditions. Results: Accuracy and response time did not differ between groups or time points. At initial testing, fMRI data between groups showed hyperactivity in the LD group within a fronto-cerebellar pathway relevant to working memory. At 6 months, within-group comparisons between time points showed that the LD group activated regions similar to their own baseline (fronto-cerebellar). However, controls shifted activity to other regions (including inferior frontal, anterior insula, inferior parietal). Regions of interest created from the LD's fronto-cerebellar regions revealed that greater fMRI activity in the frontal lobe correlated with higher test accuracy, but also with fewer days since diagnosis, suggesting that frontal hyperactivity is compensatory yet systems are recovering with time. Summary: This study supports the notion that Lyme Disease impacts cognition and the brain.

Title: A comprehensive paradigm to test neurocognitive and neuromotor effects of shift work

Authors: *M. O. CONRAD[1], N. A. DIB[2], C. EDWARDS[2], E. CARPER[2], A. HARRINGTON[2], A. STEWART[2], A. MIDDLEMAN[2], J. FELLOW[2], M. T. MAHAR[2], H. S. BAWEJA[2]
[1]Mechanical Engin., Univ. of Detroit Mercy, Detroit, MI; [2]San Diego State Univ., San Diego, CA

Abstract: Extended workdays (more than10 hours) are increasingly prevalent in healthcare, manufacturing and the public service sectors. Published studies regarding shift length rely on subjective data rather than physical measurements. To our knowledge, no paradigm exists capable of rapidly conducting an overall physical and mental work assessment for work.
The purpose of this study was to (1) develop an efficient battery of tests quantifying the physical

and mental effects of extended work shifts on employees, and (2) validate the test protocol and data analysis system through a pilot study of physical therapy students with two distinct yet rigorous work schedules.
A battery of tests was developed to assess both motor and cognitive aspects of work. Tests included 1) Neuropsychological testing: Groton Maze Learning Test (GML), Two Back Memory Test (TWOB), Continuous Paired Associate Learning Task (CPL) (CogstateTM, CogState Ltd., Melbourne, AU)), and 2) Motor performance testing: maximal pinch & grip strength for both hands, balance (Better Balance Test, Balance Tracking Systems, San Diego, CA), and dexterity (Purdue Pegboard, Lafayette Instruments, Lafayette, IN). A pilot study was conducted to validate the protocol.
Nineteen participants were divided into 2 groups consisting of a 4-day work week (10 total; 5 females, mean age 26.2 years ± 3.68 years) or a 5-day work week (9 total; 7 females, mean age: 24.4 ± 0.73). All subjects participated in two, one-hour test sessions at the start and end of the work week. All participants were tested on the entire battery of tests in each session.
Results indicate a significant effect for both groups on work week in the cognitive domains of associate learning (CPAL; $F_{1,17} = 4.73$; P=0.044) and executive function (GML; GML $F_{1,17} = 29.71$; P=0.00). Within groups there is not a significant effect on motor performance. There were additional significant between group differences for CPAL ($F_{1,17} = 4.73$; P=0.044). Initial interpretations suggest a learning effect for some of the measures.
The study presented a comprehensive battery of tests that objectively and efficiently quantified multiple domains of physical and mental function. Young adults experienced an effect of work week on cognitive, but not motor function. Future studies will apply experimental paradigm to test effect of work week on healthcare profession, manufacturing applications and less active older adults.

Title: Multiple visual working memory items can guide attention and facilitate perceptual processing

Authors: *J. R. WILLIAMS, T. F. BRADY, V. S. STÖRMER
Psychology, Univ. of California San Diego, La Jolla, CA

Abstract: Previous research has shown that contents of visual working memory (VWM) can guide attention to features that match those actively held in mind. This memory-based attentional guidance has been shown for a single item, but whether similar guidance occurs for multiple items in VWM is under debate. Furthermore, it is unclear whether VWM contents can facilitate perceptual processing in tasks that do not require a narrow focusing of attention.
Here we demonstrate that VWM can guide attention and facilitate visual processing of features that match the memory content, even for two items. Participants were instructed to remember one or two colors while performing another task. In Experiment 1, on 80% of the trials, instead of reporting the memory color, participants performed an unrelated visual search task in which the target either appeared in a circle that matched the color held in VWM or not (as in Soto, 2005). Participants were faster in finding the target when it matched the memory color relative to when it did not for both set sizes even though the memory color was uninformative in the search task ($t(19)=-2.5, p<0.05$), consistent with automatic memory-based guidance. In Experiment 2, instead of a visual search task, we used a perceptual dot estimation task in which participants had to determine which one of two briefly presented dot arrays showed an overrepresentation of one color (as in Fang, Becker, & Liu, 2017 VSS). We found that the number of dots required to accurately identify the target array was significantly lower when the target color matched a memory color, suggesting that VWM contents facilitate visual processing. Importantly, this pattern was present for single and multiple memory items ($t(28)=-2.6, p<0.01$).
Overall, this suggests that two items held in VWM can affect perceptual tasks and attentional guidance in a relatively automatic fashion.

Title: Speeded visual working memory performance during standing and exercise: New insights from event-related EEG lateralizations

Authors: *T. TÖLLNER[1,2], G. DODWELL[2], H. J. MÜLLER[1,3]
[1]Ludwig-Maximilians-University Munich, Muenchen, Germany; [2]Grad. Sch. of Systemic Neurosciences, Munich, Germany; [3]Birkbeck Col., London, United Kingdom

Abstract: While a substantial body of research has investigated the effects of aerobic exercise on cognitive performance, few have monitored exercise-concurrent cognitive processes via

electroencephalography (EEG), and fewer still using an event-related lateralization (ERL) approach. As such, little is known regarding how the temporal dynamics of cognitive processing are influenced during aerobic activity. Here, we aimed at elucidating what influence aerobic exercise and upright posture might have on the temporal dynamics of a concurrent visual working memory (VWM) task.
To this end, participants performed a retro-cue task during both rest (sitting vs. standing) and acute aerobic exercise (cycling vs. walking), using a stationary bicycle and a treadmill, respectively. In the analyses, we combined mental chronometry with three specific EEG markers that can be directly linked to functionally different stages of the VWM processing pipeline. Behaviorally, we found reaction times (RTs) being speeded during exercise, while both RTs and error rates were decreased during upright posture. At the electrophysiological level, we observed CDA waves - indicating the access of WM representations - to be delayed for upright as compared to seated conditions, with no influence of exercise. However, the sLRP waves - indicating motor-response selection - mirrored the RT pattern, showing earlier onsets in active and upright conditions.
This pattern of effects demonstrates that acute aerobic exercise and upright body posture can have faciliatory effects on VWM performance. Within an optimal range of cardiovascular load, aerobic exercise can significantly improve processing speed, while upright posture can enhance both processing speed and response accuracy. Interestingly, VWM performance was found to be lowest in resting, seated conditions - the physiological state in which nearly all other neuro-cognitive research is conducted.The present study is unique in these findings, as to the best of our knowledge no prior research has attempted to disentangle the temporal dynamics of exercise concurrent VWM performance using a staged ERL approach. As such, this study provides an ample theoretical and methodological basis to inform future investigations of visual cognition during exercise.

Title: Shift in representation explains error in precision working memory tasks

Authors: *M. WOLFF[1,2], J. JOCHIM[2], T. BUSCHMAN[3], E. AKYÜREK[1], M. G. STOKES[2]
[1]Univ. of Groningen, Groningen, Netherlands; [2]Univ. of Oxford, Oxford, United Kingdom; [3]Princeton Neurosci. Inst. & Dept of Psychology, Princeton Univ., Princeton, NJ

Abstract: Recent research suggests that imprecise recalls in spatial working memory (WM) tasks are not only attributable to a noisy neural representation of the remembered location, but also to drift of the location code over time (Wimmer et al., 2014; Schneegans & Bays, 2018). We investigated whether similar processes are involved in non-spatial WM. Human participants completed a free-recall WM task while EEG was recorded. Two randomly orientated gratings were presented simultaneously at the beginning of each trial and a retro-cue indicated which of the two items was relevant shortly after. Participants were instructed to reproduce the orientation of the cued item at the end of the trial. "Impulse" stimuli were presented at two separate time-points during the maintenance period. The neural impulse response is WM content-specific (Wolff et al., 2017), and was used here to track the evolution of the neural representations of WM content during the delay. We found that orientation recalls that were either clockwise or counter-clockwise relative to the actual orientation were accompanied by corresponding shifts in the neural representations of the cued item as revealed by the "impulse" stimuli. The effect was stronger later in the delay, suggesting that the neural code of the item in WM drifts towards the final response, replicating and extending previous findings.

Title: A look into the dimensionality of recurrent neural networks

Authors: *M. S. FARRELL[1], E. SHEA-BROWN[2], S. RECANATESI[3], G. LAJOIE[4]

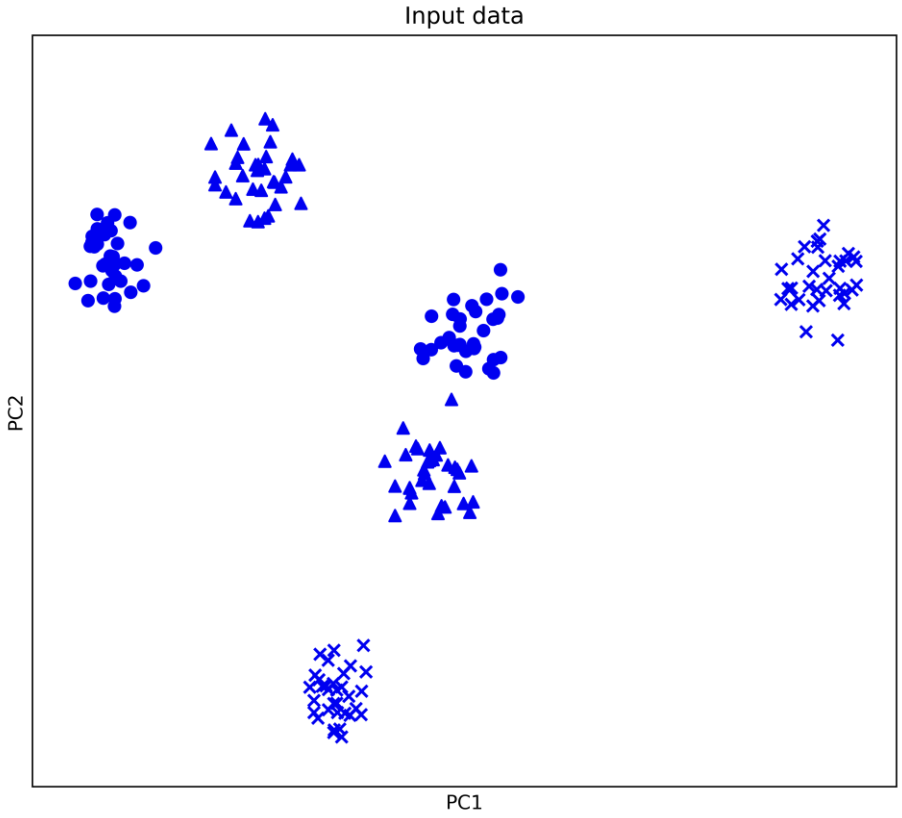
Abstract: The functional role of neural circuits in the brain can be modeled as a transformation of inputs into some desired outputs. In this work, a recurrent neural network is trained to classify spatially clustered inputs into classes using working memory. This task serves as a testbed to ask questions about the nature of neural representations as inputs are transformed into outputs defined by class assignment. We use a metric of dimensionality to quantify this transformation and see how it behaves as a function of the input and output dimension. We explore possible ways that this metric can be used to gain a deeper insight into the workings of the network and used to influence the training process for the purpose of finding new classes of solutions.



Shapes denote classes (here there are three classes and six clusters)

At the end of the working memory delay period, the trained network compresses its representation from six clusters into three.

Abstract: Previous research from our laboratory has demonstrated similarity effects in visual working memory for multiple items. We identified a "U-shape" relationship: working memory for a set of moderate similarity items is worse than for either high or low similarity items. Here we extended this research to investigate how the similarity of interfering information relative to working memory content impacts visual working memory. We hypothesized that interference effects would also show a U-shape relationship, with greatest interference by moderate similarity items. To test our hypothesis, we manipulated degree of similarity of visual and semantic properties of items across high, moderate and low similarity levels. We collected BOLD fMRI images while participants performed a continuous free recall task. In this task, a study stimulus was presented first. After a mask there was a delay period, during which four interfering images were presented sequentially. The interfering stimuli varied in degree of similarity to the study items. Finally, a probe stimulus was presented and participants were required to respond whether it was the same as the study stimulus. To ensure that interfering items were attended to, participants also performed a one-back recognition task during the delay phase. We identified regions of interest in occipitotemporal, frontoparietal executive control, dorsal attentional, and salience networks that were active during the study, delay, and probe phases of the task. We then used model-based fMRI and multivariate pattern analysis to characterize how activity in each region was affected by the degree of similarity of the interfering stimuli to the study items.

Title: Attentional effects on working memory representations: Comparing information-detection techniques and metrics

Authors: *J. MILLER[1], J. M. SCIMECA[1], N. S. ROSE[2], M. DESPOSITO[3]
[1]Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA; [2]Dept. of Psychology, Univ. of Notre Dame, Notre Dame, IN; [3]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Deploying attention within working memory (WM) helps determine which WM representations should guide behavior. When retrospective cues (retrocues) are used to guide attention during WM maintenance, neural evidence reveals different representational states: attended items are generally decodable from brain activity measures (fMRI or EEG), whereas unattended items are not generally decodable (even if later task-relevant). However, multivariate pattern analysis (MVPA) decoding techniques have yet to fully characterize the nature of attended and unattended WM representations, and mixed results render the neural substrates for "latent" WM representations unclear. For example, a recent study used a novel pattern analysis technique to successfully decode unattended WM representations in the intraparietal sulcus (Christophel et al., 2018). It remains unknown how much variability in detecting WM representations stems from true differences in attentional effects (e.g., change in representational format or cortical localization when outside the focus of attention) versus the informational approach (e.g., training different MVPA approaches on different tasks and task phases).
Here we investigated the nature of WM representations inside and outside the focus of attention using fMRI and several MVPA approaches. Human participants completed a multi-item WM task with two retrocues and two recognition probes (Rose et al., 2016). The first retrocue indicated an attended memory item (AMI) that would be tested at the first probe. The next retrocue could direct attention to the same item (repeat trials) or the previously unattended memory item (UMI; switch trials). We analyzed the fMRI timeseries with two primary MVPA methods: (1) decoding with a linear classifier, and (2) an inverted encoding model with an explicit feature space based on the stimulus categories (words, faces, and motion). Consistent with previous results, training either method on delay-period activity from an independent single-item WM task reveals high evidence for the AMI and chance-level evidence for the UMI in the retrocue task. Training on data from the retrocue task, however, revealed different evidence patterns for remembered items; e.g. training on the final delay of switch (vs. repeat) trials produced lower evidence during the initial multi-item delay but similarly high evidence after the first retrocue. These results suggest that information that was previously unattended is maintained in a modified representational format even when brought back into the focus of attention, implying a complex coding scheme for WM representations at different levels of attentional priority.

Title: Trends in interictal epileptiform activity are correlated with free recall performance

Authors: *S. MEISENHELTER[1], B. C. JOBST[2]
[1]Neurol., Dartmouth Col. Geisel Sch. of Med., Lebanon, NH; [2]Neurol., Dartmouth-Hitchcock Med. Ctr., Lebanon, NH

Abstract: We examined the relationship between the rate of interictal epileptiform activity (IEA) over long time periods and performance in a free recall working memory task.
Our previous work has demonstrated that IEA can momentarily impair cognitive function, but the cumulative effects of IEA over long periods of time have remained unstudied. A recent study has shown that epilepsy patients commonly have multi-dien rhythms in IEA rate and that these rates can govern seizure likelihood, hinting that IEA rate is associated with slow processes that govern brain activity.
We conducted this study primarily in subjects who are receiving epilepsy treatment using the NeuroPace RNS System, an implantable neurostimulator that can deliver therapeutic stimulation in response to clinician-specified patterns in electrocorticography. Using this system, we can obtain continuous records of how many times per hour the neurostimulator detected IEA, as well as electrocorticography (ECoG) recorded from the subjects' seizure onset zones during testing sessions.
We found that when subjects had elevated rates of IEA relative to their baseline rate, they had reduced performance on cognitive tasks. We also examined ECoG recorded during cognitive testing to determine whether there are changes in brain activity during periods of heightened IEA rates.

Title: Task switching and network inflexibility in obsessive compulsive disorder

Authors: *A. Z. CHOWDURY[1], L. PIVETTA[1], P. EASTER[1], P. ARNOLD[2], G. HANNA[3], D. R. ROSENBERG[1], V. A. DIWADKAR[1]
[1]Dept. of Psychiatry, Wayne State Univ. Sch. of Med., Detroit, MI; [2]Univ. of Calgary, Calgary, AB, Canada; [3]Univ. of Michigan Sch. of Med., Ann Arbor, MI

Abstract: Background
Obsessive compulsive disorder (OCD) is characterized by dysfunctional activation and brain network profiles (Diwadkar et al, 2015). How network profiles adapt to *changes* in cognitive load is not well understood, yet such dynamic adaptation is related to functional reserve in brain networks. We investigated *similarities* in network profiles *within* OCD and healthy controls (HC) as subjects transitioned between attention- and memorial-based processing. Processing was induced using a standard n-back paradigm with two levels (Attention: 0-Back and Memory: 1-Back). Network profiles were investigated using undirected functional connectivity (uFC) based on bivariate correlations (Silverstein et al, 2016).
Methods
Data were collected from 105 participants (40 OCD, 3T Siemens Verio). During the task, letters were projected in sequence and subjects signaled their response (to targets). fMRI data were processed using typical methods (SPM12). Ten co-activated peaks (**Ins**ula, **F**rontal **P**ole, **I**nferior **F**rontal **T**riangularis-1,2, **M**iddle **F**rontal **G**yrus-1,2, **S**upplementary **M**otor **A**rea, **I**nferior **f**rontal **O**percularis, **P**osterior **S**upramarginal **G**yrus and **I**nferior **P**arietal) were identified from conjunction analysis (HC ∩ OCD). Correlation coefficients from time series of the co-activated peaks were computed and normalized to the bivariate distribution curve (Fisher's Z). For each of the 45 sub-network pairs *Z* coefficients from each of the 0- and 1-Back conditions were submitted to second level correlational analyses *within* each group (OCD, HC). The resultant Pearson correlation coefficient (*r*) served as a metric of similarity between sub-network behavior in the 0- and 1-Back conditions. A higher *r* represents greater similarity and by inference, lower flexibility of network function across conditions. Corresponding *r*s (OCD vs HC) were compared for differences in significance (Wuensch, 2002).
Results
OCD evinced significantly *greater* correlations for the following network pairs, **SMA↔IFT**-1 ($p<0.05$), **SMA↔PSG** ($p<0.02$), **SMA↔IP** ($p<0.02$) and **MFG↔IP** ($p<0.02$). HC had significantly greater correlations for **IFT**-1↔**IP** ($p<0.05$).
Discussion
Our data imply that OCD subjects are characterized by a relative lack of dynamic flexibility during task switching on frontal-parietal (FPN) and frontal-motor sub-networks. This inflexibility may reflect a network-based representation of exaggerated mechanisms of frontal-cingulate control during basic processing (Diwadkar et al., 2015; Friedman et al., 2017). Successful task-switching depends on network *dynamics*; A focus on network inflexibility may enhance the search for OCD bio-markers.

Title: Working memory EEG power spectrum and academic achievement

Authors: *M. L. GARCIA-GOMAR, B. JIMÉNEZ-HIGUERA, A. J. NEGRETE-CORTÉS, P. FERNÁNDEZ-RUÍZ
Escuela de Ciencias de la Salud UABC, Tijuana, Mexico

Abstract: Working memory (WM) is defined as an important system for the maintenance of information during the execution of complex tasks. It has been described that WM is associated with information seeking knowledge. Alpha and Theta frequency bands are associated with WM. It has been described that in general students with high academic achievement have higher power in all frequency bands during WM tasks. Objective: To study the behavioral and electrophysiological differences associated with a working memory task between university students of high vs low academic achievement. Methods: 40 university students participate in the study. WM was assessed by a Sternberg verbal working memory task. We register brain electric activity while the students were responding the WM task. Results: The students included in the study were 29 women and 11 men, with an average of 18.8±0.89 years old. EEG Power spectrum was analyzed during three different conditions: Baseline, Attention and WM. We did not find significant differences in the behavioral performance in the WM task. However results indicate significant differences in EEG power spectrum between high vs low academic achievement groups. During almost all the conditions, low academic achievement group showed higher delta and theta absolute power. However, high achievement group show higher alpha absolute power during almost all the conditions. Regarding topography during working memory condition, low academic achievement group involved almost all brain regions while high academic achievement group involved only left frontal and posterior brain regions. Conclusions: There are EEG power spectrum differences that can underlie differences in academic achievement as it has previously been demonstrated. High academic achievement group show the brain activity associated with WM, higher alpha power over frontal and posterior regions. WM is a cognitive process that is very important in real life function as in the academic field.

Title: 5Hz repetitive transcranial magnetic stimulation to enhance working memory and neural factors underlying the rTMS induced behavioral plasticity in old and young adults

Authors: *L. BEYNEL[1], S. W. DAVIS[1], C. CROWELL[1], S. HILBIG[1], W. LIM[1], H. PALMER[1], A. BRITO[1], A. V. PETERCHEV[1], B. LUBER[2], S. H. LISANBY[2], R. E. CABEZA[1], L. G. APPELBAUM[1]

Abstract: Working memory (WM) is a critical cognitive function relying heavily on the prefrontal cortex (PFC), and widely affected with aging. In this study, we tested the capacity of repetitive transcranial magnetic stimulation (rTMS) to enhance WM in a group of young and elderly participants. To advance our knowledge of what neural factors underlie rTMS-induced behavioral plasticity, brain activations in the targeted PFC were tested. This study involved 6 days of participation. Participants were trained on a Delayed-Response Alphabetization Task in which an array containing 3 to 9 letters was presented, followed by a 5-second delay period during which subjects were asked to keep the stimulus in mind and reorganize the letters into alphabetical order. At the end of the delay, a probe letter with a number above it appeared on the screen. Participants were asked to report if the probe letter was in the original set and matched (Valid), or not (Invalid), the number when re-organized into alphabetical order, or if the letter was not in the original set (New). During the second visit, the same task was performed in the fMRI scanner and individualized statistical map predicting the parametric increase in BOLD activity associated with increasing set size was identified. On days 3 through 6, 25 pulses of 5Hz rTMS at resting motor threshold were delivered to the identified PFC target, on each trial, either with active or electrical sham rTMS. rTMS-induced accuracy changes were assessed, as well as correlations between those changes and the parametric PFC activations associated with increasing set sizes. Active rTMS significantly improved accuracy relative to sham only in the hardest condition (largest set size in Invalid trials). Besides, the magnitude of improvement with active rTMS showed an age-dependent pattern of correlation with the parametric PFC activation. For the young, subjects showing the lowest increase in PFC activation with difficulty increase are the ones benefitting the most from rTMS, while a positive but not significant correlation was found for the elderly. This study showed that online 5Hz-rTMS can enhance working memory abilities, but only in the most challenging condition. Interestingly, the magnitude of this rTMS-

induced improvement was found to express significantly different patterns for old adults and young adults, indicating that baseline fMRI activation in the PFC may play a mediating role in rTMS effects. These findings provide important implications towards the use of non-invasive neuromodulation to enhance cognitive function and provide specific prescriptive recommendations that may lead to optimal efficacy.

Title: Identifying Chronic Cognitive and Electrophysiological deficits in individuals with and without a history of Concussion

Authors: *A. TAPPER[1], E. NIECHWIEJ-SZWEDO[2], R. STAINES[2]
[2]Applied Hlth. Sci., [1]Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Current clinical tests for concussions have been ineffective at detecting chronic cognitive effects. In contrast, dual-task paradigms that stress cognitive resources appear to be helpful in identifying underlying cognitive deficits in individuals with a history of concussion who are symptom free. We hypothesize that persisting cognitive impairments (i.e., poorer performance) will be present in individuals with a history of concussion compared to those without when using a visual-auditory dual-task paradigm. The visual-auditory dual-task involved two tasks including, a visuospatial working memory task (i.e. computerized Corsi block Test) - subjects needed to encode and recall a sequence of blocks, and an auditory Go-NoGo task - subjects responded as quickly as possible to a target tone and withheld a response to a standard tone. Both tasks were performed individually and simultaneously. Eleven recreational athletes (6 reported a medically diagnosed concussion, 5 without) participated in the study. Three dual-task measures (Corsi cost, auditory cost and total cost) were used to compare single versus dual-task performance between groups. Additionally, event-related potentials (ERPs) were time-locked to the auditory task in both conditions (single, dual) to assess brain functioning. Two ERP measures (P50, N100) of early auditory gating were analyzed by comparing the amplitude of target tones to standard tones. Preliminary findings show that individuals with a history of concussion perform significantly worse on the Corsi cost ($p<.05$) and total cost ($p<.05$) measures compared to those without. No significant differences are shown in P50 or N100 gating mechanisms; however, there is a trend showing that the P50 gating ERP is smaller in individuals with a history

of concussion. Furthermore, a larger P50 difference between target and standard tones may be linked to the total cost measure. In conclusion, concussions may produce subtle long-term deficits in executive functions that can be detected using a dual-task paradigm and these deficits may be linked to early gating mechanisms.

Title: A scalp EEG signature of delay period activity in verbal working memory

Authors: *A. D. FRIEDMAN, P. K. BISARYA, V. MURALHIDARAN, A. R. ARON
UC San Diego, La Jolla, CA

Abstract: Research on working memory maintenance and distractibility has been hampered by difficulty in identifying sustained neural activity signatures during the delay period. Here we ran human participants in a scalp EEG experiment of verbal working memory. On each trial, participants encoded a sequence of verbally-presented phonemes, held them across a delay period, and then, when prompted, tried to say them in the correct order. We manipulated load so that, within each participant, there were four vs. two phonemes. As expected, accuracy was significantly lower for high vs. low load ($Z=1.9$, $p<0.05$). We analyzed the scalp EEG data using Generalized Eigenvector Decomposition. This looks for a subspace of weights which optimally separates signals from two conditions (here, high vs. low load, time-locked to the start of the delay period). In each participant a component was identified in the range of 10 to 15Hz. For this component there was a sustained power change (over 2 seconds of delay period) for high vs. low load. Importantly, in high load this was reduced when errors were made. Further analysis will test if and how this sustained signature relates to a left sensorimotor component for speech. Overall, the results show that a maintenance signature for verbal WM can be derived from scalp EEG.

Title: Spontaneous resolution of competing memories is impaired with age

Authors: *B. CORBETT[1], S. M. POLYN[2], M. R. DULAS[3], A. L. DUARTE[4]
[1]Psychology, Georgia Tech., Atlanta, GA; [2]Dept Psychol, Vanderbilt Univ., Nashville, TN; [3]Beckman Inst., Univ. of Illinois - Urbana-Champaign, Urbana, IL; [4]Georgia Inst. Technol., Atlanta, GA

Abstract: Proactive interference can impair our memory in daily tasks such as retrieving a recently updated email password or the updated dosage of a medication. Previous research has found that older adults are more susceptible to proactive interference, which may contribute to their episodic memory impairments. The current fMRI study investigated if age-related deficits in PFC-mediated cognitive control processes underlie age-related differences in the resolution of proactive interference in an associative memory task. Further, multivariate pattern analysis was applied to examine if competing memories (lures) were reliably reactivated during attempts to recover recent ones (targets) in both age groups and if the relative amount of target vs. lure reactivation differs as a function of mnemonic interference and age. Young and older adults were tasked with remembering which associate (face or scene) objects were paired with most recently during study, under conditions of high, low or no proactive interference. Following scanning, we tested participants' memory for varying levels of episodic detail about the pairings (i.e. face category vs. gender vs. specific face). Behavioral results show that as proactive interference increased, associative memory performance worsened similarly across groups. Across age, memory performance was worse for the specific target associate than the target category. Imaging results revealed that lures were reliably reactivated during attempts to retrieve the target. Importantly, stronger reactivation of the lure was associated with less accurate retrieval of the target. Additionally, imaging results suggest the ability to spontaneously resolve interference at encoding may be impaired in older adults. Collectively, these results shed light on the neural mechanisms behind overcoming interference in associative memory and how this differs with age.

Title: Cognitive and subjective side effect ratings following exposure to oxycodone in middle age and older adults with healthy and unhealthy alcohol consumption patterns

Authors: *M. CHERRIER[1], C. KRAY[2], X. TAO[3], J. LI[4], R. WANG[4], W. YEUNG[5], G. W. TERMAN[6], T. SIMPSON[5], A. SAXON[5], D. SHEN[7]
[1]Dept Psychiat & Behav Sci., Univ. Washington, Seattle, WA; [2]Neurobio., [3]Statistics; Psychology, [4]Psychology, [5]Psychiatry, [6]Anesthesiol. and Pain Med., [7]Pharmaceutics, Univ. of Washington, Seattle, WA

Abstract: Chronic unhealthy levels of alcohol use, may predispose adults to use illicit substances and/or modify their response to prescribed medications, such as pain medications. There is increasing recognition of an association between chronic pain conditions and heavy alcohol use. This relationship may also impact the associated side effects experienced by adults when taking a pain medication. We examined the cognitive and side effect response of middle age and older adults who met criteria for healthy and unhealthy alcohol drinking patterns after exposure to a single 10mg dose of oxycodone. We anticipated that regular unhealthy alcohol consumption would result in a different cognitive and side effect response of cognition and side effects.
Methods: Participants underwent an initial phone screen, followed by an in person screening visit that included informed consent. Eligible participants underwent a day long study, that included baseline administration of cognitive tests and side effect questions that were repeated at three intervals (90 minutes, 5 and 8 hours) following administration of 10mg of oxycodone. The cognitive test battery included measures of memory, working memory and a computerized test of sustained attention and working memory (digit symbol substitution test). Side effect assessment included an opioid adjective list.
Results: Ninety four adults completed the initial screening visit, and thirty six adults completed all study measures. Fourteen met criteria for NIAAA criteria for unhealthy alcohol consumption and 22 met criteria for healthy alcohol consumption. Participants in the middle age group had a mean age of 51 (11.2) years and older adults had a mean age of 72 (4.2) years. Between group (unhealthy vs healthy drinkers) comparison of performance on a computerized version of DSST revealed improvements in total score over all trials (baseline, and 90 minutes, 5 and 8 hrs post

dose) F(4, 32) = 25.8 p<.01 with the exception of the older, heavy alcohol consumption group which did not improve. Subjective rating of side effects was rated as more severe in the older unhealthy group compared to middle age and healthy.
Conclusion: These findings indicate that older adults, particularly those with unhealthy alcohol consumption behaviors, may experience more adverse cognitive impact from pain medication and may also subjectively rate the experience of the medication as more adverse compared to middle age participants. It is possible that alcohol consumption patterns may impact cognitive and subjective side effects of pain medications in older adults.

Title: Aging affects integration of multiple episodic details

Authors: *T. JAMES[1], M. N. RAJAH[2], A. L. DUARTE[3]
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Psychiatry, McGill Univ., Verdun, QC, Canada; [3]Georgia Inst. Technol., Atlanta, GA

Abstract: The anterior prefrontal cortex (aPFC) is believed to play a critical role in integrating the outputs of lower-order processes, such as evaluations of item or inter-item properties. While the high-order integration functions attributed to aPFC have been shown to support complex reasoning, the region's role in episodic memory is less well understood. Emerging data suggest high-order PFC functions may be particularly susceptible to the effects of age and may contribute to older adults' associative memory impairments. It is currently unknown how aging interferes with the aPFC operations necessary for integrating multiple relations for episodic encoding and retrieval. We investigated this issue in the current fMRI study. Young and older adults were presented with an occupation and an object and were asked to judge how likely the two were to interact, either in general or within the context of a given scene. When provided with a scene, participants needed to consider and integrate the distinct relations between the three items to reach a decision - a task dependent on aPFC functions. Multivariate behavioral partial least squares (B-PLS) was used to identify patterns of brain activity during associative encoding

that were associated with age and/or subsequent pair and context memory accuracy. The PLS analysis identified two significant effects. The first effect indicated that activity in the most anterior PFC areas supported both pair and context memory in young adults. The second effect showed a pattern of activity that was differentially correlated with pair and context memory in older adults: more posterior PFC areas supported context memory while bilateral precuneus supported memory for the pairs. These effects were further supported by the behavioral data. For young adults, pair and context memory were significantly correlated; older adults did not show this association and demonstrated poorer performance overall. Failure to recruit the most anterior aspects of the PFC could indicate older adults had difficulty engaging the necessary operations to encode the scene-occupation-object associations as an integrated whole.

Title: Aging is linked to a dissociation of future prospection from other autobiographical memory abilities

Authors: *C. FAN[1], H. ABDI[2], A. ESLAMI[3], B. LEVINE[1]
[1]Rotman Res. Institute, Baycrest, North York, ON, Canada; [2]Univ. of Texas at Dallas, Dallas, TX; [3]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: It is well known that autobiographical memory (AM), which involves retrieving information relevant to one's own life, is impacted with age. The Survey of Autobiographical Memory (SAM) is a validated self-report questionnaire that measures individual differences in four categories of AM—episodic, semantic, spatial, and future prospection—but the factor structure of the SAM has not been examined in different age groups. Here, we analyze data collected online from two samples to investigate whether the latent dimensional structure of AM abilities, as measured by the SAM, changes across the adult lifespan. All participants completed the SAM as part of a larger battery of online measures. Sample 1 comprised over 4000 subjects aged 18-85 who independently came across our laboratory's research on AM, and completed our online survey to learn more about their own memory. Sample 2 comprised over 1300 healthy older adults aged 50-93, recruited online through CARP (the Canadian Association for Retired Persons). We first examined the factor structure of the SAM in Sample 1 using PCA, and replicated previous research: Dimension 1 separated those with high from low self-reported

memory across all four memory categories, and Dimension 2 separated individuals with high versus low self-reported spatial memory relative to other memory types. However, when we repeated this analysis in Sample 2, comprised solely of older adults, we found that Dimension 2 separated individuals with high versus low future prospection—rather than spatial memory—from other memory types. To examine this age-related dissociation of future prospection from other AM abilities, we binned participants in Sample 1 based on age, ran a PCA on the SAM in each bin, and computed a matrix of RV coefficients between all age bins. The factor map of the age bins indicated that the dimensional structure of the SAM remained relatively constant from the ages of 18 to 60, after which the future component appeared to dissociate. A body of existing research has linked the processes underlying episodic AM to those supporting future prospection, but our results suggest that aging may be associated with subtle shifts in memory functioning such that with age, episodic recollection decouples from future prospection. These findings open the door for future work to examine whether this dissociation can be observed on behavioural and neural levels, and may ultimately be used to inform strategies for identifying individuals at risk for age-related cognitive decline.

Title: Memory benefits in older adults following real-world environmental enrichment training

Authors: *B. KOLARIK, S. RUTLEDGE, S. STARK, C. STARK
Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Memory deficits are common in healthy aging. However, in rodents, exposure to a stimulating environment (environmental enrichment) can alleviate some age-related memory deficits. Similarly, exposure to 3-D video games improves memory performance in young adults. We sought to test if environmental enrichment has the same effect on older adults using a real-world exploration task. Participants searched a local park for landmarks using a cell phone app which presented pictures of landmarks and instructed them to find that place in the park (8 landmarks/day for 20 days). We investigated whether exploration training would ameliorate mnemonic deficits as evidenced by improved performance on memory tests from pre- to post-training. We compared participant's performance on a series of neuropsychological tests as well as the Mnemonic Similarity Task, used to assess pattern separation ability. To assess

performance during the park intervention, we tracked the number of hints requested on the first and last day in each park as well as normalized excess path to each target. Participants requested fewer hints and took more efficient routes to the targets on the last day in each park than on the first day, indicating that they were learning information about the target locations during the intervention. On neuropsychological tests, participants showed no change in digit span, but did show a significant increase in RAVLT Total scores suggesting that our intervention is targeting episodic memory function. The Mnemonic Similarity Test can be used to assess both recognition memory and lure discrimination (pattern separation). Consistent with previous findings, recognition memory scores did not change, while lure discrimination showed significant improvement following the intervention. In addition, we will report on structural imaging evaluating any neural alterations following this intervention. These results suggest that a real-world behavioral intervention can help ameliorate memory deficits, specifically those related to pattern separation, associated with normal healthy aging.

Center, Stevens Inst. for Neuroimaging & Informatics, USC, Marina Del Rey, CA; [2]Dept. of Information Technology, Mayo Clin. and Fndn., Rochester, MN; [3]Dept. of Radiology, Mayo Clin. and Fndn., Rochester, MN; [4]Dept. of Radiology, Univ. of California San Francisco Sch. of Med., San Francisco, CA

Abstract: The Alzheimer's Disease (AD) Neuroimaging Initiative acquired diffusion-weighted MRI (dMRI) from a third of its participants during its second phase (ADNI2), at sites with 3T GE scanners, to evaluate the utility of white matter (WM) microstructure biomarkers of aging and AD. Recently, ADNI3 extended dMRI acquisitions to include GE, Siemens and Philips scanners, resulting in 7 protocols. ADNI3 protocols have smaller voxels and variable numbers of gradient directions compared to ADNI2. To better understand consistency of effects across

ADNI3 protocols, we assessed the ability of each protocol to detect associations with cognitive impairment. As ADNI3 data collection is ongoing, we analyzed all baseline dMRI and clinical data available as of March 2018 in the ADNI database (https://ida.loni.usc.edu/). We analyzed data from 278 (age=75.4±8.0 yrs; M/F=125:153) ADNI3 participants scanned with 5 dMRI protocols, and computed 5 dMRI indices in 24 WM ROIs - mean, radial, and axial diffusivity (MD/RD/AxD), and fractional anisotropy (FA) derived from the tensor model and from the Tensor Distribution Function (TDF). All ROI indices were tested for associations with 3 cognitive test scores (MMSE, ADAS, and CDR-sob) with multivariate linear regression, controlling for age, sex, and age*sex, with protocol and site nested as random variables. FDR was used to correct for multiple comparisons. In healthy controls (ADNI2: N=85; ADNI3: N=184), we used an ANCOVA and post-hoc pairwise tests to evaluate the stability of dMRI indices across protocols. Significant associations were detected between dMRI indices and cognitive scores throughout the WM. AxD (specifically in the Cingulum Hippocampal Bundle (CGH)) consistently showed the strongest effect sizes across cognitive tests; effects weakened with distance from the temporal lobes. As expected, protocols were significantly different, with the ADNI2 protocol differing the most, and FA measures the least consistent across protocols. Ultimately, robust clinical associations were consistently detected despite protocol differences.

Protocol-Total:	174	238	60	173	140	169	

Figure 1. a) In this analysis, we evaluated 5 of 7 ADNI3 protocols that had at least 10 subjects at the time of download. b) For each dMRI index, the number of ROIs (out of 24) significantly associated with each cognitive score reveals widespread associations throughout the WM. c) We plotted the effect size (d-Value) within protocols and across protocols for associations with AxD in the overall WM and CGH, which were consistently among the largest 10 effect sizes across all dMRI indices. d) AxD associations with CDR-sob visualized on the brain show the strongest effects in the CGH. Effects weakened with distance from the temporal lobes. e) For each ROI and dMRI index, an ANCOVA tested for significant differences between protocols. FA was the least stable dMRI index across protocols. f) For each protocol, we report the number of ROIs in which a significant difference was found in post hoc pairwise tests between protocols. ADNI2/GE46 is the most frequently different protocol across dMRI measures and ROIs. This may be due to the larger voxel size in ADNI2 (2.7x2.7x2.7 mm) as opposed to ADNI3 (2x2x2 mm).

Title: Generating cognitive reserve activities and the relationship with cognitive performance in healthy elderly

Authors: *C. GARCÍA-CAMACHO[1], T. VILLASEÑOR-CABRERA[1,2], M. JIMÉNEZ-MALDONADO[1,2], J. RUIZ-SANDOVAL[1,3], F. JAUREGUI[1]
[1]Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico; [2]Servicio de Neuropsicología, [3]Servicio de Neurología, Hosp. Civil de Guadalajara, Guadalajara, Mexico

Abstract: Cognitive reserve refers to a number of factors that protect the brain against damage or cognitive decline. This reserve accumulates through the life course. The activities that we do through life are not always the same and exhibit changes in nature and frequency. Identifying frequency and life stage in which protecting activities are made could help to establish healthy profiles that we may recommend to prevent dementia and other pathologies.
Aims: In this study, we retrospectively identified cognitive reserve generating activities that exhibit significant relationship with a better cognitive functioning in old age.
Methods: Descriptive, transversal and retrospective assessment. A sample of healthy subjects between 60 and 70 years old were included. People with a history of substance abuse, cognitive impairment, psychiatric disorders or moderate to severe brain injury were excluded. Cognitive functioning was assessed with the Montreal Cognitive Assessment (MoCA), Digit Span and Vocabulary subtests of the Wechsler Intelligence Scale for Adults (WAIS-IV). The cognitive reserve was achieved through the Rami Cuestionario de Reserva Cognitiva (CRC) and protective activities frequency was obtained through Escala de Reserva Cognitiva y Envejecimiento (ERC). The project submitted and approved by the ethics committee of the "Hospital Civil de Guadalajara Fray Antonio Alcalde" registration number 217/17.
Results: We found that 66.7% of our subjects were woman, with a mean age of 63.8 years old (SD=3.0), the mean of education was 12 years (DE= 5.3), related to the occupation the 42.4% were retired, 42.4% still work and 15.2% does not work. The range of cognitive reserve was calculated in four categories; 3.0% had a lower rank, 15.2% medium-low range, 48.5% medium-high range and 33.3% a higher rank. In the cognitive examination the mean score in MoCA test

was 25.1 (DE= 1.6), Digit Span 8.6 (SD= 2.1) and Vocabulary 10.0 (SD= 1.8). Pearson correlation showed an association between Digit span and the young-age activities (r= .355, p= 0.04) and middle-age activities (r= .432, p= 0.01) even do MoCA and late-life activities showed an association (r= .393, p=0.02).*Conclusion*: These results lead us to think that there is a strong associationamong the protective activities that take place during adulthood, which agrees with different authors reported.

Title: Identifying brain and cognitive deficits in older adults at-risk for diabetes

Authors: *J. A. FURLANO, L. S. NAGAMATSU
Western Univ., London, ON, Canada

Abstract: Globally, dementia affects approximately 47 million people, and is a major cause of disability among older adults. Type 2 diabetes (T2D) is a known risk factor for dementia; older adults with T2D have been shown to experience cerebral atrophy and cognitive decline. Consequently, older adults at-risk for developing T2D (based on body mass and blood glucose levels) are at higher risk for cognitive decline. Pre-diabetic older adults have been shown to experience some cognitive decline, however further research is needed to determine the specific cognitive domains affected and the degree to which this decline occurs. Moreover, structural and functional brain changes that may occur with these deficits is currently unknown in this population. Therefore, the aim of this study was to assess cognitive performance and brain health (using advanced neuroimaging) in older adults at-risk for diabetes. We conducted a cross-sectional analysis of older adults (aged 60-80) at-risk for diabetes (BMI > 25 or blood glucose of 6.1-7.0 mmol/L) and healthy aged-matched controls, examining 1) memory performance and executive functioning, using a battery of standardized neuropsychological tests, 2) functional brain activation, as measured by fMRI BOLD signal during an associative memory task, and 3) structural measures, such as volume of the hippocampus as well as other brain regions implicated in memory. Based on our cross-sectional analysis, older adults at-risk for diabetes show impaired associative memory performance and executive functioning, as well as altered brain structure and function that may contribute to the observed deficits. We conclude that older adults at-risk for diabetes experience cognitive decline and decreased brain health, and have implemented a 6-month resistance training intervention strategy to prevent and delay the onset of such decline.

Title: Reproductive aging shapes top-down, goal-directed modulation of visual processing

Authors: *L. A. PRITSCHET, E. G. JACOBS
Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: The neurophysiological changes that accompany age-related declines in working memory, selective attention and inhibitory control are well-established (Cabeza, Nyberg & Park, 2016). These studies generally target adults over the age of 65, but now more attention is being paid to neural and cognitive changes that unfold in the preceding decade, as adults enter midlife and women transition through menopause. The menopausal transition is marked by a decline in ovarian hormone production and is a time when many women report changes in memory and attention (e.g. “menopause fog”). Rodent and nonhuman primate studies have established the critical role sex hormones play in modulating prefrontal cortical function. Parallel evidence from human neuroimaging studies further implicates sex hormones in the regulation of memory/attention circuitry (Jacobs et al., 2018). In this study, we examine the impact of reproductive aging on top-down modulation of goal-directed behavior. Healthy midlife women and men (N=30; ages 45-60) performed a visual selective attention task during fMRI scanning. Menstrual cycle histories and serological assessments were used to determine women’s pre/peri/post-menopausal stage. The task paradigm presents face and scene stimuli. “Bottom-up” visual information is identical across conditions, only task goals differ. Subjects are instructed to selectively attend to relevant stimuli (e.g. Faces) and ignore irrelevant stimuli (e.g. Scenes) while completing a match-to-sample task. A dual attention condition requires subjects to attend to both stimulus classes. Neural activity during each ‘attend’ condition is compared to a control condition (image categorization). Superior frontal and parietal cortices are key components of top-down modulation and attentional control. Preliminary results reveal that menopausal status shapes task-evoked activity in the frontoparietal network, specifically intraparietal sulcus (IPS)/superior parietal lobule (SPL). In the dual attention “Both” condition when cognitive load is highest, postmenopausal women showed exaggerated IPS/SPL activity relative to premenopausal women, despite no significant difference in task performance. The IPS/SPL is a key node in the frontoparietal network underlying top-down control of visual processing.

Previous studies established the impact of chronological aging on top-down modulation (Gazzaley et al., 2005). Our preliminary findings suggest that neuroendocrine changes during the middle years of life ("reproductive aging") shape attentional control mechanisms by altering activity in the frontoparietal network and should be a factor in cognitive aging.

Title: BDNF polymorphisms are associated with local gyrification and default mode network integrity in healthy middle-aged adults

Authors: *J. K. BLUJUS[1], L. E. KORTHAUER[2], I. DRISCOLL[1]
[1]Psychology, [2]Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Brain-derived neurotrophic factor (*BDNF*) is a neurotrophin that promotes neuronal survival and differentiation and has been implicated in higher-order cognitive abilities such as learning and memory (Budni et al., 2015). *BDNF* is expressed throughout the brain but particularly in the prefrontal cortex and hippocampus (Peezawas et al., 2004), two regions important for learning and memory and vulnerable to Alzheimer's disease (AD). A Val to Met substitution at codon 66 in *BDNF* (rs6265) has been associated with impaired memory, compromised brain integrity, and increased risk of AD (Boots et al., 2017; Hajek et al., 2012), however, little work has been done to understand the relationship between a less common variant in *BDNF* (rs11030096) and brain integrity. The purpose of the current study was to characterize the relationship between polymorphisms in *BDNF* (rs6265, rs11030096), local gyrification index (LGI), and functional connectivity in the default mode network (DMN), measures of structural and functional brain integrity that are disrupted in AD. Our investigation focused on healthy, middle-aged adults to identify alterations in brain integrity that may occur years prior to the onset of cognitive impairment ascribed to pathological aging. Cognitively normal, middle-aged adults (age 40-60, N=150) underwent a multi-modal neuroimaging paradigm including T1-weighted structural imaging and resting-state functional MRI. Freesurfer v5.3.0 was used to analyze LGI and independent components analysis and general linear modeling were employed to identify and assess connectivity within the DMN. Results revealed that minor allele carriers (AA/AG) of *BDNF* (rs6265) exhibited lower LGI in the right superior frontal gyrus compared to homozygous major allele carriers (GG), however, no differences were evident in DMN

connectivity. The *BDNF* (rs11030096) analysis showed that minor allele carriers (CC/CT) exhibited lower LGI in the right posterior cingulate cortex, right superior parietal lobule, left paracentral gyrus and left fusiform gyrus compared to homozygous major allele carriers (TT). Additionally, minor allele carriers (CC/CT) had decreased DMN connectivity in the precuneus and superior temporal gyrus than homozygous major allele carriers (TT). These findings reveal a relationship between the *BDNF (*rs11030096, rs6265) polymorphisms, LGI, and DMN connectivity in frontal and temporal regions where BDNF is highly expressed and further demonstrates that changes in brain integrity in regions vulnerable to AD are evident in minor allele carriers as early as middle age, decades prior to the onset of cognitive decline.

Title: Age-dependent differences in cued peripheral visual perception and motor performance during dual-task natural walking

Authors: *J. PROTZAK[1], K. GRAMANN[2]
[1]Dept. of Psychology and Ergonomics, Junior Res. Group FANS, TU Berlin, Berlin, Germany; [2]Biol. Psychology and Neuroergonomics, TU Berlin, Inst. of Psychology and Ergonomics, Berlin, Germany

Abstract: With increasing age, a stable and secure gait may change from an automated task into an activity that requires increased concentration and executive control. Resources necessary to compensate for sensory and motoric declines are no longer available for parallel executed tasks like scanning the traffic environment. Thus, safety critical situations can emerge from insufficiently processed or unperceived environmental cues like approaching cars or obstacles. However, brain dynamics underlying efficient movements and performance in simultaneously executed tasks and their development throughout adulthood are not yet understood in detail. Using a Mobile Brain/Body Imaging (MoBI; Makeig et al., 2009; Gramann et al., 2011; 2014) approach, we established a set-up that enables the recording of brain dynamics underlying peripheral visual perception during natural locomotion. Furthermore, the potential of vibro-tactile warning cues to improve visual perception was evaluated as well as the impact of cues on gait and posture. Short visual targets were dynamically presented in the peripheral visual field of

the participant while standing or walking up and down a hallway of ten-meter length. In half of all test blocks, vibro-tactile cues were delivered to the upper arm preceding the target stimulus. Data recordings included button-press responses to visual targets, continuous EEG-recordings using a mobile 64-channel set-up, and motion capture data from a camera-based system. Data sets from 15 younger (<35 years, 9 female) and 17 older (>65years, 7 female) adults were analyzed. Dual-task effects on performance measures (response times, errors, misses), balance and gait parameter (walking speed, sway), amplitudes and latencies of the early (P1) and later (P300) stimulus-locked event-related potentials (ERP) served as dependent measures. Both groups responded faster to visual stimuli but showed more incorrect responses during walking. Warnings reduced response times, number of missed targets and errors but also led to decreased gait velocity. Older participants made generally more errors than younger but differences between age groups in number of missed targets while walking were eliminated through warnings. Modulations in P1 and P300 amplitudes and latencies indicate age-related as well as motor task-related differences in resource allocation processes. Moreover, directly comparing established EEG-setups (seated participants) with recordings of mobile participants in highly ecological valid settings reflect age-related impacts of motor activity on the processing of visual targets.

Title: BOLD hemodynamic response function changes significantly with healthy aging: A population-based study

Authors: *M. D. ZUPPICHINI[1], K. WEST[2], M. P. TURNER[4], D. SIVAKOLUNDU[5], D. ABDELKARIM[6], Y. ZHAO[3], J. SPENCE[4], B. P. RYPMA[7]
[1]Univ. of Texas At Dallas, Addison, TX; [2]Ctr. for BrainHealth, Univ. of Texas At Dallas, Dallas, TX; [3]Univ. of Texas At Dallas, Richardson, TX; [4]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX; [5]Dept. of Biol. Sci., Univ. of Texas at Dallas, Dallas, TX; [7]Behavioral & Brain Sci., [6]Univ. of Texas at Dallas, Richardson, TX

Abstract: Functional magnetic resonance imaging (fMRI) has been used to infer age-differences in neural activity from the hemodynamic response function (HRF) that characterizes the blood-

oxygen-level-dependent (BOLD) signal over time. The HRF results from complex interactions between neurons, glia, and vascular structures, comprising the neural-vascular coupling system. This system is finely-tuned in healthy individuals for efficient brain function. We hypothesize that age-related changes to any component of this system could alter relationships between HRF parameters and neural activity.
We analyzed a large dataset from the Cambridge Center for Aging and Neuroscience (CamCAN) study. 74 younger (18-30 years of age; 25.4±3.6, 33 males) and 173 older (54-74 years of age; 63.7±6.0, 100 males) adults viewed two checkerboards flanking a central fixation point (34ms) and simultaneously heard a 300ms binaural tone. HRFs were estimated using FMRIB's Linear Optimal Basis Sets (FLOBS) to minimize shape assumptions. We assessed age-differences in HRF parameters using one-way ANCOVAs in which each parameter was a dependent factor, age group was the independent factor, and ROI volume was a covariate. In a visual cortex ROI, there was decreased peak amplitude ($p<.001$), longer time to peak ($p=.003$), decreased trough amplitude ($p<.001$), longer time to trough ($p=.012$), and shallower rise ($p<.001$) and fall slopes ($p<.001$) in healthy older compared to younger adults. In an auditory cortex ROI, there were longer time to peak ($p<.001$), decreased trough amplitude ($p=.001$), longer time to trough ($p=.004$), and shallower rise ($p=.039$) and fall slopes ($p=.007$) in older compared to younger. There were no significant interactions for age and volume for any parameter.
Age-changes in the shape and timing of the HRF support the hypothesis of age-related changes in neural-vascular coupling. HRF age-differences arise from complex physiologic factors that complicate interpretation of BOLD as an index of age-related neural change. New imaging methods, like calibrated fMRI, permit direct assessment of age-differences in the physiologic factors underlying BOLD signal. More precise interpretations of HRF age-differences can be formulated once these physiologic factors are disentangled and measured separately.

Title: Decoding context memory representations during retrieval across the adult lifespan

Authors: *P. S. POWELL[1], J. STRUNK[1], T. JAMES[1], S. M. POLYN[2], A. L. DUARTE[1]
[1]Sch. of Psychology, Georgia Inst. of Technol., Atlanta, GA; [2]Dept Psychol, Vanderbilt Univ., Nashville, TN

Abstract: Age-related context memory declines are due, in part, to a tendency to bind too much irrelevant contextual information during encoding (hyper-binding). However, the degree to which older adults are able to engage in selective retrieval of relevant contextual information, while suppressing retrieval of irrelevant information, is unknown. In the current study, we used multivariate pattern analysis (MVPA) to explore the degree to which task relevant and irrelevant context memory representations are reactivated during retrieval and the impact of this reactivation on memory performance.
Participants were 51 adults between 18 and 80 years old.
During encoding, participants studied pictures of objects in the presence of two contextual features: a color and a scene, and their attention was directed to the object's relationship with one of those contexts (target context) and were told not to pay attention to the other context (distractor context). At retrieval, participants judged whether the context features were similar to, or different from, the context feature shown during encoding. EEG was recorded as participants made context memory decisions for both attended and unattended features.
During encoding, we used pattern classification analyses to assess whether classifier performance and evidence varied as a function of selective attention (i.e., target vs. distractor). During retrieval, we examined classifier evidence for target and distractor features to determine whether the strength of neural representations for the target and distractor context features related context memory performance and hyper-binding.
Results showed that classifier evidence was greater for target contexts relative to distractor contexts, however evidence for the distractor was greater in older adults compare to middle-aged and younger adults. Across all subjects, the strength of the distractor representation was related to a higher probability of correctly recognizing both the target and distractor as well as greater hyper-binding. Finally, the relationship between distractor classifier evidence and hyper-binding significantly varied across age with older showing a stronger relationship than middle aged and younger adults.
These results provide direct evidence that age-related episodic memory impairments are related to the spontaneous retrieval of distracting information that interferes with the ability to recover sought after episodic details. The lifespan approach in this study reveals a linear effect of age on this increased susceptibility to mnemonic interference.

Title: Music training as aneuro-cognitiveprotector for brain aging: Cognitive and neuropsychological profiles in professional musicians

Authors: *C. E. SCHNEIDER[1], Y. JIANG[3], J. WATKINS[2]
[1]Univ. of Kentucky, Villa Hills, KY; [2]Univ. of Kentucky, Lexington, KY; [3]Dept. of Behavioral Sci., Univ. of Kentucky Chandler Med. Ctr., Lexington, KY

Abstract: The proportion of older adults living with cognitive impairments is increasing rapidly. This shift will increase mortality rates, reduce perceived quality of life, and cause economic burden. Currently evidence of highly effective and noninvasive interventions that prevent or slow the onset of cognitive impairment are limited. Music playing has been shown to improve brain and cognitive functions by engaging networks of brain areas, simultaneously involving cortical mechanisms associated with executive, high-level cognitive and motor functions, and multiple sensory systems. Literature suggests strong correlations between cognition and music ability. Studies in the past have not concretely operationalized music training. Here we test the general hypothesis that music training improves neural mechanisms associated with core cognitive functions (e.g. working-memory and attention). This study was designed to control level of music involvement and genre by examining professional, classically trained orchestral musicians, establishing cognitive and neuropsychological profiles in an effort to better understand the potential for music training to protect older adults from cognitive decline. Twenty-nine professional musicians were recruited who completed five neuropsychological exams. The scalp electrophysiological signals from 14 channels were recorded wirelessly while musicians performed a modified delayed match-to-sample task, imagination of music playing, and resting states. Musicians completed neuropsychological screening (MoCA) and a music and life span questionnaire. Musicians tested above normative ranges in cognitive ability. Musicians' scores were compared with normative scores of participants at similar ages in previous studies using the same measures; current musicians performed significantly faster and more accurately on neuropsychological measures. Regression and ANCOVA showed strong positive correlations between theta oscillation in bilateral frontal sites (F3, F4) and both number of years of private music lessons and number of hours of music practice. Current new findings reveal that professional musician's cognitive scores and neural activity are associated with superior cognitive ability via enhancement of neural mechanisms of current target material and inhibition of distractions. Music training is a promising noninvasive method to control cognitive challenge, which merits further research to determine how it can be used as a beneficial cognitive training method for aging individuals.

Title: Age-related impairment of semantic integration into long-term memory is related to theta-alpha and low beta oscillations

Authors: *P. A. PACKARD[1], T. STEIGER[1], L. FUENTEMILLA[2], N. BUNZECK[1]
[1]Psychology Inst. 1 (IPSY 1), Univ. Of Luebeck,, Luebeck, Germany; [2]Univ. Barcelona, Barcelona, Spain

Abstract: Long-term memory encoding is impaired in healthy aging but the underlying mechanisms in humans remain unclear. Here, we tested whether this relates to failures in associating information with previous memories to build multi-item representations. To gain insight into age-related differences in such neural mechanisms during online encoding, we employed the temporal precision of electroencephalography to examine how semantic integration during encoding is affected by healthy aging. As expected, we found that congruent matches improved subsequent recognition memory in younger adults (i.e. congruency effect) but this effect was reduced in the elderly. At the neural level, congruence caused changes in neural activity within ~1500 ms after stimulus presentation, and there were widespread differences in ERPs and alpha-beta oscillations (8-30 Hz), which are known to support semantic processing. Importantly, these ERP differences predicted increases in memory performance, especially for congruent items. Finally, age-related differences in memory were accompanied by an early positive ERP and a later decrease in theta-alpha and low beta power (5-13 Hz), during encoding, which were greater in the younger group. Our findings provide evidence that age-related memory impairments can be explained by deficits in online semantic integration, depending on theta-alpha and low beta oscillations.

Title: Age-related decreases in the retrieval practice effect directly relate to changes in alpha-beta oscillations

Authors: *C.-N. GURAN[1], N. A. HERWEG[2], N. BUNZECK[1]
[1]Inst. of Psychology I, Univ. zu Lübeck, Luebeck, Germany; [2]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: The retrieval (or testing) of information leads to better memory performance as compared to re-encoding. This phenomenon is known as 'testing effect' or 'retrieval practice effect' and has been described in several studies using various stimulus material. The underlying neural mechanisms, however, remain unclear. To address this issue, we used a previously established paradigm in healthy young (N = 27) and elderly (N = 28) participants while their brain activity was being recorded using electroencephalography (EEG). Subjects viewed pre-familiarized scene images intermixed with new scenes and classified them as indoor vs outdoor (encoding task) or old vs new (retrieval task). Subsequently, subjects performed a final recognition memory task. As expected, both young and elderly showed the testing effect but it was less pronounced in the elderly. At the neural level, the retrieval task was, as compared to the encoding task, accompanied by power decreases in the alpha (9-13 Hz) and beta bands (13-20 Hz), and this difference was more pronounced in the elderly. In line with this observation, those elderly who displayed a more pronounced testing effect exhibited a neural pattern that was more similar to the younger subjects. Our findings provide further evidence that the testing effect decreases across the life span, and they suggest that changes in alpha-beta oscillations play a direct role.

Abstract: Aging is a multi-etiological and degenerative process that is characterized by progressive deterioration in cognitive, physiological and metabolic processes; these changes are related to numerous age-related disorders. Cellular alterations during aging process involve oxidative stress, inflammation, mitochondrial and metabolic dysfunction, cognitive and immune response decline. Recently, it was found that changes in the tryptophan metabolites proportion during aging in women. Tryptophan (Trp) is essential for synthesis of proteins and is mostly metabolized by kynurenine pathway (KP), conducing to several metabolites with neuroactive and redox properties. Specifically, kynurenic acid (KYNA), -an endogenous antagonist of α7nACh and NMDA receptors- and quinolinic acid (QUIN), an agonist of NMDA receptors, have been related with neurodegenerative diseases. Due to KP metabolites have been related with aging and some ageing-related diseases, we investigated whether the metabolites of kynurenine pathway could be related with cognitive decline in old men. The age range of participants was 19 to 93 years old. A brief neuropsychological standardized tests series (NEUROPSI), was performed in patient over 50 years old. The NEUROPSI tests serie includes assessment of orientation, attention, memory, language, visuoperceptual abilities, motor skills, and executive functions. Serum levels of Trp, kynurenine, KYNA and 3-HK were determined in eighty old men. Results showed a negative correlation between age and Trp levels and a positive correlation between age and KYNA/Trp and 3-HK/Trp ratios. The cognitive impairment showed a significant positive association with age and with KP activation and a significant negative correlation with Trp levels. This results suggest that KP activation increases with age and it is strongly associated with the level of cognitive performance in non-demented elderly men.

Title: The positive effects of a 4-week cognitive training are not modulated by contextual novelty

Authors: *D. BIEL, T. STEIGER, T. VOLKMANN, N. JOCHEMS, N. BUNZECK
Univ. of Luebeck, Luebeck, Germany

Abstract: Introduction: An optimal cognitive training not only improves specific skills but also transfers to other cognitive domains. Although a few studies have reported such 'transfer effects', the underlying mechanisms remain unclear. **Objectives**: Here, we tested the hypothesis that contextual novelty, which is known to drive plasticity, learning and memory, may enhance the transfer effects of a 4-week cognitive training. Moreover, we aimed to investigate the underlying neural mechanisms with a focus on iron, myelination, grey matter volume and white matter tracts. **Materials & methods**: 50 healthy elderly subjects (50-80 years) participated in a 4-week training including 12 training sessions of a 2-back working memory task on a tablet computer at home. During the trainings, one group watched short sequences of novel nature movies (novelty group, n=25), while a second group performed the same training intermixed with five repeating movie sequences (familiarity group, n=25). Neuropsychological assessment of various cognitive abilities as well as structural MRI (including R2*, T1, MT) and DTI was conducted before and after the training period. **Results**: All participants showed increased accuracy and faster response times in the 2-back task over time. Moreover, performance in fluid intelligence (LPS 50+), processing speed (D2 and complex trail making) and verbal and numeric memory (VLMT and digit span backwards) significantly improved within both groups. However, the training did not lead to significant changes in a digit span forward test, simple trail making and crystalline intelligence (MWT). Finally, there were no significant differences between the novelty and familiarity group in any of the acquired neuropsychological tests. At the neural level, in both experimental groups the training led to weak changes in grey matter volume within the left insula and medial temporal lobe as revealed by VBM. **Conclusion**: Our results demonstrate that a 4-week working memory training not only improves working memory skills but also leads to transfer effects within the domains of fluid intelligence, processing speed as well as verbal and numeric memory. However, at the behavioral level, contextual novelty did not further modulate the observed transfer effects.

Title: Characterizing age-related changes in brain connectivity using sparse graphs

Authors: *S. HRYBOUSKI[1], I. CRIBBEN[4], J. MCGONIGLE[5], R. CARTER[2], F. OLSEN[3], P. SERES[3], N. V. MALYKHIN[3]
[2]Dept. of Psychiatry, [3]Biomed. Engin., [1]Univ. of Alberta, Edmonton, AB, Canada; [4]Finance and Statistical Analysis, Alberta Sch. of Business, Edmonton, AB, Canada; [5]Ctr. for Neuropsychopharm., Imperial Col. London, London, United Kingdom

Abstract: Introduction: The predominant theory of brain aging suggests that the association cortices are most affected by the aging process, while primary sensory and motor systems of the brain are moderately preserved in healthy older individuals. In the present study, we applied graphical models to resting-state functional Magnetic Resonance Imaging (fMRI) data to investigate whether connectivity profiles of the association cortices are most vulnerable to healthy aging.
Methods: A total of 105 healthy volunteers (18-85 years old) were recruited for the study. Participants were excluded if they had an unstable medical illness, history of psychiatric or neurological disorders and the use of medications that might affect brain structure or function. fMRI images were collected on a 4.7T scanner using T2*-sensitive EPI sequence [TR = 3 s; TE = 19 ms; flip angle = 90°; voxel size = 3×3×3 mm^3]. SPM, FSL, ANTS, and GIFT software packages were used for image preprocessing and network decomposition. In total, 22 independent components (ICs), representing brain networks, were identified. These ICs were grouped into visual, somatomotor, auditory, attentional, executive, and default systems. Sparse graphs for young (18-39 years), middle (40-59 years), and old (60-85 years) age groups were estimated from network time courses using the SCAD estimating method with the cross-validation selection method. From the resulting graphs, we computed graph summary metrics such as edge density, graph diameter, and measures of centrality.
Results: For intra-system connectivity, we observed: (1) no age-related differences in edge density, diameter, and centralization in any of the networks; (2) age-related reduction of node closeness and node betweenness in the default system; and (3) age-related reduction in centrality for the motor and visual systems. All other age effects were identified in the between-system connectivity, where all systems, except for auditory, default, and executive displayed greater between-system edge density in older adults. Furthermore, we observed age-related increases in

between-system centrality for the motor, visual, and attentional systems. Most of these differences were statistically significant only when comparing young and old cohorts directly. **Conclusion:** Age-related differences in between-system connectivity were most pronounced in the somatomotor and visual networks, while the default system showed a reduction in node closeness and node betweenness in intra-system connectivity. Together, these results characterize substantial age-related changes in brain organization at the systems level, extending beyond the association cortices.

Title: The relationships between regional cortical thickness, intra-scan motion and associative recognition memory performance as a function of age

Authors: *M. A. DE CHASTELAINE, B. E. DONLEY, K. KENNEDY, M. D. RUGG
The Ctr. for Vital Longevity and Behavioral and Brain Sci., Univ. of Texas At Dallas, Dallas, TX

Abstract: We previously described the relationships between age, head motion (during functional scanning), mean cortical thickness and associative recognition performance in groups of young (18-30 yrs), middle-aged (45-55 yrs) and older (63-77 yrs) adults, totaling 133 individuals. To expand upon these relationships, here we utilized the same sample to conduct whole-brain analyses to determine which, if any, of these relationships might be regionally selective. Using Freesurfer's (v.5.3) semi-automated analysis pipeline, we obtained vertex-wise thickness estimates along the cortical surface to examine regional variations in the outcome of two main regression analyses. The first analysis, using an initial vertex-wise uncorrected threshold of $p < .001$ (10mm FWHM smoothing kernel), evidenced a linear relationship between thickness and memory performance, after correcting for motion, across large areas of the cortical surface in both the young and older groups. Consistent with our previous analyses using mean thickness measures, this relationship was found to be negative in the young but positive in the older sample. After applying a cluster-wise correction using the Monte Carlo simulation, however, these relationships appeared to be particularly robust in the parahippocampal cortex and posterior cingulate, indicating some level of regional specificity. In a second regression

analysis, we observed a weakening in what we had previously observed to be a strong negative relationship between age and cortical thickness, when including motion as a covariate of interest, particularly in lateral frontal cortical regions. Consistent with this observation, the relationship between the amount of head motion and cortical thickness, after controlling for age, was also most apparent in lateral prefrontal regions. These findings highlight the value of taking into account intra-scan head motion when investigating age-related differences in regional cortical thickness and cognitive performance. This research was funded by NIA Grants R01AG039103, RF1AG039103.

Title: Longitudinal frontostriatal functional connectivity and gray matter changes related to motor and cognitive symptoms in early-stage Parkinson's disease

Authors: *S. KANN[1], C. CHANG[2], R. WALES[1], H.-C. LEUNG[1]
[1]Psychology, Stony Brook Univ., Stony Brook, NY; [2]Stony Brook Univ. Sch. of Med., Stony Brook, NY

Abstract: Motor and cognitive symptoms are heterogeneous in both severity and progression across individuals with Parkinson's Disease (PD). However, the neural substrates underlying these differences in functional decline across time remain largely unknown. Several studies have demonstrated that PD patients with more severe akinetic/rigid (AR) motor symptoms also display greater impairment on executive function (EF) tasks, while severity in both domains is implicated in faster decline. The current study therefore examined longitudinal changes in gray matter volume and functional connectivity in relation to more severe EF and AR symptoms utilizing the Parkinson's Progressive Marker Initiative (PPMI) (http://www.ppmi-info.org) database. We conducted resting state functional connectivity (rsFC) analyses in early stage PD patients in order to examine frontostriatal circuits. These analyses were conducted at two timepoints a year apart (N=51, 56), and controlled for age, gender, medication status and scanner location. At both timepoints, better EF was associated with greater rsFC between striatum and dorsomedial and dorsolateral prefrontal cortex (dmPFC, dlPFC) across subjects, while at the first timepoint milder AR was associated with stronger connectivity between striatum and ventromedial PFC (vmPFC) across individuals. Additionally, we examined the rate of change in gray matter volume in 86 PD subjects across 4 timepoints (baseline to 48 months) controlling for

age at baseline, total intracranial volume, and gender. Baseline AR symptom severity predicted a greater rate of gray matter atrophy within the motor cortex, while similar effects were not found for tremor symptoms, general cognitive scores, or EF measures. These findings suggest distinct patterns of fronto-striatal functional connectivity, as well as rates of atrophy within frontal cortex, related to motor and cognitive symptom variability within PD.

Title: Enhanced associative memory and mid-cingulate activity during memory retrieval in 'superagers'

Authors: *J. M. ANDREANO[1], A. TOUROUTOGLOU[1], H. POPAL[1], B. C. DICKERSON[1], L. F. BARRETT[2]
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Dept. of Psychology, Northeastern Univ., Boston, MA

Abstract: Aging is frequently accompanied by cognitive decline, including loss of memory abilities. However, recent studies have identified a remarkable group of elderly people, known as 'superagers', who maintain cognitive abilities equivalent to middle aged and even young people on some measures (Sun et al., 2016; Harrison et al., 2012). 'Superaging' has been associated with preserved cortical thickness (Sun et al., 2016) and functional connectivity (Zhang et al., 2018) in multiple regions, notably the mid-cingulate cortex, a functional 'hub' region. However, no study to date has compared task-related activity between superagers and typical elderly adults during a cognitive task. In this study, 17 elderly adults classified as superagers, and 39 typical older adults performed a paired-associate recognition memory task during fMRI. Behavioral performance and retrieval activity were compared between the two groups. As predicted, the results indicated superior paired associate memory performance in superagers ($p < .05$), suggesting that previously observed advantages in verbal recall extend to associative recognition. Additionally, region of interest analysis indicated a significant difference in activity associated with successful retrieval between superagers and typical older adults, with a substantially greater signal difference between hits and correct rejections in superagers in a cluster of mid-cingulate cortex closely matching the area of preserved cortical thickness observed in previous studies ($p < .05$). Across all subjects, hit vs. correct rejection signal in this cluster predicted recognition memory performance, suggesting that the preserved structure and function of this region

contribute to superior cognitive abilities in superaging. Implications for successful aging are discussed.

Title: Age-related declines in neural-vascular coupling: Regional variability, effects of task demand, and relationship to cognitive performance

Authors: *B. P. RYPMA[1], M. P. TURNER[1], K. WEST[1], D. SIVAKOLUNDU[2], Y. ZHAO[1], D. ABDELKARIM[1], B. P. THOMAS[3], H. LU[4]

Abstract: Blood-oxygen-level-dependent signal (BOLD) as measured with functional magnetic resonance imaging (fMRI) arises principally from two physiologic factors underlying BOLD: cerebral blood flow (CBF), which quantifies the rate of oxygen delivery to metabolically active neural tissue as measured by cerebral metabolic rate of oxygen ($CMRO_2$). The coupling of these two factors ($CBF/CMRO_2$) reflects the integrity of the neural-vascular coupling system that underlies efficient cognitive function. Sixteen healthy younger (mean age = 23.6, SD = 3.4, 10 F) and eighteen healthy older (mean age = 58.9, SD = 4.6, 11 F) right-handed adults that had been screened for any potential cardiological, respiratory, pulmonary, or vascular conditions performed block-designed visual and motor tasks while undergoing calibrated fMRI scanning. During the visual task, participants responded via bilateral button-press whenever a fixation cross at center-screen changed in luminance. During stimulation blocks, flickering checkerboards were presented at varying frequencies (2 Hz, 4 Hz, and 8 Hz). During stimulation blocks of the motor task, participants pressed buttons bilaterally in rhythm with an auditory cue (1 Hz, 2 Hz, and 3 Hz). To estimate maximum possible BOLD, participants completed a hypercapnia challenge, in which they breathed room air for 4 minutes and then an isometabolic gas containing 5% CO_2 21% O_2, and 74% N_2 for 6 minutes while being scanned at rest. During all functional scans, BOLD and CBF were collected in separate echoes using a novel pCASL-based pulse sequence (parameters TE1/TE2=11/30 ms, TR = 4 s, 22 6-mm axial slices, no gap, in-plane

resolution = 3.4 × 3.4 mm²). In visual cortex, during visual stimulation, younger adults exhibited monotonic increases in BOLD, CBF, and CBF/$CMRO_2$ with increasing task demand. BOLD, CBF, and CBF/$CMRO_2$ for older adults plateaued as task demand increased. In motor cortex, CBF/$CMRO_2$ increased for younger but remained low for older adults. In both regions, CBF/$CMRO_2$ was lower in older than in younger adults. The lower CBF/$CMRO_2$ ratio observed in older adults supports the hypothesis that age-related changes to the neural-vascular coupling system underlie age-related declines in cognitive efficiency.

Title: Age-related decline in arterio-venous compliance and relationships to cognitive performance

Authors: *D. H. ABDELKARIM[1], M. P. TURNER[1], D. SIVAKOLUNDU[2], Y. ZHAO[1], K. WEST[1], B. P. THOMAS[3], H. LU[4], B. P. RYPMA[1]

Abstract: The neural mechanisms of age-related cognitive decline remain unknown. We hypothesize that this decline is related to compromised integrity of the neural-vascular coupling system that mediates local blood flow increases in response to increased neural activity. This system involves well-coordinated signaling between neurons, glia, and cerebral vasculature, and is known to be compromised in older adults. One way to characterize cerebrovascular decline is through measurement of cerebrovascular reactivity (CVR) of veins (CVR_V) and arteries (CVR_A). CVR describes the compliance of blood vessels in the brain in response to vasoactive stimuli. We predicted that in young, healthy brains, arterio-venous compliance (AVC), the degree to which arterial compliance changes precipitate proportional increases in arterial compliance following stimulation, will be high. In older brains, we also predicted this synchronization will be lost, and that this loss will be related to cognitive decline in aging.In this study, dual-echo functional magnetic resonance imaging (fMRI) was used to obtain blood-oxygen level dependent signal (BOLD), a measure of venous oxygenation, and cerebral blood flow (CBF), a measure of

arterial flow rate, near-simultaneously. Younger (ages 18-34) and older (ages 55-70) adult participants were scanned while they breathed room air (normocapnia) for four minutes followed by six minutes of inhalation of 5% CO2 solution (hypercapnia) to induce cerebral vessel dilation. After scanning, participants completed cognitive assessments, including the Digit-Symbol Substitution Task and Box Completion task. CVR was assessed by comparing signal change between normocapnia and hypercapnia and calculating the amount of dilation per unit of CO_2 blood concentration increase. CVR_A was calculated using whole-brain CBF signal, that measures arterial flow rate, and CVR_V was calculated using whole-brain BOLD, a measure of venous oxygenation. AVC was calculated as CVR_A/CVR_V. We found that AVC was higher in younger than in older participants, suggesting lower venous compliance in response to arterial dilation in older adults. CVR was also related to performance on cognitive tasks in young adults but not in older adults.The strong relationship between CVR_V and CVR_A in young adults indicates that arterial and venous blood flow vary together in the intact system. The loss of this relationship in older adults is probably due to age-related vascular pathology. The age-related decline in CVR-performance relationships supports the hypothesis that compromised neural-vascular coupling underlies age-related cognitive decline.

Title: Cortical thickness as a predictor of memory success across the lifespan and in the 90+

Authors: E. DOMINGUEZ, M. CORRADO, C. KAWAS, S. STARK, *C. E. STARK
Univ. of California Irvine, Irvine, CA

Abstract: Previous research has found a specialized group of individuals 80 and above, also known as SuperAgers, that exhibit superior episodic memory performance comparable to the performance of their much younger counterparts. Previous reports have shown that specific regions of the cerebral cortex are significantly thicker in SuperAgers when compared to both younger and similarly aged groups (Rogalski et al., 2012, Sun et al. 2016). In the present study, we aimed to examine the relationship between cortical thickness and memory performance across the lifespan using two existing cohorts. In one, a cohort of 20-89 year-olds, RAVLT scores were used to define SuperAgers as individuals aged 70-89 that scored within the range of

younger adults on the RAVLT delay (≥10) and within one standard deviation of normal scores on Trails B. In all participants, RAVLT was used to examine its overall relationship with cortical thickness. Our second cohort consisted of individuals aged 90 and above (provided by the 90+ Study), where SuperAgers were defined by scores greater than or equal to the mean of younger adults on the CVLT delayed recall (≥8 on short-form) and performance within 1 standard deviation of the age-based norms on Trails B. Using T1-weighted structural MRI images, cortical thickness was calculated using both ANTS and FreeSurfer pipelines and segmented according to the standard DKT atlas to examine previously implicated cortical regions. In our 70-89 SuperAger dataset, we saw no differences in cortical thickness between normal and SuperAgers in these regions, despite a correlation in the entire 20-89 year old cohort between RAVLT and anterior cingulate thickness. However, in the 90+ cohort, we found greater cortical thickness in 90+ SuperAgers in the posterior cingulate and entorhinal cortex when compared to the normal agers. These data contribute to a growing literature addressing the factors that underlie superior memory and cognitive performance in the elderly, which will be informative for further understanding and defining resilience and brain maintenance later in life.

Abstract: Life expectancy has increased substantially in recent decades. Thus diseases related to older people (aged 65 years or older) have become a serious public health problem worldwide. Specifically the non-communicable diseases such as: cardiovascular disease, diabetes mellitus (DM), cancer and dementia are the most affecting for this group. In addition, DM is associated with a faster rate of cognitive decline in those with mild cognitive impairment (MCI) and is considered a risk factor for developing Alzheimer disease (AD). The term DM describes a metabolic disorder of multiple etiologies characterized by chronic hyperglycemia with

disturbances in carbohydrate, fat and protein metabolism, resulting from defects in insulin secretion, insulin action, or both. MCI has been used to describe an isolated memory deficit in older adults in the context of otherwise normal cognitive functioning and can be the first step in the progression to AD or cognitive functional impairment. Approximately 90% of patients with diabetes have type 2 diabetes and Metformin is a first-line treatment, which increasing glucose uptake in muscle while reducing liver gluconeogenesis. The current study examined the association between the use of Metformin and the risk of developing MCI. Clinical case: We report a 78-year-old male patient that according with the Yesavage scale has depression. Their Pharmacological treatment includes: Metformin/glibenclamide, Sennosides, pentoxifylline and omeprazole. Within the analysis, mild cognitive impairment was detected (score = 19) according to the Montreal cognitive assessment (MoCA) test. Our observation agrees with previously reported for patients who are taking metformin and developed cognitive impairment.

Title: Can a deep learning neural network improve ability of the MOCA (Montreal cognitive assessment) score to predict amyloid pet positives? Sensitivity and specificity analyses from a memory clinic

Authors: *A. K. NAIR[1], S. P. NAIR[2]
[1]Alzheimer Dis. Ctr., Kottayam, India; [2]WHS, Winchester, MA

Abstract: Background: Deep learning techniques could improve sensitivity and specificity of Montreal cognitive assessment (MOCA) score to predict amyloid positive scans to make it more clinically meaningful.
Objectives: To use a deep learning neural network model to analyze sensitivity and specificity of MOCA scores for predicting positive amyloid PET scans.
Methods: Memory clinic patients from July 2010 to Dec 2017 with available MOCA score and binary amyloid-PET result were analyzed retrospectively. Univariate and multivariate analyses of age, race, gender and education with MOCA score and amyloid-PET status was performed. Sensitivity and specificity of MOCA score to predict amyloid positivity was calculated. Receiver Operating Conditions (ROC) analysis measured area under the curve (AUC) and selected the ideal cut point. A neural network model was tested to improve item level sensitivity and specificity.

Results: From July 2010 to Dec 2017, 99 patients had available MOCA scores and Amyloid-PET imaging. Mean±SD of age, education, MOCA score of subjects were 71.31±9 years, 13.33±2.52 years and 20.09±4.84 respectively. 49 females (49.5%), 93 Caucasians (94%) and 56 amyloid-PET positive (56.57%) patients were included. Lower MOCA scores significantly correlated to amyloid positivity in univariate ($\chi 2=6.39$, df=1, $p<0.05$) and multivariate logistic regression analyses after adjusting for age, gender, education, and race (OR= 0.89, 95% CI= 0.80-0.99, $p<0.05$). The established clinical cut point of MOCA<26, had 98.2% sensitivity and 9.3% specificity for predicting Amyloid-PET positivity. AUC was 0.65 (95% CI 0.54 - 0.76). Prior to applying the neural network algorithm, the ideal MOCA cut point score was 20, with 67% sensitivity and 64% specificity. A Neural network model was trained to identify items and improve accuracy for clinically meaningful use.
Conclusions: A real-world use of a neural network algorithm improved clinical utility of MOCA score to predict amyloid positives. The commonly used clinical cut point for diagnosis was not adequately specific for amyloid positivity. Additional studies are needed to detect the pre-clinical stage of dementia.

Abstract: Alzheimer's disease (AD) is an irreversible neurodegenerative disorder that faces the central nervous system and that mainly goes through three stages. Diagnosing the disease in its early stage is the main obstacle in front of the researchers due to number of factors. These factors

include mainly the variability of the disease effect among the patients. Among the diagnosing tests, brain biomarkers show effective role in this context. This paper utilizes structure Magnetic Resonance Imaging (sMRI) to mainly present a local computer-aided diagnosis (CAD) system for serving the personalized diagnosis of AD and monitoring the progression of the disease. A dataset of 146 sMRI scans, 60 normal controls (NC), and 86 mild cognitive impairment (MCI), obtained from Alzheimer's Disease Neuroimaging Initiative (ADNI) database, are used to evaluate the proposed system that goes into five steps: (1) Preprocessing to standardize the scans to the labeling atlas's space, and to extract the brain's cortex to serve the following analysis, (2) Feature extraction through: (I) cortex re-construction using marching cube algorithm, (II) shape features extraction (i.e., mean and Gaussian curvatures, sharpness, curvedness, and volume), (3) Brain labeling using automatic anatomical labeling (AAL) atlas to serve the local diagnosis goal, (4) Feature fusion using canonical correlation analysis (CCA) based technique to produce more informative features, and (5) Two diagnosis levels: (I) local diagnosis, using probabilistic support vector machine (pSVM) to visualize the disease's severity in each of the cortical regions, and (2) a global diagnosis, using standard SVM, to present a final diagnosis of the subject. System's performance evaluation is performed from three perspectives: (a) the evaluation of different SVM-based kernels, (b) the comparison with state-of-the-art classifiers, and (c) the validation of the results with related work. First, testing SVM-based kernels (i.e., radial basis function, linear, and polynomial) shows superior results of the linear with 86.3%, 88.33%, and 84.88% of the accuracy, specificity, and sensitivity, respectively. Second, the comparison with a number of the state-of-the-art classifiers shows higher results of our system where the accuracies of the tested classifiers are 71.91%, 75.34%, and 60.95% for decision tree, ensemble classifier, and k-nearest neighbor, respectively. Finally, the system's validation with the related work shows promising results in the differentiation task between NC and MCI groups.

Title: Human motion discrimination, confidence in it, and metacognitive sensitivity decrease with age, while selective visual attention effects on these visual perception performance measures do not

Authors: *L. ZIZLSPERGER[1], H. EITLER-KLENK[2], T. HAARMEIER[3]
[1]Div. of Vascular Neurol. and Neurorehabilitation, Univ. Hosp. and Univ. of Zuerich, Cham,

Switzerland; [2]Cognitive Neurology, Tübingen Univ., Tübingen, Germany; [3]RWTH Aachen Univ., Aachen, Germany

Abstract: Visual perception has been described as a process of probabilistic inference featuring metacognitive evaluations of choice confidence, the degree to which one believes that a choice is likely to be correct. Here we examine the influence of selective visual attention on human perceptual sensitivity, the subjects' confidence in it, and metacognitive sensitivity across the lifespan. 50 healthy subjects between 20 and 69 years of age performed a precue-postcue paradigm discriminating between four directions of global motion in one of two random dot kinematograms (RDK) simultaneously presented in each hemifield. A central arrow correctly indicated which of two RDKs to attend in 80% of the trials. Motion coherence levels were varied in a 4-alternative forced-choice design and subjects indicated the confidence in their decision via post-decision wagering. To quantify how precise subjects assessed their objective performance we examined their metacognitive sensitivity via a non-parametric signal detection theoretic approach. We show that objective visual motion discrimination performance and subjective confidence in the perceptual decision significantly decrease with age (perceptual sensitivity: $p = 0{,}006$; $F(4,43) = 4{,}195$ and confidence: $p = 0{,}024$; $F(4,43) = 3{,}128$). Metacognitive sensitivity was observed to decrease with age, as well ($p = 0{,}001$; $F(4,43) = 5{,}674$). Analyzing valid and invalid cueing conditions, we found significant increases in perceptual sensitivity, choice confidence and metacognitive sensitivity for attended targets, showing effects of visual spatial attention on objective and subjective performance measures. Covertly shifting attention to a target in the visual field significantly improved these three performance measures. But it was only for metacognitive sensitivity that we observed improvements with attention to differ between the age groups ($p = 0{,}030$; $F(4,43) = 2{,}963$), with the biggest increase in the oldest group (60 to 69yo). Based on these findings we conclude: (i) Visual motion discrimination performance, the confidence in this perceptual decision and metacognitive sensitivity decline with age. (ii) Improvements in cognitive and metacognitive performance due to selective attention, in contrast, do not abate with natural aging. (iii) This points to a compensatory effect of this top-down contextual neural modulation on objective and subjective measures of human visual perception that appears to be particularly essential for maintaining metacognitive sensitivity in advanced age.

Title: Age-differences in canonicality of the hemodynamic response function and relationships to cognitive performance: A population-based study

Authors: *V. PRABHAKARAN[1], M. P. TURNER[2], K. WEST[3], M. D. ZUPPICHINI[7], D. SIVAKOLUNDU[4], Y. ZHAO[5], D. H. ABDELKARIM[8], B. P. RYPMA[6]
[1]Dept Neurosci, Univ. of Wisconsin Madison, Madison, WI; [2]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX; [3]Ctr. for BrainHealth, [4]Dept. of Biol. Sci., Univ. of Texas at Dallas, Dallas, TX; [6]Behavioral & Brain Sci., [5]Univ. of Texas at Dallas, Richardson, TX; [7]Zuppichini, Univ. of Texas-Dallas, Addison, TX; [8]Univ. of Texas Dallas, Allen, TX

Abstract: Functional magnetic resonance imaging (fMRI) has been used to infer age-differences in neural activity from the hemodynamic response function (HRF) that characterizes the blood-oxygen-level-dependent (BOLD) signal over time. The HRF results from complex interactions between neurons, glia, and vascular structures, comprising the neural-vascular coupling system. This system is finely-tuned in healthy individuals for efficient brain function, and may underlie performance differences observed between younger and older adults. We hypothesize that age-related changes to any component of this system could alter relationships between the shape of the HRF and cognitive performance. We analyzed a large dataset from the Cambridge Center for Aging and Neuroscience (CamCAN) study. 74 younger (18-30 years of age; 25.4±3.6, 33 males) and 173 older (54-74 years of age; 63.7±6.0, 100 males) adults viewed two checkerboards flanking a central fixation point (34 ms) and simultaneously heard a 300ms binaural tone. HRFs were estimated using FMRIB's Linear Optimal Basis Sets (FLOBS) to minimize shape assumptions. FLOBS-generated HRFs were compared to canonical HRFs using several different measures, including Pearson's correlation coefficient and Kolmogorov-Smirnov goodness-of-fit test statistics. These metrics were combined to create a composite score indicating how closely the FLOBS-generated HRF resembled the canonical HRF, the Quantitative Canonicality Index (QCI). Results showed that for older adults, the QCI significantly predicted reaction time on the task performed in the scanner ($r = -0.21$, $p < 0.004$). Age reductions in the conformity of HRF shape (as measured by QCI) support the hypothesis of age-related changes in neural-vascular coupling. They also suggest the importance of an intact neural-vascular coupling system to fast, efficient cognitive performance. New imaging methods, like calibrated fMRI, permit direct assessment of age-differences in the physiologic factors underlying BOLD signal. More precise interpretations of HRF shape-cognitive performance relationships can be formulated once these physiologic factors are disentangled and measured separately.

Title: Neural compensation for proactive inhibitory control in healthy aging

Authors: *S. HU[1], M. JOB[2], S. K. JENKS[1], C.-S. R. LI[3]
[1]Dept. of Psychology, [2]Dept. of Psychology, Dept. of Biol. Sci., SUNY Oswego, Oswego, NY; [3]Dept Psychiatry, Yale Univ., New Haven, CT

Abstract: Aging is associated with impaired cognitive functions including inhibitory control. Previous research has reported reduced stopping efficiency during reactive inhibition, along with decreased brain activations, in older adults. Whether older adults are also compromised in proactive or anticipatory inhibition remains unclear. The current study aimed to investigate age-related behavioral and neural changes in proactive inhibitory control. One-hundred-and-forty-nine adults (83 women) between the age of 18 and 72 (31.6 ± 11.9) years participated in the study. All participants underwent fMRI performing a stop signal task (SST) in which frequent "go" signals instructed a button press and occasional "stop" signals demanded withdrawal of the response. Proactive inhibition was operationalized by the sequential effect, the correlation between the probability of stop signal occurrence, or P(Stop), and go trial reaction time (RT). P(Stop) was estimated trial by trial with a Bayesian belief model (Hu et al., 2015). Two generalized linear models were built each on trial and go signal onsets to model fMRI signals. P(Stop)s and RTs were entered as parametric modulators each in the first and second model. Behaviorally the magnitude of sequential effect was not correlated with age, suggesting spared proactive inhibitory control in older adults. On the other hand, age was associated with increased activation during P(Stop) and prolonged RT. Specifically, the left lateral prefrontal cortex (PFC), paracentral lobule, superior and inferior parietal lobule, and cerebellum showed increased activation with age during stop signal anticipation, and the right middle occipital gyrus (MOG) showed age-related increase in activation during prolonged RT. Further, Granger Causality analysis showed that the PFC Granger caused MOG, with the PFC-MOG connectivity significantly correlated with P(Stop) in older but not in younger adults, suggesting that the PFC and MOG activations and PFC-MOG connectivity may compensate for sequential effect during aging. These results revealed distinct neural processes underlying proactive inhibitory control in aging and highlighted neural plasticity in the aging brain.

Title: The neural basis of metacognition in lesion models

Authors: *I. R. GARCIA CORDERO[1], L. SEDEÑO[1], A. BABINO[2], M. MELLONI[1], M. MARTORELL[1], M. DOTTORI[1], M. SIGMAN[2], A. GARCIA[1], F. MANES[1], A. IBAÑEZ[1]
[1]Inst. of Cognitive and Translational Neuroscie, Ciudad Autonoma Buenos Aires, Argentina; [2]Univ. Torcuato Di Tella, Buenos Aires, Argentina

Abstract: Metacognition, the knowledge about own mental abilities, is strongly linked to self-control and self-awareness. While neuroscientific study on this domain has accrued in recent years, only few studies have compared metacognitive performance across brain pathologies and none has applied the lesion model approach combined with neuroimaging (MRI) analysis. To bridge this gap, we evaluated metacognition in patients with focal frontal-insular lesions (FIS) and dementias -behavioral variant frontotemporal dementia (bvFTD) and Alzheimer's disease (AD)-, who present damage in key metacognitive areas. Participants performed a visual perception task and provided two types of metacognitive report: *confidence* (judgment of trust about the performance) and *wagering* (betting on their accuracy in the perceptual task). Then, damaged areas were analyzed via structural MRI to identify an association with impaired metacognitive outcomes.Results showed that, relative to controls, FIS and bvFTD patients did not present differences in confidence, whereas AD patients proved significantly overconfident. In contrast, wagering performance was affected in all patient groups. MRI analysis evidenced that lesions in orbitofrontal regions were involved in overconfidence, and damage in dorsolateral regions was associated with excessive wagering. Therefore, this study allowed a differentiation between metacognitive performance (confidence vs. wagering) and pathologies (orbitofrontal lesions vs. dorsolateral lesions). The impairment of confidence and wagering in AD patients evidenced a lack of self-awareness in both types of metacognitive measures. Remarkably, in the frontal pathologies (FIS and bvFTD), confidence was preserved, but wagering was excessive, showing a failure to use metacognitive information to bet adequately. Finally, overconfidence was associated with orbitofrontal damage, while impaired wagering was related with dorsolateral

lesions. These results and the application of the lesion model approach across contrastive pathologies contributed to a better understanding of the brain functions, and specifically, of the metacognitive processes.

Abstract: A variety of behavioral tasks have been devised to examine component, configural, and holistic aspects of face processing. Using simultaneous presentation of face pairs, our previous study in age differences has demonstrated that an inversion effect of the component task was evident with younger but not with older adults, despite the fact that regression models suggested younger and older adults relied upon the same aspects of holistic and non-holistic processing revealed by the component task for encoding and later retrieving memory of faces (Cheng, Shyi, & Cheng, 2016, *CJP*). Here we aimed to investigate the brain mechanisms underlying the performance of component task in order to better understand whether and how younger and older adults may differ in the processing of a face and its components. 17 young adults (mean age of 22.6 yrs and *SD* of 1.80) and 9 older adults (mean age of 67.5 yrs and *SD* of 6.35) were asked to judge whether or not two simultaneously presented faces, displayed either upright or inverted, were identical. When faces were not identical, they differed in terms of the eyes or mouths. Their brain were scanned using fMRI while performing the task. The behavioral results showed the inversion effect among younger adults but not among the older adults, replicating our previous findings, and both groups did equally well in the scrambled-face control condition. Brain imaging results on the other hand revealed more regions were activated among

younger adults than among older adults for processing upright and inverted faces in contrast to processing scrambled faces. Furthermore, for younger adults, the contrast between upright and inverted faces revealed a broad array of brain regions involving frontal, prefrontal, and temporal areas that have been widely identified for their roles in processing faces. In a sharp contrast, older adults appeared to have engaged primarily non-face processing regions, such as caudate body and retrosplenial cortex, in processing the components of a face. These differences in the pattern of brain activations may help to elucidate the neural mechanisms in support of the presence of inversion effect among younger adults as well as its absence among the older adults.

Title: The neuromodulatory effects of L-DOPA across human verbal memory processes

Authors: *H. K. ISOTALUS[1], J. P. GROGAN[2], N. IRIGORAS IZAGIRRE[2], A. HOWAT[2], L. KNIGHT[3], R. A. KAUPPINEN[2], E. J. COULTHARD[4,1]

Abstract: One framework for understanding long term memory is to divide it into three core phases of processing; encoding (transcribing information into a neural representation), consolidating (organising and strengthening) and retrieving (accessing). We have previously shown that increasing dopamine availability in the brains of patients with Parkinson's disease enhances consolidation and retrieval but impairs encoding. Understanding when dopamine influences memory is pivotal to optimally target future therapeutics in memory impairment. Here, we tested if exogenous dopamine administration improves either retrieval or encoding of verbal episodic information in healthy elderly. In this placebo-controlled double-blind randomised crossover trial, 33 healthy elderly (65+ years) adults performed a verbal recognition memory task. Volunteers first learnt a word list on Day 1 without medication. On Day 2, to examine the effect of dopamine on retrieval, they were dosed with 150mg L-DOPA or placebo before their memory was tested. To target encoding, they then learnt a novel word list for which

they were tested on immediately, and 1, 3, and 5 days later, with unique targets at each test. There was no difference in verbal recognition accuracy or signal detection measures between L-DOPA and placebo when administered prior to retrieval or encoding. Furthermore, Bayesian analysis of these data provided moderate support against L-DOPA affecting retrieval (BF_{01}=4.243) or encoding (BF_{01}=4.300) in elderly adults. However, post-hoc analyses revealed that L-DOPA during encoding enhanced retrieval 3-days later for those with high trait depression or anxiety (r =.425 p=.030; r =.467, p =.016, respectively). Our findings suggest that exogenous dopamine does not enhance encoding or retrieval in healthy ageing, and that earlier results may be explained by dopamine boosting consolidation. However, elderly with high trait depression or anxiety may benefit from L-DOPA during encoding or early consolidation, although these findings need replicating in independent datasets, which we aim to do in our future work. Our ongoing work investigates the efficacy of L-DOPA administration in targeting consolidation during sleep in both healthy ageing and in amnesic disease.

Title: TDCS in a verbal recognition task: Boosting older participants' word recognition time

Authors: *L. S. BALDUIN-PHILIPPS, S. WEISS, H. M. MUELLER
Bielefeld Univ., Bielefeld, Germany

Abstract: Transcranial direct current stimulation (tDCS) may elicit an improvement of memory functions in healthy individuals of different age after multi-day anodal stimulation of temporoparietal regions. Furthermore, anodal tDCS of these areas facilitates memory and recognition processes in participants with memory deficits. Therefore, our study deals with the question to which extent even a single session of anodal tDCS applied to the left temporal cortex influences recognition performance in a verbal recognition task in older healthy subjects.
In this sham-controlled and double-blinded experiment 19 healthy, elderly participant (14 female, M∅ = 69.5y, SD = 5.2y, 64-80y) underwent a verbal recognition task. All participants were right-handed (EHI M∅ = 96.3, SD = 6.9, 80-100) and monolingual native speakers of German, and had no verified memory deficits. Participants completed two sessions (sham/anodal

tDCS), counterbalanced between subjects, with a wash-out period of at least ten days. They had to memorize auditorily presented words in a learning phase. After that, they had to recognize single words out of several distractors (semantically or phonologically related words) via button press. 20 minutes of 1.5 mA anodal tDCS was applied on the left temporal cortex including both the learning and the recognition phase. We hypothesized that already a single anodal tDCS session would lead to improved word recognition performance compared to sham.
First results indicate a positive influence of anodal tDCS compared to sham. Word recognition times are significantly shorter in the tDCS compared to the sham condition (F (1, 18) = 7.277, p = .015). Pure motor reaction times are not influenced by tDCS (F (1, 18) = .013, p = .912). Hence, a single session of anodal tDCS to the left temporal cortex selectively improves word recognition speed in healthy older individuals, but not motor reaction time. Therefore, these results are promising for further studies on patients with memory and recognition deficits.

Title: Frequency oscillations in error processing: An EEG study on age-related effects

Authors: *J. KRAUSS[1], E. NIESSEN[1], N. ROSJAT[1], S. DAUN[2], J. STAHL[2], G. R. FINK[1], P. H. WEISS[1]
[1]Forschungszentrum Jülich, Jülich, Germany; [2]Univ. of Cologne, Köln, Germany

Abstract: Event-related oscillations in different frequency bands are related to different motor cognitive functions: theta oscillations are linked to inhibition of movements, whereas alpha and beta oscillations are associated with different movement processes. Both theta and alpha oscillations are known to be influenced by error processing.
Here, we comprehensively examined error processing and its underlying neural correlates in two age groups. Brain oscillations in the theta (4-7 Hz), alpha (8-13 Hz) and beta (14-30 Hz) frequency bands measured by EEG were analysed in 22 young (age 25 ± 4 years) and 20 older (age 58 ± 6 years) adults in terms of event-related spectral perturbation (ERSP) using a previously established Go/Nogo task.
In young adults, significant changes in theta power were found between Go and (correct and incorrect) Nogo trials, suggesting a role of theta oscillations in processing infrequent stimuli. The occurrence of errors modulated alpha power by creating the exact inverse pattern as compared to correct responses and correct withholds. An increase in power was present in the beta frequency band after movement in correct Go and Nogo trials, but not in error trials. In stark contrast, none

of these condition specific effects were observed in the older adults. In fact, for the three frequency bands no significant differences between the conditions emerged in the older group. Data suggest a differential modulation of the three frequency bands during error processing in young adults. In older adults, the activation pattern within the frequency bands did not reveal any differences between conditions. The finding that the older subjects nevertheless showed similar behaviour as the young subjects suggests compensatory mechanisms in older adults.

Title: Behavioral and neurophysiological differences in cognitive and motor inhibition of aging musicians and non-musicians

Authors: *P. IZBICKI[1], E. L. STEGEMOLLER[2]
[1]Neurosci. and Kinesiology, [2]Iowa State Univ., Ames, IA

Abstract: Older adults experience a decline in the domains of cognitive and motor inhibitory control. These declines have been implicated in instrumental activities of daily living. However, studies have revealed that older musicians have behavioral and neurophysiological enhancements in various motor and cognitive domains as compared to non-musicians. This suggests that music training may delay the decline in cognitive and motor inhibition with aging. Yet, cognitive and motor inhibition has not been studied across the lifespan in musicians and non-musicians. Thus, the aim of this study was to investigate the behavioral differences in cognitive inhibition and motor inhibition in aging musicians and non-musicians. Healthy young adult (HYA) musicians and non-musicians and healthy older adult (HOA) musicians and non-musicians were recruited for the study. To measure cognitive inhibition**,** the Stroop task was performed. Participants were asked to name the color of a word presented in either red, green, yellow, or blue. Three conditions were presented randomly: neutral (infrequent words sol, helot, eft, and abjure presented in different colors), congruent (color of word matches the word), and incongruent (color of the word does not match the word itself). Accuracy and reaction time were recorded using E-Prime 2.0 (Psychology Software Tools, Pittsburgh, PA). To measure motor inhibition, participants were asked to perform an index finger flexion-extension movement (i.e., finger tap) in sync with an auditory tone (i.e., synchronized) and between auditory tones (i.e., syncopated)

presented at 1 Hz. The forearm, wrist, thumb, and fingers 2-4 were supported with a brace maintaining the forearm in a pronated position with the elbow flexed at 90 degrees. The index finger remained unconstrained to allow for full range of motion without touching a surface. Accuracy was recorded using a goniometer. For cognitive inhibition, results revealed that both HYA and HOA musicians showed faster reaction time on the Stroop task than non-musicians. For motor inhibition, results revealed that HYA and HOA musicians demonstrated greater accuracy in the syncopation task than non-musicians. Overall, these results suggest that HYA and HOA musicians display greater cognitive and motor inhibition than HYA and HOA non-musicians, respectively. Future studies will explore the neurophysiological measures associated with the tasks. At the conclusion of the study, results will demonstrate a clearer understanding of whether music training contributes to greater cognitive and motor inhibitory control during the aging process, thus, enhancing health and quality of life in older adults.

Title: Fronto-parietal functional connectivity during an n-back task decreases across the adult lifespan and predicts working memory performance

Authors: *E. E. PONGPIPAT, C. M. FOSTER, K. M. KENNEDY, K. M. RODRIGUE
Ctr. for Vital Longevity, Sch. of Behavioral and Brain Sci., The Univ. of Texas at Dallas, Dallas, TX

Abstract: Working memory (WM), an age-vulnerable process, is associated with activity in fronto-parietal association cortices. BOLD activation and modulation to task difficulty decreases with aging and has been shown to relate to task performance and cognitive ability. Differential, age-related changes in the patterns of cross-connectivity between frontal and parietal regions during WM tasks likely support proper performance. However, the nature of the aging findings are mixed and lifespan data are limited. In the present study, we examined frontal and parietal functional connectivity (FC) during an *n*-back task (i.e., 0-, 2-, 3-, and 4-digits back) and the relationship between age related alterations in FC and WM performance. Participants included 170 healthy adults (aged 20-94 years) who completed cognitive assessment sessions along with

an MRI session. FC was analyzed and measured using psychophysiological interactions (PPI) with seed regions of interest selected from local peak maxima in the frontal and parietal cortices from each hemisphere. The *n*-back contrast of interest was 2, 3, 4-back vs. 0-back from three functional runs of pseudo-counterbalanced blocks of the digits back. We observed the expected increase in fronto-parietal FC as WM load increased. We also found that FC with the two parietal seeds decreased with age but that FC with the two frontal seeds was age-invariant. To gauge the effects of decreased FC on performance, we tested models with positive FC, negative FC, age, and their interactions on a multivariate variable composed of task accuracy, Digit Span (i.e., forward, backward, and sequencing), and absolute Listening Span for each seed PPI. We found that decreased right parietal positive and negative FC was associated with poorer WM performance, as was left parietal positive FC, and left frontal positive FC, all beyond the effects of age on WM. These results suggest that fronto-parietal FC during WM decreases linearly across the adult lifespan and this age-related decreased FC is associated with poorer WM ability.

Title: Hearing impairment and cognitive decline among older, community dwelling adults

Authors: A. A. ALATTAR[1], J. BERGSTROM[1], G. A. LAUGHLIN[1], D. KRITZ-SILVERSTEIN[1], E. RICHARD[1], E. T. REAS[1], J. HARRIS[1], E. BARRETT-CONNOR[1], *L. K. MCEVOY[2]
[1]UCSD, La Jolla, CA; [2]Dept. of Radiology, UCSD, LA Jolla, CA

Abstract: Hearing impairment is an emerging risk factor for cognitive impairment in older adults. Several cross-sectional studies have shown associations between hearing impairment and poorer cognitive performance. Few prospective studies have examined whether hearing impairment is associated with a faster rate of cognitive decline with age, with mixed results. We

investigated the association between hearing acuity and cognitive function over a 24-year follow-up in a large, well-characterized sample of community-dwelling older adults. Between 1992-1996 participants of the Rancho Bernardo Study of Healthy Aging (n=1164, mean age 73·5 ±9.3 years; 64% women) had hearing thresholds measured and cognitive function assessed. Participants returned for reassessment of cognitive function up to 5 times, at approximate 4-year intervals. Participants were classified into 3 groups based on pure tone average (PTA) threshold in the better hearing ear: normal hearing, PTA<25 dB, N= 388 (33.3%); mild hearing impairment, PTA 25-40 dB, N=580 (49.8%); and moderate-or-greater impairment, PTA>40 dB, N=196 (16.83%). Multivariable mixed-effects linear regression, adjusting for age, education, cardiovascular risk factors and health behaviors, was used to assess group differences in cognitive function and rate of cognitive change over time. Hearing impairment was associated with poorer performance and steeper decline over time on the MMSE (p=0.002) and Trails B (p=0.001). Associations did not differ by sex, APOE-ϵ4 status, or after further adjustment for social engagement. Associations were modified by education (p=0.037): mild hearing impairment was associated with steeper decline on the MMSE among participants with high school education or less; but not among those with at least some college. Moderate or greater hearing impairment was associated with steeper MMSE decline relative to normal hearing adults regardless of education level. Differences in rates of decline by hearing group remained significant when the effect of informative drop-out due to death was accounted for with joint longitudinal models, indicating that the differences were not due to survival bias. This study shows that among older adults, hearing impairment is associated with a faster rate of cognitive decline, and that higher education may protect against cognitive decline associated with mild hearing impairment. Screening for hearing impairment may be important for identifying older adults at risk for accelerated cognitive decline.

Title: Remediating age-related cognitive decline in older adults through exercise and mindfulness

Authors: H. RIPPERGER[1], K. AHERN[2], N. HARPER[2], M. YINGLING[2], *J. A. SCHWEIGER[3], E. LENZE[2]
[1]Psychiatry, [2]Washington Univ. Sch. of Med., Saint Louis, MO; [3]Dept Psychiatry, Washington Univ. Sch. Med., Saint Louis, MO

Abstract: Participants were enrolled in an 18-month pilot study of exercise and mindfulness-based stress reduction (MBSR) to test whether these interventions can remediate age-related cognitive decline.
Previous research studies have shown that MBSR appears to produce neurocircuitry changes that are the reverse of those seen in age-related cognitive decline, and it also alters stress-related biological pathways that contribute to cognitive changes in older adults. Other studies have demonstrated that exercise also appears to affect brain structure and function and improves cognition.
Participants attended exercise classes twice weekly for 6 months, and then once weekly for the next year. They completed an additional 120 minutes of exercise per week at home. They also attended MBSR classes once weekly for 10 weeks, and then once monthly for the remainder of the 18 months. They were asked to practice MBSR independently up to 1 hour per day. A comprehensive cognitive battery was administered at baseline, 3-month, 6-month, and 18-month time points.
Participants in this pilot group were community-residing adults between the ages of 65 and 84 who reported a decline in their memory or concentration, but did not have a diagnosis of MCI, dementia, or Alzheimer's. In this pilot group of individuals (n=29), the average age of respondents was 71.8 years (SD=5.7), 65.5% (n=19) were female, 96.6% (n=28) were white, 6.9% (n=2) were Hispanic or Latino.
We created a memory composite (using a paragraph and word recall task, and picture sequence task) and cognitive composite (using Stroop, Flanker, CVOE, DCCS, and List Sorting). The average baseline memory composite score was 0.00 (SD = 0.79). In the overall group, the mean change in memory composite score from baseline to 6 months was 0.41 (SD=0.42). The average baseline cognitive composite score was 0.00 (SD=0.65). In the overall group, the mean change in cognitive composite score from baseline to 6 months was 0.05 (SD=0.37). These data indicate that participation in exercise and MBSR was significantly correlated with improvements in memory, but not cognitive control.
These results are part of a larger, ongoing randomized clinical trial testing the effectiveness of exercise and MBSR as a treatment for age-related cognitive in older adults. In the larger RCT (n=600), participants are randomly assigned to either MBSR, exercise, a combination of MBSR and exercise, or health education (an active control group). They will undergo a number of assessments, including structural and functional MRI. This will be a comprehensive data set that will give us more clarity on changes in memory and cognitive control as a result of MBSR and/or exercise training.

Title: Age-related differences in some but not all cognitive control functions are mediated by frontal lobe markers

Authors: *S. HSIEH, M.-H. YANG
Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: This study aimed at examining the relationships among age, cognitive functioning, and brain structure and functioning. We tested a brain-mediating model in 156 healthy participants (74 females) 20 to 78 years old by examining whether multi-modal frontal lobe variables (gray matter volume, white matter fractional anisotropy, and resting-state functional connectivity) can be mediators of age-related decline in cognitive control function. Cognitive control function was measured by the task-switching paradigm, flanker, n (1&2)-back and stop-signal tasks. The results show that although these tasks are classified as cognitive control tasks, they can be differentiated and their scores do not necessarily decline with age. In addition, although the 2-back task's sensitivity and stop-signal reaction time (SSRT) are sensitive to age, their age-related variance was not mediated by the same sets of brain structures and/or functioning. The current multimodal neuroimaging data combined with psychometric mediation models provide evidence in supporting a multi-factorial theory of cognitive control deficit in aging.

Title: Optimized multi-modal prediction of cognitive function from brain data for different age ranges

Authors: *C. G. HABECK[1], Y. STERN[2]
[1]Taub Inst., Columbia Univ., New York, NY; [2]Cognitive Neurosience Division, Columbia Univ., New York, NY

Abstract: Cognition can be broadly characterized by 4 domains: episodic memory (=MEM), fluid reasoning (=REASON), perceptual processing speed (=SPEED), and vocabulary. We investigated the predictive utility of structural and functional brain data for performance in MEM, REASON, and SPEED beyond demographics in 451 participants aged 20-80, similarly to (Hedden et al. 2014). We used gray-matter volume and cortical thickness acquired in 68 regions of interest (ROIs), and fractional anisotropy for 18 major white-matter tracts. These 3 modalities represented all brain-structural independent variables, and yielded 2*68+18=154 features in total. Further, resting-state fMRI was collected in 264 regions of interest, making up the brain-functional independent variables in form of 34,716 connectivity ROI-pairs. Demographic independent variables were constituted by age, years of education and verbal intelligence (=NARTIQ). We ran simulations with 1,000 iterations for which the data were randomly split into a training and test set. Principal-component regression was run in the training set to estimate a best-fit model to predict cognitive outcome, and this model was then applied to the held-out test data set. The prediction in the test-set was correlated with the actual values of the cognitive outcome, and the logarithmic P-value was recorded as a measure of prediction success. We were particularly interested in comparing predictive utility of brain and demographics variables between the 3 cognitive outcomes and 2 age ranges (20-50 and 50-80). The number of participants in both training and test sets was 60 for all age ranges and cognitive outcomes, to avoid differences in statistical power. Several points emerged from these analyses: (1) Demographics outperformed both structural and functional brain data substantially, regardless of cognitive outcome or age range; (2) combining brain + demographics together, however, did usually achieve even better predictive success; (3) REASON showed the best predictive utility for all independent variables for both age ranges, with the best overall prediction for the young age range where the brain + demographics model achieved 100% predictive success at $p<0.01$; (4) MEM showed the worst predictive success for either demographics or brain variables, with

demographics achieving $p<0.01$ success in 18% of the iterations, while the brain variables failed to exceed the expected false-positive rate; (5) SPEED proved intermediate with $p<0.01$ prediction success for 70% of iterations of the brain + demographics model for both age ranges. These results show significant differences in brain-cognition relations between cognitive domains.

Title: Dendritic spine structural remodeling accompanies Alzheimer's disease pathology in cognitively normal human aging

Authors: *J. H. HERSKOWITZ[1], B. D. BOROS[2], K. GREATHOUSE[3], M. GEARING[4]
[1]Neurol., The Univ. of Alabama At Birmingham, Birmingham, AL; [2]Univ. of Alabama At Birmingham, Birmingham, AL; [3]Univ. of Alabama at Birmingham, Birmingham, AL; [4]Emory Univ., Atlanta, GA

Abstract: Subtle alterations in dendritic spine morphology can induce marked effects on connectivity patterns of neuronal circuits and subsequent cognitive behavior. Past studies of rodent and non-human primate aging revealed reductions in spine density with concomitant alterations in spine morphology among pyramidal neurons in the prefrontal cortex. In this report, we visualized and digitally reconstructed the three-dimensional morphology of dendritic spines from the dorsolateral prefrontal cortex in cognitively normal individuals aged 40-94 years. Linear models defined relationships between spines and age, Mini-Mental State Examination (MMSE), APOE ε4 allele status, and Alzheimer's disease (AD) pathology. Similar to findings in other mammals, spine density correlated negatively with human aging. Reduced spine head diameter as well as morphologic changes in thin spines associated with higher MMSE scores. Individuals harboring an APOE ε4 allele displayed greater numbers of dendritic filopodia and concomitant structural alterations in thin and mushroom spines. The presence of AD pathology correlated with increased spine length, reduced thin spine head diameter, and increased filopodia density. Our study reveals how spine morphology in the prefrontal cortex changes in human

aging and highlights key structural alterations in selective spine populations that may promote cognitively normal function despite harboring the APOE ε4 allele or AD pathology.

Title: Differences in functional activation and fractional anisotropy between an age-stable ability, vocabulary, and an age-declining ability, perceptual speed, provides support for greater resilience in neural processes for vocabulary

Authors: *Y. GAZES[1], C. G. HABECK[1], Q. R. RAZLIGHI[2], P. LI[3]
[1]Taub Inst., [2]Neurol., Columbia Univ., New York, NY; [3]Col. of Physician and Surgeon, Neurol., Columbia Univ. Med. Ctr., New York, NY

Abstract: Cognitive tasks known as crystallized abilities remain stable with older age while other tasks, fluid abilities, decline as early as the third decade, which is puzzling considering these are manifested in the same brains. This cross-sectional study is a novel first step to examine whether regional distribution of processes supporting the two ability types contributes to the differential age effects. We administered tasks for a typical crystallized ability, vocabulary (V), and a typical fluid ability, perceptual speed (PS), within the same set of 316 subjects, enabling within-subject comparisons of the two abilities. ROIs were extracted based on unique functional activations for each ability and used as seeds to extract white matter tracts connecting these ability-unique regions. Mean parameter estimates were also extracted from these ability-unique ROIs as well as from regions commonly activated by both abilities. We examined within-subject ability differences in ability-common and -unique activations and in the fractional anisotropy (FA) of the white matter tracts connecting the ability-unique ROIs. Ability-common regions consisted of visuomotor areas. Vocabulary-unique regions included the left inferior frontal gyrus (BA44 and 45) and left superior temporal gyrus, and speed-unique regions included bilateral dorsolateral prefrontal gyri (BA 9) and the supramarginal gyri (BA 40). While vocabulary activations in regions common to both abilities showed strong age effects (V: $r = .316$; PS: $r = .386$; both $p<.01$), activations in vocabulary-unique areas did not correlate with age ($r = .062$, $p > .05$) whereas PS-unique activations did correlate with age ($r = .326$, $p < .01$). The

within-subject differences in ability-unique activations correlated positively with age, such that speed-unique activations became increasingly greater than vocabulary-unique activations with older age ($r = .235$, $p < .01$) whereas the age association for the differences between the common regions was not significant ($r = .107$, $p > .05$). In fact, Steiger test showed that the two correlations was significantly different ($Z=-2.64$ with Common-Unique, $p < .01$). Furthermore, FA of the white matter tract connecting vocabulary-unique ROIs showed greater FA than tracts connecting the speed-unique ROIs ($t=27.6$, $p<.001$). Together, these results provided support for the possible resilience of vocabulary-related brain structures against age relative to those involved in the processing of perceptual speed.

Title: Mind over matter, understanding the relationship between memory self-efficacy, cognition and activation in older adult women with probable mild cognitive impairment

Authors: *B. R. HORST[1], L. S. NAGAMATSU[2]
[1]Neurosci., [2]Kinesiology, Western Univ., London, ON, Canada

Abstract: In our aging population, cognitive decline and brain health are critical areas of concern for healthy aging. Evidence has shown that certain memory performance measures such as associative memory, one's ability to remember connections between distinct items, is linked with conversion to dementia in those already affected by Mild Cognitive Impairment (MCI). The need to protect memory performance is clear. Yet, memory performance is a complex construct, therefore recognizing influential variables is important to improve or maintain performance. Global cognition, functional activation of medial temporal lobe structures, and self-efficacy have each been identified as independent predictive variables of memory performance. However, it is unknown how these variables compare in their predictive value against each other. The aim of our study is to compare the predictive values of these variables. We predict that memory self-efficacy, a psychosocial construct of one's perceived memory ability, may be a significant predictor of associative memory performance beyond physiological variables. Using a cross-sectional design, community dwelling older women (age 65-80) with probable Mild Cognitive Impairment (MCI) were asked to evaluate their memory self-efficacy using the Multifactorial Memory Questionnaire (MMQ) in addition to standardized cognitive tests. T1 weighted structural imaging and BOLD signal fMRI, during an associative-memory task, was obtained using a 3T scanner. Multiple linear regression models were constructed for the prediction of

memory performance outcomes using independent variables of MSE, functional activation, and global cognitive status; co-varying for age, physical activity level, and neural structural volumes. Our results found that the memory self-efficacy added significant predictive value to the models beyond global cognition and functional activation for performance on an associative memory task. Based on these results it appears that one's perceived feelings and contentment about their memory ability is associated with how they will perform on a memory task regardless of cognitive status or physiological differences. Based on this data our research has the potential to progress into a longitudinal study of observing the relationship between changes in memory self-efficacy, brain health and cognition, as well as progression to collaborative clinical studies in memory self-efficacy modification for healthy aging

Title: Age differences in spatial navigation: Allocentric versus egocentric strategies

Authors: *M. FRICKE, O. L. BOCK
German Sport Univ., Koeln, Germany

Abstract: Spatial navigation is a complex cognitive ability, which can generally be divided into two components. One of them uses an ego perspective and includes the use of directional codes and landmarks along the way (e.g., "when I reach the pharmacy, I turn right"). It is referred to as "egocentric". The other component is independent of one's own body position and involves the use of a mental bird's eye view of the environment, called 'cognitive map'. This "allocentric" strategy is indispensable for finding shortcuts or ways around a roadblock.
Previous research showed that spatial navigation abilities decline with advancing age, prompting older adults to limit their physical and social activities and thus to reduce independence and quality of life. It has been argued that age-related decline affects mainly allocentric rather than egocentric navigation, but direct experimental evidence for this view is still missing. The present study was designed to provide such evidence.
Participants were 61 healthy volunteers (32 young, 18 - 35 years, 17 male; 29 older, 63 - 81 years, 16 male). They were tested in two game-like computer environments developed with Unreal Engine (Epic Games®). Both tests were presented in a virtual reality setting on a standard computer monitor. Participants had to find a goal by pursuing a route with 5 decision points, each with 4 branches. Test Ego provided only local landmarks (characteristic buildings in front of a featureless horizon), and test Allo only global landmarks (mountains and castles in the

distance, with all decision points looking alike). Participants performed each test eight times, with test order balanced between individuals. Performance was quantified as time to completion, distance covered and number of wrong turns.
Analyses of variance yielded significant interactions of the between-factor Age Group and the within-factor Test: older adults performed similarly to young ones on the egocentric test, but performed less well than young ones on the allocentric test. We thus now have direct experimental evidence that allocentric but not egocentric navigation declines in older age.

Title: Hybrid foraging in healthy aging

Authors: *H. SCHILL[1,2], I. WIEGAND[3], C. SEIDEL[4], J. WOLFE[5]
[1]Somerville, MA; [2]Brigham & Women's Hosp., Boston, MA; [3]Max Planck UCL Ctr. for Computat. Psychiatry and Ageing Res., Berlin, Germany; [4]Univ. of Frankfurt, Frankfurt, Germany; [5]Brigham & Women's Hospital, Harvard Med. Sch., Boston, MA

Abstract: "Hybrid foraging" tasks are those where observers (Os) look for multiple instances of multiple types of target; for example, rummaging through the Lego box for small red bricks, long blue bricks, and alligators. Wolfe et al. (2016) created an analogous task in the lab by teaching Os a set of N targets that they held in memory and asking Os to collect instances of those targets as quickly as possible from displays containing multiple instances. Os pressed a 'next' button whenever they wished to move to a new patch of targets and distractors. Wolfe et al. (2016) found that their young adults' decisions to move to the next 'patch' followed the Marginal Value Theorem (MVT) which states that foragers will leave a patch for a new one when the instantaneous rate of return from the current patch drops below the average rate of return over all patches. Previous literature has reported that healthy older adults (OA) often favor exploitative over explorative behavior (Chin et al. 2015), suggesting their behavior in a foraging task might be more conservative than what MVT would predict. Using the hybrid foraging task, we found that this is indeed the case: OA left the patch only after the instantaneous rate of return had fallen well below the average rate, which made their foraging behavior less efficient. With young

adults, response time increases in a logarithmic fashion with increases in memory set size. Interestingly, we found a very similar pattern in OA. OAs were slower overall, but they appeared to search through memory with no sign of a qualitative age-related decline. Within a patch, younger adults were also more likely than chance would predict to select another instance of the same item that they just selected. Thus, they tended to pick in 'runs.' This priming-related guidance to the previously selected target speeded foraging. OAs showed an almost identical tendency to pick up items in 'runs,' suggesting that these priming effects are preserved into older age. To conclude, OA performance on hybrid search tasks suggest that age deficits in foraging are ultimately due to strategic changes, while basic memory and visual search processes seem to remain largely intact.

Title: Age-related differences in executive function are mediated by white matter integrity and underlying white matter hyperintensity burden

Authors: *D. A. HOAGEY, L. T. T. LAZARUS, K. M. RODRIGUE, K. M. KENNEDY
Ctr. for Vital Longevity, The Univ. of Texas At Dallas, Dallas, TX

Abstract: White matter health is critically important for maintaining cognitive abilities in the aging brain. Degradation of white matter integrity has been associated with cognitive performance across many domains, but particularly with aspects of executive function (EF) and processing speed (PS). However, the impact of underlying brain and health factors, such as white matter hyperintensities and pulse pressure (PP), on overall white matter health is poorly understood. We explored these associations in a lifespan sample of 183 participants (20-94 years) using a cognitive task battery assessing EF and PS, combined with Diffusion Tensor Imaging (DTI) and T2 FLAIR scans. Demographic and health information were also collected, which included sex, education, and PP (calculated from multiple blood pressure readings). Fractional anisotropy (FA) was estimated in three white matter tracts: Superior Longitudinal Fasciculus, Inferior Fronto-Occipital Fasciculus, and Genu of the corpus callosum. White matter hyperintensity volume (WMHv) was estimated via a semi-automated lesion segmentation

pipeline. We used structural equation modeling to explore the relationship between age and cognition by investigating putative mediating factors of mean tract FA, WMHv, and PP, while also accounting for PS, a major component of EF. We specified a model in which age simultaneously predicted declines in EF and PS but was mediated by the serial progression of PP, WMHv, and white matter FA, with education and sex included as covariates. We found that FA in these tracts mediates the relationship between age and EF. Overall WMH burden, while not directly related to cognitive performance, predicts changes in tract FA, and indirectly mediates the relationship between age and EF. PP was not directly related to either WMH or FA; thus, the final fitted model included PP as a significant path from age only. Importantly, when reversing the originally estimated path to lead from FA to WMHv, the mediation was non-significant, indicating a temporal order of WMHv effects on tract FA. These results illustrate that while age leads to declines in both EF and PS, associations with EF are driven by both direct effects of fronto-parietal FA, and the effect of WMH on FA. Although white matter integrity alone is crucial to maintaining cognitive abilities in aging, these results suggest that WMH lesions play an important role in the neural changes that negatively impact cognition. Understanding the influence various insults have on white matter will help further disentangle key mechanisms in the aging brain underlying cognitive decline.

Title: HIPPOCAMPAL volume, and sub regions along the anterior-to-posterior axis contributes to maintenance of episodic recall and recognition over five years: Longitudinal findings from the Betula study

Authors: *N. PERSSON
Institutionen för Klinisk Neurovetenskap, Karolinska Inst., Stockholm, Sweden

Abstract: Individuals maintaining memory functions may have preserved structural brain volumes and integrity. However, there is a need to further disentangle potential leading or lagging relationships in brain-cognition links over time. Furthermore, specific forms of memories for episodes (EM), as recall of verbal items (RC), and more associative memories as recognition (RN) of a piece of information, involving associating different stimuli as e.g. face with a name, may depend on distinct parts of the anterior-to-posterior hippocampal axis. How these specific forms of EMs: RC, and RN, relate to anterior (aHC) and posterior hippocampal (pHC) volumes over time is largely unknown. This study investigated longitudinal relations between hippocampal (HC) volumes, and EM, in 362 community-dwelling adults (52%♀; 20-80 yrs. at baseline, 223 returned at follow-up). A series of univariate and bivariate latent change score models were specified to assess, 1) mean change, and individual differences; and 2) leading and lagging relationships between 5-year changes in HC, and EM. Measurements included a wide range of EM tasks, and FreeSurfer derived volumes from the entire HC, as well as aHC, and pHC. Chronological age, sex, and years of education were treated as covariates. Maintained structural HC integrity at baseline slowed subsequent decline in RC, and RN. Larger baseline aHC volumes selectively slowed subsequent RN loss, and larger pHC volumes hampered 5-year RC decline. Volumes of aHC was not related to subsequent change in RC, nor was pHC linked to changes in RN. No support was found for reversed causality, across models. The covariates examined, age, sex, and education, had some cross-sectional influence, but only limited longitudinal effects. To exemplify, older adults showed smaller baseline HC, and greater volume loss, in addition to lower EM scores. Higher education was associated with greater baseline EM scores, but not change. The findings inform about potential relevance of distinct neural correlates along the anterior-to-posterior HC axis of RC, and RN. These findings may further serve as a base to inform interventions to maintain HC and EM, as HC atrophy, is a major vulnerability factor for conversion to Alzheimer's disease.

Title: Cost-benefit arbitration between model-free and model-based learning strategies in human aging

Authors: *F. BOLENZ[1], W. KOOL[2], A. M. F. REITER[1], S. J. KIEBEL[1], B. EPPINGER[3]
[1]Technische Univ. Dresden, Dresden, Germany; [2]Dept. of Psychology, Harvard Univ., Cambridge, MA; [3]Concordia Univ., Montreal, QC, Canada

Abstract: To efficiently meet the challenges of our complex world, people constantly have to decide on how much cognitive effort they invest into a task. For this purpose, they weigh up the costs of cognitive effort against its potential outcomes, a form of meta-control that has been linked to the dorsal anterior cingulate cortex (dACC; Shenhav et al., 2013, *Neuron*). While dACC is part of fronto-striatal circuits that undergo extensive functional and structural changes with human aging, the impact of these aging-related changes on meta-control remains poorly understood.
We tested younger and older adults on a sequential decision-making task that provides a measure of the relative impact of a simple but inflexible "model-free" learning mechanism and a cognitively more effortful but also more accurate "model-based" learning mechanism (Kool et al., 2017, *Psychol Sci*). Across trials, we manipulated reward magnitude (leading to different pay-offs of model-based behavior) and whether the state transition structure of the task was stable or subject to changes (leading to different costs for model-based behavior).
We replicate findings from previous studies that showed reduced model-based learning in older adults compared to younger adults. Moreover, as has been shown earlier, younger adults adapted their learning strategies to reward magnitude by increasing their reliance on model-based learning when rewards were temporarily amplified. However, this effect was only observed with stable state transitions, not when subjects had to adapt to changes in the state transition structure. In older adults we found no evidence for an increased reliance on model-based control as a function of reward magnitude in either of the transition conditions.
Our results show that ageing leads to reduced model-based control during learning and decision-making. Beyond this, we find evidence for reduced meta-control of learning strategies in older adults. This suggests aging-related difficulties in trading off cognitive effort against potential outcomes.

Title: Age-related differences in the variability of BOLD signal manifest differently across tasks, and influence information processing capacity

Authors: H. WANG[1], M. N. RAJAH[2], F. BURLES[1], S. PASVANIS[3], *A. B. PROTZNER[1]
[1]Univ. of Calgary, Calgary, AB, Canada; [2]Psychiatry, McGill Univ., Verdun, QC, Canada; [3]Douglas Inst., Verdun, QC, Canada

Abstract: Brain signal variability is an important measure of brain function that reflects information processing capacity and functional integrity. However, little is known about how age-related differences in variability are influenced by task, and how these differences relate to task performance. We measured variability with fMRI during encoding and retrieval phases of spatial and temporal source memory tasks in 128 healthy adults aged 19-76 yrs of age (mean age = 46.96 yrs, 85 females, mean EDU = 15.68 yrs). We quantified variability as the standard deviation (SD) of BOLD signal (Garrett et al., 2010), and studied the relation between BOLD SD, age, and task performance using a data-driven, multivariate analysis technique, Partial least squares (PLS, McIntosh et al., 1996). We examined 1) if there were age dependent differences in BOLD SD changes between conditions, and 2) if there were age and condition dependent differences in the association between BOLD SD and performance as measured by accuracy and RT. Based on previous findings that the effects of age and performance on brain activity were mainly memory phase (encoding versus retrieval) specific (Ankudowich et al., 2016, 2017), we expected that the influence of task on age-related differences in variability would be greatest for memory phase. We also expected to find age-associated increases in variability in subcortical regions, and decreases in neocortical regions, which would be associated with worse performance (Garrett et al., 2011; Guitart-Masip et al., 2016). Consistent with these expectations, we found age-related differences in brain signal variability between encoding and retrieval phases, but not between spatial and temporal conditions, or between easy and difficult versions of the source memory tasks. At encoding, variability increased with age in subcortical regions such as thalamus and parahippocampal gyrus, but decreased with age in the superior parietal lobule and postcentral gyrus ($p < .001$). Retrieval results differed from previous work, in that variability increased with age throughout the brain ($p < .001$). All age-related variability differences during encoding ($p < .001$) and retrieval ($p < .001$) were associated with longer response time and decreased accuracy. These results suggest that age-related brain changes in variability manifest differently across tasks, and affect the information processing capacity of the brain.

Title: Relationships between hippocampal volume, subjective cognition, and cognitive performance in healthy older adults

Authors: *L. FENTON[1], S. LANDAU[2], W. JAGUST[3]
[2]Helen Wills Neurosci. Inst., [3]Helen Wills Neurosci Inst., [1]UC Berkeley, Berkeley, CA

Abstract: Background: Subjective cognitive impairment may be an early manifestation of neurodegenerative disease. Therefore, it is important to understand the relationships between subjective cognition, objective memory, and neurobiological mechanisms of cognitive decline.
Objectives: Examine the relationship between hippocampal volume, subjective cognition, and objective cognitive performance in healthy older adults.
Methods: We compared offline and online subjective cognitive monitoring, episodic memory scores, average performance across 7 neuropsychological tests (Digit Span, CVLT, Visual Reproduction, Stroop, Verbal Fluency, Category Fluency, and Listening Span), and hippocampal volume of healthy older adults (N=166, M=69, F=97, mean age=73.69). Offline monitoring consisted of 2 questions asking subjects to assess their memory in relation to other people their age, and to themselves 20 years ago on a 4-point scale. Online monitoring occurred after the completion of each of the 7 tests by asking subjects to estimate their performance on a percentile scale in relation to other people. Accuracy of online monitoring was calculated by converting scores to percentile ranks, and subtracting subjects' average percentile score from their average estimated score. Sex, education, and age were controlled for across all analyses. Geriatric Depression Scale (GDS) scores were controlled for when looking at hippocampal volume, subjective cognition, and objective performance.
Results: As depressive symptoms (GDS) increased, subjects' subjective cognition ratings on both off-line and online measures significantly decreased ($p<.01$), as did their accuracy of online cognitive appraisals ($p<.05$). Subjects with higher online ratings had better performance on all 7 tests ($p<.01$), better episodic memory scores ($p<.01$) and marginally larger hippocampal volume ($p=0.06$). Hippocampal volume was significantly correlated with episodic memory scores ($r=.279$, $p<.01$), and the relationship between hippocampal volume and average performance on the 7 tests approached significance ($r=.146$, $p=.06$). Relationships between offline cognitive

monitoring, objective cognitive measures, and hippocampal volume were not significant. **Conclusions:** These findings indicate that, while depressive symptoms are associated with less accurate assessments of increasing subjective cognitive impairment, online assessments of cognition accurately reflect cognitive ability and accepted neurobiological mechanisms. Online cognitive self-assessment therefore reflects both accurate, biologically driven self-perception, and less accurate affective components.

Title: Cortical thickness mediates the relationship between the drd2 c957t polymorphism and executive function across the adult lifespan

Authors: *G. G. MIRANDA, K. M. RODRIGUE, K. M. KENNEDY
Ctr. for Vital Longevity., Sch. of Behavioral and Brain Sci., The Univ. of Texas at Dallas, Dallas, TX

Abstract: It is well-established that both brain structure and cognition are highly heritable and partly under genetic control. Several single nucleotide polymorphisms (SNP) that regulate dopamine have been shown to influence cognitive performance, especially executive function (EF). DRD2 C957T (rs6277), which influences postsynaptic D2 dopamine availability, negatively influences executive function performance in older and younger individuals, with C allele homozygotes (who have lower dopamine availability), performing more poorly than their T carrying counterparts (who have greater dopamine availability). It is unclear through which neural mechanisms this genetic predisposition exerts it influence on cognitive performance. Here, we sought to investigate whether the effect of DRD2 polymorphism on EF was due in part to reduced cortical thickness in target regions of dopaminergic pathways. A lifespan sample of 176 healthy participants aged 20-94 (DRD2 CC *n*=51, CT *n*=76, TT *n*=49) underwent MRI and cognitive sessions in which we obtained hi-res T1-weighted MPRAGE scans and multiple measures of executive functioning. Cortical thickness was estimated using FreeSurfer, visually inspected and manually edited, before extracting parcel thicknesses. Of the frontal and parietal

parcels, we found a significant effect of DRD2 on regional thickness in the anterior cingulate, superior parietal, and precuneus, where CC homozygotes had thinner cortex than T carriers. We formed a standardized z-score cortical thickness construct from these averaged regions. An EF construct was created from the average of Stroop, Wisconsin Card Sorting Task, Trails, and Verbal Fluency tests. Using these constructs, we specified a mediation model where DRD2 group (X) predicts EF performance (Y) through the mediation of cortical thickness (M), controlling for age (i.e., X-->M-->Y) using a bootstrap estimation approach with 5000 samples. We found that DRD2 significantly predicted cortical thickness and that cortical thickness significantly predicted executive function. Importantly, cortical thickness also demonstrated significant mediation of the association between DRD2 and EF. C carriers have thinner fronto-parietal cortex and this DRD2-related thinning was associated with poorer EF. These findings help elucidate the role of brain structure as an underlying contributor to the link between risk for lower dopamine availability and poorer executive function across the adult lifespan.

Title: Differential effects of healthy aging on directed and random exploration

Authors: *J.-M. MIZELL, S. WANG, M. FRANCHETTI, W. KEUNG, M. H. SUNDMAN, Y.-H. CHOU, G. E. ALEXANDER, R. C. WILSON
Psychology, Univ. of Arizona, Tucson, AZ

Abstract: The explore-exploit tradeoff is a fundamental behavioral dilemma faced by all adaptive organisms. Should we explore new options in the hopes of finding a better meal, a better house or a better investment vehicle for our savings, or should we exploit the options we currently believe to be best? Recently, we have shown that young adults solve the explore-exploit dilemma using a mixture of two strategies: “directed exploration”, in which a competition between information seeking and ambiguity aversion drives exploration by choice, and “random exploration”, in which adaptive behavioral variability drives exploration by chance. In addition, work in adolescents has found that directed, but not random, exploration increases with age between the ages of 12 and 18. In this work we investigated whether explore-exploit behavior continues to change in old age.

Our preliminary data from older adults (n = 29, ages 65-74) suggests that explore-exploit behavior continues to change throughout the lifespan. In particular, compared to 284 healthy younger adults (ages 18-22), these data suggest that healthy aging is associated with substantial changes in explore-exploit behavior. In particular, we found that older adults showed higher ambiguity aversion overall ($p < .0001$), suggesting that they were less likely to choose an unknown, exploratory, option in general. However, we also found that older adults could overcome this ambiguity aversion through *increased* directed exploration in situations where exploration had value ($p < .05$). In contrast to this increase in directed exploration, we found a trend towards reduced random exploration, ($p = 0.07$) in older adults. The finding that ambiguity aversion changes as a function of age is consistent with previous findings in the decision-making literature. However, it is surprising that directed exploration appears to continue increasing into old age. One reason for this could be a possible relationship between directed exploration and temporal discounting which, at least in theory, suggests a negative relationship between discounting and directed exploration. It is well known that older adults discount future rewards less than young people and such an relationship could explain our effect. The finding that directed exploration has a different age dependence to random exploration is consistent with a number of recent findings suggesting that directed and random exploration rely on dissociable systems in the brain.

Title: The impact of habitual sleep quality on memory-related neural oscillations in young and olde adults

Authors: *E. HOKETT[1], A. L. DUARTE[2]
[1]Georgia Tech., Atlanta, GA; [2]Georgia Inst. Technol., Atlanta, GA

Abstract: Research has shown that sleep is essential for memory consolidation. However, the effects of habitual sleep quality on memory performance are unclear, especially regarding age-related differences in brain function. We hypothesized that sleep quality would be significantly related to retrieval-related EEG and memory performance across age groups. We investigated this relationship in young and older adults using one week of sleep data collection, a paired-

associate memory task, and retrieval-related electroencephalography (EEG). We found that memory accuracy was positively correlated with sleep quality across age groups. In addition, we found relationships between measures of sleep quality and measures of oscillatory power that supported memory performance. For older adults, there was a negative trend for sleep fragmentation (SF) and retrieval-related theta synchronization for associative hits, an index of recollection-based memory. That is, lower SF was correlated with greater theta synchronization. Both SF and theta power correlated with memory accuracy such that lower SF and greater theta power supported better memory. Moreover, we found a significant relationship across age with alpha desynchronization and memory accuracy; alpha desynchronization has been found to be associated with memory retrieval. We also found trends that suggest a relationship between sleep quality and alpha desynchronization. While our data suggests that sleep quality is important for memory performance in both young and older adults, older adults may be particularly sensitive to sleep quality. Prior research has shown that lifestyle factors such as maintaining good sleep quality and moderate physical activity may improve memory in older adults. Consistent with these findings, we found that sleep quality was positively associated with associative memory. This study extends the current literature with the finding that good sleep quality may support greater functional activity in neural correlates important for memory accuracy.

Title: Co-localization of eqtl and gwas in schizophrenia

Authors: *L. MA[1], S. CHETTY[1,2]
[1]Dept. of Psychiatry and Behavioral Sci., [2]Inst. for Stem Cell Biol. and Regenerative Med., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Schizophrenia is a debilitating psychiatric condition affecting roughly 0.7% of adults. It is highly heritable and polygenic. A recent genome-wide association study identified 145 loci that confer risk for schizophrenia, but the underlying mechanisms remain largely unknown. Our overarching goals in this study are to identify mechanisms that underlie genetic risk by investigating the role of disease related SNPs on regulating gene expression. Dorsolateral prefrontal cortex (DLPFC) has been demonstrated to be associated strongly with schizophrenia. In this study, we use RNA sequencing and whole exome sequencing data generated from 121 human postmortem brain DLPFC samples (85 males and 36 females; 14 African American and 107 Caucasian; 23-70 years old, mean = 58, SD = 10) originating from tissue collections of the

GTEx consortium. Gene counts were based on GENCODE Release 19 (GRCh37.p13), 56,203 transcripts in total. Genes with average RPKM < 0.01 were excluded. A total of 153,970 SNPs were retained after filtering SNPs that did not fulfill HWE at p-value < 1e-50 and MAF < 0.01. We modeled expression after transforming with log2 with an offset of 1 by liner regression. We performed eQTL analyses using the MatrixEQTL by allowing for a 1MB window around each SNP, and adjusting for age, sex, race and RIN. A total of 5,753,977 eQTLs were identified, in which 545 genes are strongly associated with SNPs (p-value < 1e-8). Then, we performed overrepresentation enrichment analysis using WebGestalt. Interestingly, pathways involved in human metabolism are significant: glutathione metabolism (PValue=2.95e-04; FDR=8.95e-02), drug metabolism (PValue=9.86e-04; FDR=0.102), and metabolism of xenobiotics by cytochrome P450 (PValue=1.27e-03; FDR=0.1.02). Using the gene sets, our human lifespan expression analysis across 6 brain regions by using BrainSpan datasets showed that they have a low abundance in fetus, but higher abundance in late infancy stage across amygdala, cerebellum, cortex, hippocampus, and striatum. Another abundant event occurs during adulthood across the hippocampus and striatum. To assess gene expression alteration by schizophrenia risk loci, we co-localized the 5 million eQTL results and 8 million schizophrenia GWAS summary statistics and obtained 4 million eQTLs that could be used for subsequent analyses. Six candidate genes (*U3*, *AL022393*.7, *HCG4*, *HLA-DQB1*, *HLA-DQB2* and *CYP2D6*) were identified after using stringent filtration on eQTL at p-value < 1e-8 and GWAS at p-value < 1e-8 for further assessment. In summary, our findings provide new targets for modeling schizophrenia risk at the molecular level.

Title: Parallel enhancer analysis in mouse brain to characterize regulatory variants in development and disease

Authors: *J. L. HAIGH[1], L. SU-FEHER[1], I. ZDILAR[1], K. J. LIM[1], D. M. QUINTERO[1], S. J. MORSE[1], T. W. STRADLEIGH[1], K. HINO[2], S. SIMO[2], L. C. BYRNE[3], A. S. NORD[1]
[1]Dept. of Neurobiology, Physiol. and Behavior, [2]Dept. of Cell Biol., Univ. of California, Davis, Davis, CA; [3]Dept. of Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Enhancers are cis-regulatory elements with the capacity to promote gene expression both spatially and temporally. Their activity is critical in the development of the brain and sequence variation in these regions has been linked to neurological disorders including autism spectrum disorder, epilepsy and schizophrenia (SCZ). The advancement of massively parallel reporter assays has enabled the functional characterization of enhancers both in vitro and in vivo. We adapted one such assay, STARR-seq, for in vivo delivery into the mouse brain. In a plasmid using a minimal promoter the candidate sequence is placed in the 3' untranslated region of a reporter gene, as such enhancers can be identified by RNA-seq since they will be transcribed if active. We developed a pilot library of genomic candidates containing common non-coding sequence variants associated with epilepsy and SCZ. The library was delivered to postnatal mouse brain via adeno-associated virus, and genomic DNA and total RNA collected. Results from preliminary studies suggest this method is able to identify sequences capable of acting as enhancers in in vivo mouse brain. We have further developed this method to test enhancer function at embryonic time points using in utero electroporation (IUE). A SCZ-associated regulatory element in the intron of the calcium channel subunit gene CACNA1C was validated via IUE, showing that it drives gene expression in E17.5 cerebral cortex. These methods allow us to rapidly screen libraries of DNA sequences for enhancer activity in vivo, with the further potential to identify whether these variants contribute to altered gene expression in the brain. Such functional examination of enhancers will be critical toward understanding how non-coding sequence variation in human populations contributes to brain development and neurological and psychiatric disorders.

Title: Regulatory changes or alterations in cellular proportions? Re-evaluation of pathways affected in psychiatric disorders in light of cell type proportion changes

Authors: *L. TOKER[1], O. MANCARCI[2], S. TRIPATHY[2], P. PAVLIDIS[3]
[2]Psychiatry, [1]Univ. of British Columbia, Vancouver, BC, Canada; [3]Psychiatry, Univ. British Columbia, Vancouver, BC, Canada

Abstract: High-throughput expression techniques are widely used to study neuropsychiatric and neurodevelopmental disorders. A major challenge of these studies is understanding the functional impact of the identified genes and the biological pathway underlying the observed changes. At the current state of the field, the majority of studies are based on bulk tissue samples, and it was previously noted that fluctuations in cellular abundance can induce a pronounced transcriptional signature in bulk tissue data. Thus, it is crucial to understand which part of the transcriptional pattern is driven by changes in cellular abundance (e.g, due to cellular death or inflammation) and which part can be attributed to regulatory events.
We have previously reported marker-genes for multiple cell-types based on NeuroExpresso, a database of brain cell-type transcriptomes. Here, we used these genes to estimate changes in cellular abundance in 11 bulk-tissue expression datasets, representing six independent cohorts of subjects with bipolar disorder and schizophrenia. We next performed differential expression and enrichment analyses in these datasets, accounting for the estimated cellular proportion changes. We observed a robust decrease in marker-gene profiles (MGPs) of fast-spiking PV cells and an increase in marker-gene profiles of astrocytes in subjects with both psychiatric disorders. Based on analysis of mouse and human developmental data, we demonstrate that the changes in fast-spiking PV interneurons are not likely to represent defects in maturation of these cells.
We next looked at the correlation of genes previously reported to be affected in brains of subjects with schizophrenia with the estimated proportion of astrocyte and fast spiking PV cells. We found that the majority of the over- and underexpressed genes are highly correlated with astrocyte and fast spiking PV cell MGPs, respectively. Moreover, while mitochondrial genes were highly enriched among the downregulated genes in data not adjusted for MGPs, this enrichment was not observed when MGPs were included in the model. This could be explained by overexpression of mitochondrial genes in fast spiking PV cell transcriptomes, as we report based the cell-type specific data in NeuroExpresso.
Our results suggest that the pathophysiology of bipolar-disorder and schizophrenia involves changes in astrocytes and fast-spiking PV cells and highlights the need to account for cellular changes in bulk tissue expression data.

Title: A protein interaction network in human neurons of risk factors incriminated by genetics in schizophrenia

Authors: *E. NACU[1], A. KIM[2], W. CROTTY[1], E. MALOLEPSZA[2], N. PETROSSIAN[2], K. LILLIEHOOK[2], J. JAFFE[2], K. EGGAN[1,2], K. LAGE[2,1]

Abstract: Genetic studies of psychiatric disorders have provided us with putative risk factors implicated in those disorders. A 2004 GWAS study of schizophrenia has implicated 108 gene loci in the disease with some of the loci containing only a single gene and some containing multiple genes, giving estimates of more than 400 putative risk genes. Given this plethora of putative risk factors, we decided to build an interaction network of the risk proteins with the aims of (1) identifying molecular interactors of each of the risk factors, (2) uncover risk factors that are connected through their interactors and thus potentially are part of a pathological pathway, and (3) discover risk factors from multi-genic loci that are part of the network and thus potentially the relevant gene for the disease in that locus. To build the network we took the approach of performing co-immunoprecipitaton (co-IP) of risk proteins from human patterned induced Ngn2 neurons (piNs) that are cortical glutamatergic excitatory-like. We started our study with the schizophrenia GWAS hits, prioritizing risk proteins based on whether they were in a single gene locus, have been implicated in psychiatric disorders in other studies, and were expressed in iNgn2 neurons. We have performed 17 IPs of 6 different risk proteins at different time points of maturations of piNs. As an example, we identified a total of 304 interactors of CACNA1C as compared to 54 of the known interactors of CACNA1C found in InWeb. Furthermore, among the 304 interactors we identified 21 interactors implicated in other psychiatric or developmental disorders.We then created an interaction network of all identified interactors, and integrated our network with genes located in schizophrenia GWAS loci to uncover interesting direct connections between putative schizophrenia risk factors. One exciting connection is between CACNA1C and C4 that we are currently pursuing.

Title: Synaptic protein-protein interactions in schizophrenia

Authors: *A. FUNK[1], G. LABILLOY[2], K. GREIS[1], J. MELLER[2], R. E. MCCULLUMSMITH[1]
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Cincinnati Children's, Cincinnati, OH

Abstract: Background: Mounting genetic, proteomic, and biochemical evidence indicate rare mutations, abnormal protein-protein interactions, and altered synaptic signaling pathways may be at the root of the severe phenotypes seen in patients with schizophrenia. A major area yet to be fully elucidated is the understanding of the complex synaptic protein-protein interactions in normal and pathological conditions. Increasing focus has been directed toward the NMDAR and PSD-95 protein-protein interactomes, members of which are identified as high-yield risk factors for the development of schizophrenia. PSD-95 is the most abundant scaffolding protein in the PSD, with well characterized protein-protein interactions that modulate the trafficking of glutamate receptors and other PSD constituent proteins relevant for synaptic plasticity.
Methods: Magnetic dynabeads conjugated with anti-PSD-95 antibody were used to isolate PSD-95 protein complexes from 10 control and 10 schizophrenia dorsolateral prefrontal cortex samples. The complexes were eluted from the beads and processed for data-independent acquisition (DIA) LCMS/MS analysis on an ABSciex 5600+ mass spectrometer.
Results: Bioinformatic analyses revealed increased DNA and RNA processing in schizophrenia. Additionally, the data show upregulation of protein and glucose metabolism along with increased signaling through PKA, PKC, SRC, MAPK1, and CSNK2. Pathway analyses indicate integrin signaling, glycolysis, synaptic vesicle trafficking, and cytoskeletal rearrangement are all dysregulated in schizophrenia.
Conclusions: Our data reflect cutting-edge efforts in the field of psychiatry on schizophrenia research. These data indicate significant abnormalities of synaptic protein-protein interactions which indicate the disruption of important signaling, trafficking, and metabolic pathways for normal neurological function.

Title: Effects of risperidone on the proteome in olfactory cells from individuals with schizophrenia and at-risk for the illness

Authors: *K. BORGMANN-WINTER[1,3], M. DSOUZA[1], S. BANDYOPADHYAY[1], N. MIRZA[4], M. CALKINS[2], B. TURETSKY[2], C.-G. HAHN[1]
[1]Dept Psychiatry, [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Dept. of Otolarnyngology, Head and Neck Surgery, Hosp. of the Univ. of Pennsylvania, Philadelphia, PA

Abstract: Olfactory dysfunction has been well characterized in patients with schizophrenia and more recently in younger subjects who are at-risk for developing psychosis. Molecular underpinnings of olfactory dysfunction, however, are largely unknown in schizophrenia or during the prodromal period. Previously, we examined odorant and neurotransmitter induced receptor-G protein coupling in olfactory neuroepithelial (ON) cells from subjects with schizophrenia and found G protein activation decreased in response to odorants but increased in response to dopamine. Subjects at at- risk for the illness did not show similar changes in G protein signaling yet showed alterations in molecules critical for odorant signaling. In this study we examined the expression of proteins that are enriched in synapse, mitochondria and signaling molecules using quantitative proteomics in vitro ON cells derived from ten schizophrenia and 8 at-risk subjects and their matched controls and tested the effects of antipsychotic treatment. Method: Olfactory neuroepithelial cells from eight antipsychotic treatment free at- risk subjects and ten schizophrenia subjects, each with controls matched for age and sex were examined. Cell cultures from all groups were treated with and without 50nM for risperidone for 7 days. Tenμg of cellular extracts after exclusion of nuclei were mixed with [13C6]lysine-labeled internal standards. Samples were trypsin-digested, and processed for LC-SRM/MS on a triple quadrupole mass spectrometer for 200+ proteins. Peak areas for “light” endogenous peptides and “heavy” standardpeptides were calculated, and ratios (l/h) between the two were used as dependent variables. Between group differences were examined for the effects of diagnosis as well as for risperidone treatment. In patients with schizophrenia, risperidone treatment significantly altered peptides representing 54 proteins and while it altered 48 proteins in control subjects. Interestingly, risperidone treatment of the same concentration and duration induced changes in a much smaller number of proteins in cell cultures from at-risk subjects and their matched controls. These together suggests differential responses to proteins expression between patients with schizophrenia and at-risk for the illness.

Title: Abnormalities of glucose metabolism in schizophrenia

Authors: E. MCCULLUMSMITH[1], C. R. SULLIVAN[2], *R. E. MCCULLUMSMITH[1], A. FUNK[1], S. M. O'DONOVAN[3]
[2]Psychiatry, [3]Psychiatry and Behavioral Neurosci., [1]Univ. of Cincinnati, Cincinnati, OH

Abstract: Schizophrenia affects approximately 1% of the world's population and is a severe mental illness associated with cognitive deficits. Alterations in the brain in schizophrenia include changes in glutamate and GABA neurotransmission, in a manner that suggests diminished energy supply in these systems. Based on prior work in our laboratory, we extended our studies of glycolysis in postmortem brain to include molecules that had not previously been evaluated in this illness. We used QPCR to assess mRNA expression for hexokinase 2 (HXK2), phosphoribosyl pyrophosphate synthetase 2 (PRPS2), and phosphorylase kinase regulatory subunit beta (PHKB) in the dorsolateral prefrontal and anterior cingulate cortices of subjects with schizophrenia (n = 16) and normal controls (n = 16). We also assessed expression of these transcripts in an animal model of schizophrenia, the GluN1 knockdown mouse. We found increased expression of HXK2 (35%, $P < 0.05$), PHKB (40%, $P < 0.05$), and PRPS2 (50%, $P < 0.05$) in the frontal cortex of the GluN1 knockdown mouse compared to wild type animals. Expression levels for these transcripts in schizophrenia will be presented. We will also present correlations between clinical dementia ratings (CDR) and mRNA expression. Our data inform the hypothesis that glycolytic pathways are dysregulated in schizophrenia, and offer insights for an animal model of schizophrenia that may be utilized to further explore the pathophysiology of this illness.

Informatics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: A growing body of evidence suggests abnormal bioenergetic function in chronic schizophrenia. Bioinformatic analyses can address important biological questions without using valuable resources, offering insights on the connectivity of biological networks in human disease. We examined glycolytic pathways in pyramidal neurons and astrocytes in the dorsolateral prefrontal cortex in control and schizophrenia subjects (n=16/group) using laser capture microdissection coupled with quantitative real-time polymerase chain reaction (t-test analysis). We next built a disease signature in the Library of Integrated Network-based Cellular Signatures web portal (iLINCS) based on selectively downregulated glycolytic enzymes in schizophrenia. We developed a discovery based workflow to identify of drug perturbagens likely to “reverse” this disease signature. Finally, we administered a candidate drug to the GluN1 knockdown model of schizophrenia (n=4-9 per group) and examined sensorimotor gating, social and anxiety related behaviors, locomotor activity, and executive function. Behavior data were analyzed using 2-way ANOVA with Bonferonni multiple comparison corrections. We found a decrease in mRNA expression of several glycolytic enzymes in pyramidal neurons in schizophrenia (phosphofructokinase muscle ($p=0.003$, 22%), phosphofructokinase liver ($p=0.010$, 27%), glucose phosphate isomerase ($p=0.015$, 26%)). We identified 12 unique drug perturbagens likely to reverse the schizophrenia signature in iLINCS. Of these perturbagens, PPAR agonists presented as promising therapeutic targets. We found that administration of the PPAR agonist pioglitazone in GluN1 knockdown animals selectively restored explicit memory ($p<0.01$). Taken together, these analyses build upon previous reports of glycolytic defects in schizophrenia, and suggest possible mechanisms to restore these deficits and cognition include PPAR agonist intervention.

Title: Exploratory use of machine learning to model metabolic outcomes based on genetic risk factors in patients with schizophrenia

Authors: *A. C. BASU[1], S. R. STOCK[2], G. W. CAVANAUGH[1], M. YU[2], D. C. HENDERSON[3,4]
[1]Psychology, [2]Mathematics and Computer Sci., Col. of the Holy Cross, Worcester, MA; [3]Psychiatry, Boston Univ. Sch. of Med., Boston, MA; [4]Psychiatry, Massachusetts Gen. Hosp., Boston, MA

Abstract: Metabolic symptoms adversely affect overall health and shorten life expectancy in schizophrenia. The relative contributions of genetics, behavior, and antipsychotic drugs to metabolic risk are not well-understood. We modeled risk of various metabolic outcomes based on genetic, demographic, and clinical covariates using data collected from 306 patients recruited from the Freedom Trail Clinic at Massachusetts General Hospital. Classification trees were used to group patients into homogeneous metabolic risk categories. Classification tree analysis is a nonparametric statistical method that handles variable selection among highly correlated covariates, can accommodate complex interactions among covariates, and provides easily interpretable results in the form of a decision tree. To avoid overfitting from this small data set, we selected the most parsimonious classification tree that was within 1 standard error of the lowest error overall. Single Nucleotide Polymorphisms (SNPs) identified as putative genetic risk factors for diabetes by a previous genome-wide association study emerged as useful covariates in the grouping of patients according to risk for abdominal obesity (high waist circumference), chronic hyperglycemia (high glycated hemoglobin), and insulin resistance (according to homeostatic model assessment). The allelic variants associated with diabetes risk in previous studies also were associated with risk in our study, indicating that genetic risk for metabolic disease follows a similar pattern in the special sample of antipsychotic-treated schizophrenia patients as in the general population. In the classification tree for risk of abdominal obesity, a SNP allowed for further classification of patient risk with respect to different classes of antipsychotic drugs. Thus, our results from this exploratory study suggest that genetic screening may prove useful for personalized clinical decision making and treatment management in the

context of schizophrenia. A larger patient sample will be required to establish and validate a robust clinical decision-making tool.

Title: Inhibition of brain and liver kynurenine aminotransferase ll activity by N-acetylcysteine in rodent, pig and human

Authors: *K. V. SATHYASAIKUMAR[1], T. BLANCO AYALA[1], A. E. S. FOO[1], M. A. R. THOMAS[1], L. S. PIDUGU[2], R. SCHWARCZ[1]
[1]MPRC, Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Biochem. and Mol. Biol., Univ. of Sch. of Med., Baltimore, MD

Abstract: Kynurenic acid (KYNA), a metabolite of the kynurenine pathway of tryptophan degradation, is increasingly understood to play an important role in the mechanism(s) underlying normal and abnormal cognitive processes, most likely by acting as an antagonist of α7 nicotinic and NMDA receptors. Specifically, elevated KYNA levels are detrimental in psychiatric diseases such as schizophrenia. KYNA is synthesized from its immediate precursor kynurenine - either by non-enzymatic oxidation or through irreversible enzymatic transamination by kynurenine aminotransferases. In the mammalian brain, kynurenine aminotransferase II (KAT II) is the principal enzyme responsible for the neosynthesis of rapidly mobilizable KYNA. KAT II therefore constitutes an attractive target for pro-cognitive interventions (Schwarcz et al., 2012). N-acetylcysteine (NAC), a brain-penetrant drug with pro-cognitive efficacy in humans, including individuals with schizophrenia, has been proposed to exert its actions by increasing the levels of the endogenous anti-oxidant glutathione (GSH) in the brain (Steullet et al., 2016). We now examined a possible alternative mechanism of NAC action, namely KAT II inhibition. Using a well-established assay (Sathyasaikumar et al., 2013), we first tested the effect of NAC on KAT II activity in liver and brain tissue homogenates from mice, rats, pigs and humans *in vitro* and observed IC_{50} values in the high micromolar to the low millimolar range. Using pure human recombinant KAT II protein, NAC was found to inhibit enzyme activity with an IC_{50} of ~500 μM, while GSH was approximately 40 times less potent (IC_{50} >20 mM). By microdialysis in the medial prefrontal cortex (mPFC) of unanesthetized adult rats, we next examined the effect of

NAC on the neosynthesis of KYNA from peripherally administered kynurenine (50 mg/kg, i.p.) *in vivo*. To this end, NAC (20 mM) was locally applied by reverse dialysis for a period of 6 h. 120 min after starting the perfusion, kynurenine was administered systemically while NAC perfusion continued for the remaining 4 h. In separate animals, NAC was administered systemically twice (500 mg/kg, i.p., each; 120 and 60 min before the administration of kynurenine). NAC reduced the *de novo* production of KYNA from its immediate precursor by ~45% and ~50%, respectively, in the two experimental paradigms. Taken together, these results raise the possibility that NAC exerts its neurobiological effects at least in part by reducing cerebral KYNA levels via KAT II inhibition.

Title: Effects of acute tryptophan depletion on blood kynurenic acid concentrations and reinforcement learning performance in individuals with schizophrenia

Authors: *F. M. NOTARANGELO, J. A. WALTZ, M. A. R. THOMAS, K. V. SATHYASAIKUMAR, Y. MURTAZA, A. K. WELLS, R. R. RUIZ, R. SCHWARCZ
Maryland Psychiatric Res. Center, Dept of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: An excess of kynurenines has been associated with cognitive dysfunction in schizophrenia (SZ) and other forms of mental illness. Because over 95% of dietary tryptophan is metabolized into kynurenines, such as L-kynurenine ("kynurenine") and kynurenic acid (KYNA), acute tryptophan depletion (ATD) is one potential method for manipulating kynurenine levels in human subjects. Although studies have revealed effects of ATD on learning and memory, it is not known if those effects stemmed from changes in the levels of kynurenines or serotonin, and ATD has so far been used in only a small number of studies involving SZ patients. Using a double-blind within-subject crossover design, we administered 16 SZ patients both an ATD challenge and a balanced (BAL) amino acid load (in two separate sessions, at least a week apart, in randomized order). In each session, we collected samples of saliva and blood at baseline, 90 and 180 minutes after mixture consumptions and measured tryptophan, kynurenine, KYNA and the serotonin metabolite 5-hydroxyindoleacetic acid. Participants also performed a

probabilistic reinforcement learning (PRL) task 180 minutes after administration. Following a training phase, in which two Gain stimulus pairs (involving either positive or neutral feedback) and two Loss-avoidance stimulus pairs (involving either negative or neutral feedback) were presented in an interleaved fashion for 160 trials, participants indicated their valuation of the stimuli in the absence of feedback in a Test/Transfer phase. We found that SZ patients exhibited better PRL performance under ATD [$F(1,15) = 7.014$, $p = 0.018$] than after consuming the BAL ("tryptophan-loading") drink. Furthermore, PRL performance following consumption of the BAL drink correlated significantly ($r = -0.540$, $p = 0.031$) with the intra-session change in KYNA levels, such that patients showing the worst performance displayed the greatest KYNA increases. The performance advantage shown by patients under ATD also correlated significantly ($r = 0.515$, $p = 0.041$) with the full dynamic range of KYNA levels, such that patients experiencing the greatest performance advantage showed the greatest KYNA dynamic range. These results support the idea that acute modulation of kynurenine levels in the body has subtle effects on cognitive performance, with patients deriving benefits from reductions in KYNA levels. These results point to the kynurenine pathway in the brain as a potential target for therapeutic agents.

Title: Prenatal THC exposure permanently disturbs kynurenic acid and glutamate levels and amplifies the responsivity to an acute kynurenine challenge in the rat prefrontal cortex

Authors: *S. BEGGIATO[1], L. FERRARO[1], R. SCHWARCZ[2]
[1]Life Sci. and Biotech., Univ. of Ferrara, Ferrara, Italy; [2]Maryland Psychiatric Res. Ctr., Baltimore, MD

Abstract: Throughout the world, cannabis remains one of the most widely used illicit drugs during pregnancy (Porath-Waller, 2015). The main psychoactive component of marijuana (delta9-tetrahydrocannabinol, THC) passes through the placenta, and its use is correlated with early physiological effects in the offspring. Neurobehavioural and cognitive impairments have been reported in several longitudinal studies on children and adolescents prenatally exposed to

marijuana (Calvigioni et al., 2014), and a link to psychiatric disorders has been proposed (Jutras-Aswad et al., 2009; Mathews et al., 2014). Prenatal exposure to cannabinoids induces cognitive deficits in rat offspring (Ferraro et al., 2009) and is associated with alterations in cortical/hippocampal glutamate and GABA levels (Antonelli et al., 2005, Beggiato et al., 2017). Interestingly, the deleterious effects of cannabinoids on cognitive functions are similar to those observed in adult rats prenatally exposed to (L)-kynurenine (KYN), which is the direct bioprecursor of kynurenic acid (KYNA), a neuroactive metabolite of tryptophan degradation (Pocivavsek et al., 2014). We therefore investigated whether alterations in KYNA levels in the rat brain might play a role in the long-term consequences of prenatal cannabinoid exposure. Pregnant Wistar rats were treated daily with THC [5 mg/kg or vehicle (sesame oil) by oral gavage] from gestational day (GD) 5 through GD 20. One adolescent [postnatal day 35-45] and one adult male rat per litter was then used to determine the extracellular levels of KYNA and glutamate before and after a challenge with KYN (5 mg/kg i.p.) by in vivo microdialysis in the medial prefrontal cortex (mPFC). Compared to vehicle-treated controls, extracellular basal KYNA levels were higher in adolescent and adult rats that had been prenatally treated with THC ($p<0.01$; $p<0.05$, respectively). These rats also had lower extracellular glutamate levels than respective controls ($p<0.01$; $p<0.05$, respectively). Following a challenge with KYN, extracellular KYNA levels increased in both adolescent groups (i.e. vehicle- and THC-treated; $p<0.05$) Interestingly, this effect was more pronounced in adult rats which had been prenatally exposed to THC. KYN also caused a trend towards a reduction in extracellular glutamate levels in vehicle-treated adolescent and adult rats. We propose that these permanent alterations in KYNA and glutamate signalling in the mPFC of prenatally THC-exposed rats could be relevant for cognitive dysfunction. Our results are also in line with the hypothesis that a “double-hit” may precipitate psychiatric disorders such as schizophrenia later in life.

Title: Perivascular and putative parenchymal macrophages are increased in people with schizophrenia who also demonstrate signs of cortical inflammation

Authors: *H. Q. CAI[1,2], V. S. CATTS[1,2], M. J. WEBSTER[3], C. S. WEICKERT[1,2]
[1]Neurosci. Res. Australia, Sydney, Australia; [2]Sch. of Psychiatry, Univ. of New South Wales, Sydney, Australia; [3]Stanley Med. Res. Inst., Rockville, MD

Abstract: Background: A proportion of individuals with schizophrenia are in an elevated inflammatory state and express increased levels of intercellular adhesion molecule-1 (ICAM1) in the cortex. ICAM1 is involved in leukocyte transmigration and the elevation found in the prefrontal cortex in schizophrenia suggests more peripheral immune cells could adhere to the brain endothelium and potentially enter the brain. The aim of this study was to investigate if immune cells can be identified in prefrontal cortex of people with schizophrenia using immunohistochemistry for macrophages.
Methods: Gene expression for a macrophage marker CD163 (cluster of differentiation 163) and for a microglia marker, IBA1, was measured using qPCR in the prefrontal cortex of 37 people with schizophrenia and 37 controls. We further defined "high inflammation" and "low inflammation" schizophrenia and control subgroups based on mRNA expression of inflammation-related genes in the prefrontal cortex. Fresh frozen sections of orbital frontal cortex (14µm) were obtained from 38 schizophrenia and 38 control cases. 3,3-Diaminobenzidine immunohistochemistry was used to localize CD163 while immunofluorescence was used to determine the anatomical relationship between CD163+ cells and collagen-IV, a vascular membrane marker. Immunoreactivity was qualitatively assessed blind to diagnosis by microscopically scanning an entire bank of the gyrus rectus.
Results: IBA1 mRNA levels did not differ between diagnostic groups or inflammatory groups. CD163 mRNA did not differ according to diagnosis, but was elevated in "high inflammation" schizophrenia compared to "low inflammation" schizophrenia and controls. Immunofluorescence double labelling confirmed CD163+ cells occur in blood vessels, the perivascular space and on the parenchymal side of the lumen in both schizophrenia and control brains. CD163+ cells were present in the parenchyma in close association with neurons and not clearly associated with any blood vessels in 6% of "low inflammation" controls, 9% of "low inflammation" schizophrenia cases and 43% of "high inflammation" schizophrenia brains.
Conclusion: We provide evidence that CD163+ macrophages are elevated and are more frequently found in the parenchyma in people with schizophrenia who also have increased cytokines. As CD163+ macrophages were found away from blood vessels, they may be capable of infiltrating the parenchyma and interacting directly with neurons. These peripheral immune cells residing in the cortex, in addition to microglia, may be producing inflammatory factors to further drive the inflammatory cascade by signalling between astrocytes and the endothelium.

Title: Topographic biomarkers reveal defective neurovascular units in schizophrenia

Authors: *S. YEO, J. YOON, H.-J. JUNG, Y. CHOI, D. KIM, S. CHOI, Y. CHOE
Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: Schizophrenia (SZ) is known as developmental alterations of synapse structures that lead to the deterioration of the neural circuit functions. Thus, drugs targeting the disease have been based on studying several neuron-specific candidate genes such as Disc1, Shank3 and Ube3b. To expand our understanding of SZ, we questioned abnormal subcellular targeting of functional proteins might represent the underlying mechanism for the disease. To reveal the topographic proteomic landscape and subcellular protein localization in SZ neurons, we utilized human SZ patient derived-olfactory epithelial cells (hOE). hOE are easy to obtain, cultivate, well polarized, and most importantly differentiate into neurons during development. We compared proteomic profiles of hOE derived from normal donors and SZ donors. To categorize subcellular localization of proteins, we analyzed fractionated hOE proteins. Interestingly, several neurovascular proteins showed significant changes in their subcellular localization. These neurovascular protein expressions were also defective in Disc1 mutant mouse brains. These results imply that the abnormal development of neurovascular structures may contribute to the SZ neural dysfunction.

Title: Plasma metabolites on first-onset psychosis: Schizophrenia and bipolar disorder biomarkers

Authors: *H. P. JOAQUIM, A. C. COSTA, L. L. TALIB, W. F. GATTAZ
Psychiatry Intitute HCFMUSP, Lim-27, São Paulo, Brazil

Abstract: Background: Schizophrenia (SCZ) and bipolar disorder (BD) are severe psychiatric disorders and share many characteristics and symptoms since the first-onset. Identify molecular biomarkers for psychiatric disorders can assist in the diagnosis of disease and treatment and monitoring of patients. **Methods:** Plasma metabolites were quantified with a targeted quantitative and quality controlled metabolomics approach using the AbsoluteIDQ® p180 Kit (BIOCRATES Life Science) followed by mass spectrometer operating in the MRM mode. Data analysis was performed using the MetIDQ software (Biocrates) and Metaboanalyst version 3.0. **Results:** 37 metabolites were different between the groups: 5 Lyso- phosphatidylcholines, 11 phosphatidylcholines, 6 acylcarnitines, 1 sphingomyelin, 10 amino acids and 4 biogenic amines. Analyzing the pathways, we found three metabolites alterated: Nitrogen metabolism (FDR = 4.8 x 10-3), Arginine and proline metabolism (FDR = 4.8 x 10-3) and Aminoacyl-tRNA biosynthesis (FDR = 1.66 x 10-6). In order to determine the 5 main metabolites able to differentiate the diagnosis, ROC curves were used. Considering SCZ patients and healthy controls, the area under the curve (AUC) was 0.534, applying metabolites Met-SO, Gly, LysoPCaC26:1, C16-OH; PCaaC40:3. Considering BD patients and healthy controls the AUC was 0.947, applying metabolites t4-OH Pro, Creatinine, PCaaC24:0; PCaaC26:0 and LysoPCaC26:0. Considering SCZ and BD patients the AUC was 0.921, applying metabolites t4-OH-Pro; C16:2-OH; C3-OH; PCaaC36:1 and Met. **Discussion:** Our results clearly show that different classes of metabolites are implicated in both schizophrenia and bipolar disorders comparing to healthy controls. Besides that, we observed that the metabolites implicated in each disorder are not the same since the first onset psychosis.

Abstract: The mechanisms underlying schizophrenia (SZ), one of the most severe and debilitating mental health disorders, are not well understood. Studies and clinical evidence suggest that multiple environmental and genomic risk factors contribute to the risk of developing SZ. As such, preclinical animal models do not fully recapitulate the complexity of the disease and can be only used to characterize specific endophenotypes associated with disease presentation. Integrative translational approaches that include *in vitro* models and fine-tuned human genetic studies are therefore necessary to elucidate the contribution of these genomic risk factors to endophenotypes of SZ. Emerging evidence indicates that dysregulation of the protein kinase B (AKT)/glycogen synthase kinase 3β (GSK3β) pathway is a risk factor for SZ. As such, there is a need to understand the molecular targets of this pathway. We have previously shown that GSK3β regulates the complex assembly and protein:protein interactions (PPI) within the voltage-gated sodium (NaV) channel complex at the axon initial segment (AIS), the molecular determinant of neuronal excitability. Based on this premise we hypothesized that dysfunction of the GSK3/AKT pathway could disrupt PPI of the AIS and excitability that could recapitulate molecular endophenotypes of SZ. Using a split-luciferase in-cell assay we have reconstituted the PPI complex between neurofascin, an important AIS cell adhesion molecule, and NaV channels and found that this interaction increases by increasing the level of active GSK3. By integrating genomic and functional studies neurons differentiated from induced pluripotent stem cells (iPSCs) from a small, homogeneous population with SZ we have also found a decrease in the mRNA level of GSK3β in SZ patients ($p<.05$, $n=11$, T-test with Welch's Corrections) compared to controls. We also identified a missense mutation in the NFASC protein associated with the disease in a combined cohort including patients from the NIMH Human Brain Collection Core ($p<.01$, $n= 424$, 1-sample test of proportions). We are currently evaluating whether changes associated with SZ and GSK3β distribution and intensity of neurofascin and Nav channels could be identified in neurons derived from patient iPSCs compared to unaffected relatives, which may underlie changes in intrinsic excitability that have previously been linked to SZ. Overall, these studies might help elucidate new endophenotypes associated with SZ due to dysregulation in the GSK3 pathway that could lead to a biological based classification of the disease and future targeted therapeutics.
This research was funded by NIMH R01 MH095995 and UT System BRAIN Initiative.

Title: Disruption of the axonal initial segment composition in schizophrenia

Authors: *M. A. ALSHAMMARI[1], T. K. ALSHAMMARI[1], J. DI RE[2], F. LAEZZA[3]
[1]Pharmacol. and Toxicology, Col. of Pharmacy, King Saud Univ., Riyadh, Saudi Arabia; [2]Neurosci. Grad. Program, Univ. of Texas Med. Br., Galveston, TX; [3]Dept. of Pharmacol. & Toxicology, Univ. of Texas Med. Br. at Galveston, Galveston, TX

Abstract: The axon initial segment (AIS) is the site of action potential initiation in neurons and a critical determinant of neuronal excitability. This highly specific subcellular domain is composed of ion channels and scaffolding proteins that include ankyrin-G, beta-IV spectrin and intracellular fibroblast growth factor 14 (FGF14). Growing evidence indicates that the appropriate recruitment of the AIS macromolecular complex is essential for synchronized firing. Studies have also shown that disruption of the AIS structure and/or mutations in its molecular components are linked to the etiology of neuropsychiatric disorders, including schizophrenia (SZ). However, until now, a phenotypic description of the AIS structure in SZ patients has remained elusive. Here we applied confocal imaging to interrogate whether any potential changes in the AIS could be identified as an endophenotype of the disease. Quantification of immunofluorescence images from the dorsolateral prefrontal cortex (DLPFC) deep layer III of post-mortem human brain tissue of SZ (n=4) versus control subjects (n=5) revealed significantly reduced (p=<0.05) expression of ankyrin-G in the soma of NeuN positive neurons in SZ (n=132 neurons) vs control (n=117). In addition, in these cells ankyrin-G and FGF14 were both significantly upregulated in SZ (n=42 AIS p=<0.05) vs control patients (n=58 AIS). This study provides the first direct evidence of previously undescribed structural changes of the AIS macromolecular complex in the human brain as a potential causative link to the biology of SZ.

Title: Dysbindin regulates axonal mitochondrial movement

Authors: *B. SUH[1], S.-A. LEE[2], C. PARK[3], S. LEE[1], S. PARK[1]
[1]Dept. of Life Sci., Postech, Pohang, Korea, Republic of; [2]SK Biopharmaceuticals, Seongnam, Korea, Republic of; [3]UCSF Sch. of Med., San Francisco, CA

Abstract: Neurons have a fine system for mitochondrial movement regulation to meet high demand of energy and calcium buffering. Therefore, specialized machineries are required to distribute mitochondria to the appropriate cellular locations through the transport system. Defects in mitochondrial transport have been reported to cause neuronal disorders, however, a detailed mechanistic link to the pathogenesis is not fully understood. We found axonal mitochondrial movement was significantly decreased in Dysbindin-deficient Sandy mice. Dysbindin, a schizophrenia susceptibility factor, shows interaction with a motor protein complex. Dysfunction of the motor protein complex resulted in reduced mitochondrial movement in neurons and it is partially rescued by Dysbindin overexpression. In addition, abnormal local calcium homeostasis was observed in neurons from Sandy mice or neurons with defects in the motor complex. These results and further investigation of the mechanism will collectively suggest that Dysbindin is involved in regulation of axonal mitochondrial movement cooperating with the transport machinery and support a potential link between mitochondrial movement and schizophrenia pathogenesis.

Title: Targeted and genome-wide approaches reveal alterations to the JAK-STAT1 transcriptional signature in psychosis

Authors: *J. K. MELBOURNE, B. FEINER, Y. PANG, M. PARK, C. ROSEN, R. P. SHARMA
Psychiatry, Univ. of Illinois At Chicago, Chicago, IL

Abstract: Changes in immune activity are widely reported in individuals with psychotic disorders. These findings, in conjunction with epidemiological data and recent research demonstrating the influence of the immune system in modulating brain activity and behavior, suggest that these alterations may be related to symptom development and exacerbation. Peripheral immune cells, particularly monocytes and macrophages, are proposed to contribute to increased levels of inflammation in psychosis. While activation of the JAK-STAT1 signaling pathway by IFN-γ is understood to induce and stabilize the monocyte and macrophage proinflammatory phenotype, there a scarcity of data on this pathway and its relation to clinical

measures in the literature. Therefore, five genes (IFNG, CXCL10, IRF1, STAT1 and TLR4) were selected as measures of the JAK-STAT1 transcriptional signature, and expression was measured in peripheral blood mononuclear cells from a cohort of 89 participants with psychosis and 44 non-psychiatric controls. These measures were assessed in relation to clinical characteristics such as illness duration and acuity. Results demonstrated a suppressed JAK-STAT1 transcriptional signature earlier in illness and with greater acuity, that increased with illness duration. Additionally, the immune modifying effects of risperidone on the JAK-STAT1 transcriptional signature were assessed using a monocyte cell line. Treatment resulted in an increase in JAK-STAT1 signature gene expression in these cells, and thus potentially contributes to the increase in expression seen with illness duration. Finally, RNA sequencing was carried out using isolated monocytes from an independent cohort of 14 participants with schizophrenia (divided into 2 illness duration categories) and 14 non-psychiatric controls. Participants in the shorter illness duration category once again had a decreased enrichment of IFN-γ response genes (JAK-STAT1 signature) compared to participants with a longer illness duration. Interestingly, an opposing pattern was seen for TNF-α via NF-κB response gene enrichment, another important proinflammatory pathway, indicating a dichotomy between these signaling systems in monocytes in psychosis that warrants further investigation.

Title: Characterization of foxo1 in the anterior cingulate cortex in schizophrenia

Authors: *E. A. DEVINE[1], S. M. O'DONOVAN[2], C. R. SULLIVAN[3], R. E. MCCULLUMSMITH[4]
[1]Psychiatry and Behavioral Neurosci., Univ. of Cincinnati Col. of Med., Cincinnati, OH; [2]Psychiatry and Behavioral Neurosci., [3]Psychiatry, [4]Univ. of Cincinnati, Cincinnati, OH

Abstract: Schizophrenia is a devastating neuropsychiatric disorder that affects approximately 1% of the world's population. Its pathology involves the dysregulation of bioenergetics including the disruption of glucose metabolism as well as changes in the AKT pathway. This decrease in glucose metabolism has been linked to cognitive deficits, a primary symptom of schizophrenia. Previous studies have shown an increase in AKT kinase activity in postmortem schizophrenia in

the anterior cingulate cortex (ACC). We hypothesize that altered AKT kinase activity will lead to dysregulation of downstream signaling targets and bioenergetic pathways, contributing to cognitive deficits associated with schizophrenia. Forkhead box O1 (FOXO1) is a transcription factor involved in the regulation of cell metabolism and promotion of gluconeogenesis. Activated FOXO1 binds to the promoter for glucose-6-phosphatase, which in turn, promotes gluconeogenesis. FOXO1 is directly phosphorylated by AKT resulting in its translocation from the nucleus into the cytoplasm, thus preventing the activation of FOXO1 and leading to the suppression of gluconeogenesis. We propose that increased AKT kinase activity in schizophrenia will lead to an increase in FOXO1 phosphorylation, reducing FOXO1 levels in the nucleus causing dysregulation of gluconeogenesis pathways leading to cognitive deficits in illness. Preliminary in silico analysis has identified cell-specific decreases in FOXO1 in neurons in a model of schizophrenia. Using postmortem ACC (Bronx-Mt. Sinai Brain Bank) from schizophrenia and control subjects (n=20 per group), we will characterize mRNA and protein expression of FOXO1 and other AKT pathway components at the region-level and cell-level in enriched populations of astrocytes and pyramidal neurons. qPCR and in-situ hybridization will be used to assay mRNA expression and localization, and Western immunoblotting and immunohistochemistry will be used to analyze protein expression and localization.

Title: Computational analysis of genetic and transcriptional landscapes of the caudate nucleus in schizophrenia

Authors: *K. J. BENJAMIN, A. PAQUOLA
Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Schizophrenia, affecting 1% of the population worldwide, is a neurodevelopmental disorder arising from altered connectivity and plasticity. Currently it is established that there are numerous and heterogeneous risk factors that contribute to schizophrenia including genetic and environmental factors. Genome-wide association studies (GWAS) have determined more than hundred independent loci that contribute to schizophrenia risk. As such, the importance of large-scale studies has increased in recent years. The first effective treatments for schizophrenia, developed in the late 1950s, where shown to affect dopamine D_2 receptors. Interestingly, dopamine and dopamine D_2 receptors are known to have upregulated expression in schizophrenic

brains compared to neurotypical controls, and more specifically, the caudate nucleus. While decades of research have pointed to a major role of the dopaminergic pathway in the caudate nucleus with regards to schizophrenia, there are no large scale studies that investigate this relationship.
Here we investigate the caudate nucleus transcriptome using post-mortem samples from hundreds of individuals diagnosed with schizophrenia and neurotypical controls. We use genetic information on these individuals to assess whether genotypes that confer increased risk of schizophrenia are associated with transcriptional changes in the caudate nucleus, and which expression quantitative trait loci (eQTLs) are detected in the caudate nucleus. We apply machine learning techniques to build predictive models of primary diagnosis and other clinical outcomes (eg hallucinations), and identify which transcriptional and genetic features contribute most to prediction. We compare these findings with those from dorsolateral prefrontal cortex and hippocampus and identify those that are caudate nucleus-specific. Finally, we conduct a gene network and pathway study to investigate what predictive features are related to dopaminergic pathways. Altogether, our work presents a comprehensive analysis of caudate nucleus transcriptional and genetic landscapes and identifies predictive models of schizophrenia that could lead to new insight into its molecular nature and new lines of treatment.

Title: Novel, non-catechol dopamine d1 receptor agonists exhibit g protein biased, beta-arrestin independent signaling

Authors: *A. N. NILSON, D. E. FELSING, P. WANG, J. ZHOU, J. A. ALLEN
Univ. of Texas Med. Br., Galveston, TX

Abstract: The dopamine D1 receptor (D1R) is essential for many neurological functions including voluntary movement, working memory, attention and reward. The D1R canonically activates Gs/olf proteins to increase cyclic adenosine monophosphate (cAMP) production and increases neuronal excitability. However, the D1R also engages β-arrestin proteins which may facilitate receptor endocytosis and limit canonical receptor signaling. We recently discovered the first non-catechol D1R selective agonists and many of these ligands activated the D1R via G proteins without activating β-arrestin (Gray, Allen et al *Nature Comm., vol* **9**: 674, 2018). Here we further evaluate these non-catechol D1R agonists for their G protein and β-arrestin dependent signaling activity. The non-catechol D1R agonists PF-1119, PF-6142 and PF-2334 dose-

dependently increased D1R/G protein/cAMP signaling in HEK293 cells similar to dopamine using the Glosensor assay, but did not activate D1R/β-arrestin2 interactions using the Tango assay. To investigate D1R endocytosis and involvement of β-arrestin, we conducted confocal imaging and ELISA-based D1R endocytosis assays in wildtype HEK293 cells or cells lacking β-arrestin 1 and 2 using CRISPR/Cas9 genome editing. The catechol agonists dopamine and A77636 induced robust D1R endocytosis, but this trafficking was entirely blocked by knockout of β-arrestin. In stark contrast, the non-catechol agonists PF-6142 and PF-1119 did not induce D1R endocytosis. To further define D1R β-arrestin signaling outcomes, we conducted D1R desensitization assays by treating cells with agonists for 30 to 240 minutes followed by detection of D1R cAMP production using wildtype or β-arrestin knockout cells. The catechol agonists dopamine and A77636 significantly desensitized D1R cAMP signaling but this was prevented by knockout of β-arrestin 1 and 2. However, non-catechol agonists PF-6142 and PF-1119 did not induce D1R desensitization. Taken together, these results indicate that β-arrestins are required for D1R endocytosis and desensitization and that non-catechol D1R agonists signal independently from β-arrestin. Future studies will further investigate the mechanisms underlying this G protein biased signaling by non-catechol agonists. In addition, discovery of these non-catechol D1R agonists with limited desensitization may provide therapeutic value for neurological diseases involving reduced dopaminergic signaling.

Abstract: Schizophrenia is a heterogeneous, neurodevelopmental disorder associated with poor functional outcomes. Despite it's heritability, uncovering the mechanisms of inherited risk in schizophrenia has proven challenging. Previous work has suggested that schizophrenia may actually represent a group of neurobiologically distinct disorders with variegated phenomenological subtypes. We tested the hypothesis that a primary dopaminergic deficit underlies vulnerability to schizophrenia, incorporating machine learning and optimization research to solve complex combinatorial problems not approachable with traditional statistics. We studied a unique ethnocultural sample (n=288) of subjects with chronic, never-treated schizophrenia, their unaffected relatives and matched controls who were evaluated blindly for measures of motor function, cognitive performance, personality traits, and transcranial ultrasound of the brainstem. A broad-coverage genome wide scan was also obtained. Following multi-step clustering and optimization, we combined genetic and phenotypic information in an unbiased fashion and uncovered nonlinear relations that predicted risk status (affected, relatives or controls). The function underlying this prediction is the first demonstration of a map of schizophrenia risk, where independent genomic clusters relate to distinct clinical phenotypes. Pathway analysis of the genomic clusters implicates molecular networks with known functional significance to neural development and synaptic function. Our data suggests that genetic risk for schizophrenia may act primarily by modulating dopaminergic pathways and biasing phenotypic plasticity.

Title: Transcriptional regulation of dopamine D1 receptor by DISC1-DRRF repressor complex

Authors: *Y. SUH[1], S. LEE[2], S.-J. NOH[1], S. KIM[1], S. PARK[1]
[1]Dept. of Life Sci., Pohang Univ. of Sci. and Technol., Pohang, Korea, Republic of;

Abstract: Dopaminergic system is important for motor functions and cognitive processes and its abnormality is linked to several neuropsychiatric disorders. Accumulating evidence suggests that Disrupted-in-schizophrenia 1 (DISC1) modulates dopamine mediated function and is involved in

gene transcription in the brain. In this study, we report a DISC1-involved transcriptional repressor complex playing a role for the expression of dopamine D1 receptor (DRD1). First, we found that DISC1 mutant mice showed increased level in DRD1 transcription. Scrutinizing the underlying molecular mechanisms, we identified a novel co-repressor complex for the DRD1 gene locus composed of DRRF and DISC1. First, we observed physical interactions between DISC1 and DRRF in the nucleus and subsequently among mSin3A binding with DRRF and DISC1. The interaction between DRRF and mSin3A was significantly altered by DISC1 co-expression. In chromatin immunoprecipitation assays, these potential co-repressor complex repressed the transcription of DRD1 and DISC1 seemed to strengthen the association of the complex to the promoter region. Finally, we confirmed the participation of DISC1 in DRD1-related dopaminergic system, by measuring the basal level of cAMP and p-ERK in primary cultured neurons and analyzing behavior patterns of DISC1 mutant mice. Collectively, our study provides a novel epigenetic mechanism in dopamine receptor-mediated signaling toward further understanding molecular views of psychiatric disorders.

Title: Altered subcellular EAAT2 localization in the DLPFC in schizophrenia

Authors: *S. M. O'DONOVAN[1], R. C. ROBERTS[5], J. ROCHE[6], C. DORSETT[6], C. R. SULLIVAN[2], K. A. HASSELFELD[3], R. KOENE[4], E. DEVINE[2], R. MEEKS[3], R. E. MCCULLUMSMITH[3]
[1]Psychiatry and Behavioral Neurosci., [2]Psychiatry, [4]Dept. of Neurosci. and Behavioral Psychiatry, [3]Univ. of Cincinnati, Cincinnati, OH; [5]Psychiatry and Behavioral Neurobio., Univ. of Alabama, Birmingham, Birmingham, AL; [6]Univ. of Alabama, Birmingham, AL

Abstract: Schizophrenia is a major mental illness with complex pathology, including abnormalities in the glutamate system. Glutamate is rapidly removed from the synapse by a family of membrane excitatory amino acid transporters (EAATs). To prevent glutamate spillover, EAATs must be expressed at high levels on the astrocytic plasma membrane and be localized adjacent to the synapse. Postmortem cortical tissue (dorsolateral prefrontal cortex (DLPFC)) was obtained from the Maryland Brain Collection from control and schizophrenia

subjects. EAAT2 protein expression (Western immunoblot n=10/group), activity (glutamate uptake assay n=10/group) and EAAT2-related gene expression (qPCR, n=16/group) were characterized at the region-level and/or cell-level in enriched populations of astrocytes and pyramidal neurons. Electron microscopic examination of EAAT2 subcellular localization was assayed in a subset of subjects (n=9-10/group). EAAT2-related gene expression was significantly reduced (Student's t-test, $p < 0.05$) in schizophrenia in the DLPFC in a region and cell-subtype specific manner, including a decrease in EAAT2 mRNA in an enriched population of astrocytes. Electron microscopy analysis found that the mean distance from EAAT2 labeling in perisynaptic astrocytic processes to the nearest edge of asymmetric synapses was significantly ($p<0.05$) further in schizophrenia cases ($0.440 \pm 0.072\mu m$) than in controls ($0.290 \pm 0.05\mu m$). EAAT2 labelling was also increased in the post-synaptic density in schizophrenia subjects ($22.3 \pm 10.5\%$) compared to controls ($11.4 \pm 6.6\%$). These studies suggest that glutamate transporter expression and localization is significantly altered in the DLPFC in schizophrenia. Such changes in EAAT2 could lead to diminished buffering and reuptake of glutamate at the synaptic cleft, leading to increased spillover of glutamate into the extrasynaptic space. Our findings suggest that altered ultrastructural localization of EAAT2 is part of a pathophysiological mechanism contributing to deficits of synaptic plasticity that underlie cognitive symptoms found in schizophrenia.

Title: JNK1 provides a point of convergence for schizophrenia polygenes and controls cell surface availability of NMDA receptors

Authors: *Y. HONG[1], A. VARIDAKI[2], P. CIFANI[3], R. MYSORE[2], L. ELO[4], P. JAMES[3], E. T. COFFEY[5]
[1]Univ. of Turku, Turku, Finland; [2]åbo akademi, Turku, Finland; [3]Lund Univ., Lund, Sweden; [4]Turku Univ., Turku, Finland; [5]ABO Akademi Univ. Turku, Turku, Finland

Abstract: Schizophrenia is a polygenic disorder where no single major risk factor has been found in a large number of patients making it difficult to understand molecularly, though an imbalance of inhibitory and excitatory neurotransmission is a hallmark. Human genetic studies have linked MAPK regulators (*TAOK2, MKK4, MKK7, TNIK, TAK1* and *ULK4*) with schizophrenia, implicating involvement of the JNK cascade, however no mechanism is known. Here we characterize the brain phosphoproteome of *Jnk1-/-* mice over a lifetime. We show that *Jnk1* deletion alters 12 % of brain phosphoproteins and impacts previously unrelated signaling. This dataset is enriched for schizophrenia risk proteins and regulators of NMDA receptor trafficking. Consistent with bioinformatics analysis, we demonstrate that genetic deletion of *Jnk1* induces diametrically opposed regulation of excitatory NMDA. This is partly mediated by PKC which is activated in *Jnk1-/-* cortex. We show that the JNK1 pathway comprises a signaling framework for over 100 schizophrenia polygenes, to control inhibitory/excitatory balance.

Title: The role of HINT1 in several neuropsychiatric diseases

Authors: *Y. DANG[1], P. LIU[2], G. LEI[2]
[1]Xi'An Jiaotong Univ., Shaanxi, China; [2]Xi'an Jiaotong Univ., Xi'an, China

Abstract: Although many studies have investigated the functions of histidine triad nucleotide binding protein 1 (HINT1), its roles in neurobiological processes remain to be fully elucidated. Accumulating clinical and pre-clinical evidence suggests that HINT1 may play an important role as a mediator in neuropsychiatric diseases, such as schizophrenia, mood disorders, drug addiction and so on. Therefore, we investigated the function of HINT1 in several neuropsychiatric diseases related animal models. We found that HINT1 plays a role in social isolation (SI) mouse model, characterized by behavioral abnormalities similar to those in schizophrenia. We also investigated the function of HINT1 in knockout mice. Both male and female HINT 1 knockout (KO) and heterozygosity (HT) mice had a trend of anxiolytic like behavior and anti-depression like behavior at control group. In regard of the researches on pain,

hot-plate test and formalin test showed that HINT1 KO mice showed higher pain sensitivity in the basal state, with no gender differences. We also investigated the role of HINT1 in methamphetamine (METH) and morphine addiction. In nucleus accumbens (NAc) of the METH-induced conditioned place preference (CPP) group mice, the HINT1 expression level initially increased after acquisition phases, and then dropped to the normal level after extinction phase, and again increased after reinstatement phase. In the METH-induced behavioral sensitization model, the HINT1 expression level increased in the prefrontal cortex (PFC) after the development phase. In addition, the HINT1 KO mice seem to be more sensitive in METH-induced behavioral sensitization, but only during the development phase. Interestingly, the situation of morphine addiction is just the opposite. The mRNA and protein expression level of HINT1 did not show any difference during the development phase, but both became higher in PFC in the morphine-induced behavioral sensitization group than the saline control group during the expression phase of this model. The HINT1 KO mice show less sensitivity in this addition model, and statistically difference emerges during the expression phase. In another model, mentioned as CPP, expression level of HINT1 protein of morphine-paired group in NAc significantly decreased during the acquisition phase. For the HINT1 KO mice, they need more training times than the wild-type control mice for the acquisition and extinction phases, but show no difference during the reinstatement test.

Title: AMPK dysregulation in a human induced pluripotent stem cell model of DISC1-related schizophrenia

Authors: *E. BENTEA[1], S. O'DONOVAN[1], E. DEPASQUALE[2], J. MELLER[2], C. XU[3], Z. WEN[3], R. MCCULLUMSMITH[1]
[1]Dept. of Psychiatry, Univ. of Cincinnati, Cincinnati, OH; [2]Dept. of Biomed. Informatics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [3]Dept. of Psychiatry and Behavioral Sci., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Disrupted-in-schizophrenia 1 (DISC1) is a well-known genetic risk factor for severe mental illness including schizophrenia. A large array of animal studies supports an etiopathogenic role of DISC1, by linking it with regulation of processes such as synapse

formation and neuronal development. However, much less is known regarding the involvement of DISC1 in human neurons. Induced pluripotent stem cells (iPSCs) generated from patients have emerged as powerful tools to study cellular dysfunction in a disease-relevant context. In this study, we investigated serine/threonine kinase networks in a human iPSC model of DISC1-related schizophrenia. Using PamChip kinome arrays, we mapped the serine/threonine sub-kinome of neuronally differentiated iPSCs generated from a patient with schizophrenia presenting with a 4-bp deletion in DISC1, an unaffected family member without the mutation, and isogenic iPSC lines in which the mutation was either introduced in the control cell line or corrected in the DISC1 cell line. Arrays were run in triplicate and the results of the three chips averaged. Using a novel bioinformatics workflow, we identified kinases that were commonly changed in the DISC1 cell line, the control cell line with the DISC1 mutation introduced, and the DISC1 cell line which was genetically rescued, in order to identify disease pathways that are causally linked with the DISC1 mutation. This analysis highlighted 5' adenosine monophosphate-activated protein kinase (AMPK) as a common node of kinase dysregulation. AMPK is a subfamily of the CAMKL family of kinases involved in regulating cellular energy metabolism, and may link bioenergetic perturbations with changes in synaptic plasticity. To confirm the involvement of this signaling pathway, we screened for mRNA expression changes of 84 targets linked with AMPK signaling, using a previously generated RNA-Seq database of DISC1 cells. This approach confirmed significant AMPK dysregulation in DISC1 cells, with a wide range of targets linked with AMPK signaling differentially expressed at mRNA level. Our unbiased, and combined kinomics and transcriptomics approach supports evidence of AMPK dysregulation in a human iPSC model of DISC1-related schizophrenia. These findings provide further support of kinase network dysregulation in schizophrenia and may open new avenues for treating this highly disabling neuropsychiatric disorder.

Title: Characterization of adenosine kinase in schizophrenia

Authors: *C. MOODY[1], A. FUNK[1], R. E. MCCULLUMSMITH[1], S. M. O'DONOVAN[2]
[2]Psychiatry and Behavioral Neurosci., [1]Univ. of Cincinnati, Cincinnati, OH

Abstract: Schizophrenia is a devastating neuropsychiatric disorder characterized by positive, negative, and cognitive symptoms. Hyperfunction of the dopamine system contributes to positive symptoms and hypofunction of the glutamate system contributes to negative and cognitive symptoms. Adenosine is a neuromodulator that regulates both the glutamate and dopamine systems. The adenosine hypothesis of schizophrenia states that hypofunction of the adenosine system, driven by overexpression of adenosine kinase (ADK), disrupts the role of adenosine as a neuromodulator and contributes to the pathophysiology of schizophrenia. This hypothesis has yet to be tested in postmortem schizophrenia. Postmortem tissue from the dorsolateral prefrontal cortex (DLPFC) and anterior cingulate cortex (ACC) of schizophrenia subjects and age and sex matched controls were obtained from the Maryland Brain Collection and Bronx-Mt.Sinai Neurobiobank, respectively. ADK protein levels were measured using Western immunoblot in the DLPFC. *In silico* analysis of ADK expression in postmortem schizophrenia databases was used to examine the effects of antipsychotic medication on ADK. There was no significant change in the expression of the long (ADKL; n=15-16/group, Student's t-test p=0.2). or the short (ADK S; n=16/group, Student's t test p=0.8) variant in schizophrenia compared to control. All samples were normalized to housekeeping gene beta actin. ADK protein expression was not significantly altered in schizophrenia in the DLPFC in tissue from the Maryland Brain Collection (n=17-18/group, p=0.7), or the NIH brain bank (n=35-36/group, p=0.1). ADK protein expression was also not altered in the ACC in tissue from the Bronx-Mt Sinai Neurobiobank (ANCOVA $F_{(1,21)}$ =1.09, n=12/group, p=0.31). ADK was normalized to beta tubulin prior to analysis. *In silico* analysis of the Stanley Online Genomics Database found an effect of antipsychotic administration on ADK gene expression, fold change (FC) >1, p=0.00046 in schizophrenia (SCZ) subjects on antipsychotics compared to off antipsychotics. However, there was no significant difference in ADK expression due to lifetime alcohol (EtOH) consumption (p=0.136), drug abuse (p=0.763), or sex (p=0.438). ADK protein expression is not significantly changed in the DLPFC or ACC in schizophrenia. The adenosine hypothesis of schizophrenia postulates that overexpression of ADK is central to dysregulation of this system in disease. Our results suggest that dysregulation of other components of the adenosine system contribute to the pathophysiology of schizophrenia.

Title: Easy tissue clearing mediated imaging of the brain and tissues using sunhyun 3dimensionalimage kit

Authors: *S. PARK[1], K.-S. KIM[2]
[1]Predictive Model Res. Ctr., [2]Korea Inst. of Toxicology, Daejeon, Korea, Republic of

Abstract: Despite the recent advances in tissue clearing methods, it remains challenging to reproducibility and simplification due to the complexity of the method and the limit of the cost. We have developed the SunHyun method to overcome current problems by simplifying the process of the tissue clearing, increasing reproducibility, and lowering costs. SunHyun method was able to protect protein loss without using a nanoporous hydrogel-hybridized form. This method also made the undamaged tissue transparent without using organic solvents or harsh detergents or conditions. Finally, SunHyun method preserved the fluorescent proteins over several months, and overcame the working distance of the microscope reducing the size of the transparent tissue. We use SunHyun method to image the transparent whole brain by light-sheet microscope and show important differences in the distribution of excitatory and inhibitory neurons in the hippocampal area. We were also able to quickly discover the degree of drug diffusion and side effects of the brain in a drug delivery system. Therefore, this method can be applied to read the latest research on diseases and therapeutic drug development.

Title: Viral-mediated transgenesis in the brain as a method to determine molecular mechanisms of aggression in stickleback fish

Authors: *N. JAMES[1], A. BELL[2]
[1]Neurosci. & Animal Bio, [2]Animal Biol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Establishing a causal relationship between genes and social behavior is challenging since gene expression is dynamic. One gene may have drastically different effects when expressed in different parts of the social behavior network (areas in the fore- and mid-brain) or at different times. Thus, to determine the causal relationship between a gene of interest and a behavior, it is crucial to have a method for manipulating gene expression at a specific time and location. We developed one such method, viral-mediated transgenesis, for stickleback fish. Threespine sticklebacks (*G. aculeatus*) are a classic system for the study of behavior, ecology, & evolution. Our recent studies have identified hundreds of differentially expressed genes in the

brain following social interactions. Viral-mediated transgenesis is an appealing method for directly manipulating gene expression in this system. The technique is flexible, as different promoters can alter the targeted location or timeframe. It's also fast, since stable transgenic lines are not required.
Based on work in zebrafish, we hypothesized that a herpes simplex 1 (HSV1) derived virus with the mCMV, hCMV or hEF1a promoters would drive continuous expression of a target gene. Adult fish were injected with 300nL of either a saline control or suspended virus causing expression of a fluorescent protein. Successful transgenesis was determined via widefield microscopy on whole mount brains. Behavioral recovery was also assessed based on stress levels and mating behaviors – female fecundity and male nesting.
We successfully altered expression in stickleback brains using both the short-term promoter mCMV, showing expression by four days post-injection, and the longer-term promoter hCMV, reaching peak expression at ten days post-injection with continued expression for several weeks afterward. No fluorescence was seen in saline-injected controls. Breathing rate returned to baseline within two hours. Behavioral recovery following the injection occurred within nine days for females and three days for males, prior to peak expression of the long-term construct.
Next, we will test the behavioral consequences of manipulating the expression of candidate genes. These genes (*prl*, *ajap1*, *npas4*, *nsmfb* and *trpc4*) were differentially expressed in male sticklebacks following a territorial challenge. Functionally altered expression will be confirmed by qPCR, comparing expression between injected and un-injected brain regions of an individual. Aggression will be assayed prior to transgenesis and at 14 and 16 days. This technique will enable us to demonstrate that gene expression is sufficient to induce behavioral change.

Title: Development of temporal sensitive lentiviral-based luciferase reporter for real-time monitoring of stress-induced GR activations in mouse infralimbic prefrontal cortex

Authors: *S. HER
Western Seuol Ctr., KBSI, Seoul, Korea, Republic of

Abstract: Application of luciferase bioimaging has been extended to valuable means for real-time monitoring of biological processes in various organ of living animals including brain.

During longitudinal analysis of deep brain, however, technical limitations to monitor the biological processes exist such as weak signals as well as less dynamic monitoring of signals. To overcome these limitations, we designed and tested various combination of lentiviral-based luciferase glucocorticoid response element (GRE) reporters *in vitro* and *in vivo*. Replacing luciferase reporter gene *Luc* with *Luc2* showed a 142% brighter bioluminescent signals in H19-7 cells, whereas reduction of insulator size from 1.kb to 0.3kb had no significant improvement in bioluminescent brightness. Addition of destabilized sequences into the C-terminal of *Luc2* also reduced half-life of luciferase activity by 69% in H19-7 cells and 61% in right IL-PFC of CD-1 mouse. In the assessment of in vivo usefulness, the tagging destabilizing sequences allowed to sensitively monitor temporal variation in stress-induced GR activations as demonstrated by a 64% increase in intra-individual coefficients of variation (iCV) of GR activity compared to control group. Taken together, our results provide a useful tool for real-time monitoring of neurobiological processes in deep brain, opening a window into the new insight of neurobiological dynamics in brain.

Abstract: [Introduction]We have previously reported the beneficial effects of transplanting human induced pluripotent neural stem progenitor cells (hiPSC-NS/PC) into the spinal cord of contusive injury model. However, transplanting certain hiPSC-NS/PC that are known to have tumorigenic properties resulted in the deterioration of motor function secondary to the oncogenic transformation. Tumors derived from these “bad clones” consisted of immature undifferentiated human-specific NESTIN positive cells. It is known from previous studies that NS/PC co-express 18kDa translocator protein (TSPO) with neural stem cell marker such as NESTIN. Therefore, the

purpose of this study is to develop a method that allows us to visualize the immature neural tissues using TSPO ligand PET. [Methods]253G1-NS/PC (oncogenic clones) or 414C2-NS/PC (benign clones), PBS was injected into the striata or intact cervical spinal cord of immunodeficient mice. These cells were cultured and labeled with firefly luciferase genes via lentiviral transduction. After transplantation, we monitored the growth of transplanted cells through weekly Bio-imaging. Four to eight weeks later, gadolinium enhanced MRI was performed followed by PET with ^{18}F-TSPO ligand (^{18}F-FEDAC). The mice were immediately sacrificed and the brain and spinal cord were dissected out for *ex vivo* autoradiography (ARG). [Results]Bio-imaging revealed that the cells had been successfully engrafted in all mice. Among them, the 253G1 group demonstrated rapid cell proliferation. MRI revealed a region with gadolinium enhancement and high intensity T2 weighed area at the transplanted site in the 253G1 group, whereas there were no specific findings in the 414C2 or PBS group. ^{18}F-FEDAC PET revealed a significant increase in tracer uptake at the transplanted site in the 253G1 group compared to the others . We found that there was a higher binding of ^{18}F-FEDAC at the transplanted site in the 253G1 group using ARG compared to the others ($p<0.05$). [Conclusion]We successfully detected the remnant immature neural tissues of hiPSC-NS/PC using ^{18}F-FEDAC PET.

Abstract: Transgenic animals expressing fluorescent proteins are widely used to label specific cells and proteins. GFP-dependent gene regulation enabled us to utilize these transgenic animals for selective gene expression in GFP-expressing cells; however, application has been limited to fluorescent proteins derived from Aequorea jellyfish so far. In this study, we generated Cre dependent on RFP (Cre-DOR) by combining split-Cre with RFP-specific small binding proteins such as nanobodies and designed ankyrin-repeat proteins. We constructed both monomeric RFP-specific Cre and dimeric RFP-specific Cre. We confirmed target RFP-dependent gene expression in mouse brains using adeno-associated virus vectors. Selective expression by Cre-DOR in mRFP1-expressing neurons of transgenic rats was also confirmed. Translocation of target RFPs greatly affected the efficiency of Cre-DOR. Using a light-sensitive translocation domain, we achieved optical downregulation of Cre-DOR activity by inducing translocation of target RFPs from the nucleus to the cytosol. Using the glucocorticoid receptor, we achieved chemical upregulation of Cre-DOR activity by inducing translocation of target RFPs from the cytosol to the nucleus. Using dimer-dependent RFPs, we detected dimer formation of RFPs as an increment of recombinase activity of dimeric RFP-specific Cre. Taken together, our findings extend the potential use of RFP-expressing transgenic animals and provide unique methods to monitor or manipulate cellular signaling such as glucocorticoid receptor activation.

Title: Targeting mesocortical and mesoaccumbens dopamine neurons with DREADDs using the combination of adeno associated viral vectors and retrograde transported herpes simplex viral vectors

Authors: *J. B. EELLS[1], J. M. NUTTER[2], H. S. PARTINGTON[2]
[1]Anat. & Cell Biol., [2]Anat. and Cell Biol., East Carolina Univ. Sch. of Med., Greenville, NC

Abstract: The mesencephalic dopamine neurons have various physiological roles depending on the areas of the brain they innervate. Dopamine neurons innervating the prefrontal cortex have been found to be critical for executive control and working memory while dopamine neurons innervating the nucleus accumbens signals salient or relevant environmental stimuli. Abnormalities in these pathways contribute to diseases including schizophrenia and addiction. Understanding how alterations in signaling to these neurons alters their function is critical to understanding how exposure to drugs of abuse or environmental risk factors for schizophrenia contribute to these diseases. This current work is focused on using viral vectors to specifically target these dopamine neuron populations based on the area of the brain they innervate and to activate or inhibit these neurons with DREADDs (Designer receptors exclusively activated by designer drugs). Preliminary studies tested independently the efficiency of retrograde transport of a herpes simplex viral (HSV) vector from the nucleus accumbens and dopamine neuron infection in the ventral tegmental area with an adeno associated viral (AAV) vector. Both independently labeled dopamine neurons in the ventral tegmental area. We next tested a combination of an HSV expressing Cre recombinase and yellow fluorescent protein (YFP) injected into either the nucleus accumbens or prefrontal cortex with an AAV vector with Cre dependent expression of the DREADD hM3Dq coupled with mCherry. Analysis found good retrograde transport of the HSV and expression of mCherry indicating co-infection of those neurons with AAV. Of interest was the observation that some mCherry labeled neurons did not show detectible YFP labeling, suggesting that only low levels of cre appear necessary for expression of mCherry. As expected a much larger dopamine neuron population was labeled with nucleus accumbens injection as compared to prefrontal cortex injection. Initial trials expressing hM3Dq+Cherry via the HSV in combination with an AAV expressing cre were not successful. Studies are ongoing to determine the specificity of this approach for targeting dopamine neurons. Future studies will also investigate molecular changes that result from altering activation of these dopamine neuron populations with the DREADD agonist clozapine to help understand how environmental stimuli and drugs of abuse alter dopamine function and contribute to disease.

Title: Revealing the chromatin-bound long noncoding RNA landscape of the brain

Authors: *H. M. CATES[1,2], S. AKBARIAN[2]
[1]New York, NY; [2]Psychiatry, Icahn Sch. of Med. at Mt. Sinai, New York, NY

Abstract: Long noncoding RNAs (lncRNAs) are a diverse set of transcripts that bind the genome and regulate epigenetic states. They comprise approximately 58,000 genes in the human genome. Recently, there has been a growing interest in the role of lncRNAs in many psychiatric disorders, including drug addiction. While there have been many studies implicating histone-modifying enzymes and other epigenetic proteins, it has never been entirely clear what the mechanism is to bring an epigenetic modifier to a specific locus. Evidence has shown that lncRNAs can act as scaffolds to help recruit these complexes. To date, epigenetic regulation by lncRNAs has largely been studied on a single transcript basis. To better understand the global landscape of lncRNA in the brain, we are optimizing a recently published method which allows us to capture all chromatin-bound RNA and identify the RNAs as well as the loci to which they are bound. This will allow us to leverage available sequencing data from similar brain tissue-sets to determine how lncRNA are associated with histone marks, nuclear organization, expression levels, and more. This will lead to better understanding of how lncRNAs are regulating the epigenome in the brain both at baseline and in disease states.

Title: Mapping of schizophrenia risk genes and isoforms using *in situ* RNA sequencing

Authors: *M. M. HILSCHER[1,2], C. YOKOTA[1], D. MALHOTRA[2], M. NILSSON[1]
[1]Sci. for Life Lab., Solna, Sweden; [2]F. Hoffmann-La Roche Ltd, Basel, Switzerland

Abstract: Schizophrenia (SZ) is a debilitating neuropsychiatric disorder with a strong genetic etiology. Major progress has been made in identifying genes/loci associated with risk of SZ. Recent advances in single-cell RNA sequencing allow investigating the cell type-specific expression of SZ risk genes and link genetic risks to individual cells. In single-cell RNA sequencing studies of dissociated brain tissues, however, the information on the spatial context is lost.
Here, we use *in situ* RNA sequencing with padlock probes to study the cell type- and cortical layer-specific expression of selected SZ risk genes. We profiled the cell type-specific expression

of Cacna1c (Cav1.2) isoforms that target brain and heart enriched exons. Cacna1c is a SZ risk gene and subjected to extensive alternative splicing. In order to study which isoforms are significantly enriched in the brain, we compared their spatial distribution on brain and heart tissues. We identified regions of interest and found certain exons to be highly expressed in heart samples while being almost absent in brain tissues. Moreover, we show that a pair of mutually exclusive Cacna1c exons displays an opposite enrichment in heart and brain and that specific cell types are implicated in SZ pathogenesis. For a subsequent set of experiments we designed our probes to promote comparisons between healthy control tissues with either postmortem human SZ tissues or genetic mouse models of SZ in order to allow further investigations on potential molecular targets for SZ.
Thus, by performing high resolution analysis on *in situ* RNA sequencing data we are able to map schizophrenia risk genes and isoform expression which is important to understand tissue functionality and pathological changes during schizophrenia.

Title: rsCaMPARI: An erasable marker of neuronal activity

Authors: *F. SHA, E. R. SCHREITER
Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Identifying and comparing active neuron ensembles underlying different complex behaviors is a key challenge in neuroscience. Recent tools such as CaMPARI have enabled the optical marking and selection of active neuron populations.[1] However, CaMPARI is based on the activity of a photoconvertible fluorescent protein whereby the marking is permanent and irreversible. These properties limit the utility of CaMPARI in samples where multiple snapshots of activity are desirable or where different activity profiles must be compared within the same sample. We sought to overcome these limitations by developing an erasable neuronal activity marker based on a reversibly switchable fluorescent protein. Here we introduce a new tool named rsCaMPARI, a reversibly switchable calcium marker that enables spatiotemporal precise marking, erasing, and remarking of active neuron populations under widefield illumination. rsCaMPARI photoswitching kinetics are modulated by calcium concentration when illuminating with blue light, and the fluorescence can be reset with violet light. We demonstrate the utility of rsCaMPARI for repeated marking and erasing of calcium activity in cultured neurons.

Abstract: Neurons of the medullary reticular nucleus gigantocellularis (NGC) and their targets have recently been a focus of research on mechanisms supporting generalized CNS arousal (GA), required for proper cognitive functions. NGC neurons project to the spinal cord and to the midbrain, but little is known about the gene expression of NGC neurons with ascending projections. Using the retro-TRAP method, we characterized transcripts enriched in NGC neurons which have projections to the thalamus. We identified several hundred transcripts that are enriched in these neurons as compared to the surrounding tissue. Signaling pathway in these cells appeared to indicate that these neurons are involved in neurovascular coupling; a finding that was strengthened by our observation of their physical proximity to blood vessels. Pharmacological inhibition indicated that these pathways were involved in modifying behavioral arousal in response to environmental change.

Title: *In vitro* delivery of large plasmids with temporal control of gene expression via polyamidoamine (PAMAM) dendrimer nanoparticles

Authors: *M. FLORENDO[1], B. SRINAGESHWAR[1,2,3], A. FIGACZ[1,2], R. KIM[1,2], C. THOMPSON[2,3], D. SWANSON[4], G. L. DUNBAR[2,3,5], A. SHARMA[4], J. ROSSIGNOL[1,2,3]
[1]Central Michigan Univ. Col. of Med., Mount Pleasant, MI; [2]Field Neurosciences Inst. Lab., Mount Pleasant, MI; [3]Neurosci., [4]Chem., [5]Psychology, Central Michigan Univ., Mount Pleasant, MI

Abstract: Polyamidoamine (PAMAM) dendrimers are nanoparticles composed of the following features: (1) diaminobutane (DAB) core, (2) variable branching which determines its generation (G)/size, and (3) a surface composed of terminal groups. Each feature of a PAMAM dendrimer can be modified to determine its structure and interaction with other molecules. Dendrimers are one of the smallest known nanoparticles, with its fourth generation (G4) measuring at a size of 4 nm. Features of dendrimers including its modularity, its similar size to biomolecules, and its ability to cross the blood-brain barrier (BBB) allow it to have great potential for therapeutic application. In particular, dendrimers can be used in gene therapy to deliver therapeutic DNA plasmids of 10kb or more to cells *in vitro* and *in vivo*. Terminal surface groups, such as positively charged -NH2, can allow dendrimers to be more positively charged. Not only are these positive charges necessary for crossing the BBB and the membrane of the cell, but is necessary for complex formation with DNA since it will allow the dendrimer to be attracted to the negatively charged phosphates of DNA. The following experiments used fluorescently labeled fourth generation dendrimers composed of 90% neutrally charged -OH and 10% positively charged -NH2 (G4-90/10). These slightly positively charged dendrimers facilitated complex formation with DNA plasmids of varying sizes without causing cytotoxicity. Our study compared delivery between two large sized plasmids (6 kb and 10 kb) having a fluorescent reporter gene (mCherry). Gel electrophoresis and fluorescence microscopy confirmed complex formation and delivery of DNA plasmids (6 kb and 10 kb) to cells *in vitro* via the G4-90/10

dendrimers. MTT Assay confirmed minimal cytotoxic effects to cells that received the dendrimer DNA complex. Further, we delivered Tetracycline-ON (TET-ON) system plasmid (gift from Dr. Breunig, Cedars-Sinai Medical Center) via G4-90/10 to cells *in vitro*. The TET-ON system plasmid allows for expression of gene of interest only upon administration of tetracycline or its equivalent, doxycycline (DOX), which was subsequently confirmed via fluorescence microscopy. Combining our results, we developed a system of delivering large DNA plasmids of various sizes, including TET-ON system plasmids which contained temporal control of gene expression, to cells *in vitro.* This technique can be applied to the development of non-invasive treatment for neurodegenerative diseases by delivering these DNA dendrimer complex via intravenous administration in order to cross the BBB and target diseased cells *in vivo.*

Abstract: A shortcoming of serial electron microscopy is its inability to show the locations of multiple molecules within tissue volumes without compromising the quality of the underlying ultrastructure. We recently developed NATIVE (Nanobody-Assisted Tissue Immunostaining for Volumetric Electron microscopy), a correlated light and electron microscopy approach for thick-section tissue imaging that preserves ultrastructure. The success of NATIVE originates from the penetrating property of single domain antibodies (nanobodies) that are only several nanometers in their longest dimension. They stain both the intra- and extra-cellular epitopes in densely packed thick tissues, such as brain, with only mild paraformaldehyde fixation. We used this approach to label and image in a confocal microscope fluorescent nanobody-tagged microglial cells, astrocytes and vascular endothelial cells in mouse hippocampus. We then reconstructed the

same immunolabelled cells in a serial section electron microscopy volume of the same tissue (using the ATUM approach). We are extending this approach by generating many additional fluorescent nanobody markers to make identification of neuronal and glial cells types in electron microscopy data sets routine.

Title: Systems-level analysis of gene expression heterogeneity in the songbird song system

Authors: *B. COLQUITT[1,2], F. GREEN[3], M. S. BRAINARD[1,2]
[1]Physiol., UCSF Ctr. For Integrative Neurosci., San Francisco, CA; [2]Howard Hughes Med. Inst., Chevy Chase, MD; [3]Chan Zuckerberg BioHub, San Francisco, CA

Abstract: Birdsong is a powerful framework for understanding how the brain, at multiple levels of analysis, subserves the performance and modification of learned behavior. At the molecular-genetic level, a key goal is to build models of how environmental and behavioral states influence gene expression in the song system - the multi-locus neural circuit dedicated to song - and how molecular features of the song system influence song behavior. To further this effort, we have developed a high-throughput and low-cost RNA-sequencing approach for laser capture microdissected (LCM) tissue. The protocol combines an optimized bead-based RNA purification protocol for LCM sections with Drop-seq style library construction for sub-nanogram amounts of total RNA. This protocol allows genome-wide expression estimates from single LCM sections, thus permitting the analysis of multiple anatomically defined regions within single animals and multiple subsamples per region. The protocol flexibly accommodates experimental designs that require large numbers of animals and an integrated analysis of expression across neural systems. Here, we used this approach to characterize the song system of the Bengalese finch (*Lonchura striata domesticus)* along three different axes of transcriptional heterogeneity: inter-region variation, cell type identity, and axial variation. First, we compared expression among the four major telencephalic song nuclei and adjacent non-song-associated regions, with a focus on defining differential gene regulatory networks. Correlation network analysis combined with random forest regression modeling incorporating transcription factor motifs in accessible

chromatin produced a collection of transcription factors that we predict drive song/non-song nuclei transcriptional differences. Second, we leveraged the high density collection and sequencing of LCM sections from one song motor pathway nucleus, the robust nucleus of the arcopallium (RA), to perform within-nucleus correlation network analysis, yielding cell type-associated sets of genes and leading to the identification and characterization of multiple neuronal subpopulations in RA. Finally, the ordered collection of sections along the dorsal-ventral axis of RA allowed us to identify axial-varying genes. This systems-level approach to transcriptional analysis will complement finer-scaled delineations of cellular heterogeneity using single-cell RNA-seq methods and serve as an important tool to characterize the complex changes to gene expression that occur during behavioral plasticity.

Title: Development of efficient autophagosome sensors by detecting endogenous LC3 using modified Legionella RavZ

Authors: Y.-W. JUN[1], S.-W. JUN[1], P. JEON[2], J.-A. LEE[2], *D.-J. JANG[1]
[1]Kyungpook Natl. Univ., Sangju-Si/Gyeongsangbuk-Do, Korea, Republic of; [2]Hannam Univ., Dajeon, Korea, Republic of

Abstract: Autophagy is the intracellular bulky degradation pathway in lysosomes and its dysfunction is tightly associated with many human diseases including neurodegenerative diseases. RavZ is secreted from Legionella and inhibits host autophagy through irreversible Atg8 deconjugation in autophagosome membrane via LC3/GABARAP binding and membrane association. Based on its property on LC3/GABARAP binding, we have developed a new probe for autophagosomes that detects endogenous LC3 in the autophagosome by modifying RavZ. To do this, we generated RavZ(Δcat)-EGFP, a catalytic domain deletion mutant of RavZ. RavZ(Δcat)-GFP was efficiently localized to mRFP-LC3B- or mRFP-GABARAP-positive autophagosome in an autophagy-dependent manner in mammalian cell line and in post-mitotic neurons. We found that both the LIR motif within N- or C-terminus of RavZ and a PI3P binding motif are required for the stable targeting to autophagosome. Thus, our new developed autophagosome sensors are expected to be widely used in autophagy research in live cells in physiological or pathological conditions.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by aberrant protein aggregation, including amyloid beta (Aβ) peptide accumulation. AD is the most common cause of dementia among older people. There are no effective medications currently available to prevent and treat AD and halt disease progression. Modulation of muscarinic M1 receptor by non-selective agonists improve cholinergic neurotransmission and reduced the symptoms of AD. However, undesired cholinergic side effects prevented their further development. Selective activation muscarinic M1 sub-type using positive allosteric modulators could be a useful approach to treat cognitive deficits associated with AD without any cholinergic side effects. SUVN-I2004 was evaluated for its ability to potentiate the effect of endogenous agonist acetylcholine and also it's binding potential towards orthosteric site of muscarinic receptors in binding and cell based assays.SUVN-I2004 was tested in assays employing G-protein dependent and independent signaling pathways of muscarinic M1 receptors. SUVN-I2004 was also tested in in-vivo IP1 assays for assessment of efficacy translation from in-vitro assays. Cardiovascular safety was assessed using the patch clamp technique. SUVN-I2004 demonstrated positive allosteric modulatory activity with no agonistic activity towards muscarinic M1 receptor sub-type. It also displayed selectivity over closely related muscarinic receptor subtypes M2 to M5 and tested panel of serotonin, adrenergic, cannabinoid, dopamine, histamine receptor sub-types and monoamine transporters. SUVN-I2004 did not show inhibitory potential when tested in hERG patch clamp assay. SUVN-I2004 has demonstrated selective modulation of muscarinic M1 receptor in in-vitro pharmacological characterization.

Title: Characterising the schizophrenia-associated dysregulation of microRNA biogenesis

Authors: *M. GEAGHAN, M. J. CAIRNS
Univ. of Newcastle, Australia, Callaghan, Australia

Abstract: The canonical microRNA (miRNA) biogenesis pathway involves three major proteins - DGCR8, DROSHA, and DICER1. These proteins and their associated genes have been associated with psychiatric disease, including schizophrenia. The *DGCR8* gene is located within the 22q11.2 locus; hemizygous microdeletions in this region cause 22q11.2 deletion syndrome, which predisposes to a ~30% risk of developing schizophrenia. We have also previously identified elevated expression of *DGCR8*, as well as *DROSHA*, *DICER1*, and numerous miRNAs in the dorsolateral prefrontal cortex (DLPFC) and superior temporal gyrus (STG) of individuals with schizophrenia. More recently we observed reduced expression of the transcription factor YY1 in the same tissue, which has been shown to regulate *DGCR8* expression in some cell lines. To further explore these findings, *DGCR8* was overexpressed in an *in vitro* neuronal cell culture model to examine the changes to the mRNA and miRNA expression profiles using next-generation RNA sequencing. We also knocked down *YY1 via* RNA interference to determine if this transcription factor was capable of regulating *DGCR8*, *DROSHA*, and *DICER1* in neuronal cells. Following *DGCR8* overexpression, we observed 267 miRNAs and 396 genes which were significantly differentially expressed (FDR < 0.05, absolute $\log_2$ fold-change > 0.6). Several schizophrenia-associated miRNAs were dysregulated, such as miR-132-3p and various miR-181 and let-7 family members. Functional analysis of the differentially expressed mRNA revealed 43 schizophrenia-related genes enriched in the dataset, including glutamate receptor subunits *GRIK4* and *GRIN2C*, calcium channel subunits *CACNB2* and *CACNG8*, and the miR-137 host gene *MIR137HG*. Following knockdown of *YY1*, we observed the downregulation of *DGCR8*,

DROSHA, and *DICER1*, suggesting *YY1* may regulate miRNA biogenesis in neuronal cells. These results suggest that downregulation of YY1 in schizophrenia could be associated with the dysregulation of miRNA biogenesis also associated with this disorder. Our data also suggests that *DGCR8* elevation is sufficient to disrupt normal neuronal miRNA expression and has a significant impact on the expression of genes important for neuronal function and schizophrenia.

Title: Rapid phenotyping of CNS development with single-cell mass cytometry

Authors: *A. VANDEUSEN[1], I. CHENG[2], A. KEELER[2], C. WILLIAMS[3], T. LARSON[2], K. FREAD[3], K. MCNEELY[4], N. DWYER[4], A. SPANO[2], C. DEPPMANN[2], E. ZUNDER[3]
[2]Biol., [3]Biomed. Engin., [4]Cell Biol., [1]Univ. of Virginia, Charlottesville, VA

Abstract: Mass cytometry employs metal-conjugated antibodies and time-of-flight detection to quantify single-cell expression of up to 45 biomarkers, vastly improving our ability to phenotype changes occurring during development and disease. However, this emergent technology has not been applied to analyze neural cell subtypes. Using a curated library of 200+ antibodies targeting neural-related filaments, transcription factors, transmembrane receptors, adhesion molecules, and glycoproteins, we developed a modular system of interchangeable cassettes specific for neural stem cells and precursors, neuronal and macroglial progenitors, neurons, astrocytes, oligodendrocytes, microglia, and endothelial cells. Panels assembled from various cassettes were used to validate the ability of mass cytometry to recapitulate established developmental paradigms in the developing central nervous system (CNS) of mice aged embryonic day 10.5 to postnatal day 4. Our ability to enumerate the heterogeneity and relative abundances of neural cell types using high-dimensional clustering algorithms permits organization of cells present into taxonomic groups, similar to data presented in single-cell transcriptomic studies. However, in contrast to such analyses, our proteomic map of mouse CNS development can account for the signaling status of cells, thus enhancing interpretation of functional cell states. Moreover, by examining more than 3×10^7 cells representing daily time points for four neuroanatomical regions (i.e. telencephalon, diencephalon, mesencephalon, and rhombencephalon), our approach facilitates rapid discernment of discrete changes in the specification and fate of individual neural cell types, as well as a global overview of neural and non-neural components of the developing brain. In addition to gaining new insights into the spatiotemporal progression of nervous system development, this method has an unprecedented ability to elucidate potentially significant factors

related to disease. Thus, in addition to proof-of-principle studies characterizing early CNS development, we are currently focused on validating the robustness of this methodology for rapid high-resolution phenotyping of neurological disorders – a strategy that is certain to have broad applicability in the future.

Title: Using enhancer-driven gene expression (EDGE) to generate viral vectors capable of driving transgene expression in particular cell types of targeted brain regions in any species

Authors: *R. R. NAIR, S. BLANKVOORT, C. KENTROS
The Kavli Inst. for Systems Neurosci. / CNC, Trondheim, Norway

Abstract: The past decade has seen the development of a variety of molecular tools capable of revolutionizing systems neuroscience. However, fully taking advantage of these tools requires their expression with a higher degree of anatomical specificity than commonly available in most model systems. Furthermore, the development of methods to express transgenes at the level of anatomical specificity at which circuits operate will not only enhance our understanding of normal and pathological brain functions: delivery of therapeutic transgenes to specific circuit elements associated with brain pathologies may ultimately provide novel avenues for therapy. Unfortunately, most native promoters lack the required specificity, as they express in multiple neuronal cell types. However, there are orders of magnitude more transcriptional cis-regulatory elements (i.e. enhancers) than promoters, raising the intriguing possibility that they may help solve this problem. Recently we identified region-specific enhancers via differential ChIP-Seq analyses of histone modifications from microdissected rodent brain tissues and combined them with a heterologous minimal promoter to generate transgenic mice targeting distinct cell-types of the targeted brain region, an approach we term ‘’Enhancer-Driven Gene Expression’’ (EDGE) (*Blankvoort et al, Curr Biology in press*). While transgenic mice are excellent research tools, some experiments are more appropriate in other species, and transgenics cannot provide avenues for direct therapeutic interventions. Towards these ends, we created anatomically-specific adeno-associated viruses regulated by a hybrid promoter consisting of relatively small enhancers

specific to mouse entorhinal cortex (EC) and an optimized minimal promoter. Stereotaxic injections of relatively large volumes of such EC-specific enhancer-driven viruses in wildtype mice showed restriction of gene expression to the same specific set of EC neurons as obtained in the EDGE transgenic lines based upon that enhancer. Interestingly, these viruses drove cell type-specific expression not only in mice, but in rats as well. Our results suggest that the region-specific transgene expression that we attained in EDGE-transgenics is achievable with EDGE-viral vectors as well in wildtype animals of multiple species. Morever, because one can perform differential enhancer ChIP-seq in any species with a well-annotated genome, EDGE-viruses may ultimately provide a means to introduce transgenes to any specific cell-type in the brain of any species.

Title: Biolistic gene transfer reveals diverse synaptic organization of retinal ganglion cells

Authors: *F. HASAN[1], B. G. BORGHUIS[2], A. LOVETT[2]
[1]COMSATS Univ., Rawalpindi, Pakistan; [2]Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: To process information, neurons of the sensory systems integrate excitatory and inhibitory input at synapses expressed on their dendritic arbors. How many excitatory and inhibitory synapses a particular neuron type expresses—and where on the dendrites they are located—is important because it determines how a neuron responds to sensory stimulation. Within the visual system, it is well established that retinal ganglion cells differ strongly in their light-evoked responses, but the extent to which these differences reflect differences in distribution density of their excitatory and inhibitory synaptic inputs remains unclear. Measuring the distribution density of synapses is a challenge. For example, the sheer number of synapses and high degree of overlap of dendritic arbors precludes the use of immunohistochemical labeling for efficiently resolving the excitatory and inhibitory synaptic organization of a particular neuron type. To address this, we developed a biolistic (gene gun) approach for labeling excitatory and inhibitory synapses in single retinal ganglion cells and used anatomical reconstruction to compare the distribution density of synapses across morphologically identified ganglion cell types.

Our results show that ganglion cell types differ in (1) the number of synapses expressed on their dendrites; (2) the density of synapses expressed on their dendrites, for example, a cell with a small arbor can receive as many inputs as a cell with a large arbor; and (3) the ratio of excitatory to inhibitory synapses, which ranged from predominantly excitatory to predominantly inhibitory. The demonstrated experimental paradigm efficiently resolves the synaptic organization of morphologically identified ganglion cell types. Because the same cell types can be subsequently targeted for electrophysiological whole-cell recording, to assess relative magnitude and signal-to-noise ration of excitatory vs. inhibitory synaptic inputs, we expect this paradigm to help explain the response properties of visual neurons by relating structure to function.

Title: Flexible and inducible BDNF gene knockdown in rat neurons

Authors: *M. T. WONG-RILEY[1], D. WANG[2], M. GRZYBOWSKI[3], L. MU[2], D. A. BAKER[4], S. CHOI[4], A. M. GEURTS[3]
[2]Cell Biology, Neurobio. and Anat., [3]Physiol., [1]Med. Col. of Wisconsin, Milwaukee, WI; [4]Dept Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Brain-derived neurotrophic factor (BDNF) is known to be critical in neuronal development, survival, differentiation, synaptic transmission, and synaptic plasticity. Its presence is important throughout life, and its down-regulation is implicated in a host of neuropsychiatric disorders and neurodegenerative diseases. To tease out the exact relationship between BDNF and neuronal functioning during development and adulthood, appropriate animal models are necessary. BDNF-null mice suffer from severe developmental defects and sensory system degeneration, ending in death within days after birth. Knocking out the BDNF high-affinity TrkB receptors leads to even more severe phenotypes and death on postnatal day 1. Conditioned BDNF knockout in the postnatal brains of mice results in mature-onset obesity, hyperactivity to stressors, and a severe deficit in 5-HT_{2A}-mediated neurotransmission. To more closely mimic the natural state of adjusted neurotrophin levels in various neurological disorders, we generated an inducible BDNF knockdown rat model. These transgenic rats harbor an inducible, Synapsin 1 promoter-driven, Tet-On^{3G} for doxycycline-regulated expression of a second, responsive transgene harboring a fluorescence reporter and shRNA targeting the endogenous rat BDNF

mRNA. The responsive transgene contains sites for recombinase-mediated cassette exchange (RMCE), allowing swapping of the BDNF shRNA for other expression cassettes using the ΦC31/attP system. We tested the efficacy of doxycycline (Dox) in the drinking water for 2, 3, and 7 days and found that as brief as 2 days of Dox down-regulated the expression of BDNF and TrkB in both the prefrontal cortex and the visual cortex as compared to non-Dox littermate controls. Induced BDNF knockdown also reduced the expressions of a metabolic marker, cytochrome oxidase, and glutamatergic NMDA receptor subunit 1, but up-regulated the expressions of GABA and $GABA_A\alpha 1$ receptor in both the prefrontal and visual cortices as compared to non-Dox controls. Thus, our BDNF knockdown rats serve as a viable model for investigating the effects of BDNF down-regulation in a variety of systems and neurological disorders. (Supported by NIH grant R21 DA039681).

Title: Composite viral vectors for receptor-mediated gene delivery

Authors: A. ZDECHLIK[1], Y. HE[1], *D. SCHMIDT[2]
[1]Univ. of Minnesota, Minneapolis, MN; [2]Genetics, Cell Biol. & Develop., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Viral vectors are a major means of gene delivery with the potential to impact both basic research as well as clinical applications. Naturally evolved properties of many viral vectors are, however, mismatched to the needs of either. In gene therapy, for example, cell type specificity is paramount, as ectopic expression in off-target tissues or cells is undesirable and poses a safety risk.
Using Adeno-associated virus (AAV) as a model, we remove these legacy constraints of natural evolution by functionally separating viral entry (host recognition) and viral replication (gene delivery). We achieve this by producing a tropism-null AAV and then, in a programmable fashion, ‘arm’ it with covalenty linked antibodies and other non-immunoglobulin scaffold. We

demonstrate that these virus composites infect cells in receptor-specific manner. We also demonstrate re-targeting to a different receptor only requires arming virus with a different antibody and no modification of the virus itself.
Viral vectors that use well-understood binding scaffolds (e.g., antibodies) for receptor-mediated infection have broad utility, ranging from cell-type specific manipulation of neural circuits to new kinds of gene therapy approaches could significantly impact the care of persons with neurological disorders.

Abstract: Single cell RNA sequencing (scRNA-seq) has revealed an enormous diversity of transcriptionally distinct cell types in mouse brain. However, single cell sequencing cannot identify the locations of the corresponding cell types, which is essential not only to understand the spatial architecture of brain circuits, but also to relate transcriptomic cell types to other experimental methods such as two-photon calcium imaging.
We describe an improved method for in situ RNA sequencing of hundreds of molecules simultaneously, and apply it to characterize the spatial organization of interneuron subtypes in hippocampal area CA1 of mouse. We used a scRNA-seq dataset to identify key genes required to distinguish CA1 interneuron subtypes, and designed a set of padlock probes to target these genes, with multiple probes per target gene. The laminar organization of CA1 allowed us to calibrate the method using known locations of particular genes. We found that signal density was greatly improved by using specific primers in the initial cDNA synthesis step. Furthermore, read accuracy improved substantially with longer barcodes, with redundant coding allowing for accurate RNA calling despite background autofluorescence and other sources of error.
To classify cells based on these gene detections we used a probabilistic model. The mean

expression level of the selected genes in each type was taken by scRNA-seq, and we modelled the spatial distribution of each RNA species as a spatial point process centered on the cell centroids as determined by DAPI staining. Using variational Bayesian inference, we obtained a probability for a cell to belong to each class, and a probability for an RNA detection to belong to each cell. This approach avoided the necessity of accurately delimiting cell borders histologically, which is difficult in cell-dense structures such as the CA1 pyramidal layer. We verified the technique by confirming that it placed classical cell types in their expected laminar locations, and also used the method to identify the laminar locations of novel interneuron types identified by scRNA-seq.

Title: A real time screening assay for cannabinoid cb1 receptor-mediated signaling

Authors: *H. K. ANDERSEN, K. B. WALSH
Pharmacology, Physiology, & Neurosci., Univ. of South Carolina - Sch. of Med., Columbia, SC

Abstract: Cannabinoid-type 1 receptors (CB1) are highly expressed in the central nervous system where they modulate neurotransmitter release and synaptic plasticity through intracellular signaling. Specifically, CB1 activates the $G_i\beta\gamma$ subunit, which binds to G protein-coupled inwardly rectifying potassium (GIRK) channels and initiates an efflux of K^+ ions. GIRK channels suppress neuronal excitation through driving the neuronal membrane potential to more negative potentials, or hyperpolarizing the neuron. We developed a real-time, membrane-potential fluorescent assay for cannabinoids using pituitary AtT20 cells that endogenously express GIRK channels and were stably transduced with the human CB1 receptor using a

recombinant lentivirus (AtT20/CB1). In whole-cell, patch-clamp experiments, application of the cannabinoid agonist WIN 55, 212-2, to the AtT20/CB1 cells, activated GIRK currents that were sensitive to block by $BaCl_2$. WIN 55,212-2 activation of the GIRK channels was associated with a time- and concentration-dependent (EC_{50} = 309 nM) hyperpolarization of the membrane potential in the AtT20/CB1 cells when monitored using the fluorescent assay. The WIN 55,212-2-induced fluorescent signal was inhibited by pretreatment of the cells with the GIRK channel blocker, tertiapin-Q, or the CB1 receptor antagonist, SR141716. Using this assay, we determined the efficacies of four common cannabinoids tested at maximal concentrations: WIN 55,212-2 ≈ anandamide (AEA) > CP 55,940 > Δ9-tetrahydrocannabinol (THC). Additional testing identified cannabinoid compounds displaying unique efficacies and kinetics. In conclusion, this method provides a reliable and efficient screen for cannabinoid compounds that signal through $G_i\beta\gamma$, with possible future applications for the treatment of neuropathic pain.

Dept. of Neurosurg., Palo Alto, CA; [7]Depts. Biol. & Applied Physics, Stanford Univ. Dept. of Biol., Stanford, CA

Abstract: Understanding how the brain works at the circuit level requires sensors that can track various types of neuronal activity with sufficient resolution in space and time. Genetically-encoded voltage indicators (GEVIs) offer great potential in achieving this goal, but still require a lot of optimization to be routinely used in vivo. Development of GEVIs has been hampered by a lack of a high-throughput screening methods, which have been instrumental for rapid improvement of calcium indicators. GEVI screening is challenging because one must induce a change in membrane potential while accurately monitoring fluorescence output from the sensor on a fast timescale. Here we report the development of a fast screening platform for improving GEVI variants based on a novel concept for inducing rapid membrane voltage changes. Using

this approach, we obtained an improved ASAP-family GEVI, ASAP3, with a response amplitude of 50% to steady state voltage changes from -70 to +30 mV, and 20% to individual neuronal action potentials. We also report in vivo data using these same indicators.

Title: Combinatorial cadherin expressions in the mouse visual cortex detected by targeted *in situ* sequencing

Authors: *Y.-C. SUN, X. CHEN, A. M. ZADOR
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Cell adhesion molecules are required to establish the highly diverse neuronal projections in the vertebrate brain. Individual cadherins have been shown to specify fiber tracts and target areas, but it is unclear to what extent the expressions of multiple cadherins within a single neuron contribute to the complexity of neuronal projections. Testing this hypothesis requires detection of many cadherins within the same neuron for a comprehensive combinatorial cadherin expression profiling. Here, we adapt a targeted *in situ* sequencing technology to detect multiple endogenous mRNA transcripts simultaneously. We characterize the combinatorial neuronal expressions of over 60 cadherin superfamily members in the visual cortex of juvenile and adult mice. Because targeted *in situ* sequencing is also compatible with BARseq (Chen et al, 2018), a high-throughput technique for mapping long-range axonal projections based on *in situ* sequencing of RNA barcodes, this approach can be combined with *in situ* sequencing of endogenous mRNAs and barcodes to correlate gene expression and projections at cellular resolution. Such an approach would uncover the degree to which combinatorial cadherin expressions can predict neuronal projection patterns.Reference:

Title: A single spectrum of neuronal identities across thalamus

Authors: J. PHILLIPS[1], *A. SCHULMANN[1], E. HARA[2], C. LIU[3], L. WANG[1], B. SHIELDS[4], W. KORFF[1], A. LEMIRE[1], J. T. DUDMAN[1], S. NELSON[3], A. HANTMAN[1]
[1]Janelia Res. Campus, HHMI, Ashburn, VA; [2]CUNY Sch. of Med., Bronx, NY; [3]Brandeis Univ., Waltham, MA; [4]Duke Univ., Durham, NC

Abstract: Uncovering common principles by which diverse modalities of information are processed is a fundamental goal in neuroscience. In mammalian brain, thalamus is the central processing station for inputs from sensory systems, subcortical motor systems, and cortex; a function subserved by over 30 defined nuclei. Multiple thalamic nuclei send convergent information to each region of the forebrain, but whether there is a conserved architecture across the set of thalamic pathways projecting to each forebrain area has remained unresolved. To uncover organizational principles of thalamic pathways, we produced a near-comprehensive transcriptomic atlas of thalamus. This revealed a common logic for thalamic nuclei serving all major cortical modalities. We found that almost all nuclei belong to one of three major profiles, with a given cortical area getting input from each of these profiles. These profiles lie on a single axis of variance aligned with the mediolateral axis of thalamus, and this axis is strongly enriched in genes encoding receptors and ion channels. We further show that each projection profile exhibits different electrophysiological signatures. Single-cell profiling revealed that rather than forming discrete classes, thalamic neurons lie on a spectrum, with intermediate cells existing between profiles. Thus, in contrast to canonical models of thalamus that suggest it is a switchboard primarily concerned with routing distinct modalities of information to distinct cortical regions, we show that the thalamocortical system is more akin to a molecularly-defined ‘filter bank’ repeatedly applied across modality. Together, we reveal striking covariation in the organization of thalamic pathways serving all input modalities and output targets, establishing a simple and comprehensive thalamic functional architecture.

Title: Biodistribution of AAVHSCs in the central nervous system of non-human primates

Authors: *J. GINGRAS[1], K. OLIVIERI[2], N. ZAPATA[2], L. SMITH[2], H. RUBIN[2], P. MORALES[3], J. ELLSWORTH[2], A. SEYMOUR[2]
[1]Neurosciences and Ophthalmology, [2]Homology Medicines Inc, Bedford, MA; [3]The Mannheimer Foundation, Inc., Homestead, FL

Abstract: Adeno-associated viruses (AAVs) have emerged as key viral-based delivery vehicles for gene therapy in the nervous system due to their stable transgene expression in post-mitotic cells, neuronal tropism, lower risk of insertional mutagenesis and diminished immune response. We have recently reported the identification of novel AAVs derived from human hematopoietic stem cells (AAVHSCs). These novel AAVHSCs map to AAV Clade F alongside AAV9, which has been demonstrated to successfully cross the blood-brain-barrier (BBB) following systemic administrations. We set out to characterize the AAVHSCs to: 1) determine whether crossing the BBB was a generalized trait of Clade F AAVs and 2) assess whether the AAVHSCs could be attractive viral-vehicle candidates for gene therapy applications in the central nervous system (CNS). Herein, we report the biodistribution of AAVHSC7, AAVHSC15 and AAVHSC17 compared to that of AAV9 in the nervous system of 3- to 4-month old male cynomolgus macaques (*Macaca fascicularis*). Animals pre-screened for anti-AAVHSC neutralizing antibodies received a single intravenous (IV; 0.7-1E14 vg/kg) injection of recombinant AAVs packaging a self-complementary enhanced green fluorescent protein (sc-eGFP) transgene driven by the chicken beta actin (CBA) promoter. Biodistribution of AAVHSCs and AAV9 was assessed by anti-eGFP immunohistochemistry (IHC). All three AAVHSCs showed anti-eGFP immunoreactivity in the brain following IV administration. Furthermore, the three AAVHSCs displayed a distinct rostro-caudal distribution of anti-eGFP expression with the highest levels seen in the mesencephalon and myelencephalon. The largest cellular population displaying anti-eGFP were of glial origin, but anti-eGFP-positive neurons were also observed throughout different regions of the brain. Both neuronal cell bodies, dendrites and axons /axonal tracts were detected. These data demonstrate that, like AAV9, AAVHSCs effectively cross the BBB

following intravenous delivery in non-human primates, creating the potential for therapeutic applications in treating human genetic diseases of the CNS.

Title: Fluorescent biosensors for the “inside-out pharmacology” of nicotinic and opioid drugs

Authors: *A. K. MUTHUSAMY[1], A. V. SHIVANGE[2], P. M. BORDEN[3], A. L. NICHOLS[2], A. KAMAJAYA[2], J. JEON[2], J. S. MARVIN[3], E. K. UNGER[4], B. N. COHEN[2], H. BAO[5], E. R. CHAPMAN[6], L. TIAN[4], L. LOOGER[3], H. A. LESTER[2]
[1]Chem., [2]Biol. and Biol. Engin., Caltech, Pasadena, CA; [3]Janelia Res. Campus, Ashburn, VA; [4]Biochem. and Mol. Med., Univ. of California, Davis, Davis, CA; [5]Neurosci., Univ. of Wisconsin-Madison, Madison, WI; [6]Neurosci., Howard Hughes Med. Inst., Madison, WI

Abstract: Some chronic effects of nicotine begin when the drug enters cells and then, in the endoplasmic reticulum and *cis*-Golgi, binds to nascent nicotinic receptors (nAChRs). To quantify the extent and dynamics of this permeation with imaging in live cells, we employ genetically encoded fluorescent biosensors, targeted to various organelles. Our biosensors are built on a OpuBC-GFP platform. OpuBC is a bacterial periplasmic binding protein (PBP) with a cation-π box, favorable for binding amines common in neural drugs. Ligand binding induces a “venus fly-trap” conformational change. We connect hinge sequences to a circularly permuted “superfolder” GFP (cpGFP). With the aid of structural data, we used directed evolution to create a family of “intensity-based nicotine-sensing fluorescent reporters” (iNicSnFRs) meeting the criterion of

ΔF/F0 > 1 at 1 μM. Complementing previous studies, we directly show that nicotine itself enters the ER in clonal cell lines and in primary hippocampal cells, within 10 s of application of the sub-micromolar CSF concentrations of a cigarette smoker or vaper. When nicotine is removed from the external solution, it leaves the ER just as rapidly. Moreover, the nAChR ligand varenicline, a smoking cessation drug, shows only slightly slower kinetics, with implications for both the successes and weakness of varenicline. We now extend to other neural iDrugSnFRs, because most orally available and inhaled neural drugs have pK_a and logP metrics consistent with an "inside-out" pathway. We have curated a "panel" of biosensor mutants with varying binding pockets and linkers. Our drug "library" includes molecules with indications for analgesia, nicotine addiction control, schizophrenia, bipolar disorder, major depressive disorder, anxiety, and epilepsy. We screen "biosensors x neural drugs". This work also tests the first step in the hypothesis that μ, δ, and κ-opioid opiate drugs also exert some chronic effects via an "inside-out" pathway, beginning in the ER. We are optimizing iOpioidSnFRs for methadone and morphine, hoping to achieve sub-100 nM detection. This work complements other efforts to more completely understand the mechanism of tolerance to opioids.

Abstract: In order to enable high spatial and temporal resolution optical interrogation of neuromodulatory circuits, we set out to generate a genetically encoded fluorescent sensor for serotonin. To do this we chose to use the bacterial periplasmic binding protein (PBP)

superfamily as a source of scaffolds. This has three major benefits: soluble PBPs are amenable to high-throughput bacterial screening and easy crystallization, they have no known endogenous activity in eukaryotic cells, and most importantly, they have the potential for very large dynamic range, due to large ligand binding-dependent conformational changes. One disadvantage is that there are no known PBPs that bind serotonin; thus we opted to redesign the binding pocket of an existing acetylcholine-binding protein to recognize serotonin. In addition to using traditional methods for protein engineering, we developed a machine learning based approach to directed evolution that has the potential to produce very large improvements in performance with only low- to medium-throughput screening burden. Our method first employs a random forest model to identify which positions will be most efficient to mutate, then an absorbing Markov chain Monte Carlo simulation to calculate the minimum library size to be screened, and finally, once screening is underway, a generalized linear model to determine the contribution of individual mutations to the overall improvement in performance of the sensor, which can also predict the best amino acid combinations. This method is straightforward, easy and free to implement (requiring only rudimentary knowledge of statistics and coding), and can be used in conjunction with other methods, thus adding a powerful new tool to the protein engineering toolbox. Using this method, we were able to redesign the binding pocket to generate a fluorescent serotonin sensor whose affinity for serotonin is four orders of magnitude greater than the parent sensor, and which has three times the dynamic range. Furthermore, this sensor is sensitive enough to detect endogenous serotonin release.

Title: Molecular-fMRI of intracellular calcium using a novel, small molecule sensor

Authors: *B. B. BARTELLE[1], A. BARANDOV[2], C. G. WILLIAMSON[2], A. JASANOFF[1]
[1]Biol. Engin., [2]MIT, Cambridge, MA

Abstract: Developing a whole brain, noninvasive readout of intracellular calcium signaling is one of the greatest challenges in chemical neuroscience. Here we present a new calcium responsive MRI contrast agent (ManICS1) and its cell trappable variant (ManICS1-AM) that can report MRI signal changes in response to stimuli that elevate intracellular calcium. We demonstrate the utility of ManICS in cells and present the first *in vivo* neuroimaging of intracellular calcium activity using KCl stimulation seizure model in the striatum of an adult rat. The ManICS sensor consists of a cell permeable contrast agent and a BAPTA-based calcium chelator(**a**). Prior to cell entry BAPTA carboxylates are protected with AM esters, allowing water exchange at the metal center and T_1-weighted MRI contrast. Once in cells, AM esters are cleaved, and sensor enters the calcium-free "off" state (exchange blocked), with low MRI contrast. When calcium binds, BAPTA and paramagnetic center disengage, activating the sensor. ManICS1 shows significant relaxivity (r1) changes over physiologically relevant levels of calcium ManICS1-AM-loaded cells permeablized with a calcium ionophore showed calcium-induced changes over physiologically relevant concentrations of calcium with a midpoint at $[Ca^{2+}] = 5$ µM (**b**). Infusing ManICS-AM into the brain of an adult rat shows a broad distribution of the sensor across the striatum, similar to a non-functionalized cell permeable contrast agent (**c**), however an infusion of KCl causes T1 contrast changes only in the ManICS infused regions with a dynamic response over time (**d,e**). These results demonstrate Calcium-fMRI as a breakthrough technique for analysis of neural circuits in animals, with the short term potential for brain wide distribution and imaging and longer term applications in humans.

Title: Multimodal microscopic imaging of atherosclerosis plaque multi-composition for cerebrovascular events study

Authors: H. HUI[1], *X. YANG[1], J. TIAN[2]
[1]Key Lab. of Mol. Imaging, CAS, Inst. of Automation, Chinese Acad. of Scienc, Beijing, China; [2]Key Lab. of Mol. Imaging, CAS, Beijing City, China

Abstract: Atherosclerotic plaques are the main cause of cerebrovascular events such as ischemic heart disease and stroke. The cell components and structure of atherosclerotic plaques are the basis of plaque stage, events prediction and intervention evaluation. There is a high temporal and spatial heterogeneity in cell components and structure of atherosclerotic plaques. The current microscopic evaluation methods of plaques are evaluating a single sample in cross-sectional and single-component way. They cannot meet the needs of basic research in atherosclerotic plaques. Here we present a multimodal microscopic imaging system which integrating the technologies of two-photon excitation fluorescence imaging, nonlinear optical microscopy and photoacoustic microscopy imaging. It consists of two-photon microscopy imaging module, second harmonic imaging module, third harmonic imaging module, photoacoustic microscopic imaging module, dual-frequency laser light source module and image acquisition module. The equipment provides label-free, quantitative, sub-micron imaging of the different components and overall structure of the atherosclerotic plaque. The multimodal images are registered, three-dimensional and visualized within a unique software platform. This imaging device can be used to investigate the temporal and spatial heterogeneity of plaque stage and components and provides accurate and convenient image for basic research in atherosclerotic plaque and cerebrovascular diseases.

Title: Fast 3D imaging method for long-term recording neuronal activity and plasticity by acousto-optical two-photon microscopy

Authors: *D. PINKE[1], M. MAROSI[1], G. DOBOS[2], G. SZALAY[1], D. NAGY[1], C. CSUPERNYÁK[1], A. PLAUSKA[1], G. KATONA[1], B. RÓZSA[1,3]

Abstract: Introduction: The systematic understanding of brain function requires methods that allow neuronal activity to be recorded at different spatial scales in 3D at a high temporal resolution. Recording techniques are required that collect information from a neuronal population situated in an extensive volume of tissue.
Aims: Technical challenge of two-photon imaging in long-term is the stability of cell recordings. Lateral and Z displacement can be managed with 2D shift scanning and Z-focusing, however, effects of XYZ rotation and tissue deformation remain unsolved.
Methods: Here we present a novel fast 3D volumetric imaging method, suitable for long-term in vivo tracking of neuronal activity in mouse cortex by acousto-optical two-photon microscopy. We could precisely identify and record from the center plane of cell bodies and track the visually evoked neuronal activity. On the first day of the experiment after a control Z-stack acquisition in near-cubic-millimeter scan range, 3D drifting acousto-optical volumetric imaging (50x50x50µm Multi-cube scans) were recorded around the selected cell bodies. On the next imaging sessions the recording coordinates were re-loaded to the acquisition software and the recording sites were roughly identified by the vascular architecture. Then new Multi-cube scans were acquired and used for fine alignment in a 3D volume.
Results: With the Multi-cube scanning method we are able to locate and record Ca2+ activity (with GCaMP6f) of the same neuronal ensemble during our 10-20 days long protocol including baseline, training and post learning imaging sessions of up to 200 cells. Our results show this method is significantly more accurate than a conventional Z-stack ROI selection.
Conclusions: We demonstrate a method, that allows us to record long term neuronal plasticity from the same cell population in a near-cubic millimeter 3D volume, up to 2 months. For this reason, the Multi-cube scanning method is suitable for long term imaging behavior protocols.

Title: Machine learning for conjugate light-electron array tomography

Authors: *O. GLIKO, S. SESHAMANI, F. COLLMAN, L. ELABBADY, M. KARLSSON, M. NAUGLE, R. SERAFIN, J. SCHARDT, S. J. SMITH
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Conjugate array tomography (AT) integrates immunofluorescence (IF) and scanning electron microscopy (SEM) imaging of arrays of serial ultrathin sections with volume reconstruction. IF imaging using multiple molecular markers enables localization of presynaptic and postsynaptic proteins. The pipeline for generating such datasets involves several complex

steps that can be enhanced with the use of machine learning. Here, we highlight 3 such applications: focus classification, cross modal registration and synapse detection and show how the results can be integrated back into the AT pipeline.
Fully automatic identification of focus quality of a single image cannot be achieved using standard algorithmic approaches. Deep neural networks have been shown to classify out-of-focus microscope images with higher accuracy [1]. We use this approach to assess absolute defocus levels of image sub-regions. This information can then be fed back into the pipeline for automated quality control during image acquisition where images would either pass quality control, be restorable by deconvolution using an adjusted point spread function or require a retake.
Registration of IF and SEM images is a challenging problem since the appearance of structures can vary widely between these modalities. In initial work [2] we used deep learning for the prediction of myelin basic protein (MBP) IF images from SEM images. This enabled us to perform simple cross correlation based registration to register these two modalities in areas where sufficient MBP is present. Here, we generalize the application by using deep learning to estimate multiple IF markers which enhance registration by reducing dependency on a single channel and provide varied densities of features for global and local registration.
Currently used manual synapse detection methods are very tedious and time consuming for analysis of large volume datasets. We use deep networks to learn to localize synapses from multi-channel IF data. Ground truth information is collected from SEM data that is manually annotated and we show that we are able to perform pixel based detections at a rate of 85% which conforms with the current state of the art synapse detection rate in high resolution EM.

Title: Beam shaping oblique light sheet tomography

Authors: *X. QI, A. NARASIMHAN, K. U. VENKATARAJU, D. F. ALBEANU, P. OSTEN
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Brain functions involve neural circuits with long-range projections, such as corticospinal layer 5B neurons of the motor cortex neurons mediating movement control and motor learning.
Furthermore, neurodevelopmental and psychiatric disorders have been speculated to include deficits of long-range neural circuits connecting multiple brain regions. Thus, mapping whole-brain neuron morphology at submicron resolution has the potential to reveal novel circuit organizations in normal brain and shed light on circuit pathologies in mouse models of human brain disorders.
Oblique Light Sheet Tomography (OLST) is a whole-brain volumetric imaging platform operating on the principle of light-sheet microscopy combined with serial tissue sectioning. The light-sheet illumination is based on a Gaussian beam with z thickness varying between ~ 5~7 μm. To further improve the z resolution of OLST for imaging fine details of neuronal morphology, we developed an advanced beam-shaping OLST instrument that employs beam shaping methods (Bessel, Airy and lattice beams) to achieve high axial resolution with a more uniform illumination field. Additional instrument improvements include algorithms for 3D stitching of the large whole-brain datasets and the integration of 2 cameras for two channel imaging. The 2nd generation OLST instrument promises to open new avenues to single neuron reconstructions across the whole mouse brain, improving our understanding related to the relationships between long-range neuronal circuits and brain functions as well as brain disorders.

Title: Somato-dendritic morphological analysis using oblique light sheet tomography

Authors: *A. NARASIMHAN[1], U. SÜMBÜL[2], K. UMADEVI VENKATARAJU[1], R. PALANISWAMY[1], D. ALBEANU[1], P. OSTEN[1]
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Allen Inst. For Brain Sci., Seattle, WA

Abstract: The somato-dendritic morphology is a classic feature in defining neuronal types. While morphologies of smaller subsets of anatomical regions have been studied in more detail, we aim to study the morphology and axonal projections of the pyramidal cells of the entire mouse neocortex using a custom-built Oblique Light Sheet Tomography (OLST). OLST is a whole-brain volumetric imaging platform operating on the principle of light sheet fluorescence microscopy. Briefly, the illumination/detection paths in OLST are oriented obliquely (45°) with respect to the tissue surface, allowing for imaging up to ~400 μm depth from the surface in an XY raster pattern. An integrated vibratome sections the imaged portion of the tissue once the raster scan is completed. The raster scan and automated sectioning are repeated iteratively to obtain whole brain coverage. We report that the current instrument configuration allows us to image an adult mouse brain within ~14 hrs at 0.4 x 0.4 x 2.5 μm voxel resolution with overlapping regions for image registration and reconstruction.
To identify individual neurites in our images, we obtain a sparse labeling of the pyramidal cells in Emx1-Cre mice using intravenous injections of Cre-dependent reporter AAV viruses. We also report an optimized CUBIC tissue clearing protocol to improve image quality, especially deeper into the tissue. Clearing, however, removes the lipids in the tissue, and makes the brain structurally soft. Therefore, we developed a novel gelatin-based embedding to improve the rigidity of the brain for sectioning. Finally, we developed a supervised machine learning-based approach to overcome the limitations of manual annotation and to process large volumes of data that our OLST platform generates: deep neural networks were trained to binarize the raw images and subsequently obtain the skeletons of neuronal arbors automatically. This framework enables us to study fine morphology and the spatial patterns of cortical neurons at a high-throughput, a prerequisite for identification of cell types.

Title: Light sheet fluorescence expansion microscopy: Fast mapping of neuronal connectivity at super resolution

Authors: *J. E. RODRIGUEZ GATICA[1], I. PAVLOVA[2], J. BÜRGERS[1], M. K. SCHWARZ[2], U. KUBITSCHECK[1]
[1]Inst. of Physical and Theoretical Chem., [2]Functional Neuroconnectomics Group, Inst. of Cell. Neurophysiol., Rheinische Friedrich-Wilhelms-University Bonn, Bonn, Germany

Abstract: The goal of understanding the architecture of neural circuits at the synapse level with a brain wide perspective (connectome) has powered the interest in high-speed and large field of view volumetric imaging at subcellular resolution. The critical details of neuronal connectivity, e.g. synapses, occur on length scales of about 100 nm. Structures small like this can optically be resolved using super resolution light microscopy. Unfortunately, this is not feasible for the reconstruction of extended neuronal networks, because all available super resolution approaches are restricted to thin samples of about 20 µm in depth, and synaptically connected neurons can be spatially separated from each other by hundreds of micrometers.
Here we combined tissue expansion and light sheet fluorescence microscopy to allow volumetric super resolution high-speed imaging of large mouse brain samples. These two methods are an ideal match to obtain super-resolved images of extended neuronal circuits with three distinctive features, namely (i) high imaging rates up to 50 Hz, (ii) high contrast and (iii) low photobleaching.
We achieve a virtual lateral and axial optical resolution of 80 and 250 nm, respectively.
We demonstrate the capabilities of this method by performing fast volumetric super resolution imaging of mouse dentate gyrus. Additionally, our approach allows us to observe eGFP-labeled proteins, thus avoiding antibody staining. In this manner neural connections can be mapped throughout all the acquired/imaged sample, allowing a better segmentation of dentate granule cell neurites for further morphology analysis, e.g. a three-dimensional Sholl analysis within the context of large cell ensembles spanning several orders of magnitude.

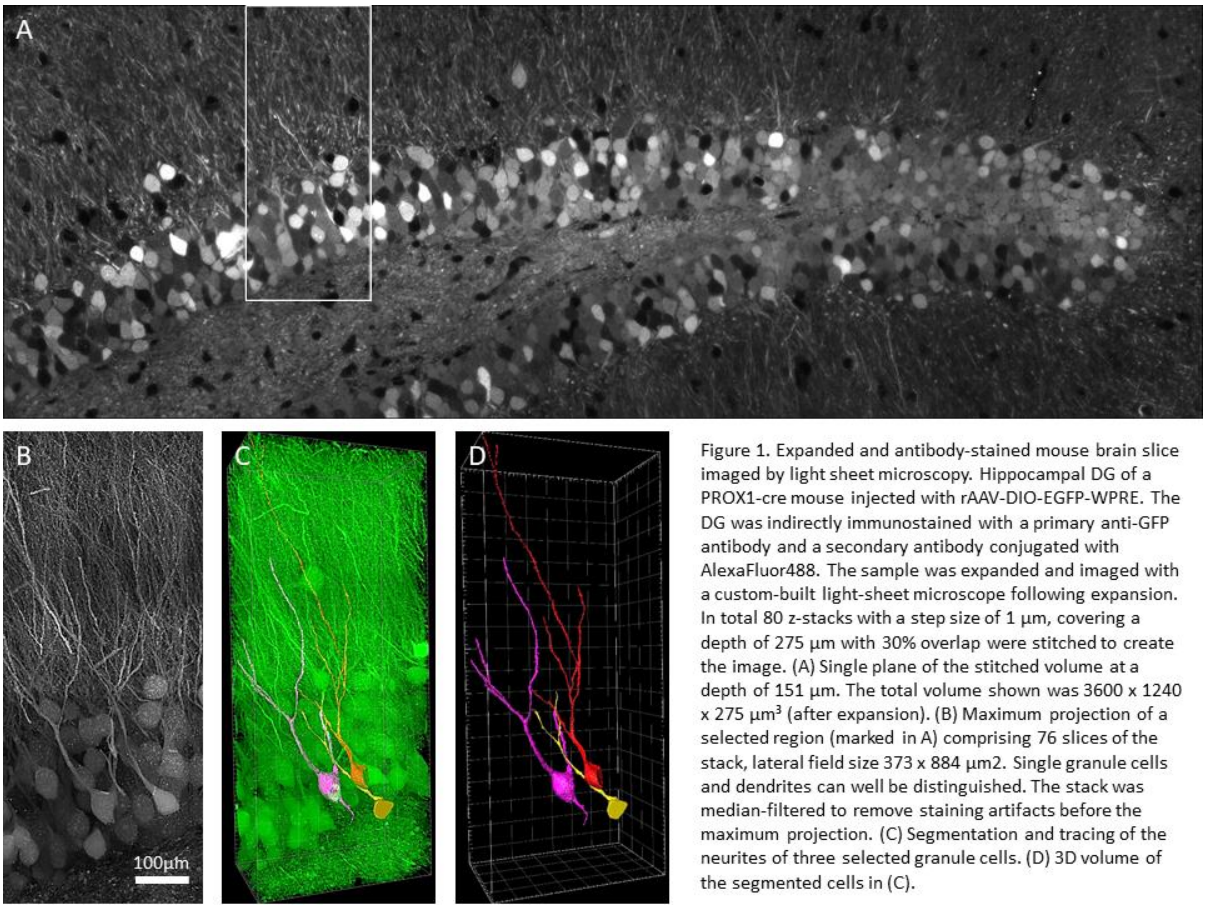

Figure 1. Expanded and antibody-stained mouse brain slice imaged by light sheet microscopy. Hippocampal DG of a PROX1-cre mouse injected with rAAV-DIO-EGFP-WPRE. The DG was indirectly immunostained with a primary anti-GFP antibody and a secondary antibody conjugated with AlexaFluor488. The sample was expanded and imaged with a custom-built light-sheet microscope following expansion. In total 80 z-stacks with a step size of 1 µm, covering a depth of 275 µm with 30% overlap were stitched to create the image. (A) Single plane of the stitched volume at a depth of 151 µm. The total volume shown was 3600 x 1240 x 275 μm^3 (after expansion). (B) Maximum projection of a selected region (marked in A) comprising 76 slices of the stack, lateral field size 373 x 884 µm2. Single granule cells and dendrites can well be distinguished. The stack was median-filtered to remove staining artifacts before the maximum projection. (C) Segmentation and tracing of the neurites of three selected granule cells. (D) 3D volume of the segmented cells in (C).

Title: Generalized registration of multiple views in light sheet microscopy

Authors: N. PAPP, *K. KILBORN
3i, Denver, CO

Abstract: Many approaches to light sheet imaging involve acquiring 3D volumes from multiple directions in order to achieve higher resolution, reduce artifacts, and overcome limited light sheet penetration. However, proper registration of these views often requires either embedding

fluorescent beads as fiducial markers ('interest points') or locating punctate structures in the specimen itself that can serve as substitutes for deliberate fiducial markers. Either way, these approaches typically require significant user interaction and parameter selection, making registration a labor-intensive process. We propose a method which does not rely on the detection of interest points, but uses localized cross-correlation to determine shifts between corresponding small sub-volumes of the component views. Our only assumptions are that registration between views can be approximated with an affine transformation and that there is non-periodic high-frequency content in the component views.
We assume that registration error can be bounded by the physical geometry or motion control precision that has produced the individual views. The overall volume of each view is divided into sub-volumes that are large enough to span this error bound. From these sub-volumes we can construct corresponding points between views to be solved as a system of linear equations, producing a 4 x 4 matrix that describes an affine transformation from one view to another or from one view to a canonical orientation. Multiple iterations will improve the accuracy of the transformations.
Examples drawn from data collected using dual inverted selective plane illumination microscopy (diSPIM) and other light sheet architectures are presented and performance is compared to other registration approaches.

Western Switzerland (HES-SO), Geneva, Switzerland; [7]Stanford Univ., Stanford, CA; [8]Columbia Univ., New York, NY

Abstract: Light sheet microscopy is a fluorescence imaging technique that allows visualization of whole organs or small organisms while preserving their physical integrity i.e. without the need to slice them prior imaging. Although the principles of this technology were developed more than 100 years ago, it is only in the last fifteen years that researchers have started to routinely apply it to biological specimen and that it has developed into a field of research of its own. At the Wyss Center for Bio and Neuroengineering in Geneva, Switzerland, we have created an imaging center which integrates a series of cutting edge and custom-tailored tools into a single working pipeline aimed at imaging whole organs at high temporal or spatial resolution. The center includes a customized version of the COLM/SPED (Tomer *et al.*, Cell 163, 2015; Tomer *et al.*, Nat. Protoc. 9, 2014) microscope for near diffraction-limited resolution imaging of large clarified samples (cm range). We have optimized the design of this microscope to allow a quick exchange of different objectives and to enable the imaging of very large samples (> 10 cm) at a sub micronic spatial resolution. Recently we expanded the capabilities of light sheet microscopy, setting up a large-scale imaging system: mesoSPIM (see poster by Fabian F. Voigt). This customized system enables whole brain imaging at cellular resolution, in a few minutes with no need for further image-stitching processes. Finally, we are collaborating with research groups setting up innovative analysis tools (e.g. MIRACL pipeline now available for automated segmentation of clarity-optimized data sets and registration in the Allen Brain Atlas) and developing in house innovative 3D exploration that will enable researchers to navigate and segment their own light sheet data in a Virtual Reality environment. This pipeline offers to the researcher the possibility for large scale screening, high-resolution imaging and data visualization and analysis. We will show, as an example, how using this unique pipeline, it is possible to map anatomical projections emerging from and targeting the posterior medial nucleus of the thalamus in mouse brain. We will also show how this unique technical approach may help to understand the organization of the ascending motor pathways from the spinal cord to different brain regions involved in the control of voluntary movement.

Abstract: Tissue clearing methods have recently seen a renaissance with a wide variety of clearing approaches now available. In neuroscience, the combination of tissue clearing with light-sheet microscopy is ideal to bridge scales from the µm to cm-level, thus providing a link on the mesoscale for detailed 3D anatomical investigations. To optimally image cleared samples, we set out to design a modular light-sheet microscope that combines extremely simple sample mounting and exchange with large field-of-views (FOV) of 2-22 mm to provide users with overview datasets within minutes. Especially for such large FOVs, common light-sheet microscopes suffer from non-uniform axial resolution due to the varying thickness of the light-sheet which in turn drastically reduces data quality. To circumvent this problem, we are using tuneable lenses to shift the excitation beam waist through the sample in synchrony with the rolling shutter of the camera. For whole mouse brains, typical datasets are isotropic (5 µm sampling), small (12-16 GB/colour), and generated quickly (7-8 minutes). Together with standardized quick-exchange sample holders, these features allow fast screening of samples for clearing, imaging, and labelling quality and thus speed up research projects tackling questions involving cell distributions and projection patterns. After creating overview datasets, users can zoom in and acquire high-resolution data. The microscope has been tested and validated in combination with common clearing methods ranging from hydrogel-based techniques such as CLARITY to organic solvent approaches such as iDISCO – by using a modular design of the imaging chambers, switching between different imaging media can be done in less than a minute. Recently, we have realized four such microscopes at various institutions across Switzerland as

part of the mesoSPIM initiative (mesospim.org) – a project aimed at creating a community to accelerate the exchange of tissue clearing and mesoscale imaging expertise. Microscope hard- and software are open-source and we welcome suggestions and improvements.

Title: SPED microscopy with GPU accelerated deconvolution

Authors: *P. SCHWARZ, M. HIRTE, C. R. YU
Stowers Inst. for Med. Res., Kansas City, MO

Abstract: The advent and evolution of tissue clearing methods has increased demand for microscopy methods capable of acquiring images with a high speed and a large field of view. One such method, Spherical-aberration-assisted Extended Depth-of-field light sheet microscopy (SPED-LSM) generates and scans a light sheet along a depth of field that has been elongated by induced spherical aberration. SPED-LSM can theoretically acquire data as fast as modern sCMOS cameras can operate, but it suffers from computationally expensive deconvolution after the acquisition. Here we discuss the construction of a SPED-LSM using salvaged components from a decommissioned microscope including lasers, acousto-optic tunable filters, and galvanometric scanning mirrors. Together with an improved embedding method and modified software, we performed imaging of entire mouse brains cleared with CUBIC and SCALE. We also implemented a modified algorithm to accelerate the deconvolution by moving the computation from the CPU to a GPU. The deconvolution approach improved speed performance by two to four times when compared with the algorithm used in the original demonstration of SPED microscopy, making SPED microscopy more practical for large datasets. These improvements enable us to analyze the structure and function of interconnected neurons throughout the brain.

Abstract: Recent strategies for large-scale microscopy enable micron-resolution imaging over cubic millimeters of tissue, hence transforming brain imaging. These approaches however currently lack efficient multicolor contrast modalities. We present chromatic serial multiphoton (Chrom-SMP) microscopy, a novel method combining multicolor two-photon excitation through wavelength mixing (Mahou et al. Nature Methods 2012) and serial block-face acquisition. This approach enables organ-scale imaging of spectrally distinct fluorescent proteins with intrinsic submicron channel registration and constant diffraction-limited resolution over the entire imaged volume. This technology also permits whole-brain label-free imaging based on third harmonic generation (THG) and coherent anti-Stokes Raman scattering (CARS) contrast which provide detailed morphological context. We combine Chrom-SMP with Brainbow transgenic markers and viral or electroporation-based multicolor labeling strategies in the mouse brain and demonstrate continuous 3D multicolor imaging over cubic millimeters of neural tissue as well as brain-wide serial 2D multichannel imaging. We illustrate the potential of this method through color-based analysis of astrocyte morphology and spatial interactions in the cerebral cortex, and

multiplexed whole-brain mapping of axonal projections labeled with distinct tracers. Chrom-SMP is therefore a robust and broadly applicable scheme for high resolution multicolor imaging over large tissue volumes, enabling to upscale color-based approaches for analysis of neural cell morphology, connectivity and lineage to the whole brain.

Title: Registration methodology for cleared rodent brain tissue

Authors: *A. E. BRANCH[1], D. J. TWARD[2], V. CHANDRASHEKHAR[3], M. MILLER[3], J. T. VOGELSTEIN[3], M. GALLAGHER[4]

Abstract: Anatomical mapping of brain imaging data is essential for assessing disease-relevant alterations in brain structure and analyzing neural circuit connectivity. Numerous protocols were recently developed to render brain tissue optically clear, facilitating intact whole-brain lightsheet microscopy. However, methods for mapping the resulting cleared-brains to reference atlases are both ineffective and computationally burdensome. We are building a computational ecosystem to register cleared brains to atlases which is reliable and compatible with multiple clearing protocols, lightsheet imaging modalities, and species. Existing nonrigid registration methodologies were largely developed for human MRI. Application of such algorithms to lightsheet generated whole brain image sets requires overcoming challenges not present in human brain MRI. The primary challenge is missing data, caused by limited field of view acquisitions or removed tissue, resulting in a mismatch between the atlas and data set. We address this by registration of observed data only, employing binary masks in the case of limited field of view, or non-binary weights when the location of missing tissue must be estimated. The second challenge is inconsistent image intensities between available atlases and observed images. When intensities of anatomical structures are ordered consistently locally, for example a structure in the atlas is brighter than its surroundings whenever the same is true for the observed

image, a local rank transformation is sufficient to bring the intensities into agreement, and estimating mappings by minimizing a mean square error objective function is appropriate. When this is violated, we use an objective function based on mutual information. The final challenge is modality specific artifacts that arise in lightsheet imaging. Shadowing artifacts that occur when tissue interfaces are tangent to the direction of an illuminating laser are removed with a notch filter to remove spatial frequencies normal to each laser. Grid artifacts from stitching together small volumes of nonuniform illumination are removed by estimating the nonuniformity using its consistency from one slice to the next. These strategies have enabled accurate registration between well characterized atlases and small animal images, allowing us to quantify the distribution of cells and their connections by anatomical region. These approaches are being combined into a open source package called ndreg, available from neurodata.io, which can be used to align CLARITY and iDISCO cleared brains generated from either mouse or rat brains.

Abstract: Topoisomerase I (Top1) is a transcriptional regulator that is broadly expressed in postmitotic neurons of the developing and adult brain. Inhibition of topoisomerase activity dose-dependently downregulates transcription of long neuronal genes typically involved in synaptic function, neurotransmission, and axonogenesis. Mutations in topoisomerases have also been linked to autism, intellectual disability, and neurodegeneration, yet little is known about the functional or structural brain deficits caused by these mutations. To address this question, we generated a conditional knockout mouse (cKO) model using a Nex1-CRE driver to specifically delete Top1 in excitatory neurons. By performing whole mount immunostaining of P15 mice using iDISCO+ along with rapid imaging by light-sheet microscopy, we observe 1) a dramatic

reduction of cortical thickness including a complete loss of layer V throughout the cortex and 2) degeneration of pyramidal layers within the hippocampus. This suggests Top1 preferentially influences the survival of only certain neuronal populations. To automatically localize and quantify cell-types within these structures, we implement a novel cascading convolutional neural network (CCNN) to accurately segment cell nuclei in densely labeled regions and random forest regression of image landmarks to map anatomical correspondence in the Top1 phenotype. Currently we are upgrading our CCNN to whole brain 3D nuclear segmentation scenario while also acquiring cellular resolution images of multiple whole brain samples. Using this approach, we will quantify whole brain structural impacts of Top1-associated neuropathology. Furthermore, the tools developed here will be useful in quantifying cellular level structural deficits in other animal models of neuropsychiatric disease or human samples.

Title: Optimizing tissue clearing method for human brain tissue: Preparing methods, clearing efficiency, staining methods, and imaging strategy

Authors: *K. MIN SUN[1], J. AHN[2], J. MO[2], H. SONG[2], H. CHOI[2]
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Functional Neuroanatomy of Metabolism Regulation laboratory, Seoul, Korea, Republic of

Abstract: Currently, the tissue clearing method is actively used in neuroscience research. Recent advances in tissue clearing method allow visualization of neural networks inside of unsectioned whole brain tissues. However, a protocol applicable for human brain tissue has not yet been optimized because of difficulty to gain fresh human samples. We aimed to optimize human brain clearing and imaging methods using fresh human samples. Fresh human brain samples obtained at autopsy and cadavers donated for medical school practice were used. The cadaver sample was fixed for more than one year, and the autopsy sample was fixed for about one week. We applied active electrophoretic clearing for human brain tissue. Every hour after clearing, we quantified the degree of transparency using Image J. DAPI(Nucleus, 5days dye incubation) and GFAP(Astrocyte, 5 days primary antibody incubation) was stained. Confocal microscope was

used to investigated staining depth. Fresh human brain samples showed higher clearing efficiency compared with cadaver samples (30% transparent; 1hr vs. 30hr). Fresh human brain samples showed fewer autofluorescence compared with cadaver sample. DAPI was stained to over 300μm for fresh human brain samples. However, there was no DAPI staining in cadaver sample. GFAP staining was vivid until the staining depth of 20-50um, on the other hand, DAPI showed higher penetration pattern 300um. For GFAP staining, fresh human brain samples were stained denser than cadaver samples. For NeuN, no staining was shown. We have shown successful human brain 3D imaging results using fresh human samples. Fresher samples have better clearing efficiency, fewer autofluorescence, high number of stained antigen. Fresh human brain samples are prerequisite for 3D visualization of human brain.

Title: Creation and anatomically based registration of 3D histological brain atlas in the prairie vole

Authors: *R. MUÑOZ CASTAÑEDA[1], K. UMADEVI VENKATARAJU[1], T. BURKHARD[2], S. M. PHELPS[2], P. OSTEN[1]
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Complex behavior requires the coordinated function of a complex network of different types of neurons and glia. To understand how behavior emerges from these many interacting cell types, it is essential to study the three-dimensional brain at cellular resolution. New imaging techniques, such as serial two-photon tomography (STPT) and light-sheet fluorescence microscopy (LSFM), allow us to generate whole-brain datasets at a cellular resolution. To acquire and make sense of this enormous amount of information, however, it is also essential to automate acquisition and analysis of such data. In order to better understand the neurobiology of bonding, we are developing an automated pipeline for the acquisition and analysis of cellular resolution data from the brains of the socially monogamous prairie vole. Such data can be compared to similar data from traditional model species like the laboratory mouse. The first step in creation of an automated computational pipeline for each new species is the creation of a 3D reference brain whose regional volumes are co-registered to an anatomical atlas. Since Nissl and related stains are the standard methods to define anatomical brain structures, we used

NeuroTrace fluorescent Nissl-staining on intact prairie vole and mouse brains to perform 3D imaging with STPT and LSFM. We use genetic labels such as Cre-based reporter mouse lines (eg ChAT-IRES-Cre) to provide additional delineations of neuroanatomical structures. We demonstrate the validity of the present pipeline by creating mouse and prairie vole 3D brain atlases with cellular resolution. The resulting atlases allow us to analyze whole brain anatomy and cell distribution in the two rodent species and suggest a general framework for the creation and analysis of such maps in other useful species.

Title: Identification in male rats by manganese enhanced magnetic resonance, of the neural circuits controlling sexually motivated behaviors

Authors: *L. GAYTAN[1], R. PAREDES[2]
[1]Intituto de Neurobiología, UNAM, Querétaro, Mexico; [2]Neurobiología, UNAM, Juriquilla, Mexico

Abstract: Two motivated behaviors that are crucial for the expression of sexual behavior are sexual incentive motivation (SIM) and partner preference (PP). In the SIM test no physical contact is possible while In the PP test the subjects can interact with the stimulus animals quantifying the sexual interaction and the time spent in each compartment. The possible circuits controlling these behaviors have not been studied using magnetic resonance imaging. The aim of the present study is to determine by manganese enhance magnetic resonance imaging (MEMRI) the different neural circuits, activated in SIM and PP**.** The use of MEMRI allows mapping the brain of the animal in vivo where manganese ions (Mn2+) pass through the blood brain barrier and enter into excited cells via voltage-gated calcium channels identifying brain regions activated by a particular behavior (Takeda et al., 2003). In the present experiments, MnCl2 (16 mg/kg) was administered 24 h before the behavioral tests and immediately thereafter the subjects were placed in a Bruker 7T MR scanner. Sexual behavior, PP and SIM were not affected by the administration of manganese at 16 mg/kg. With this dose, we obtained a good contrast for MRI analysis. The image analysis revealed an activation of the medial preoptic area, anterior

hypothalamus, amygdala, nucleus accumbens and hippocampus after the SIM and PP tests. These regions were activated in the females when tested in week 5 and 10. The same regions were activated in males in week 10 suggesting that experience in males and females induces a differential activation of circuits controlling motivated behaviors such as SIM and PP. **Technical assistance F. Title: Identification of brain regions by hyperspectral imaging without staining

Authors: *S. INOUE[1], K. HOTTA[2], K. OKA[2]
[1]Keio Univ., Yokohama, Japan; [2]Keio Univ., Yokohama, Kanagawa, Japan

Abstract: Brain has many anatomically identified regions with specific functions. For the comparative studies of brains from different animals, brain map plays an important role. However, in previous studies, specific brain regions are generally identified by the cytoarchitectures visualized by several staining methods. Furthermore, their validity and reproducibility as brain maps have not been adequately studied, so brain maps have been conventionally prepared empirically. In this study, we propose a new method for identifying specific brain regions by hyperspectral imaging of brain tissues. The transmitted light of tissues reflects anatomical structure and compositions as spectral intensity. We detect difference of the hyperspectral information and rationally identify specific brain regions. This method requires non-staining of tissues, so we expect the results different from preceding study. It is difficult to identify specific anatomical information from the spectrum, *a priori*. Therefore, we analyzed

broad-band spectrum with several information technique and tried imaging without staining or specific targets. We applied this method to the brain of zebra finch (*Taeniopygia guttata*). The brain sections were irradiated with white light and transmitted light was acquired with a hyperspectral camera. The spectral resolution was 5 nm in the observable wavelength range (380-1000 nm). Each band provided different images from the same sample. We applied principal component analysis to the spectrum, and the image of the second principal component showed a specific structure that cannot be seen obviously in the original image.

Title: 3D brain structure in zebra finch by CUBIC and voronoi tessellation

Authors: *M. ENDO, S. INOUE, M. INDA, K. HOTTA, K. OKA
Keio-Univ, Yokohama-Shi, Japan

Abstract: The zebra finch (*Taeniopygia guttata*) is one of the species that acquires song, and communicates each other by songs. The male zebra finch leans tutor's song and acquires his own song with individually difference. While the female zebra finch discerns male's songs and shows preference for specific songs. From these sexually different functions in vocal communication, the brains of male and female finches have different brain structures and functions. Recently, sexual differences of the brains have been studied, but it was mainly to focus on limited auditory areas such as LMAN and HVC (Long *et al*., 2009). We, therefore, comprehensively investigate the whole brain structure by using transparent technique. We focused on the female brains because there is no detailed brain map for female zebra finches. Also, even in the male zebra finch, a 2D brain map has been produced, but a 3D brain map has not been created. Therefore, in this research, we attempt to create 3D brain maps of male and female finches to compare between their brain structures. We succeeded in clearing the female brain using the clearing method, CUBIC (Susaki *et al*., 2014) with a little modification. In addition, we succeeded to detect the nucleus by propidium iodide (PI) staining with light sheet microscopy (Alpha ^{3}, PhaseView) and we obtained about 50,000 positions of the nuclei in part of the midbrain and cerebellum. Based on these nuclear positions, Voronoi tessellation is performed to create a draft map of the brain. By comprehensively observing, we explored sexual differences that have not been characterized before.

Abstract: Cutting tissues into thin slices has been the standard practice for many years in scientific research. This method provides two-dimensional information about the tissue. However, life occurs in three dimensions (3D); for this reason, scientists have always tried to extend tissue imaging to thick specimens. In neuroscience, visualization of intact brains in 3D is of intense focus. Previously, we developed a new imaging platform termed DIPCO (Diagnosing Immunolabeled Paraffin-Embedded Cleared Organs) that uses 3D light-sheet microscopy and whole-mount immunolabelling of cleared samples to study proteins and micro-anatomies deep inside of tumors (Tanaka et al., Nature Biomedical Engineering, 2017). Here, we have further optimized this method for whole-mount immunostaining of mice brains to calculate the number of cells in the intact tissue. We were able to accurately calculate the number of microglial cells to 1.599.622 in the cerebral hemisphere of a P28 mouse using the Iba-1 marker. To our knowledge this is the first time that the exact number of cells has been determined in a mouse brain. We believe that this pipeline can be applied for precise calculations of the cellular composition of various brain regions to help us understand the structure and function of adult brain.

Title: Volumetric analysis of hexachlorophene-treated rats by MRM and stereology for neuropathology

Authors: *M. A. STAUP[1], D. BROWN[1], C. JOHNSON[1], P. LITTLE[2], R. SILLS[3], G. A. JOHNSON[4]

Abstract: Standard neuropathological assessment of the effect of toxic compounds on supraspinal areas of the central nervous system (CNS) involves a routine examination of seven coronal brain sections. A microscopic evaluation of prescribed 2-dimensional fields of view from

these sections is the traditional approach for identifying suspect lesions and other abnormalities. This method draws conclusions about whole structures in the brain based upon abnormal histological findings and, occasionally, length and area measurements. Two methods that complement our standard neuropathological assessments include magnetic resonance microscopy (MRM) and stereology, which offer the advantage of absolute and estimated (respectively) volumetry of lesions and other regions of interest. In the present study, myelinated tracts of adult male Sprague-Dawley rats were targeted with oral-administration of hexachlorophene. Hexachlorophene is a well-characterized organochlorine compound that causes vacuolation within the intraperiod line of central and peripheral myelin sheaths. Volume differences of discrete fiber bundles within the CNS were measured in hexachlorophene-treated (n=7) and vehicle-treated (n=10) animals using the stereology-based Cavalieri method of volume estimation from systematic uniform random sections. Volume analysis was also performed on the same animals using diffusion-weighted, 3-dimensional renderings reconstructed from MRM sectioning of the entire brain. The areas analyzed were the anterior part of the anterior commissure (aca), the longitudinal fasciculus of the pons (lfp), and the pyramidal tracts (py). Sampling for the Cavalieri method was adjusted to obtain a suitable coefficient of error (CE), which contributed less to the overall variance than the biological variability between animals. The standard deviations generated by both techniques were tested for statistical power. Our results lead us to the conclusion that volumetric analysis by MRM and stereology add significant value to our standard 2-dimensional microscopic evaluations.

Title: Optogenetic blood oxygenation level dependent (BOLD) and cerebral blood volume (CBV) fMRI

Authors: *F. SCHMID[1], M. CHOY[1], A. J. WEITZ[2], J. H. LEE[1,2]
[1]Neurol., [2]Bioengineering, Stanford Univ., Stanford, CA

Abstract: fMRI is an important technique that offers non-invasive assessment of activity across the whole brain. It provides crucial information about network activity, complimenting electrical and optical neurophysiological methods that offer high specificity and cellular resolution. fMRI

can detect signal changes due to the inherent blood oxygen-level dependent effect (BOLD), or due to mediated signal changes using iron oxide nanoparticles as a vascular contrast agent reflecting changes in cerebral blood volume (CBV). Both techniques can indirectly measure changes in brain activity with good spatial and temporal resolution, revealing information about changes in network activity related to external stimulations such as sensory stimulation or selective direct activation of cells in the brain through neuromodulation technologies such as optogenetics. However, fMRI detected signal changes are usually small and limited by the contrast to noise ratio (CNR). Especially at high magnetic fields strengths and in the presence of implants, images are prone to artifacts. This calls for careful optimization of MRI methods to find the optimal balance between CNR, image quality and spatial and temporal resolution.
Here, we optimize both BOLD and CBV fMRI. We compare gradient echo MRI using echo-planar (EPI) or Spiral readouts, assess choice of acquisition bandwidth and echo time related to the T_2^* relaxation time and discuss shimming and use of saturation bands to remove unwanted signal. Experiments were performed on rats expressing ChR2 virally transduced under the CamKII promotor. MRI was performed on a Bruker Biospec at 7 T. Optogenetic stimulations were performed under medetomidine sedation for BOLD and CBV fMRI in subsequent experiments in the same animals, and imaging sequence parameters were varied to assess signal-to-noise and CNR dependence. For CBV fMRI, ferumoxytol was injected into the tail vain prior to imaging.
Results show larger areas of activation from CBV scans compared to BOLD fMRI. Variation of echo times (TE) showed the highest CBV contrast with a signal change of approximately 10%. Highest BOLD contrast was achieved with a signal change of 3.5%. Repeated measurements of T_2^* in CBV experiments showed a continuous increase in T_2^* of approximately 1 ms/h, hinting that for long scan sessions and quantitative analyses of CBV signal amplitudes, adjustment of TE could be beneficial.

Title: Accurate and rapid estimation of cell culture confluency, transfection efficiency and total cell number

Authors: *L. ANTANAVICIUTE[1], S. DUBACQ[2], O. VARET[2]
[1]Bertin Corp, Rockville, MD; [2]Bertin Technologies, Montigny le Bretonneux, France

Abstract: Accuracy and efficiency in cell culture quality checks are extremely important in cell biology based studies in order to avoid any potential complications in the downstream analysis. Usually, key cell parameters such as total cell counting, confluency and cell size measurement are assessed and estimated visually in a subjective way. However, visual assessments are unreliable, time consuming and often yielding inaccurate results which lead to incorrect conclusions and recommendations. A novel approach was employed and investigated for rapid and accurate estimation of cell confluency, transfection efficiency and total number of cell counting in an automated manner using a smart cell imager (InCellis®, Bertin Technologies) in this study. An appropriate application embedded on the imager was used to estimate cell confluency and a total cell number using breast cancer cell line (MCF-7) cultures, whereas HeLa cell line culture was used for transfection efficiency estimation. Images of both cell lines were captured in series using smart cell imager in phase contrast mode using 20x magnification across the three-day experiment. The results obtained showed the MCF-7 cell culture confluency increased over the period as expected, and ranged from 14% on day-1 to 77% on day-3. Total cell counting was performed on two MCF-7 culture dilutions (1/5 and 1/10) to investigate the accuracy of the application capabilities. A total of 6.3M cells were observed in the culture petri dish with a 3% standard deviation for 1/5 dilution and a 3.5% for 1/10 dilution. The cell counting results obtained using InCellis® were further compared to the results obtained from the manual cell counting (Malassez cell) method, which was also used a reference. No significant difference was observed in a total cell number between the two methods. HeLa cell culture line and GFP fluorescence label were used for validation of an automated transfection efficiency application. A user-friendly transfection application that requires only a 3-step workflow allows for easy and spontaneous observation of transfected cells. All three applications (confluency, transfection and total cell counting) tested here, yielded robust results in a significantly less “hands-on” time compared to the traditional methods, and is a reliable new tool for all cell-based assays.

Abstract: PA imaging can provide high spatial and temporal resolution images based on a technique that can distinguish the location and quantify the amount of light absorption from chromophores in tissue. This has wide applicability, such as in PA functional imaging, a technique based on endogenous chromophores. However, PA imaging is not limited to endogenous compounds, it is also inclusive of exogenously-added contrast agents. Selective organic dyes and nanoparticles with high optical absorption at wavelengths where endogenous chromophores absorb weakly can be valuable for generating a targeted signal with a high contrast to noise ratio. For example, virally-infected tumor cells can be made to heavily express enzymes capable of cleaving colorless substrates into colored products, a process observed in the lacZ gene enzyme system. This system is ideal for contrast-enhanced PA as a vast array of available substrates can be used to create dyed products that absorb light strongly in the near infrared window (650-900 nm), where many endogenous chromophores have lower absorptivity. Both X-gal (absorption peak = 615 nm) and Green-gal (absorption peak = 665 nm), have the potential to be effective contrast agents. We used a PA phantom setup to observe where PA signal differences between the exogenous dyes and blood, the strongest endogenous signal, are maximized. Our phantom consisted of a tube filled with the colored product of interest submerged in an acrylic box filled with milk to simulate brain tissue's optical scattering. We used an 18.5 MHz, 128 element L-22 Ultrasound transducer to record PA signal produced by pulsed laser illumination and compared it to blood and saline at 550-1100 nm. We report PA signal, as a function of wavelength, for X-gal and Green-gal products, and blood. We then found wavelengths on the scanned electromagnetic spectrum with the highest difference in PA signal between blood and colored products to be maximized for Green-gal and X-gal product at 700 nm and 725 nm, respectively. At these wavelengths, we tested substrates to optimize the concentrations needed to create a PA signal that was significantly higher than blood's background intensity. Overall, our findings support use of Green-gal as a potential agent for contrast-enhanced PA based on our acquired signal differences.

Title: Three-dimensional single-cell-resolution whole-brain atlas using CUBIC-X expansion microscopy and tissue clearing

Authors: *T. MURAKAMI, T. MANO, H. UEDA
The Univ. of Tokyo, Tokyo, Japan

Abstract: A three-dimensional single-cell-resolution mammalian brain atlas will accelerate systems-level identification and analysis of cellular circuits underlying various brain functions. However, its construction requires efficient subcellular resolution imaging throughout the entire brain. To address this challenge, we developed a fluorescent-protein-compatible, whole-organ clearing and homogeneous expansion protocol based on aqueous chemical solution (CUBIC-X). The expanded highly-cleared brain enabled us to construct a mouse brain atlas with single-cell annotation (CUBIC-Atlas). The CUBIC-Atlas demonstrated inhomogeneous entire-brain development, revealing a significant decrease in the cerebral visual and somatosensory cortical areas during post-natal development. Probabilistic activity mapping of pharmacologically stimulated Arc-dVenus reporter mouse brains onto CUBIC-Atlas revealed the existence of distinct functional structures in the hippocampal dentate gyrus. Since the CUBIC-Atlas is shareable by an open-source web-based viewer (CATMAID), this pointillistic brain atlas provides a new platform for whole-brain cell profiling.

Title: Temporal dynamics of spatial information encoding within retrosplenial cortex

Authors: *M. SEHGAL[1], S. MARTIN[1], A. PEKCAN[1], D. AHARONI[2], A. LAVI[1], D. J. CAI[3], M. R. MEHTA[4], A. J. SILVA[5]

Ctr., Los Angeles, CA

Abstract: Memories are dynamic in nature and a cohesive representation of the world requires memories to be altered over time, linked with other memories and eventually integrated into a larger framework of sematic knowledge. Our laboratory has recently demonstrated that two contextual memories encoded close in time are stored by overlapping hippocampal CA1 neuronal ensembles and the recall of one can lead to the recall of another, i.e. the two memories are linked (*Cai et al. 2016*). Retrosplenial cortex or RSC is another brain structure that is also critical for contextual learning and memory. It is unclear whether memory linking is due to overlap in neuronal ensembles in certain key brain regions, such as hippocampus for contextual memories, or the entire neural circuit involved in contextual memory formation displays this neuronal overlap. We addressed this question by investigating the overlap in neuronal ensembles encoding contextual memories at varying time intervals within the RSC. Using head-mounted miniature microscopes, we imaged GCaMP6f-meadiated calcium dynamics in retrosplenial cortical neurons while the mice explored distinct contexts. We found greater overlap in the neuronal ensemble activated in response to two distinct contexts when the contexts were explored 5h vs. 7d apart. These data indicate that the RSC can mediate temporal memory linking by recruiting a shared neuronal ensemble for memories encoded within a day. To understand whether such ensemble overlap was driven by neurons encoding spatial information, we performed linear track experiments where RSC calcium transients were imaged using miniaturized microscopes. We found that ~10% of RSC cells displayed place cell like dynamics. Furthermore, the same cells could be tracked over repeated linear track sessions and displayed stable firing patterns. We are currently investigating whether neuronal overlap is changed as a function of information content. Our data indicate that co-allocation of neuronal ensembles encoding temporally proximate contextual memories may be a general mechanism of memory linking across the brain regions that process spatial and contextual information.

Abstract: The goal of this NSF Neurotechnology Hub is to develop and broadly share hardware that integrates optical and electrophysiological sensing of large-scale neural dynamics, as well as real-time signal processing and feedback capabilities. Our team has developed miniaturized microscopes (Miniscopes), which, in combination with genetically encoded calcium indicators, allow recordings from 100s of genetically identified neurons over weeks in freely moving animals. Additionally, our team has developed silicon-based microelectrode arrays and tetrodes that allow recording of local field potential (LFP) and units from up to a hundred cells. These approaches (calcium imaging and ephys) have distinct advantages and disadvantages, and thus are highly complementary.
Here we will present our progress towards developing a variety of tools that combine calcium imaging and electrophysiology, enabling multimodal measurements of neural dynamics: 1) Miniaturized microscopes with integrated circuitry for calcium imaging and electrophysiology in a single device, 2) Manufacture high density silicon microprobes or tetrode drives which can be implanted and connected to a single device for simultaneous cellular-resolution or bulk photometric calcium imaging and electrophysiological recordings, and 3) Develop a new generation of light field miniaturized microscopes to facilitate volumetric imaging. A further hardware challenge we will address is that analysis of imaging and electrophysiological recordings is usually done offline and can take days to weeks; but to understand how defined neurons drive specific networks during behavior it is essential to integrate real-time feedback capabilities into recording devices. To address this we will develop FPGA-based tools for real-time alignment, segmentation of calcium imaging movies, as well as real-time spike sorting and

LFP phase detection for on-the-fly optogenetic feedback. Building off the already existing online open-source resource, miniscope.org, we will share all these devices with the neuroscience community.

Title: Open-source silicon microprobes for large-scale neural recordings

Authors: *L. YANG, K. LEE, S. C. MASMANIDIS
Dept. of Neurobio., UCLA, Los Angeles, CA

Abstract: As part of an NSF-funded NeuroNex Neurotechnology Hub, we have produced a silicon-based multielectrode technology aimed at addressing the growing need to inexpensively scale up electrophysiological recordings in vivo. These probes contain up to 256 independently addressable electrodes for extracellular single-unit and local field potential measurements, with over a dozen user-inspired electrode array designs. Moreover, they were explicitly developed for the purpose of being widely and openly distributed to the community, and we present a straightforward procedure for sharing these tools with other labs at a cost of about $300 per probe. To enable widespread dissemination the silicon devices are mass produced at a commercial microelectronics foundry, and all other components such as printed circuit boards and electrical connectors, are also readily available from third party manufacturers. Furthermore, the probes are fully compatible with commercially available head stage amplifiers, data acquisition, and impedance testing systems. The devices are primarily aimed at recording from behaving head-restrained rodents. In addition to using individual microprobes to record from up to a few hundred units in parallel, we show how probes can be combined together to simultaneously record from multiple brain areas. We also show how the devices can be readily paired with optical fibers for optogenetic tagging and perturbation studies. We demonstrate the recording capabilities of the tools in head-restrained mice performing a reward-guided task. Together, this technology provides an inexpensive, plug-and-play approach to measuring large-scale neural dynamics. Information on obtaining probes is found at: masmanidislab.neurobio.ucla.edu/technology.html.

Title: CCR5 closes the window for contextual memory linking by regulating neuronal ensemble overlap

Authors: *M. ZHOU[1], Y. SHEN[1], D. CAI[1,2], Y. CAI[1], A. LAVI[1], S. HUANG[1], T. SILVA[1], A. J. SILVA[1]
[1]Neurobio., Univ. of California Los Angeles, Los Angeles, CA; [2]Mount Sinai Sch. of Med., New York, NY

Abstract: Although the mechanisms involved in the encoding, consolidation and retrieval of memory have been widely studied, little is known about the mechanisms that link multiple memories across time. Previous studies in our laboratory showed that a temporary increase in neuronal excitability biases the representation of a subsequent memory to the neuronal ensemble encoding the initial memory. As a result, the recall of one memory increases the likelihood of recalling the other memory, thus linking the two memories. Understanding the mechanisms that regulate the temporal window of memory linking is critical for understanding how different memories are either linked or separated across time. Here, we show that CCR5, a G-protein coupled receptor, plays a key role in closing the temporal window for memory linking. Our studies showed that following contextual learning the hippocampal mRNA levels for Ccr5 and its ligand Ccl5 increase over time in a pattern consistent with the hypothesis that these increases close the window for memory linking. Experiments with head-mounted fluorescent miniscopes showed that a Ccr5 null mutation extended the temporal window for the overlap between CA1 neural ensembles encoding two separate contextual memories. Accordingly, the Ccr5 null mutation also results in an extension of the window for contextual memory linking. Importantly, aging increases the levels of Ccl5 and Ccr5, and the Ccr5 mutation reverses the age-related decline both in neural ensemble overlap and in contextual memory linking. These results demonstrate that delayed increases in CCR5 levels following memory formation decrease the overlap between memory ensembles, and therefore close the window for memory linking. Additionally, our results also showed that age-related increases in CCL5/CCR5 signaling contribute to age-related deficits in memory ensemble overlap and memory linking, and indicate that these deficits can be reversed by manipulations that target this signaling pathway.

Univ. Col. of Med., Seoul, Korea, Republic of; [7]Dept Neurobiol, UCLA Med. Ctr., Los Angeles, CA

Abstract: Noonan Syndrome (NS) is an autosomal genetic disorder that affects 1 in 2,500 live births. Clinical studies have reported that 30-50% of patients with NS display cognitive deficits. Mutations in *Ptpn11* are responsible for most cases of NS. Here, we report neuronal circuit studies in mice of a *Ptpn11* mutation described in humans: *Ptpn11*^{D61G} heterozygous germ line mutation. We have previously demonstrated that this gain-of-function mutation causes deficits in spatial learning in the hippocampus-dependent water maze task, ERK signaling, AMPAR function, and hippocampal CA1 long-term potentiation (*Lee et al. Nature Neuroscience, 2014*). Since water maze learning involves the integration of information gathered in multiple trials across days, we investigated whether the *Ptpn11*^{D61G} mice show deficits in a circuit process known to be critical for integrating or linking spatial/contextual information across time. Our previous studies showed that mice link memories encoded close in time (e.g. within a day), but not memories encoded across a week. Furthermore, we demonstrated that the overlap between the CA1 neuronal ensembles encoding each contextual memory is critical for the animal's ability to link contextual memories close in time (*Cai et al. Nature, 2016*). Here, we studied calcium transients in the hippocampal CA1 region, with GCAMP6f and head mounted fluorescent miniscopes in *Ptpn11*^{D61G} mice (and their wild type controls). We found that there was significantly lower overlap in the neuronal ensemble activated by two different contexts separated by 5 or 24 hour intervals in *Ptpn11*^{D61G} mice relative to their WT littermates. These results demonstrate that *Ptpn11*^{D61G} mice have deficits in circuit processes that integrate information across time and suggest that these circuit deficits contribute to their impairments in spatial learning.

Title: Engineering designer AAVs for non-invasive systemic delivery to specific cell-types or organs using CREATE 2.0

Authors: *S. RAVINDRA KUMAR, Q. HUANG, X. CHEN, X. DING, E. MACKEY, N. FLYTZANIS, N. GOEDEN, D. BROWN, Y. LUO, T. DOBREVA, K. CHAN, B. DEVERMAN, V. GRADINARU
Caltech, Pasadena, CA

Abstract: With increased use of recombinant adeno-associated viruses (rAAVs) as gene delivery vehicles in research and for gene therapy, there is a need for rAAVs with enhanced transduction for specific brain cell-types and regions with minimal off-target expression in other organs. In 2016 we reported a Cre recombination-based AAV targeted evolution (CREATE) method and looked for positively enriched variants with better transduction capabilities across the central and peripheral nervous systems (CNS and PNS). We identified a few highly efficient CNS transducing variants AAV-PHP.B (Deverman BE, et al, Nat. Biotech., 2016) and AAV-PHP.eB (enhanced PHP.B); and a PNS transducing variant, AAV-PHP.S (Chan K, et al, Nat. Neurosci., 2017). However, CREATE's positive selection strategy is limited to selection of capsids with enhanced transduction. To select for capsids with cell-type or tissue specificity, we designed a new library recovery method, CREATE 2.0, that enables us to perform both positive and negative selections across multiple Cre transgenic lines *in vivo*. CREATE 2.0 uses next generation sequencing (NGS) to obtain a complete recovery of viral capsid libraries across multiple Cre transgenic mouse lines. NGS can facilitate positive and negative selections across cell-types or organs in a high-throughput parallelized manner and this selection strategy can increase the efficiency of finding variants with desired specificity and enhanced transduction properties. Access to this depth of sequencing information also facilitated the investigation of selected variants for their unique tropisms using the amino acid characteristics of the peptide insertions/substitutions, Rosetta modeling and advanced machine learning algorithms. As a proof-of-concept, we built a rAAV capsid library by mutating the exposed surface of the capsid and performed two rounds of in vivo selections across different brain cell-types using the following mouse Cre lines: Tek-cre for endothelial cells, SNAP25-cre or Syn-cre for neurons, and GFAP-cre for astrocytes; and extracted the transduced viral libraries from brain and liver. After one round of selection, we identified a novel variant with biased transduction for brain endothelial cells, and another variant that preferentially transduced the liver. After two rounds of selection, we identified a few novel variants with biased transduction towards neurons while being de-targeted from liver. Collectively, CREATE 2.0 is a powerful selection strategy that

multiplexes engineered viral library selections, accelerating experimental outcomes while also providing mechanistic insight into viral tropism.

Abstract: Neuromodulatory systems exert profound influences on brain function. Understanding how these systems modify the operating mode of target circuits requires measuring spatiotemporally precise neuromodulator release. We developed dLight1, an intensity-based genetically encoded dopamine indicator, to enable optical recording of dopamine dynamics with high spatiotemporal resolution in behaving mice. We demonstrated the utility of dLight1 by imaging dopamine dynamics simultaneously with pharmacological manipulation, electrophysiological or optogenetic stimulation, and calcium imaging of local neuronal activity. dLight1 enabled chronic tracking of learning-induced changes in millisecond dopamine

transients in striatum. Further, we used dLight1 to image spatially distinct, functionally heterogeneous dopamine transients relevant to learning and motor control in cortex. We also validated our sensor design platform for developing norepinephrine, serotonin, melatonin, and opioid neuropeptide indicators.

Abstract: A longstanding challenge in neuroscience is to stimulate and record simultaneously from many genetically defined neurons in intact tissue. Achieving all-optical neurophysiology requires selection of a spectrally orthogonal actuator/reporter pair, as well as development of an optical system capable of targeted stimulation and optically sectioned imaging in a highly scattering, three dimensional tissue. Optical tools can in principle access $>10^5$ neurons in acute brain slices, but two-photon (2P) all-optical neurophysiology in tissue has been limited to ensembles of ~50 neurons due to the high optical power requirements of 2P stimulation. To record and stimulate neuronal activity simultaneously, we paired a trafficking-optimized variant of the most blue-shifted channelrhodopsin, TsChR, with a nuclear-localized red-shifted calcium (Ca^{2+}) indicator, H2B-jRGECO1a. This combination allowed optical induction and detection of

single action potentials in cultured neurons with negligible optical crosstalk or photoartifacts. To apply these tools in tissue, we devised a computational structured illumination method using a digital micromirror device (DMD) to illuminate neighboring sample locations with orthogonal functions of time (Hadamard codes). A demodulation algorithm rejected scattered and out-of-focus light from large field of view (4.6 x 4.6 mm^2) series of images. This approach enabled large area optical sectioning in acute brain slice, yielding >6,000 simultaneous single-cell recordings. We developed a protocol to quantify neuronal excitability via the relative change in Ca^{2+} response as a function of optogenetic stimulation strength. To map effect of antiepileptic drugs, we compared responses before and after drug applications: Carbamazepine, phenytoin, and retigabine produced qualitatively distinct inhibition patterns across layers of the cortex. We further developed a technique to map synaptic transmission by expressing the optogenetic actuator and the Ca^{2+} reporter in disjoint subpopulations. These results demonstrate the combination of spectrally orthogonal TsChR and jRGECO with Hadamard optical sectioning to obtain wide-area maps of neuronal function.

Title: Minimally-invasive optogenetic circuit modulation with designer channelrhodopsin variants and systemic AAVs

Authors: C. N. BEDBROOK[1], *J. E. ROBINSON[2], K. K. YANG[3], F. H. ARNOLD[3], V. GRADINARU[1]
[1]Biol. and Biol. Engin., [3]Chem. and Chem. Engin., [2]Caltech, Pasadena, CA

Abstract: In mammalian systems, current optogenetic tools based on the light-gated ion channel channelrhodopsin (ChR) require approximately 1-15 mW light delivered near the target cell population to reliably elicit cell firing, which confines light-dependent activation to a small volume of brain tissue [approximately 1 mm^3]. It would be desirable to have optogenetic access to large brain volumes and/or non-invasive optogenetic access to the brain without stereotaxic injections for opsin delivery or implantation of invasive fiberoptics for light delivery. We have recently reported on engineered AAV capsids that can efficiently deliver transgenes to the central and peripheral nervous systems via systemic injection [AAV-PHP.eB and AAV-PHP.S]. However, relative to direct injections, systemic delivery has a low multiplicity of infection. Therefore, systemic delivery of ChR2 results in modest light-induced currents that are at times insufficient for neuronal activation. In order to overcome these limitations, we leveraged the significant collection of published ChR variants to train statistical models that enable the design of new high-conductance ChR variants with strong currents under low intensity light ($1x10^{-3}$ mW mm^{-2}) and reaching ≥1 nA currents with $5x10^{-2}$ mW mm^{-2}. These ChRs display significantly larger light-evoked currents than ChR2(H134R) across all light powers tested in cultured neurons and in acute brain slices after direct injection [$p = 2x10^{-5}$ and $8x10^{-5}$, respectively at $8x10^{-3}$ mW mm^{-2} light intensity] and exhibit 100% spike fidelity with 1-2 orders of magnitude lower light intensity than ChR2(H134R). After systemic delivery ($1x10^{11}$ vg/mouse), our high-conductance ChRs exhibit 100% spike fidelity in acute cortical slices at 0.7 mW mm^{-2} light intensity, while ChR2(H134R) expressing cells do not reliably produce light-evoked firing with any light intensity tested. Preliminary testing *in vivo* revealed that the sensitivity of systemically delivered high-conductance opsins to low light intensities allows for optogenetic behavioral control with the light source placed on the skull surface, enabling neuronal modulation with high temporal precision without invasive intracranial surgery for virus delivery or fiberoptic implantation. Additionally, these high-conductance tools could be particularly useful when activating large brain nuclei in mice or in model systems with larger brains (e.g. rats or non-human primates). Ongoing studies seek to characterize these variants across the central and peripheral nervous system and extend the application of minimally invasive optogenetic manipulations past superficial brain structures.

Title: Scalable single-cell profiling by systemic AAVs for sparse stochastic labeling compatible with tissue clearing and multiplexed RNA labeling, applied to mouse GnRH neurons

Authors: G. M. COUGHLIN, *A. KAHAN, M. JANG, V. GRADINARU
Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Amongst standing challenges for neuroscience are the efficient phenotyping and reconstruction of neurons with complex patterns (whether in distribution or morphologies). Gonadotropin-releasing hormone (GnRH) neurons represent one particularly challenging population for reconstruction. These neurons play key roles in the entry to puberty and in the normal functioning of the mature hypothalamic-pituitary-gonadal axis. The challenge inherent in labeling and reconstructing this population arises during their unique developmental trajectory; these neurons are sparsely distributed through an expansive spatial continuum from the olfactory bulb into the anterior hypothalamus (Wray), and they send long-range projections (up to 3 mm) to divergent brain regions. Thus, the efficient and accurate reconstruction of GnRH neurons requires molecular-phenotyping and tract-tracing through whole brain regions. We have approached this problem using a toolbox comprised of: (1) systemically delivered adeno-associated virus (AAV) vectors such as AAV-PHP.eB (Chan et al.), which achieve sparse, stochastic, and brain-wide multicolor labeling of genetically specified cell types (akin to a "Genetic Golgi stain"); (2) tissue clearing by PACT (Passive CLARITY) and RIMS (Refractive Index Matching Solution) (Yang et al.); and (3) multiplexed RNA labeling by hybridization chain reaction (HCR)-based fluorescence in situ hybridization (FISH). Tracing GnRH neurites over long distances in the brain of GnRH1-cre mice was facilitated by the delivery of multiple spectrally distinguishable fluorescent proteins, resulting in combinatorial labeling of the target population (VAST, for vector-assisted spectral tracing; see Chan et al.). These multicolor-labeled thick (<0.5 mm) sections were optically cleared through incubation in RIMS, and then imaged with confocal microscopy. Molecular identification and phenotyping of GnRH neurons in thick tissue was performed using HCR-based FISH (Greenbaum et al.), using probes directed against *GnRH1* and other transcripts of interest. Compared to antibody staining, this RNA-based labeling approach is advantageous as it enables high signal amplification, easy multiplexing, and efficient penetration of the probes into thick tissue. Individual GnRH neurons were identified and reconstructed, yielding important morphological parameters, such as cell body position and projection targets. This work demonstrates the utility of the VAST system in combination with multiplexed HCR-based FISH and tissue clearing, for high-throughput labeling, phenotyping and reconstruction of broadly distributed neuronal populations.

Title: Tissue clearing and optogenetics help reveal pathological effects of seeding alpha synuclein fibrils in enteric and olfactory systems

Authors: *C. CHALLIS[1], T. R. SAMPSON[1], B. B. YOO[1], S. K. MAZMANIAN[1], L. A. VOLPICELLI-DALEY[2], V. GRADINARU[1]
[1]Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Aggregation and accumulation of alpha synuclein (aSyn) is the defining feature of synucleinopathies. aSyn pathology has been well studied in Parkinson's disease (PD), where pathological hallmarks include loss of dopamine neurons in the substantia nigra pars compacta and motor impairment. Though 10% of PD cases are genetic, there is no consensus on the origin of the 90% of idiopathic diagnoses. Reports have identified a prodromal phase of PD where patients exhibit non-motor symptoms prior to motor dysfunction. Postmortem biopsies have revealed Lewy pathology in associated peripheral tissues such as olfactory mucosa and gastrointestinal (GI) lining. Pathologic staging studies suggest that formation of aSyn-containing inclusions originates in the periphery before appearing in the brain[1-3]. However, the direct impact of pathologic aSyn on the peripheral nervous system has not been thoroughly investigated. Here, we introduced aSyn preformed fibrils (PFF) into duodenal lining of the GI tract or nasal cavity of adult, wild type C57Bl/6N mice and assessed functional and physiological adaptations. We used tissue clearing (e.g. PACT, Bone CLARITY)[4,5], optogenetics, and behavioral paradigms to pursue this question in higher resolution than previous work. After inoculation of aSyn PFF in the gut, we observed reductions in fecal pellet weight and water content 21 days post inoculation (1WA, $F = 6.044$, $p < 0.001$). This was accompanied by decreased enteric nervous system (ENS) network connectivity (1WA, $F = 39.99$, $p < 0.001$), which we evaluated by systemically delivering jRGECO1a packaged in AAV-PHP.S, a novel capsid with preferential tropism for peripheral cells[6]. Morphological and histological evaluation of the ENS showed persistent gliosis

and accumulation of phospho-aSyn (S129P), and further analysis revealed that aSyn PFF impaired lysosomal mechanisms (i.e. decreased glucocerebrocidase) and inflammation (i.e. increased IL6). Irrigation of aSyn PFF in the nasal cavity caused immediate olfactory-dependent behavioral deficits, which was accompanied by S129P signal in the olfactory epithelium and olfactory bulb. Ongoing work is evaluating the pathological mechanisms that underlie olfactory symptoms associated with aSyn pathology. Together, our data strengthens our knowledge of pathological aSyn and provides the framework to study peripheral synucleinopathy.

Title: Multiplexing imaging development using phase light interference and fluorescence microscopy to bridge the scales from single molecule to whole organ

Authors: *J. A. MALDONADO[1], C. BEST[2], A. SMITH[3], G. POPESCU[4]
[1]Univ. of Illinois Urbana Champaign, Urbana, IL; [2]Dept. of Bioengineering, Univ. of Illinois Urbana Champaign, Urbana -Champaign, IL; [3]Dept. of Bioengineering, Univ. of Illinois Urbana Champaign, Urbana Champaign, IL; [4]Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Microscopy techniques are allowing the neuroscience field to better understand single cell dynamics, cellular and whole organ architectures through super high resolution features and novel imaging technologies. Most of these super resolution microscopy techniques require invasive and targeted labeling through staining or fluorescent methods that require expensive, lengthy and time consuming protocols. Our objective is to explore and investigate a label-free approach which identifies cellular structures based on their intrinsic physical and mechanical properties such as dry mass, refraction index, and elastic modulus in living cells and *ex vivo*

brains. We also couple quantum dots with SLIM to probe the single molecule dynamics associated with AMPA receptor trafficking.To achieve our goal, we used both 4 micron slices of murine hippocampi, and primary neuron cells in culture, Alexa 488 labeled AMPA receptors, DAPI nuclear stain, Mito-tracker, and quantum dots, coupled with Spatial Light Interference Microscopy (SLIM). We collected information about subcellular molecules and tissue properties that provide unique indicators for synaptic receptors, cell nucleus and mitochondria. These properties were then used to identify and differentiate these structures from surrounding cellular structures independent of extrinsically added labels.We provide a powerful tool to augment fluorescence imaging studies which can be used for long duration, live cell imaging. Subcellular structures including vesicles, mitochondria and the post synaptic density are easily identified with SLIM following fluorescence correspondence confirmation. Furthermore, this technique may lead to identification of clinically relevant biomarkers as well as pathological receptor trafficking mechanisms. We show that following validation with fluorescence, SLIM can be utilized for identification of intracellular structures at the cell and across the whole organ level. Our technique avoids the invasive and extensive protocols with inherent processing artifacts, and preserves the natural environment of the tissue. This will provide access to enhanced and dynamic data from cellular and tissue properties in future studies.

Title: Optical activity readout and modulation of serotonergic neurons in the dorsal raphe show frequency-dependent, bidirectional effects on sleep

Authors: *M. ALTERMATT, J. CHO, G. OIKONOMOU, D. PROBER, V. GRADINARU
Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: A role for serotonin (5-HT) in sleep has first been reported 60 decades ago (Bradley, 1958). Early discoveries from pharmacological inhibition of 5-HT synthesis and lesion experiments led to a hypothesis that 5-HT is a sleep-promoting neurotransmitter (Delorme et al., 1966; Jouvet, 1968). However, single-unit recordings showed that 5-HT neurons are mostly active during the wake state, followed by the non-rapid eye movement (NREM) sleep and were almost silent during the rapid-eye movement sleep (REM) (McGinty & Harper, 1976). This influenced the current view of a wake-promoting and REM-inhibiting action of 5-HT (Scammell et al., 2017). Although 5-HT neurons exhibit both phasic and tonic firing patterns, causal investigations of frequency-dependent effects on sleep-wake regulation are lacking. We first measured population activity levels of dorsal raphe 5-HT neurons of serotonin transporter-cre mice across behavioral states, using fiber photometry in combination with EEG/EMG recordings, which confirmed earlier observations that 5-HT neurons display the highest activity during wake state and a decreasing activity from NREM to REM state. Fluorescence changes of GCaMP6s at behavioral state transitions were significant for all transitions ($n = 4$, $p<0.001$). Next, we used optogenetics to induce phasic and tonic firing modes in 5-HT neurons, which revealed opposite effects on regulating sleep-wake states. Phasic stimulation (25 Hz; 3 s of stimulation with 7 s break; Duration: 5 min) during the light phase caused a transient >70% increase in time spent in wake state ($n = 9$, $p<0.001$) and a persistent inhibition of REM state ($n = 9$, $p<0.01$). Conversely, tonic activation (3 Hz; Duration: 12.5 min) during the dark phase decreased the time spent in wake state by >20% ($n = 9$, $p<0.05$). These results show a complex role for 5-HT neurons in modulating sleep and provide evidence that distinct firing modes of 5-HT neurons play distinct roles in controlling arousal states.

Title: Engineering better, brighter bioluminescent light sources for neuronal imaging

Authors: L. M. BARNETT, G. G. LAMBERT, *N. C. SHANER
Scintillon Inst., San Diego, CA

Abstract: To observe authentic biological processes in living cells, it is critical to avoid damaging or perturbing them. Fluorescence microscopy suffers from the need to illuminate biological samples with extremely bright light to collect sufficient signal. A majority of this incident light is not absorbed by the fluorophores being imaged and is a source of collateral damage to many other components of the cell. Bioluminescent proteins, luciferases, produce light via enzymatic oxidation of a small molecule substrate, a luciferin. These substrates, such as coelenterazine, are essentially biologically inert in cells, and because the light they produce does not require exogenous excitation, imaging with bioluminescent probes does not lead to phototoxicity or other undesirable perturbations. In theory, bioluminescence is ideal for live cell imaging. Unfortunately, all of the available bioluminescent probes are too dim for use in most imaging experiments. Increasing the photon output is difficult because luciferases are fundamentally limited by the need to balance catalytic rate and luminescence quantum yield. In other words, to achieve a high quantum yield, the luciferase must stabilize the excited oxyluciferin in a protected binding pocket that discourages non-radiative relaxation to the ground state. This requirement places major constraint on the dissociation constant of the ground state oxidized substrate, slowing down substrate turnover and reducing the number of photons emitted per second. Here, we use a novel approach leveraging Förster resonance energy transfer (FRET) to eliminate this trade off. First, we optimize FRET efficiency between our highest-activity luciferases and our brightest fluorescent protein variants to increase total light output. We then use structure-guided design and directed evolution to improve the turnover number of the luciferase component. This combination design process circumvents the critical 'catalytic rate versus quantum yield' barrier, giving way to the next generation of bright bioluminescent light sources.

Title: Bioluminescence driven optogenetics for investigating functional synaptic communication across co-cultured neuronal networks on multi-electrode arrays

Authors: *M. PRAKASH[1], R. S. LAURENT[2], A. PAL[1], A. BJOREFELDT[1], B. W. CONNORS[2], D. LIPSCOMBE[2], J. A. KAUER[3], C. I. MOORE[2], U. H. HOCHGESCHWENDER, 48859[1]
[1]Neurosci., Central Michigan Univ., Mount Pleasant, MI; [2]Dept. of Neurosci., [3]Dept. of Neurosci. & Dept. of Mol. Pharmacology, Physiology, and Biotech., Brown Univ., Providence, RI

Abstract: In BioLuminescent driven OptoGenetics (BL-OG) a genetically encoded light source, a luciferase, activates a light-sensing optogenetic element, a channelrhodopsin or a pump. When light emitter and light sensor are tethered, as in luciferase-opsin fusion proteins (luminopsins, LMO), application of luciferase substrate coelenterazine (CTZ) and subsequent light production will change the membrane potential of the cell expressing the LMO. Here we co-cultured cortical neurons expressing the luciferase with hippocampal neurons expressing the opsin, with the goal of investigating BL-OG effects across synapses between these two neuronal populations. Neurons isolated from E18 rat cortex and hippocampus were nucleofected with a pre-synaptically targeted luciferase construct and either an excitatory or inhibitory opsin construct, respectively, and were plated on multi-electrode array (MEA) dishes using a two-chamber silicon insert to separate the two populations. Neuronal processes originating from both populations crossed the gap separating them, forming synaptic contacts between cortical and hippocampal neurons. Recordings were carried out between DIVs 14-28. External blue light from an LED source was used to modulate opsin expressing hippocampal neurons directly, while bioluminescence emission by cortical neurons generated with application of CTZ was used to drive hippocampal neurons across synapses. Responses from hippocampal neurons elicited with CTZ were likely due to trans-synaptic communication. Electrical stimulations of cortical neurons by individual electrodes were carried out in parallel to confirm the inter-population connectivity. The overall effect of CTZ application on activity of opsin-expressing hippocampal neurons in the co-cultures was significantly higher compared to that of non-expressing hippocampal neurons and of the cortical neurons in the co-cultures. Such biological light activation, across synaptic partners originating from brain regions known to be synaptically connected, offers the potential to optogenetically dissect synaptic communication non-invasively.

Abstract: Bioluminescent Ca^{2+} sensors have distinct advantages over fluorescent Ca^{2+} indicators; first and foremost they function without external illumination. Rather, they produce light in the presence of Ca^{2+} and of a luciferase substrate, a feature that can be exploited for combining Ca^{2+} sensing with optogenetic applications. We developed a bioluminescent Ca^{2+} indicator, Lumicampsin (LMC) that employs a split, mutated Gaussia luciferase (sbGluc) with a CaM-M13 calcium sensing moiety introduced between the two split halves. To date we have several versions of LMC with varying sensitivities to Ca^{2+} by using different, pre-established CaM-M13s (from GCaMP6f, GCaMP6m, GCaMP6s, etc.). In order to investigate subcellular Ca^{2+} dynamics, we have fitted the LMC with various organelle localizing sequences that effectively shuttles it to the organelles of interest (ER, Mitochondria and Golgi apparatus). The superior light emission from LMC, capable of producing a delta RLU/RLU_o of around 200% *in vitro*, has motivated us to explore activity dependent neuronal modulation by co-expressing LMCs with various optogenetic elements in primary neuronal cultures. We are currently optimizing conditions to achieve reliable and efficient coupling of Ca^{2+}-induced light production and optogenetic effector activation.

Title: Bioluminescent Optogenetics produces fewer nonspecific effects compared to DREADDs

Authors: *M. L. WADDELL[1], W. E. MEDENDORP[2], U. HOCHGESCHWENDER[3]
[1]Central Michigan Univ., MT Pleasant, MI; [2]Neurosci., Central Michigan Univ., Mount Pleasant, MI; [3]Col. of Med., Central Michigan Univ., Mt Pleasant, MI

Abstract: Neuroscience offers many tools for manipulating neural activity in genetically targeted neuronal circuits during specific time windows, with tools varying in modes of activation and types of actuator molecules. Chemogenetic approaches, such as Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), and bimodal chemogenetic and optogenetic approaches, such as Bioluminescent Optogenetics (BL-OG), provide control of neuronal firing by a systemically applied small molecule, clozapine N-oxide (CNO) and coelenterazine (CTZ), respectively. Recent evidence suggested that the ligand for the DREADDs, CNO, is converted to clozapine before crossing the blood brain barrier. This has raised questions of nonspecific effects from the chemogenetic effector molecules. Here we compare the BL-OG and DREADD models in a variety of experimental settings with respect to nonspecific effects in control animals. Heterozygous knock-in mice with Lox-Stop-Lox (LSL)-LMO3 and LSL- hM3Dq transgenes were bred with heterozygous Emx1-Cre mice. Experiments then were carried out applying CTZ and CNO, respectively, during early postnatal development and acutely. When testing control animals not expressing the respective actuators on the rotarod and in open field, application of CNO produced reduced time to fall on the rotarod and reduced exploration in open field; application of CTZ had no effect in control groups. This research will assist investigators in choosing a suitable model for their specific research question with appropriate controls.

Title: Tracking neocortical dynamics using genetically-encoded bioluminescent molecules *in vivo*

Authors: *M. GOMEZ-RAMIREZ[1], J. W. MURPHY[1], A. I. MORE[2], A. PAL[4], D. LIPSCOMBE[3], U. HOCHGESCHWENDER[5], C. I. MOORE[1]

Abstract: Fluorescence imaging with genetically-encoded calcium indicators, such as GCaMP, has provided fundamental insights into the role of cell-specific populations in neural coding and perception. Recent advances and pragmatic advantages have made 1-photon imaging a viable strategy for interrogating activity within and across large-scale neural populations. Yet, a limitation of fluorescence imaging is that the technique requires a light source to excite fluorescent proteins. This light creates artifacts that may lead to a reduction in the signal to noise ratio (SNR) of the image. Noise artifacts from the excitation light include: (1) Autofluorescence, (2) Photon scattering from the incoming light, and (3) Photobleaching. As an alternative to fluorescent imaging, we are developing calcium-dependent genetically-encoded molecules using bioluminescent probes. Bioluminescence is chemically generated light that occurs when a photon-containing molecule (luciferin) is catalyzed by a photoenzyme (luciferase). Bioluminescence does not require light excitation and creates very little thermal reaction, thus substantially reducing noise related to autofluoresence, photon-scattering, and photobleaching. Our calcium-dependent bioluminescent molecule, Lumicampsin-4 (LMC4), is a split variant of the slow-burn Gaussia luciferase (sb-GLuc). The two elements are joined by the Ca2+-sensing peptide CaM-M13, thereby providing activity detection. Here, we tested the efficacy of LMC4 to track neural dynamics in mouse somatosensory cortex. To date, we have found that CTZ and a Ca+2 driver (NMDA or L-Glutamic Acid) generate robust bioluminescence signals restricted to the area neighboring the injection pipette. In addition, pilot experiments show that vibrissae deflection generates LMC4-mediated bioluminescence in primary somatosensory neocortex. A key future direction will be to assay the reliability of imaging neural activity across multiple areas using LMC4 while animals engage in perceptual tasks.

Title: Radiationless bioluminescence resonance energy transfer from luciferase to opsin in the luminopsin fusion protein

Authors: *K. BERGLUND[1], U. HOCHGESCHWENDER[2], R. E. GROSS[1]
[1]Neurosurg., Emory Univ., Atlanta, GA; [2]Neurosci., Central Michigan Univ., Mt Pleasant, MI

Abstract: Although molecular tools for controlling neuronal activity by light have vastly expanded, there are still unmet needs which require development and refinement. For example, light delivery into the brain is still a major practical challenge that hinders potential translation of optogenetics in human patients. In addition, it would be advantageous to manipulate neuronal activity acutely and precisely as well as chronically and non-invasively, using the same genetic construct in animal models. We have previously addressed these challenges by employing bioluminescence and have created a new line of opto-chemogenetic probes termed luminopsins by fusing light-sensing opsins with light-emitting luciferases. Bioluminescence is inherently dim light, yet it is bright enough to activate nearby opsins and change rodent behaviors as we have shown in several iterations of luminopsins. Although the utility of luminopsins has been firmly established, the nature and mechanisms of this efficient energy transfer from luciferases to opsins are thus far not known. Specifically, the energy to activate opsins may be transmitted via radiationless bioluminescence resonance energy transfer (BRET) due to proximity of the two molecules in the fusion protein. Alternatively, luciferases may activate opsins simply through bioluminescent radiation similar to physical light sources, such as LED and laser. In this study, we tested these two opposing hypotheses by conducting a series of systematic examination of BRET within the luminopsin molecules. We compared luminopsin fusion proteins with co-expression of opsins and luciferases in bioluminescence measurements and electrophysiological recordings *in vitro*. Our results indicate that BRET is the dominant form of energy transfer in activating opsins, supporting the hypothesis of radiationless energy transfer in the luminopsin fusion protein. These results may be useful in rationally designing and developing new luminopsins in the future.

Title: Effect of chemogenetic inhibition of mammillary bodies in a rat pentylenetetrazole seizure model

Authors: *A. FERNANDEZ[1], K. BERGLUND[2], F. SHIU[1], C.-A. GUTEKUNST[1], R. E. GROSS[1]

Abstract: Epilepsy affects 1% of the world population with approximately one third of patients being resistant to conventional pharmacotherapy. Thus, there is a need for alternative modes of treatments for seizures. Optogenetics has proven to be a useful tool to understand network dynamics, but it has translational challenges. We have developed a chemogenetic tool, called luminopsins, that consists of a light-sensitive channel fused with a luciferase enzyme that bioluminesces in the presence of its substrate coelenterazine (CTZ), eliminating the need for hardware implantation. Previous studies in our laboratory have shown that simultaneous inhibition of glutamatergic cells in the dentate gyrus (DG) and anterior nucleus of thalamus (ANT), with an inhibitory luminopsin, lead to a reduction in seizure severity and duration (Tung et al., 2018). The present study aimed at exploring the effect of modulating neuronal activity in the mammillary bodies (MB), another structure within the Papez circuit. We hypothesized that inhibition of this structure would suppress seizures in the pentylenetetrazole (PTZ) model. To test this, rats were injected with a recombinant adeno-associated viral vector carrying the inhibitory luminopsin gene into the medial mammillary nucleus and subjected to a PTZ seizure test two weeks after virus injection. Rats were pre-treated with either vehicle or CTZ (intravenously) five minutes before intraperitoneal PTZ injection and monitored for 40 minutes. Three days later, this procedure was repeated but rats were pre-treated with the opposite treatment (vehicle or CTZ). Thus, rats served as their own control. Seizure latency, duration, and severity were calculated and compared. Compared to controls, a decrease in seizure duration was observed following inhibition of the MB with CTZ injections. Postmortem histology confirmed adequate targeting of the MB with inhibitory luminopsins. These results support our hypothesis of seizure suppression in the PTZ model due to inhibition of the MB. Similar to our previous study of simultaneous inhibition of two targets, DG and ANT, we expect that this anticonvulsive effect of MB inhibition can be further augmented by simultaneous neuromodulation by luminopsin in other targets in the brain.

Title: Imaging and control of neurons in mice expressing luminopsins

Authors: D. K. JOHNSTON, J. R. ZENCHAK, W. E. MEDENDORP, A. BJOREFELDT, *U. HOCHGESCHWENDER
Neurosci., Central Michigan Univ., Mt Pleasant, MI

Abstract: Luminopsins (LMOs) are fusion proteins of a light emitting luciferase and a light-sensing opsin. Application of the luciferase substrate coelenterazine (CTZ) leads to emission of bioluminescence and subsequent activation of the fused optogenetic element. Depending on the biophysical nature of the opsin, this will result in hyper- or hypo-polarization of membrane potential of cells expressing LMOs. At the same time, emission of bioluminescence allows activated neurons to be imaged in vivo.
Here we compared efficiencies of LMOs delivered to mice through viral transduction and transgenic expression, and after applying CTZ through various routes. Readouts are in vivo bioluminescence imaging for real-time monitoring of light emission and c-fos staining to determine activation of neurons upon light emission.

Title: Chemogenetic modulation with luminopsin in rat septo-hippocampal pathway

Authors: *S.-E. PARK[1], A. FERNANDEZ[2], K. BERGLUND[2], C.-A. N. GUTEKUNST[2], R. E. GROSS[2]
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Dept Neurosurg., Emory Univ. Sch. Med., Atlanta, GA

Abstract: The medial septum (MS) provides an advantageous upstream target to modulate hippocampal activity. Three distinctive neuronal subpopulations in MS form complex local connections as well as distant connections with hippocampal neurons. Chemogenetics can help to understand the effect of neuromodulation in the septo-hippocampal pathway with cell type specific excitation and inhibition. Luminopsin, a fusion protein consisting of marine luciferase fused to light sensitive opsins activated in the presence of coelenterazine (CTZ), has the advantage of homogeneously activating or inhibiting a larger region of the brain compared to conventional optogenetics. Two different adeno-associated viral vectors were used, carrying two different luminopsins: an excitatory channelrhodopsin (LMO3) with a hSynapsin promoter transfecting neurons non-selectively and an inhibitory halorhodopsin (iLMO2) with a CamKIIa promoter targeting glutamatergic neurons. Virus (LMO3 or iLMO2) was injected into the rat medial septum, and after 10-14 days a 16 channel multi-electrode-array was driven to the hippocampus: a row of 8 electrodes targeted CA1, and the other row targeted CA3. Experiments were performed under anesthesia with 2% isoflurane. A baseline local field potential (LFP) recording was followed by a modulation recording period after administration of CTZ through tail vein. All recordings were performed for 10-15 minutes. All data analysis including the statistical test was performed in MATLAB. Power spectral density (PSD) reflects the neural activity of the recording region, and it has been reported that PSD is related to a specific brain state or behavior. Clear differences were observed in the low frequency band between iLMO2 and LMO3 modulations. First, LMO3 increased theta band (4-12Hz) power in CA3 whereas iLMO2 decreased theta band power in the same region. Delta band (0.1-3Hz) power was increased in CA1 region only when iLMO2 modulation was applied. However, both luminopsin modulations induced a similar pattern in higher frequency bands with beta (13-30Hz) and low gamma (30-50Hz) band power increased in CA1 and CA3. These results indicate that the chemogenetic modulation with different luminopsins induce different, and not predictable, effects in the septo-hippocampal pathway. Relating these results well-known biomarkers of hippocampal activity (e.g. theta and gamma band power) can shed light about the appropriate neuronal subpopulation that should be targeted.

Title: Dual-plane two-photon mesoscopy: Multi-column calcium imaging of mouse visual cortex

Authors: *N. ORLOVA, D. TSYBOULSKI, F. GRIFFIN, J. LECOQ, P. SAGGAU
Allen Inst., Seattle, WA

Abstract: Several canonical cortical circuit models propose interaction between two full cortical columns as one possible elementary unit of sensory processing. In particular, the dynamic interplay of bottom-up and top-down circuits across two connected cortical columns plays a key role in how sensory information is processed. Testing these models has been limited by the inability to measure activity across multiple layers and multiple columns simultaneously. Two-photon laser scanning microscopy (2P-LSM) allows for recording of neural activity in the mammalian brain using fluorescent Ca^{2+} indicators of neuronal activity. Recent advances in 2P-LSM have increased the imaging field-of-view (FoV) from ~ 0.4 x 0.4 mm^2 to ~ 5 x 5 mm^2 and now support random positioning of multiple regions-of-interest (RoI) within this large FoV [1]. However, even in such a mesoscope, simultaneous recording of the spread of neuronal activity across two interconnected cortical columns has been limited to a small subset of pairs of cortical layers. We have developed an advanced system that combines two-photon random-access mesoscopy (2P-RAM) with dual-plane remote focusing, increasing the number of simultaneously recorded RoIs and achieving imaging of multiple layers of two cortical columns at frame rates of up to ~11 Hz. We compare signal-to-noise (SNR) in *in vivo* data recorded with this system to conventional 2P-LSM and discuss inter-plane cross talk as well as post-processing methods of de-mixing calcium signals from two planes. We demonstrate *in vivo* imaging at two cortical columns located in mouse primary visual cortex (V1) and other higher visual areas with image planes located at different cortical layers.

Title: Dual-plane two-photon mesoscopy: System design and characterization

Authors: *D. TSYBOULSKI, N. ORLOVA, F. GRIFFIN, J. LECOQ, P. SAGGAU
Allen Inst., Seattle, WA

Abstract: Multiphoton microscopy has become a standard tool for morphological and functional imaging of neuronal structures given its ability to achieve increased imaging depths without

significant loss of resolution. At present, the technique achieves data acquisition rates of about 10 Mpixels/s and allows for observation of fluorescently labeled neurons within ~ 1x1 mm area at 10-40 frames per second. Nevertheless, functional recordings from large ensembles of neurons labeled with Ca^{+}- or voltage-sensitive indicators within optically accessible volume remain challenging due to limitations in scanning speed and data acquisition rates. Recently introduced Two-Photon Random Access Mesoscope (2P-RAM) [1] features ultra-large field of view (FoV) of ~ 5 mm in diameter while maintaining high excitation and collection aperture, and enables access to ~25× larger imaging volume as compared to conventional multiphoton microscopy systems. The system utilizes principles of remote focusing [2] for fast imaging depth adjustment and galvo-galvo lateral positioning of the scanning beam to enable rapid transition between regions of interest in 3D in less than 10 ms. Nevertheless, limited data acquisition rate requires compromises between the size of an imaging area, the number of laterally positioned regions of interest (ROIs), and the number of axial planes within ROIs which can be imaged sequentially with a satisfactory temporal resolution.
Here, we introduce a modification to the 2P-RAM system that enables simultaneous imaging with two focal planes independently positioned in axial direction. We have introduced a secondary excitation beam that is orthogonally polarized relative to the original beam. These two beams utilize different remote focusing units, but share the rest of the scanning and imaging optics. Femtosecond laser pulses in each beam path are delayed relative to each other by ~ 6.25 ns to create temporally interleaved fluorescence signals from each channel, which are detected by a single photomultiplier and then de-multiplexed into separate channels with custom electronics based on fast analog multiplication. Our de-multiplexing scheme features full synchronization with a dithered laser pulse rate and provides adjustable duty cycle of gating signals, resulting in a reduced cross-talk between imaging channels. The upgraded system features similar signal-to-noise ratio and the same dynamic range of recorded fluorescence signals as the original design.

Title: Development of 3D imaging processing system for neural network analysis

Authors: *N. KIM[1], J. CHOI[1], B. KANG[2], S. JEONG[1]
[1]Korea Brain Res. Inst., Daegu, Korea, Republic of; [2]SYSOFT, Daegu, Korea, Republic of

Abstract: The massive data are being generated by new technologies in neuroscience such as monitoring tools for neural activity and imaging tools for circuit formation. High resolution images, especially, are produced by the techniques of tissue processing and optical equipment so that the data processes are essential in this field.
Confocal and light sheet microscope are widely used for neural network and generates high-resolution images. However, it is still necessary to develop an efficient 3D rendering and visualizing system because it is nonexchangeable imaging file format in huge volume affecting data analysis.
In this study, we propose the web-based 3D visualization and analysis system that supports the entire process of storage, extraction, analysis, visualization of neural network information. To visualize 3D objects converted from 2D images, the overlapping feature points of x and y axis were crossed between the input images of A and B matched through the Fourier transform. The images coordinated the feature of first and second brain images at z-axis side utilizing Rigid transformation technique. The aligned 3D data were applied in Marching Cubes algorithm following transformation to volume geometry and expansion into web. Total 5440 images produced by Lavision light sheet microscope were aligned at 2x2 matrix [0.0],[0.1],[1.0],[1.1] points of each 2D images and matched to generate 3D data based on real used 8GB RAM.This performance enabled a set of n images tiles configuration to create 3D image data in approximately 45GB, which make the reduction of the memory load for data analysis process. This strategy showed that 2D slice images were rapidly converted and visualized to 3D data with rendering approach based on web service allowing us to image process faster than possible with other current methods.

Abstract: Over the past decades, optogenetics has been transforming neuroscience research enabling neuroscientists to drive and read neural circuits. Recent development of new illumination approaches combined with two-photon (2P) excitation, either sequential or parallel, has opened the route for brain circuits manipulation with single-cell resolution and millisecond temporal precision. However, a deeper understanding of complex brain circuits requires pushing light shaping methods into a new regime: the simultaneous excitation of hundreds of targets, arbitrarily distributed in the three dimensions. To this end we developed a new optical scheme for multiplexed temporally focused light shaping (MTF-LS), based on the spatio-temporal shaping of a pulsed laser beam, to project several tens of spatially confined 2P excitation patterns in a large volume. The compatibility with several different phase shaping strategies allows the system to be optimized towards flexibility, simplicity or multiple independent light manipulations, thus providing new routes for precise three-dimensional optogenetics. By combining MTF-LS with a high-peak power low-repetition rate fiber amplifier we showed *in vivo* optogenetics activation at very low excitation intensity (<1 $mW\mu m^{-2}$). These findings, together with the fact that amplified lasers can deliver several Watts of exit power, indicate that laser power is not the limiting factor for the maximum achievable number of targets using MTF-LS. Yet, establishing the optimal configuration for multi-target *in vivo* optical manipulation, raises questions about the induced heating inside samples. To account for this effect, we present and experimentally validate a theoretical model that enables to simulate both 3D light propagation and heat diffusion in optically scattering samples at unprecedented high spatial and temporal resolution under the illumination configurations most commonly used to perform 2P optogenetics: single- and multi-spot holographic illumination and spiral laser scanning. By investigating the effects of photostimulation repetition rate, spot spacing, and illumination dependence of heat diffusion, we found conditions that enable to design a multi-target 2P optogenetics experiment with minimal sample heating.

Abstract: The International Brain laboratory (IBL, Neuron 2017) is a collaboration of 21 labs aiming to understand the neural basis of decision-making. A major goal of the IBL is to establish and implement a mouse behavioral task in multiple institutions, each contributing standardized data to a global repository. In the pilot phase of the project, we implemented the same visually guided task in mice across three institutions (UCL, CCU, and CSHL) in three countries to assess behavioral reproducibility.
We built rigs in accordance with a single assembly protocol and components list, and prepared mice for the headfixed task using similar surgical and animal-handling protocols. To run the task, we developed custom software that automates the progression of training by adaptively adjusting task parameters. A total of 23 mice were trained across the three institutions (11 at UCL, 4 at CCU, 8 at CSHL) on 7 behavioral rigs using this automated training protocol. Behavioral data were saved to a centralized repository using a standard file format (ALF) for integration into a common analysis pipeline.
Mice were considered successfully trained on the spatial contrast detection task (Burgess et al. 2017) if performance on the highest contrasts was > 85% correct and median reaction times were <3 s. 70% of all animals were successful. On average, animals took 11 days of training to reach stable performance, and trained animals did on average 526 trials per day (UCL:454±184; CCU:587±84; CSHL:565±99). As expected, choice accuracy increased and reaction time decreased with visual contrast. Mice were significantly biased towards one choice in the majority (76%) of sessions. Within each mouse, we examined the distribution of biases across sessions; in

16/23 mice, biases were consistently towards the same response side.
These pilot data suggest that reproducible mouse behavior can be achieved in multiple laboratories using a standardized set of materials and methods. We will subsequently implement this behavior in 8 additional experimental laboratories within the collaboration and proceed to neural recordings. Ongoing efforts include documenting experimental procedures and environmental conditions within each lab, creating detailed instructions for rig construction, developing video processing systems to track multiples movements/ physiological indicators, and building a shared data repository and analysis pipeline.
With these considerations, the IBL aims to generate an integrated large-scale dataset for in-depth modeling of neural activity during behavior, and produce standardized and centralized resources for collaborative data acquisition and analysis.

Title: The international brain laboratory: Data architecture

Authors: *K. D. HARRIS[1], N. BONACCHI[2], M. L. HUNTER[1], C. REDDY[1], C. ROSSANT[1], N. ROY[3], N. A. STEINMETZ[1], M. J. WELLS[1], O. WINTER[2], .. THE INTERNATIONAL BRAIN LABORATORY[4]

Abstract: The International Brain laboratory (IBL) is a collaboration of 21 labs aiming to understand the neural basis of decision-making. Ten experimental labs will record from a variety of brain regions, using a variety of modalities, in mice performing a common behavioral task. A primary requirement of the IBL is to establish a common data architecture, seamlessly integrating data from all labs so it can be analyzed together.
Establishing this data architecture presents several challenges. The first challenge is of social

engineering: ensuring that scientists in all labs accurately record metadata concerning their mice and experiments. The second is to integrate and organize this metadata so it is searchable and linked to experimental data files. The third is to organize the large quantities of highly diverse experimental data in a coherent and human-understandable way. The fourth is to establish an analysis pipeline that will automatically run on new data as it arrives.
To solve the first challenge, we have developed a user-friendly, web-based electronic lab notebook system for colony management and metadata entry, known as Alyx (https://github.com/cortex-lab/alyx). Information concerning experimental subjects is entered when they are crossed, born, genotyped, or undergo any procedure, allowing labs to keep an up-to-date record of their animal colony. This information is stored in a relational database.
The second challenge requires linking metadata to files. Because bulk experimental data is too large to store relationally, Alyx stores references to binary files, in a manner that allows copies of the files to be archived and backed up in multiple locations. When an experiment or analysis is performed, the recording or analysis software automatically registers the data files in the database.
For the third challenge of organizing the bulk data files, we have designed a file-naming convention called ALF (github.com/cortex-lab/ALF). ALF provides a principled way to organize diverse data (such as electrophysiology, movies, behavioral traces) in their native formats, with a standard and simple way to represent relationships between them including time alignment. All IBL files are stored on a common central server, and when a contributing lab registers a file with the database, an automatic upload to the central server begins.
Finally, for pipelined automatic analysis, we will make use of DataJoint to compute basic standard analyses and store the results in relational form. This will allow users to browse and download the results using a web interface as well as through protocols such as Neurodata Without Borders.

Title: Beyond correlation in zebrafish whole brain activity

Authors: *C.-M. YEH[1], G. PAO[2], A. GROISMAN[3], J. R. FETCHO[4], S. CHALASANI[5]
[1]Mol. Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA; [2]LOG-V, Salk Inst., La Jolla, CA; [3]UCSD, San Diego, CA; [4]Cornell Univ., Ithaca, NY; [5]Mol. Neurobio. Lab., The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Much of data analysis in neuroscience has been dominated by concepts such as Hebbian learning in which correlation of activity patterns lead to learning, sensory, motor or homeostatic activities. In this way, much of the analysis has relied heavily on correlation based methods of brain activity patterns. Since correlation does not imply causation, it is difficult to infer function from correlation. In the present work we used a time delayed embedding approach to identify relationships from whole brain imaging in the hypoxia response of larval Zebrafish. Our analyses reveal that the hypoxic response is complex and state dependent even at the single neuron level. The observation support the view that complexity is low dimensional and it exhibits complex attractor dynamics. Within our data, we identify neurons whose dynamics contain information that allow the prediction of out of sample aggregate whole brain activity. These observations are in vivo evidence for the existence of locally embedded presages of global network bursts as hypothesized by Satohiro Tajima et al. (Tajima et al. PNAS *2017 doi: 10.1073/pnas.1705981114*) from in vitro model random networks. The identified neurons can predict the whole brain activity with >60% accuracy (observed/predicted) although their activities show little correlation (Rho =0.29). These findings suggest a substantial presence of nonlinear responses due to low dimensional attractor dynamics that warrant further investigation. Our results establish a novel approach to map functional connectivity for causal network reconstruction that allows the distinction of correlation from causation and even find causation in the absence of correlation. This was shown in the zebrafish hypoxic response, but should be widely applicable and complement the physical connectome for the understanding of brain maps.

Title: Loss of inhibitory control causes network-specific functional underconnectivity: A DREADD-fMRI study in C57BL/6J and PV-Cre mice

Authors: *M. MARKICEVIC[1], B. D. FULCHER[2], M. RUDIN[3], N. WENDEROTH[4], V. ZERBI[4]
[1]Dept. of Hlth. Sci. and Technology, Neural Control of Movement Lab., ETH Zurich, Zuerich,

Abstract: One popular method for estimating brain-wide functional connectivity patterns is resting-state-fMRI. However, it is unclear how this macroscopic measure reflects local alterations of excitation: inhibition balance (E:I) at the circuit-level. Here we hypothesize that population-wide neuronal synchrony gives rise to BOLD correlated activity under the control of GABAergic interneurons. To address this, we combine resting-state-fMRI with Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), immunohistochemistry and electrophysiological recordings. Specifically, we perturb the E:I in the somatosensory network, a structurally and functionally well-known brain circuit, by i) increasing the overall asynchronous neuronal firing and by (ii) reducing the activity of Parvalbumin interneurons. Right primary somatosensory cortex of C57BL/6J (n=19, 13 controls) and PV-Cre mice (n=28, 14 controls) is unilaterally targeted with hM3Dq and DIO-hM4Di DREADDs, respectively. Four weeks after surgery, cerebral blood flow (CBF) and resting-state-fMRI measurements are acquired with a 7T scanner equipped with a cryogenic coil following well-established pipelines for animal handling, anesthesia, and data acquisition. In both sessions (45 minutes long), 30µg/kg of Clozapine is intravenously injected after 15 minutes to activate the DREADDs. Rs-fMRI data is analyzed to determine changes in connectivity (Zerbi et al., 2018) and classification models are utilized to identify which features of the univariate dynamics of the BOLD signal reflect E:I changes (Fulcher et al., 2013). Increasing asynchronous neuronal firing with hM3Dq results in a significant increase of CBF around the injection site. Rs-fMRI data in both C57BL/6J and PV-Cre mice indicate that increasing neuronal excitability or reducing inhibition via DREADS cause a local disruption of connectivity near the injection site, and long-range interhemispheric connectivity reductions, which are limited to the somatosensory and somatomotor cortices. Feature classification revealed significant decreases in BOLD variance and an increase in the stationarity dynamics of the signal in hM3Dq group compared to controls in both injection site and contralateral regions, but not outside the somatosensory network. In conclusion, we link brain *underconnectivity* (i.e. an output often described in psychiatric disorders) to reduced within-network dynamics due to loss of sufficient local inhibitory control. Our results form the first step towards identifying a causal link between E:I at the cell population level and markers of brain-wide, macroscopic functional connectivity.

Title: The importance of empirical data on the anatomical connectivity of mouse neocortex

Authors: *A. GAMANUT[1,2], K. KNOBLAUCH[1], B. GAMANUT[1,2], A. H. BURKHALTER[3], H. KENNEDY[1,4]

Sch., Saint Louis, MO; [4]Inst. of Neuroscience, State Key Lab. of Neuroscience, Chinese Acad. of Sci. (CAS) Key Lab. of Primate Neurobiology, CAS, Shanghai, China

Abstract: Cortical areas in the mouse are very small and it is difficult to restrict injections of tracers to individual areas. Hence, either connectivity studies are based on empirical data obtained from a relatively small number of successfully area-restricted injections [1], or they use more numerous injections involving multiple areas and then computational methods to indicate the connectivity of individual areas [2, 3]. Cortical networks extracted from empirical data on cortico-cortical connectivity in mouse neocortex show significantly higher density than modeled data. Importantly, the latter fails to accurately capture the connectivity profiles of individual areas; hence errors in the determination of connectivity profiles in modeled data will not reflect the actual specificity of the mouse cortex [1]. Here, we further address the advantages of empirical vs modeled data. Using injections with the retrograde tracer Diamidino Yellow, we analyzed the experiments in which the injection site was restricted to one cortical area. The weight of a given projection is defined by the proportion of labeled neurons (FLN) in a source area divided by the total number of labeled neurons in the cortex. We extend our investigation to the contralateral hemisphere and include the projections from claustrum. The contralateral projections are considerably less numerous than the ipsilateral projections and present a different distribution of weights. We find projections from the ipsilateral claustrum in all experiments, and we provide a quantitative comparison with the contralateral claustrum. Altogether, our results show that there are important differences between the connectivity profiles of ipsi- and contralateral projections, and validate our claim on the need for empirical data. *[1]* Gămănuț, R., et al., The Mouse Cortical Connectome, Characterized by an Ultra-Dense Cortical Graph, Maintains Specificity by Distinct Connectivity Profiles. *Neuron*, 2018. 97(3): p. 698-715.e10. *[2]* Oh, S.W., et al., A mesoscale connectome of the mouse brain. *Nature*, 2014. 508(7495): p. 207-14. *[3]* Knox, J.E., et al., High resolution data-driven model of the mouse connectome. bioRxiv, 2018.

Abstract: The study of neural systems is most frequently approached as following the neural activity that is closely correlated in time with a sensory input or behavioral output. However higher order functions that integrate multiple sensory inputs and more complex processes are slower processes and are more separated in time from both the sensory input and motor output and necessarily become more decorrelated. In many cases the processing and reprocessing with multiple feedbacks will lead to the appearance of complex attractor dynamics in neural systems and is frequently observed as a loss of correlation making understanding difficult when using correlation based methods which dominate most of neural activity data analysis. Here in observations of the larval zebrafish brain, we observe low dimensional dynamics that are consistent with this notion and appear to be ideally suited using the analytical framework of embedology based on the Whitney embedding theorem and the generalized Takens theorem. Our results quantify the changes in dimensionality from the "default state" to a flight response and identifies likely sites of large scale integration in the larval zebrafish brain.

Abstract: We have applied optogenetics and mGRASP, a light microscopy technique that labels synaptic contacts, to map the synaptic strength (physiology) and organisation (anatomy) of auditory corticocollicular (CC) connections. Using mGRASP, we show that CC projections form small, medium and large synapses, and both the number and distribution of synapse size varies between different IC regions. Using optogenetics, we show that low-frequency stimulation of CC axons expressing channelrhodopsin produces prolonged elevations of CC miniature EPSC (mEPSC) rate. Remarkably, functional analysis of CC mEPSCs reveals small, medium and large amplitude events, that mirror the synaptic distributions observed with mGRASP. Our results reveal descending ipsilateral projections dominate CC feedback via increased number of large synaptic contacts, especially onto the soma of IC neurons. This study highlights the feasibility of combining microscopy (i.e. mGRASP) and optogenetics to reveal synaptic weighting of defined projections at the level of single neurons, enabling functional connectomic mapping in diverse neural circuits.

Title: Wide-field calcium imaging deconvolution methods

Authors: *M. STERN[1], D. WITTEN[2], E. T. SHEA-BROWN[1]
[1]Applied Mathematics, [2]Dept. of Statistics, Univ. of Washington, Seattle, WA

Abstract: Wide-field Calcium imaging techniques allow recordings of high resolution neuronal activity across one or multiple brain regions. However, since the recordings capture light emission generated by the fluorescence of the calcium indicator, the neural activity that drives the calcium changes is masked by the calcium indicator dynamics. Since we usually wish to explore neural activity dynamics, the recorded signal needs to be de-convolved based on the calcium properties, to reveal the underlying neural spiking rates.
Much effort has been put into de-convolving a calcium trace that originates from a signal neuron. However, the signal recorded in the wide-field method, in contrast with that recorded in two-photon imaging, originates from dozens to thousands of neurons. Hence, different, or modified, de-convolution techniques are required to reveal the spiking rate dynamics from the calcium traces in wide-field recordings. We survey here three different approaches to de-convolution that are standard in distinct disciplines, and their utility for the wide-field recordings. First, we explore the direct convolution by the inverse shape of the calcium response to spiking. This method, while naively correct, magnifies noise at specific frequencies. Second, we explore calculating the positive part of the derivative of the signal. While this method is highly simplified, we show that it relates linearly to the original spiking rate and estimates it well under some conditions. Third, we explore the 'Richardson-Lucy' image recovery method, adopted here to recover temporal dynamics rather than spatial images. The method accounts for signals created by Poisson processes but over smooths and misses some signal fluctuations.
We also develop and test a novel method to de-convolve the calcium traces. This method is based on statistical machine learning, and takes into account both the noise existent in the

recordings and the full shape of the calcium indicator response. The method generates time binning for the original rate signal dynamically, where each bin size depends on the data, and for each bin finds the proper spiking rate.
We compare results for the four methods on both synthetic data where the underlying truth is known, as well as for wide-field calcium recordings where cues from behavior and stimuli are available.

Title: An unbiased workflow for isolating and mapping functional dynamics across the developing neocortex

Authors: *B. R. MULLEN, S. C. WEISER, J. E. LAMB, C. P. SANTO TOMAS, J. B. ACKMAN
UC Santa Cruz, Santa Cruz, CA

Abstract: The neocortex contains a constellation of sensory-motor regions whose functional interactions during development are thought to shape adult brain function. Simultaneously recording neuronal group activity across the cortical hemispheres may provide insight on functional interactions necessary for establishing cerebral networks. To this end, we transcranially image pan-neuronally expressed genetically encoded calcium indicators across the neocortex in unanesthesized mice. Recording from behaving mice produces a unique set of challenges, including optical and blood artifacts associated with movement. In addition, areal patterning of the cortex can vary widely across ages and genotypes- thus an unbiased, flexible workflow for video acquisition and analysis is necessary to map the functional structure of the cortex. To address these challenges, we have developed an eigendecomposition-based workflow that isolates blood and optical artifacts to recover underlying calcium activity patterns, and maps independent regions of the brain to create maps of functional units in the developing cortex. To verify these functionally defined cortical structures, we align our maps to molecular expression patterns that delineate cortical structure. In addition, we quantify the quality of independent source separation, and use the resulting metrics to optimize our recording parameters. These open-source methods are flexible enough to be implemented on different recording rigs, and will become publicly available for use upon publication. Overcoming these hurdles opens the possibility of expanding this technique to address a variety of questions including the exploration of network development by tracing neuronal projections of functionally associated regions,

characterizing intra- or inter-areal connectivity neurodevelopmental disease models, and investigation of plasticity of higher-order cortical regions in real-time feedback experiments.

Title: MRI marker to predict subcortical vascular cognitive impairment: Comparison among integrity of normal appearing white matter, integrity of white matter hyperintensities, and cortical thickness

Authors: *J.-J. YANG[1], B.-H. KIM[1], G. PARK[1], S. SEO[2], J.-M. LEE[1]
[1]Dept. of Biomed. Engin., Hanyang Univ., Seoul-City, Korea, Republic of; [2]Dept. of Neurol., Samsung Med. Center, Sungkyunkwan Univ. Sch. of Med., Seoul, Korea, Republic of

Abstract: The most common cause of subcortical vascular cognitive impairment is known as white matter hyperintensities (WMHs) and lacunes. However, not all individuals with an apparent identical degree of WMHs experience the same level of cognitive deficits. In this study, we investigated which of cortical thinning, integrity of normal appearing white matter (NAWM), and integrity of WMHs is an appropriate risk-stratification tool to distinguish patients with vascular cognitive impairment from cognitively normal elderly with the same degree distribution of patients' WMHs. We further examined group differences in WMH's spatial distribution over the brain, white matter (WM) integrity, cortical thickness, and the relationships between WM integrity and cortical thickness. We hypothesized that integrity of NAWM can predict for cognitive impairment than those of WMHs because it is likely that the compromised integrity of NAWM affects the overall connective integrity of the brain.
We selected 64 high-risk individuals with the same degree distribution of patient's WMHs but cognitively normal as a beginning in which symptoms are not yet present (wNC). We defined 84 patients with 'pure' subcortical cognitive impairments (pSVCI), who show negative on PiB-PET, as a continuum of disease progression related to only vascular pathology. White matter integrity was estimated by averaged fractional anisotropy (FA) and mean diffusivity (MD) from diffusion tensor imaging in each area of WMHs and NAWM, respectively. Cortical thickness was calculated from structural MRI. Classification accuracy was evaluated from the area under the

curve (AUC) to assess which parameter independently discriminated best between wNC and pSVCI patients. A general linear model was conducted with controlling age, gender, education years to examine local differences of the group in cortical thickness on vertex, FA and MD on skeletonized voxel level.
We found that integrity of NAWM had better contribution on discriminating between wNC and pSVCI with AUC of 85 % FA and 84 % MD than those of WMH (78 % FA and 71 % MD). In contrast, averaged cortical thickness produced 70 % classification. Structural differences were revealed in overall WM integrity with decreasing FA, increasing MD, and cortical thinning in pSVCI when compared to those of wNC. Furthermore, significant relationships between cortical thickness and WM integrity were shown only in pSVCI patients.
Our findings may lead to a better understanding which tissue damage influences with neurological function and clinical status in patients related to vascular cognitive impairment.

Title: DBScope: Visualizing DBS effects mapped to standard space

Authors: *W. OH[1], H. JEON[1], Y. LIM[2], S. PAEK[2], J. KIM[1,3]
[1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technol. (KIST), Seoul, Korea, Republic of; [2]Dept. of Neurosurg., Seoul Natl. Univ. Hospital, Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [3]Div. of Bio-Medical Sci. & Technol., KIST-School, Univ. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Deep brain stimulation (DBS) not only provides an effective treatment modality for advanced Parkinson's disease (PD) and other neurological diseases, but also offers a rare opportunity to infer causal relations between neural circuit activity and behavioral outcome in humans. However, clinical data required for such inference is often highly sporadic, heterogeneous, and multi-dimensional, necessitating a systematic approach based on programmatic platforms. Here we fully utilize the open-source software ecology to build a data processing pipeline, named DBScope, that maps clinical benefits and adverse effects of subthalamic DBS in PD patients to volumes of brain tissue electrically activated by DBS. Centered around the R programming environment, the workflow includes 1) a chain of scripts for tidying raw data, 2) a package to interface with a MATLAB toolbox specialized in localizing

DBS electrodes within standard spaces, and 3) an application to interactively visualize the 3-dimensional circuit-behavior mapping. Inputs to the pipeline consist of tabular and imaging data; tabular data include demographics, intervention profiles, and clinical outcomes, while imaging data comprise preoperative magnetic resonance (MR) and postoperative computed tomography (CT) images. Each step is heavily documented under the literate programming paradigm. We provide postoperative profiles of improvement and worsening of various motor and non-motor clinical features. These profiles are mapped to anatomically annotated voxels in the standard Montreal Neurological Institute (MNI) space. We plan to extend this pipeline beyond exploratory analysis to inference and prediction of areas that elicit therapeutic ("hot spots") and adverse ("danger zones") effects following DBS.

Title: Intrinsic connectivity network efficiency for evaluating its contribution to brain network integration

Authors: *Y.-H. PARK, J.-J. YANG, J.-M. LEE
Biomed. Engin., Hanyang Univ., Seoul, Korea, Republic of

Abstract: Brain networks are composed of several intrinsic connectivity networks (ICNs), with integration and segregation. Frequency specificity of ICN are revealed by previous studies. However, the previous studies have some deficiency in brain network integration analysis. Sasai, et al. (2014) evaluated the brain network integration using global efficiency in the frequency dimension. But, the global efficiency is only indicators of the overall network. Thompson and Fransson (2015) evaluated the brain network integration through strength contribution in the frequency dimension. But, the strength contribution of ICN considered first degree of each node only. In this study, we used the novel measure called ICN efficiency, which is defined as the difference between the global efficiency and the efficiency of the whole brain network excluding the ICN.
The present study used fMRI data of 352 subjects in Human Connectome Project S900 data released in December 2015. First of all, the connectivity matrices along the frequency were constructed from time-varying frequencies of each region of ICN. Hierarchical clustering

analysis was conducted by considering the difference between connectivity matrices of each frequency. The low-frequency band was divided into two frequency bands with the highest silhouette value. Finally, the ICN efficiency was calculated along the two frequency bands. Paired sample t-test between ICN efficiency of two subbands was performed to confirm that the ICN contribution to brain network integration were different from each other.
We found that ICN efficiency has various tendencies along the frequency. Ascending, descending, or flat tendencies of ICN efficiency were same to the tendencies of number of betweeness centrality (BC) hub in many ICNs including DMN, VN, LN, ECN, SN and PCN. This result supports the suggestion that ICN efficiency is useful for evaluating ICN contributions to brain network integration, because ICN efficiency and the number of BC hubs were used as cross check. We conclude that ICNs have frequency specific contribution to brain network integration.

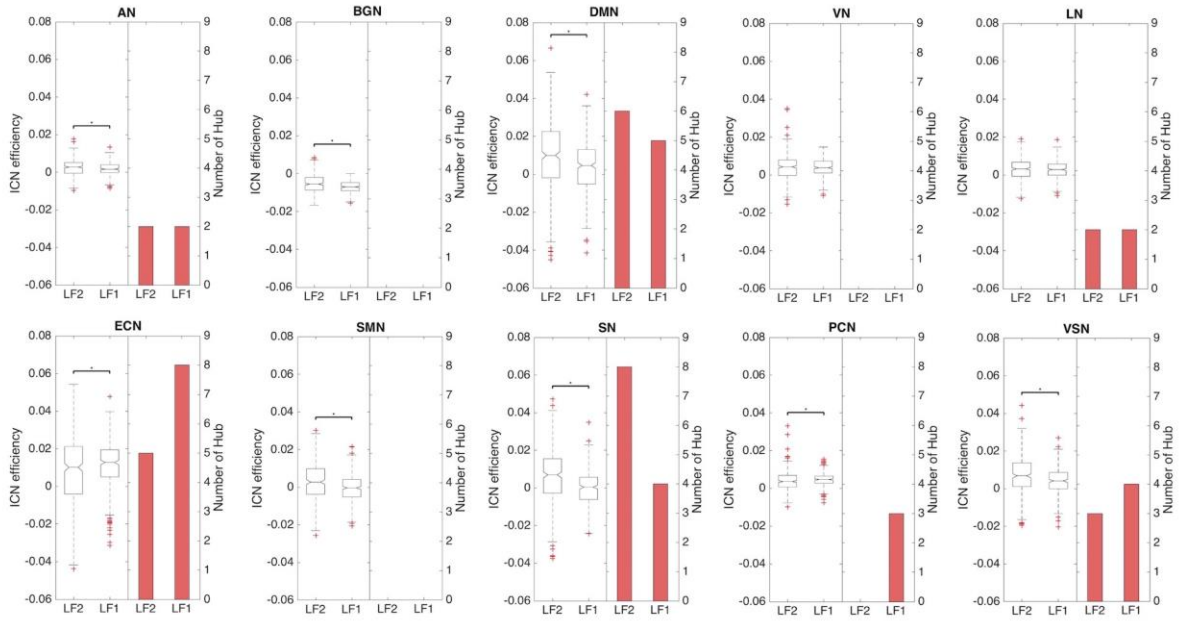

Fig.1 The tendencies of ICN efficiency and number of BC hub along the frequency.
The ICN efficiency of the 10 ICNs compared using paired t-test analysis between the 2 subbands. The results were corrected by Bonferroni correction ($p<0.005$). AN, auditory network; BGN, basal ganglia network; DMN, default mode network; VN, visual network; LN, language network; ECN, executive control network; SMN, sensorimotor network; SN, salience network; PCN, precuneus network; VSN, visuospatial network. LF1= 0.027~0.08 Hz, LF2 = 0.009~0.013 Hz.

Title: Genetic risk factors for cortical thickness in patients with Alzheimer's disease

Authors: *B.-H. KIM, Y.-H. CHOI, J.-M. LEE
Biomed. Engin., Hanyang Univ., Seoul, Korea, Republic of

Abstract: In recent GWA studies have been identified risk SNPs for Alzheimer's disease, including APOE, CLU, BIN1. However, these genetic variants only explain the small portion of phenotypic variance of disease. The aim of this study was to identify novel AD susceptible genes through the imaging genetic analysis.
We used 908 (161 AD, 481 MCI, 266 NC) subject's T1-weighted images and genotype information from Alzheimer's Disease Neuroimaging Initiative (ADNI). We downloaded impute genotype information and performed quality control, call rate < 95%, HWE $p < 10^{-6}$, MAF < 5%. We estimated whole brain mean cortical thickness that used as an endophenotype for further analysis using CIVET v2.1. We performed GWAS testing 3,041,429 SNPs, with age, sex, education level, diagnosis, scanner field strength, and APOE4 genotype as covariates using PLINK v1.90. Then, we performed gene-based and protein-protein interaction(PPI) based analysis using KGG v4.0. In gene-based analysis, SNPs that were fell within 5kb of the 3'/5' untranslated regions were considered 'within' gene and summary P value for each gene was calculated by GATES(Gene-based Association Test using Extended Simes Procedure). In PPI based analysis, we used high confidential network (confidence score > 0.7) and combines gene-based P-values for each protein interactions and detects PPI pairs in which two genes are associated with the phenotype using HYST (Hybrid Set-based Test).
In GWAS, no marker reached the genome-wide significant threshold. The SNP rs12320537, which is an intronic SNP of B4GALNT1 (beta-1,4-N-acetyl-galactosaminyltransferase 1) gene on chromosome 12, achieved the strongest evidence for cortical thickness ($P=8.60 \times 10^{-7}$). Six of the 10 most suggestive SNPs were annotated into B4GALNT1 gene and 2 SNPs (rs2619470, rs2640607) were located within 5kb of B4GALNT1 gene. In gene-based analysis, B4GALNT1 (nominal $P=2.71\times10^{-6}$, corrected $P=3.87\times10^{-2}$), LOC1001927583 (nominal $P=4.79\times10^{-6}$, corrected $P=3.87\times10^{-2}$), SLC26A10 (nominal $P=4.79\times10^{-6}$, corrected $P=3.87\times10^{-2}$) genes were significantly associated with cortical thickness. In PPI based analysis, B4GALNT1 and GALNT8 gene pair (1.57×10^{-7}), both on chromosome 12, is significantly associated.
In this study, we identified 4 genes implicated in the pathogenesis of AD using the cortical thickness, among which B4GALNT1 was the most associated genes. Yamaguchi et al. (2016) identified the expression of B4GALNT1 gene enhanced the β-site cleavages of APP protein that produce Aβ which play a central role in AD pathology. We discovered genetic variants on B4GALNT1 underlying the cortical thinning in patients with AD.

Title: Convergent excitatory and inhibitory connectivity in the subthalamic nucleus

Authors: *H. LEE[1,2], W. OH[1], H. JEON[1], J. KIM[1,2], L. FENG[1], J. KIM[1,2]
[1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technol. (KIST), Seoul, Korea, Republic of; [2]Div. of Bio-Medical Sci. & Technol., KIST-School, Univ. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: The subthalamic nucleus (STN) is a network hub of the basal ganglia, receiving extensive inputs from diverse cortical and subcortical areas. Proposed as an integrative regulator of information flow, the STN is considered the primary target of deep brain stimulation (DBS) in various neurological and psychiatric disorders including Parkinson's disease. However, the circuit-level mechanism underlying the effects of STN-DBS remains unknown, and even fundamental characteristics such as functional anatomy and synaptic profile of the STN circuitry are unclear. We thus provide detailed connectome descriptions of excitatory and inhibitory inputs into the STN, i.e. cortico- and external globus pallidus-subthalamic circuits, respectively, both known to be critical in generating and coordinating motor program of the basal ganglia. In particular, we used fluorescent protein-expressing viral tracers and mammalian GFP reconstitution across synaptic partner (mGRASP) for mapping connectivity of the STN at meso- and micro-scale, respectively. We identified complex projection patterns in the STN from cortical regions and external globus pallidus, suggesting STN convergences far more intricate than the conventionally posited discrete tripartite STN division. Our results provide comprehensive axonal projection patterns and input-specific synaptic distributions in the STN area. Such multiscale connectivity landscape will lay the foundations for understanding the cortical and pallidal contributions to the therapeutic mechanism of STN-DBS.

Title: Detecting neural assemblies in calcium imaging data

Authors: *J. MÖLTER[1], L. AVITAN[2], G. J. GOODHILL[1]
[1]Queensland Brain Inst. & Sch. of Mathematics and Physics, [2]Queensland Brain Inst., The Univ. of Queensland, St Lucia, Australia

Abstract: Activity in populations of neurons often takes the form of assemblies, where specific groups of neurons tend to be co-active. However, in calcium imaging data, reliably identifying these assemblies is a challenging problem, and the relative performance of different assembly-detection algorithms is unknown. Here we show that only some of these algorithms work well in this case. First we generated large surrogate datasets of calcium imaging data and tested the abilities of independent components analysis (ICA), PCA-Promax, frequent item set mining, and a recently proposed graph theory algorithm (SGC) to recover known assemblies. We then applied the same algorithms to evoked activity data from zebrafish tectum. While both SGC and novel variants we propose for ICA and PCA-Promax performed well for the simulated data, on the real data SGC performed best. These findings suggest that SGC is a very reliable algorithm for detecting neural assemblies from calcium imaging data.

Abstract: The common marmoset (*Callithrix jacchus*) is a small primate that is increasingly used in neuroscience and bio-medical research. Its rapid reproduction rate compared to other primates makes it an attractive species to model genetic conditions. A key process in developing new disease models using the marmoset is the ability to characterise, *in vivo*, brain anatomy, and to monitor, longitudinally, neuro-chemical changes that may occur as a result of evolving pathological processes. State-of-the-art neuro-imaging techniques are invaluable tools to achieve such goals. Moreover, obtaining high-quality images is critical to accurately determine the precise co-ordinates of targets, to ensure the precision of stereotaxic surgery, as there is individual variability in the marmoset brain and as most atlases were designed with a limited number of animals. We have developed protocols that enable us to conduct magnetic resonance imaging (MRI), computed tomography (CT) and positron emission tomography (PET) in the common marmoset. Here, we present preliminary data of experiments in which marmosets underwent MRI, CT and PET as part of a pre-surgical characterisation process. We present the image and image juxtaposition data, in addition to target reconstruction, in the striatum, using the Rogue Research Vet Robot Brainsight® neuro-navigation software. Lastly, we present anatomical images obtained in *post-mortem* brain tissue that demonstrate the accuracy of our approach at reaching its target.
