[1]Bayrlor Col. of Med., Dept. of Neurol., Houston, TX; [2]Baylor Col. of Med., Houston, TX

**Abstract:** Transient-type low-voltage activated calcium channels (T-channels) regulate the intrinsic excitability of thalamic cells and facilitate the genesis of rebound burst firing which enable thalamocortical oscillations and contribute to the modulation of brain states of awareness. The thalamus takes part in sensory, motor and cognitive functions by transmitting information to the cortex via numerous distinct nuclei. These nuclei are divided into two different categories: first order and higher order relays. First order nuclei receive driver input from the periphery or a subcortical source, while high-order nuclei mainly receive descending inputs from the cortex. Precise regulation of T channels is important for healthy thalamocortical processes since abnormal function of T-channels has been implicated in pathological conditions, including epilepsy, neuropathic pain, and sleep disorders. We examined whether different thalamic nuclei develop T-channel expression simultaneously during early development, or whether bursting in these pathways show distinctive stages of maturation? We performed whole-cell recordings in the developing mouse thalamus (postnatal day 3 to 35). We found that across subregions of the lateral thalamus, there is a high-to-low gradient from dorsal to ventral nuclei in the expression of T-channels. Specifically, all laterodorsal thalamic (LD) neurons projecting to associative retrosplenial cortex show a distinctively high expression of T-currents which enable them to fire low-threshold and rebound spikes in as early as one week old C57BL/6 mice. These spikes could be blocked by a T-channel specific blocker, Z944. At this age, a small fraction of neurons in other higher-order nuclei including lateral posterior nucleus (LP), posterior complex (PO) and the dorsal part of medial geniculate complex (dMG) of the thalamus, can fire low-threshold and rebound spikes. In sharp contrast, similar low-threshold and rebound spikes in first-order primary sensory thalamic relay neurons, including visual (lateral geniculate nucleus, LGN), somatosensory (ventral posteromedial nucleus, VPM), and auditory (ventral part of medial geniculate complex, vMG) neurons appeared nearly one week later. Functionally, our preliminary data showed that optogenetic and electrical activations of GABAergic circuit could elicit burst spiking in LD neurons with cell-attached recording. Together, these results indicate

that higher-order thalamic relay neurons utilize firing supported by T-channels earlier than those in the primary sensory pathway and could be recruited by GABAergic inputs.

**Title:** Rapid modulation of L-type voltage-gated calcium channels during brain development by vitamin D

**Authors: *H. M. GOOCH**, X. CUI, V. ANGGONO, T. H. BURNE, D. EYLES, P. SAH, J. MCGRATH
Queensland Brain Inst., St Lucia, Australia

**Abstract:** The secosteroid vitamin D [1,25$(OH)_2D_3$] drives ***genomic*** changes in the body via classical steroid hormone pathways. While 1,25$(OH)_2D_3$ is also known to drive ***non-genomic*** effects in some peripheral tissues, most notably the rapid modulation of L-type voltage-gated calcium channels (L-VGCC), its non-genomic effects within the brain remain unexplored. Since accumulating evidence links common L-VGCC genetic variants with neuropsychiatric disorders, and developmental vitamin D deficiency is an established risk factor for schizophrenia, we are investigating the non-genomic effects of 1,25$(OH)_2D_3$ on L-VGCCs in the developing brain. Using wide-field calcium imaging and electrophysiology in the prefrontal cortex (PFC), we found that physiological concentrations of 1,25$(OH)_2D_3$ (0.1 nM) rapidly enhanced L-VGCC activity in a subset of PFC neurons, termed ***vitamin D responsive neurons*** (***I-VDRNs***). 1,25$(OH)_2D_3$ increased activity-dependent somatic cytosolic $Ca^{2+}$ levels by as much as 250% in I-VDRN in both intact (av αF/F increase 29 ± 4%; n=110/1245 cells, 8.8%), and synaptically blocked imaging preparations (av αF/F increase 24 ± 2%; n=53/720 cells, 7.4%). Consistent with this, nucleated patch recordings revealed 1,25$(OH)_2D_3$ enhanced high voltage-activated (HVA) $Ca^{2+}$ channel currents (33 ± 5%, n=5) in a subset of layer 2/3 PFC cells (n=5/21, 24%), suggesting that $Ca^{2+}$ influx through VGCCs contributed to the increased cytosolic $Ca^{2+}$ levels observed during imaging. Further, pre-incubation of imaged slices in the L-VGCC channel blocker nifedipine (10 μM) almost entirely blocked the 1,25$(OH)_2D_3$-induced increase in cytosolic $Ca^{2+}$ levels (av αF/F increase 11 ± 1%; n=8/675 cells, 1.2%), demonstrating that

$1,25(OH)_2D_3$ enhanced L-VGCC activity in a subset of PFC neurons during development. Interestingly, wide-field $Ca^{2+}$ imaging also revealed a second subset of PFC neurons that showed decreases in activity-dependent cytosolic $Ca^{2+}$ levels following bath application of $1,25(OH)_2D_3$ (av αF/F -29 ± 3%; n=38/426 cells, 8.9%), termed ***D-VDRNs***. This effect was not dependent on L-VGCC modulation (av αF/F -22 ± 2%; n=59/675, 8.7%), however pre-incubation with synaptic blockers significantly reduced the proportion of responsive D-VDRN neurons (av αF/F -26 ± 4; n=26/677 cells, 3.6%), suggesting network effects beyond vitamin D responsive neurons. Since L-VGCC activity is required for developmentally critical processes such as neuronal maturation and gene transcription, these findings suggest a significant role for vitamin D during healthy brain development, and suggests potential consequences for developmental vitamin D deficiency.

**Title:** Axonal branches of layer 2/3 dual projection neurons targeting an ipsilateral distant area extend more rapidly than locally targeting branches in mouse neocortex

**Authors: *M. SATO**[1,2], Y. LIN[1], M. DOI[1], Y. OKA[1,2]

**Abstract:** Direct connections between different cortical areas have been shown to be important for sensorimotor integration. Developmental processes of these connections and their underlying mechanisms, however, have not been fully understood. By using a subtype-specific promoter and our new vector for enhancing sparse labeling of cortical neurons combined with tissue clearing of flat-mounted cortices, we visualized a population of layer 2/3 (L2/3) neurons in the mouse primary somatosensory area (S1) that had axons projecting to the contralateral hemisphere as well as to the ipsilateral hemisphere. We analyzed the processes of their axon projections and

found that these neurons first extended the main axonal shaft projecting to the contralateral hemisphere, already crossing the midline before birth. In contrast, collateral branches projecting to the ipsilateral hemisphere emerged around postnatal day 3 at the level of layer 5. Only one among these collateral branches reached the distant areas, such as the primary motor area (M1) and the secondary somatosensory area (S2). Temporal analysis of the branch length suggested that far-reaching branches grew at a higher rate than those projecting to the local targets. This observation raises the possibility that a branch might be selected at a very early stage, if not at the timing of the budding, to target an area distant from the original area of the soma.

**Abstract:** The brain's ability to support cognitive processes, such as perception, attention, and memory, represents a critical evolutionary advancement. Neural networks underlying these processes mature over the course of development, and are influenced by ongoing synaptic activity. Modulation of this synaptic activity early in development has the potential to disrupt normal maturation, but the underlying mechanisms of this impairment remain unclear. Here, we examine the properties of cortical neural networks during physiologic development compared to pharmacologic and genetic conditions that alter the excitatory-inhibitory balance. We perform in vivo neurophysiological recordings from mouse pups aged postnatal day 5 to 14 that are cycling through natural waking and sleep epochs. With the use of the NeuroGrid, a high spatiotemporal resolution surface array, we simultaneously record from multiple cortical regions as determined by post-mortem immunohistochemical analysis. We study the effects of acute changes to GABAergic neurotransmission using pharmacologic agonists and antagonists, as well as chronic alteration of excitation-inhibition in a mouse model of pediatric epileptic encephalopathy (KCNT1). Although neural networks exhibit some common responses to these neuromodulatory alterations, expression of oscillatory activity is modified by postnatal age and prior synaptic

experience. These data allow us to better understand the neurophysiologic patterns that characterize normal maturation, and how they can be impacted by aberrant synaptic activity in diseases such as epilepsy.

**Title:** Postsynaptic mGluR signaling controls the development of somatostatin interneurons

**Authors: *G. POUCHELON**[1], E. FISHER[1], R. MACHOLD[2], G. FISHELL[1]
[1]Harvard Med. Sch., Boston, MA; [2]New York Univ., New York, NY

**Abstract:** Our internal representation of the outside world is created within the neocortex. Inhibitory interneurons (INs) sculpt cortical activity and are thus critical in shaping these representations. During development, the inhibitory circuits that allow for the emergence of cortical function are assembled early during the postnatal period. Activity has been increasingly associated with these developmental processes, however the role and the type of activity in IN development remain largely unexplored.
Although Parvalbumin (PV) and Somatostatin (SST)-INs both arise from the same embryonic structure, the medial ganglionic eminence (MGE), they differentiate into two very distinct IN types within the cortex. It seems likely that the afferent activity impinging upon these distinct cells is central to their integration into cortical circuitry. Recent single-cell RNA-seq analyses has revealed that each interneuron subtype expresses a specific set of neurotransmitter receptors, which are potential candidates for activity-dependent controls of their development.
Using in vivo monosynaptic rabies tracing at the postnatal developmental stage when INs settle in their cortical position, we discovered that the earliest presynaptic input to SST-INs is glutamatergic and originate from the thalamus. Analyzing glutamatergic receptors expression during postnatal development revealed that the postsynaptic metabotropic glutamatergic receptor 1 (mGluR1) is specifically expressed in SST-INs and continues to be expressed into adulthood. In addition, we found that mGluR1 is activated by thalamocortical inputs. Therefore we

hypothesize that mGluR1 regulates the integration of SST-INs into cortical networks. Using a combination of mouse genetics, rabies monosynaptic tracing and electrophysiology, we discovered that SST-INs show a defect of maturation upon deletion of mGluR1. Together these findings reveal an activity-dependent postsynaptic mechanism for IN-type differentiation and provide a better understanding of cortical inhibitory circuit development.

**Abstract:** In the mammalian cerebral cortex, inhibitory interneurons sculpt the flow of excitatory information. This complex task is carried out by a wide variety of interneuron subtypes which play distinct roles in cortical function. Two major classes of interneurons, parvalbumin (PV)+ fast-spiking basket cells and somatostatin (SST)+ Martinotti cells, are both derived from a common embryonic origin yet differentiate into highly specialized cell types. Mechanisms that control the diversification of these cell types and specify their integration into their respective circuits are not well understood. Increasing evidence suggests that this process depends not only on initial genetic determinants of cell fate, but also activity-dependent signals once the interneurons invade the cortex and begin to form synapses. One candidate signaling factor to mediate cortical interneuron maturation and synaptic integration is brain-derived neurotrophic factor (BDNF), which is a neurotrophin critical for the development of several cells types and has been shown to regulate inhibition in the developing cortex. However, the contribution of the BDNF high-affinity receptor TrkB to interneuron development has never been tested. Here, we employ a combination of longitudinal fate-mapping, electrophysiology, and synaptic puncta analysis to demonstrate that TrkB controls the circuit integration of SST and PV cortical interneurons.

**Title:** Early prenatal exposure of rats to homocysteic acid leads to lasting changes in NMDA receptor subunit expression and GABAergic interneuron markers

**Authors: *A. LUNDERBERG**, S. SIMKO, J. ROYER, L. CHASE
Hope Col., Holland, MI

**Abstract:** Homocysteic acid (HCA), a NMDA receptor agonist, is an endogenous metabolite formed from the oxidation of homocysteine. Since hyperhomocysteinemia is a risk factor for several neuropsychiatric disorders, including bipolar disorder and major depressive disorder (MDD), we previously tested the hypothesis that elevated HCA levels in developing rats may induce the development of behaviors associated with MDD and/or bipolar disorder. Our earlier work demonstrated that exposure of postnatal rats to HCA from P3-21 leads to a mixed depressive/manic phenotype that develops post-puberty. Specifically, HCA treated rats exhibit increased risk-taking behavior, reduced social behavior, novelty-induced hyper-locomotion, anhedonia in the saccharine preference test, and reduced spatial learning in the Morris water maze, consistent with a depressive state with manic tendencies. Therefore, in this study, we focused on examining the effects early postnatal HCA exposure had on glutamatergic and GABAergic markers in the hippocampus and the cortex in the adult rat. We hypothesized that early postnatal HCA exposure would lead to excitotoxicity and loss of NMDA-receptor containing GABAergic interneurons which are hypothesized to play an important role in the pathology associated schizophrenia, bipolar disorder and depressive disorder. However, contrary to our hypothesis, we observed that HCA exposure led to an increase in expression of the GABAergic marker, GAD-67 in the cortex of both male and female rats. This finding suggests that perhaps GABAergic interneurons were not appropriately pruned during the critical period. In addition, we observed that HCA exposure led to a significant increase in the NR2A:NR2B subunit expression ratio in the cortex and the hippocampus of male and female rats, but no changes in NR1 subunit expression. Functionally, this would result in NMDA receptors with faster gating kinetics which may be less susceptible to HCA-induced excitotoxicity. Furthermore, we also found that HCA leads to an increase in the expression of BDNF, a neurotrophic factor important for maintenance of GABAergic interneurons. This finding is consistent with the observation that the relative NR2A subunit expression increases as activation of NR2A-specific receptors is associated with an increase in BDNF release. Collectively, these data suggest that early HCA exposure may lead to a shift in the NR2A:NR2B subunit expression, leading to an increase in BDNF expression and GABAergic interneuron survival during the

critical period. *This research was supported by the Hope College Neuroscience Program, Biology Department and Chemistry Department.*

**Title:** Mechanistic insights into autocrine an paracrine roles of endothelial GABA in the embryonic forebrain

**Authors: Y. CHOI**, A. VASUDEVAN
Dept. of Psychiatry, Angiogenesis & Brain development Laboratory, McLean Hosp., Harvard Med. Sch., Belmont, MA

**Abstract:** The developing cerebral cortex uses a complex developmental plan involving angiogenesis, neurogenesis and neuronal migration. After establishment of the periventricular vascular gradient by embryonic day 11 (E11), neurons and/or neuronal progenitors from ventricular zones navigate along diverse courses, radially and tangentially, to adopt final laminar positions and integrate into specific brain circuits. Our recent studies have shown that the developing periventricular vascular network exquisitely patterned amidst neurons not only acts as a physical substrate for neuronal migration, but also holds the key to several novel developmental mechanisms and pathways. It highlights the importance of endothelial cell secreted GABA signaling in the embryonic forebrain and establishes novel autonomous links between blood vessels and the origin of neuropsychiatric diseases like epilepsy, autism and schizophrenia. Since a common GABA pathway operates in both endothelial cells and GABAergic neurons of the embryonic telencephalon, it is essential to gain further mechanistic insights by segregating this pathway in individual cell types. Our recently generated *Vgat* $^{\Delta Tie2\text{-}Cre}$ or *Vgat* $^{ECKO}$ (endothelial cell knockout; ECKO) mouse model that blocks GABA release from endothelial cells, serves as a new tool to study how endothelial GABA signaling shapes angiogenesis and neurovascular interactions during prenatal development. Here, we isolated individually periventricular endothelial cells and GABAergic neurons from E15 *Vgat* $^{\Delta Tie2\text{-}cre}$ and *Vgat* $^{fl/fl}$ telencephalon and characterized them further by using molecular (RNA seq) and cellular techniques. Our results reveal that the endothelial GABA signaling pathway influences angiogenesis related genes and specific processes like tight junction formation, vascular sprouting and migration. It also shows how components of the neuronal GABA pathway, for

instance receptor mediated signaling and transcription factors are affected in the absence of endothelial GABA release. Taken together, our findings delineate the close relationship between vascular and nervous systems that begin early in embryogenesis establishing their future interactions and interdependence.

**Abstract:** Neural circuits in the brain communicate through diverse types of synapses. Synapses between different types of neurons can vary widely in their structural and functional properties, and this diversity is required for proper circuit function. Cell adhesion molecules play important roles in synapse development, as they connect pre- and postsynaptic cells and recruit the molecular machinery necessary for synaptic function. However, their potential role in specifying distinct synapse types is still largely unexplored. Single-cell sequencing studies have shown that different neuronal cell types express distinct combinations of adhesion molecules, but whether the structural and functional diversity of different synapse types is reflected in unique adhesion molecule compositions is not known. Typically, the molecular composition of synapses is studied in bulk synaptosome preparations containing many different synapse types. Therefore, the establishment of new methods to elucidate the molecular properties of distinct synapse types is crucial for understanding the molecular basis of synaptic connectivity, function and plasticity. Here, I developed a new method to profile the proteome of a specific hippocampal synapse type, the mossy fiber-CA3 (MF-CA3) synapse, by combining biochemical fractionation, live-labeling for a synapse-specific surface marker, Fluorescence Activated Synaptosome Sorting (FASS) and liquid chromatography-tandem mass spectrometry (LC-MS/MS). Proteomic analysis reveals that

several dozen adhesion molecules are specifically enriched at this synapse. To reveal protein-protein interaction networks within these enriched molecules I am performing a small, unbiased oligomerization-based screen to detect extracellular interactions between individually expressed recombinant extracellular domains. The ultimate goal is to map multiple surface protein complexes at an individual synapse type, the MF-CA3 synapse, and analyze the consequences of synaptic loss of validated adhesion molecules on MF-CA3 synapse structure, function, and plasticity.

**Title:** Patterning of cerebellar inhibitory interneurons by the gamma-Protocadherins

**Authors: *W. X. WANG**[1,2], J. L. LEFEBVRE[1,2]
[1]Neurosciences and Mental Hlth., Hosp. for Sick Children Res. Inst., Toronto, ON, Canada; [2]Dept. of Mol. Genet., Univ. of Toronto, Toronto, ON, Canada

**Abstract:** The developmental events that orchestrate neural circuit formation are dependent on coordinated interactions of neurons with their local environment. Central to these interactions are cell-surface receptors and adhesion molecules, whose concerted actions allow for remarkable specificity in neuronal cell numbers, distributions, and connectivity patterns. Among these are the clustered Protocadherins, which have emerged as key regulators due to their immense capacity for isoform diversity and recognition specificity. The Pcdh locus encodes ~60 different cadherin-like genes, tandemly arrayed into the *–alpha, -beta,* and *–gamma* clusters. This isoform diversity is further amplified through stochastic and combinatorial expression of small subsets of isoforms among single neurons. Genetic ablation of the Pcdh-γs revealed diverse functions in neuronal development, including neuronal survival, dendrite arborization, and synaptic development. However, the temporal timeline of Pcdh function, and how these developmental roles are coordinated in a given cell-type have not been explored. To address this gap in knowledge, we devised genetic strategies for targeting the cerebellar molecular layer interneuron (MLI) population during discrete stages of their development: *prior to, during,* or *post* MLI settlement in the molecular layer. We provide evidence for separate roles of the Pcdh-γs in

regulating interneuron survival and neurite arborization. Early deletion of the Pcdh-γs in MLIs, during the final stages of neuronal migration, leads to reduced survival of MLIs and to reduced neurite arborization. By contrast, late deletion of Pcdh-γs, past the time-point of MLI settlement, did not affect MLI numbers, but led to similar reductions in dendritic and axonal branching. Our results suggest a critical role for the Pcdhs in interneuron survival during a discrete period of MLI integration. We propose a model in which the Pcdh-γs are required for interneuron survival and neurite branching during two windows of development. Further analyses also revealed that survival of a later-born MLI subpopulation, the stellate cells, were preferentially reduced following Pcdh-γ deletion. We are currently using quantitative imaging methods to investigate the expression patterns and roles of Pcdh isoform diversity in mediating these diverse functions.

**Title:** Purkinje cell axonal torpedoes are associated with reduced spike propagation failures and enhanced cerebellar-related behaviour

**Authors: *D. LANG-OUELLETTE**, C. A. VAN EITREIM, P. DE VANSSAY DE BLAVOUS, C. ROSEN, M. VIRDEE, A. J. WATT
Dept. of Biol., McGill Univ., Montreal, QC, Canada

**Abstract:** Focal swellings in the axons of Purkinje cells, or torpedoes, have been frequently observed during disease progression, as well as transiently in the developing cerebellum. Given their prevalence in neurodegenerative diseases, current hypotheses suggest that Purkinje cell axonal torpedoes contribute to pathophysiological axonal function.
To elucidate the functional role of Purkinje cell axonal torpedoes in the cerebellum, we used transgenic L7-*tau*-eGFP mice that brightly label Purkinje cells. Using simultaneous dual recordings from visually-identified Purkinje cells and their axons, we measured the properties of spike propagation with and without the presence of axonal torpedoes. Purkinje cell axons propagate action potentials with high fidelity, with low rates of axonal failures. Surprisingly, we found that Purkinje cell axonal torpedoes displayed even lower axonal failure rates compared to axons without torpedoes. We wondered whether an increase in axonal failure rate led to the formation of axonal torpedoes. Using time-lapse two-photon imaging of live cerebellar slices, we

found that Purkinje cell torpedoes were stable over hours, with no new torpedoes formed in ACSF. A non-saturating dose of tetrodotoxin (TTX) caused differential reductions in the firing rate of Purkinje cell somata and axons, thereby mimicking an increase in axon propagation failures. This caused formation of new torpedoes, supporting our hypothesis that torpedoes form when axonal failures are elevated. Finally, we wondered if torpedoes had a functional consequence. To address this, we took advantage of the naturally-occurring variability in motor learning across mice. We found that mice that displayed elevated levels of motor learning had a greater number of Purkinje cell axonal torpedoes, whereas mice that displayed lower levels of motor learning had fewer torpedoes.
Taken together, our results suggest that Purkinje cell axons form torpedoes to improve axonal action potential fidelity. The presence of axonal torpedoes is functionally relevant, as they are associated with enhanced cerebellar-related behaviour. These findings argue that rather than reflecting pathophysiology, axonal torpedoes reflect a homeostatic cellular adaptation that preserves axonal function.

**Title:** Organophosphate pesticides cause physiological and architectural changes to spinal neurons and somatic muscle in 72-hour zebrafish embryos

**Authors: *E. A. FRADINGER**, T. H. WATANABE, R. C. WILLRICH
Biol. Dept., Whittier Col., Whittier, CA

**Abstract:** Organophosphate pesticides inhibit acetylcholinesterase causing an accumulation of acetylcholine at the synapse and hyperstimulation of the cholinergic neurons in both the CNS and PNS. This study seeks to understand the acute effects of organophosphate pesticide exposure on developing neurons. Using the zebrafish model system, we have shown that developmental organophosphate exposure inhibits acetylcholinesterase activity and causes changes to acetylcholine-dependent physiological processes including an increase in spontaneous movement generation at 24 hours-post-fertilization. To further investigate the effects of these pesticides on

neuromuscular development we have utilized wholemount immunohistochemistry to investigate the effects of organophosphate pesticides on the architecture of spinal cholinergic neurons and trunk muscle in 72 hour-post-fertilization embryos. Confocal observations of the trunk spinal region showed that embryos exposed to chlorpyrifos had reduced numbers of cholinergic cell bodies and this effect was amplified in chlorpyrifos-oxon exposed zebrafish. Similarly, changes to trunk muscle architecture were observed in chlorpyrifos exposed embryos and these effects were more pronounced for chlorpyrifos-oxon exposed embryos. Thus, hyperactivity of cholinergic neurons and overstimulation of developing muscle due to acetylcholinesterase inhibition results in structural changes. Interestingly, diazinon did not affect the cholinergic physiology of developing zebrafish embryos. Together, these data highlight the importance of understanding the developmental effects of USDA approved organophosphate pesticides.

**Title:** A phase transition in activity of Hydra's nervous system as it reassembles from individual cells

**Authors: *J. LOVAS**, R. YUSTE
Columbia Univ., New York, NY

**Abstract:** A growing body of evidence suggests that neural circuits in the cortex and other parts of the brain may operate at a state of self-organized criticality, a concept used to describe the complexity that emerges in systems attracted to dynamics on the verge of a phase transition. Despite the observation of these dynamics and their accompanying power-law scaling in various preparations, there is little *in vivo* experimental evidence for any proposed function of this transition state in the nervous system.
To explore this issue, we work with the small Cnidarian *Hydra vulgaris*, a representative of some of the earliest nervous systems in evolution. *Hydra's* simple nervous system of 300-2,000 neurons is organized in two independent nerve nets in its ectoderm and endoderm and is distributed through the body of the animal without any cephalization or ganglia. Moreover, under the right conditions *Hydra* can reassemble itself into a normal animal after complete dissociation into individual cells. Using transgenic Hydra which express the calcium sensor GCaMP6s in

every neuron (Dupre and Yuste, 2017) we have imaged the neuronal activity of dissociated preparations as they re-aggregate over a period of several days. Our data show how the subcritical activity of dissociated cells transitions to the supercritical state of the reassembled circuitry of the intact animal. The phase transition of *Hydra's* nervous system through a critical regime of activity during the process is reminiscent of the scale-free dynamics of the constantly fluctuating activity of neuronal ensembles of the mammalian cortex. With experimental manipulations to alter the profile of critical dynamics of the process in *Hydra*, we provide *in vivo* experimental evidence in support of the proposed roles of criticality in extending the dynamic range and information capacity of susceptible neural circuits as they form and process information.

**Abstract:** Stem-cell (SC) derived brain organoids represent an attractive in vitro model system to study the mechanisms underlying early brain development, and there is a growing body of evidence that cerebral organoids do recapitulate key molecular milestones of early corticogenesis (Di Lullo and Kriegstein, 2017). To what extent cerebral organoids are also capable of giving rise to functional neuronal networks, resembling the structure of in vivo microcircuits, however, remains to be determined. Experimental work, both in vitro and in vivo, suggests that distinct patterns of spontaneous neuronal activity during development represent hallmarks of neuronal network maturation (Blankenship and Feller, 2009). Spontaneous neuronal activity is thought to be involved in key developmental processes, such as neurogenesis and migration, as well as in the formation and refinement of neuronal connectivity (Luhmann et al., 2016). In rodents, sparse intrinsic activity in few cells has already been found at embryonic time points (Owens et al.,

2000), followed by more coherent activity among gap-junction-coupled ensembles around birth (Garaschuk et al., 2000), and early oscillatory patterns in the first postnatal weeks (Crépel et al., 2007), driven by synaptic transmission. Here, we used a genetically encoded calcium indicator to study the trajectories of spontaneous activity in developing cerebral organoids derived from mouse embryonic SCs. Using confocal microscopy, we tracked activity within the same organoid over two weeks in vitro and characterized their intrinsic calcium dynamics. We found that immature neurons showed spontaneous calcium activity already in the second week in vitro. At this stage calcium transients were rare, uncoordinated and of small amplitude. Only few days later, the number of active neurons increased significantly, and spontaneous activity became synchronized over small ensembles of cells; also the amplitude of calcium transients increased strongly during this time. Finally, at three weeks in vitro, the repertoire of activity patterns observed in cerebral organoids was multifaceted, comprising both single-cell and large-scale network-level events. Interestingly, calcium dynamics of developing organoids resembled some of the typical activity patterns observed in acute slice recordings from juvenile cortex. Our results indicate that cerebral organoids also undergo distinct phases of spontaneous activity during neural development, some of which are similar to the patterns reported previously in slices. Thus, cerebral organoids represent a useful tool to explore further the self-organizational principles of neuronal networks.

**Abstract:** Neurons with distinct genomic differences from one another have previously been identified by a number of studies in the frontal cortex and hippocampus, in a phenomenon termed genomic mosaicism. Myriad genomic variations in these brain regions have been identified to date, ranging in size from megabase-scale copy number variations to single nucleotide variants. The majority of large somatic variations appear to occur during neurodevelopment, however, several studies provide evidence that smaller changes can occur to the genome throughout the cellular lifespan of neurons, which in adults, is roughly equal to the age of the individual. The potential physiological role of DNA alterations to adult neuron genomes remains largely unknown, but characterizing the genomic integrity of postmitotic neuronal populations is essential. We developed a novel assay to assess dynamic, postmitotic alterations to the genomes of adult neurons, and characterized postmitotic genomic changes across several brain regions. Surprisingly, we identified an entirely new form of genomic alteration that actively occurs in adult neurons. This phenomenon appears to be highly correlated with behavioral conditioning paradigms in mice and plays an important role in active neuronal circuits. Establishment of a unique sequencing approach allowed us to characterize this process across several brain regions that are involved in learning and memory.

**Title:** Implication of the spatial position of immediate early genes for the formation of DNAdouble strand breaks

**Authors: *I. DELINT-RAMÍREZ**, R. MADABHUSHI
UT Southwestern Med. Ctr., Dallas, TX

**Abstract:** It is known that neuronal activity by the activation of NMDA receptors causes a rapid expression of immediate early genes that play an important role in neuroplasticity. Recently it was reported that this activity stimulation triggers the quick formation of DNA double strand breaks (DSBs) in the promoters of early-response genes, including Fos, Npas4, and Egr1. Surprisingly, these DSBs increase the expression of immediate early genes after NMDA stimulation. Activity-dependent DSB formation is mediated by the type II topoisomerase (Topo

IIβ). Whereas Topo IIβ binds to the promoters of a broad range of genes, neuronal activity induces DSB in only a selective subset of early-response genes. The mechanisms underlying the specificity of DSB formation remain poorly understood. In this work, we examine the signaling mechanisms that affect the formation of activity-induced DSBs in neurons. We further describe how these activity-dependent signaling pathways modulate Topo IIβ activity. Furthermore, we describe the effects of chromatin organizational features in neurons that underlie the positional specificity of activity-induced DSB formation.

**Abstract:** Facial motor neurons of the rat embryo are first generated in rhombomere 4 and then migrate toward the caudo-ventral direction. This migration forms a unique axonal trajectory called the "genu", a loop of facial motor axons around the abducens nucleus. It is still unclear when and how this unique structure is functionally established during ontogenesis. Using voltage-sensitive dye (VSD) recording and the DiI staining method, we identified neural responses evoked by facial nerve (N.VII) stimulation and examined developmental processes of the facial motor nucleus in E12-E17 rat brainstems. We identified two types of fast spike-like signals; a long-duration signal, which corresponded to the action potential in N.VII soma, and a short-duration signal, which reflected the action potential in N.VII axons. The long-duration signal was detected as early as E13, suggesting that the N.VII motor neuron is already excitable at the beginning of cell migration. The response area of the long-duration signal extended caudally at E13-E14, and shifted in a ventral direction at E15. At E16-E17, the long-duration signal was concentrated in the caudo-ventral area, which was comparable to the location of the facial motor nucleus in the adult rat brainstem. These results demonstrate that developmental processes of cell migration and nuclear organization can be visualized and identified functionally with the VSD recording. We discuss the results by comparing functiogenesis and morphogenesis of the N.VII pathway.

**Abstract:** One major challenge in developmental neurobiology is clarifying when and how the brain is functionally organized during embryogenesis. Although such investigations are significant, they have been hampered by the limited conventional electrophysiological means available for immature neurons and assessing spatio-temporal patterns of neural responses. In the present study, a multiple-site optical recording technique with a voltage-sensitive dye was applied to the mouse embryo, and functional organization of the vestibular nucleus was examined. Stimulation of the vestibular nerve in E12-13 mouse brainstems elicited fast and slow optical signals, which corresponded to the action potential and the excitatory postsynaptic potential (EPSP), respectively. The EPSP was mediated by glutamate and was sensitive to extracellular $Mg^{2+}$, which suppresses the NMDA receptor. In the E13 embryo, the EPSP-related signals were detected from the region extending longitudinally to the levels rostral and caudal to the vestibular ganglion, with high signals concentrated in the caudal region. At E12, the EPSP was lower and generally restricted to the caudal region even when extracellular $Mg^{2+}$ was removed to enhance the glutamate receptor function. These results suggest that the developmental sequence of functional synaptic expression is different between the vestibular subnuclei, and that the EPSP initially appears in the caudal vestibular nucleus in the mouse embryo.

**Title:** Structural and functional remodeling of the axon initial segment in a mouse model of autism

**Authors: *M. P. JORDAN**, C. CORCELLI, S. VORWALD, N. JAMANN, C. SCHULTZ, M. ENGELHARDT
Med. Fac. Mannheim, Heidelberg Univ., Inst. of Neuroanatomy, Mannheim, Germany

**Abstract:** The classical view of neurons emphasizes the role of dendrites for synaptic signal integration and plasticity. In contrast, the axon has been recognized as a rather static output device. This view is rapidly changing, with recent research revealing a much more active role for axonal microdomains in neuronal signal processing. A key regulator in this regard is the axon initial segment (AIS), strategically positioned at the proximal axon and essential for action potential initiation. It further exhibits significant structural and functional plasticity, depending on network activity. By regulating AIS length and position, neurons can modulate their excitability and therefore contribute to maintain the functional stability of neuronal circuits. Here we asked whether altered network states in a mouse model of autism spectrum disorder (ASD) result in structural and functional remodeling of the AIS. Typically, ASD is characterized by aberrant fronto-striatal circuitry, presumably leading to an imbalance of neuronal excitation/inhibition. In our model, mouse pups were subjected to in-utero exposure with the anticonvulsant valproic acid (VPA), a common rodent model for ASD. Using multi-channel immunofluorescence, confocal microscopy, morphometrical analysis, and electrophysiological recordings, we investigated putative changes in structural maturation and integrity of the AIS in two ASD-relevant anatomical circuits: (i) the dorso-lateral striatum (DLS), mainly controlling automated motor sequences and habitual behaviours and (ii) the barrel field in primary somatosensory cortex (S1BF), which projects to DLS. We found that pyramidal neurons in S1BF layer 2/3 and 5 in VPA-exposed mice display significantly shorter AIS than in saline controls. This decrease in length correlated with a decrease in cellular excitability. Interestingly, inhibitory medium spiny neurons in DLS show significantly longer AIS than saline controls, possibly indicating a higher cellular excitability. In which way these differential cellular responses correlate with the ASD-driven changes in network activity remains to be investigated. Taken together, our results point to a role for AIS plasticity in the development of ASD phenotypes in mice.

**Title:** Multiple waves of developmental delays in fragile X cortical circuits *in vitro*

**Authors: *H. MOTANIS**[1], A. GOEL[4], C. PORTERA-CAILLIAU[2], D. V. BUONOMANO[3]
[1]Dept. of Neurobio. and Pshychology, [2]Neurol., [3]Dept Neurobiol, UCLA, Los Angeles, CA; [4]Neurol. and Neurobio., Univ. of California, Los Angeles, CA

**Abstract:** Neurodevelopmental delays characteristic of fragile X (FX) syndrome have also been observed in vitro (Motanis et al., 2015). The presence of neurodevelopmental delays in vitro suggests that they are a direct consequence of the *Fmr1* mutation, as opposed to an indirect product of compensatory mechanisms or abnormal sensory experience. Here, we used whole-cell recordings and $Ca^{2+}$-imaging of cortical slice cultures from wild-type (WT) and Fmr1 knockout mice to characterize the development of spontaneous and evoked activity, and determine if they undergo normal network-level homeostatic plasticity. $Ca^{2+}$-imaging of spontaneous activity with GCaMP6f revealed that at 14-16 days in vitro (DIV) mean activity was reduced in FX circuits ($0.051\pm0.006$ vs. $0.130\pm0.032$, $p<0.05$). Recordings at 25-30 DIV revealed no difference in spontaneous activity, confirming the presence of an in vitro developmental delay. Interestingly, whole-cell recordings revealed no significant genotype difference of the input-output functions of evoked EPSPs at 11-15 DIV. But there was a difference at 25-30 DIV ($p<0.01$) as EPSP strength underwent a developmental increase in WT, but not FX circuits. By 35-40 DIV there were no differences in EPSPs strength or evoked network activity between WT and FX circuits. To examine network-level homeostatic plasticity we used chronic optogenetic stimulation (COS-ChR2) to emulate an increase in externally driven activity. Whole-cell recordings revealed that COS-ChR2 (25-30 DIV) induced a significant reduction of evoked EPSP strength ($F_{1,62}=15.56$, $p<10^{-3}$), with no genotype difference—i.e., COS-ChR2 resulted in a decrease in EPSP strength in both WT and FX circuits despite the reduced baseline difference in the FX unstimulated slices. To examine homeostatic plasticity across the network, we used COS together with 2-photon $Ca^{2+}$-imaging in slices co-transfected with GCaMP6f and Chrimson (25-30 DIV). COS-Chrimson induced a significant reduction of both spontaneous ($F_{1,27}=18.75$, $p<10^{-3}$) and light-evoked activity in both genotypes. To begin to understand the nature of the abnormal

development activity we targeted Ca2+ imaging to parvalbumin (PV)_interneurons (PV-Cre mice x ai9 mice, GCaMP6s). Preliminary results indicate normal spontaneous activity of PV neurons in FX circuits. Together these results reveal there were multiple delayed developmental "waves" in FX circuits: first a delay in spontaneous activity, followed by a delay in evoked EPSP strength. In addition, our results indicate that FX circuits exhibit normal homeostatic plasticity, suggesting that some previously described neural phenotypes observed in FX may be compensatory.

**Title:** Impaired sensory discrimination in fragile X syndrome mice is mediated by abnormal interneuron dynamics

**Authors: *A. GOEL**[1], D. CANTU[1], J. GUILFOYLE[2], G. R. CHAUDHARI[1], A. NEWADKAR[1], B. TODISCO[1], D. DE ALBA[1], N. KOURDOUGLI[1], L. M. SCHMITT[2], E. PEDAPATI[2], C. A. ERICKSON[2], C. PORTERA-CAILLIAU[1]
[1]Neurol. and Neurobio., Univ. of California, Los Angeles, CA; [2]Psychiatry, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, CA

**Abstract:** Fragile X Syndrome (FXS), one of the most common inherited forms of mental impairment, is associated with abnormalities in sensory processing, including a propensity for impaired cognitive performance in the setting of sensory distractors. We investigated the abnormal cortical network dynamics in *Fmr1* knockout (*Fmr1*$^{-/-}$) mice that mediate deficits in learning. Using a go/no-go visual discrimination task for head-restrained mice, we found that, compared to wild-type (WT) mice, *Fmr1*$^{-/-}$ mice take significantly longer to discriminate between gratings drifting in two orthogonal orientations (90$^{o}$ task). Because this delayed learning was associated with higher rates of false alarm responses in *Fmr1*$^{-/-}$ mice in early sessions, which could result from an abnormal state of hyperarousal, we tested whether *Fmr1*$^{-/-}$ mice were more susceptible to sensory distraction. We found that introduction of visual or auditory distractors, after mice learned the basic 90$^{o}$ task, significantly impaired performance in *Fmr1*$^{-/-}$, but not WT

mice. These deficits are consistent with an inability of *Fmr1*$^{-/-}$ mice to "tune out" sensory distractors and focus on the task, a hallmark of FXS symptoms that could be mediated by alterations in cortical sensory processing and/or decision making. We next used in vivo two-photon calcium imaging (with rAAV-syn-GCaMP6s) to record network dynamics in layer 2/3 of primary visual cortex (V1) and found a significantly lower fraction of and broader tuned orientation tuned pyramidal (Pyr) cells in V1 in *Fmr1*$^{-/-}$ mice compared to WT mice, which correlated with task performance. Dysfunction in parvalbumin (PV) neurons have been implicated in FXS. PV interneurons in sensory areas sharpen orientation tuning of Pyr cells and indirectly modulate attention via alterations in cortical gain, both of which can affect visual feature detection and sensory discrimination. Thus, we recorded from PV neurons by expressing AAV-flex-GCaMP6s in PV-Cre x LSL-TdTom (ai9) WT and *Fmr1*$^{-/-}$ mice and, found a decrease in functional output of PV cells in *Fmr1*$^{-/-}$ mice. Pharmacogenetic manipulation of PV cell activity using designer receptors exclusively activated by designer drugs (DREADDs) restored both normal PV cell dynamics and orientation selectivity, and rescued the visual sensory discrimination deficit. Interneurons expressing vasoactive intestinal polypeptide (VIP) also dynamically regulate sensory responses and plasticity as a function of the behavioral brain state of the animal, thus affecting arousal and attention during learning. Hence, we are currently examining the contribution of VIP cell activity during presentation of sensory distractors in *Fmr1*$^{-/-}$ and WT mice.

**Abstract:** Fragile X Syndrome (FXS), the most common inherited form of intellectual disability and a leading genetic cause of autism, is predominantly caused by silencing of *FMR1* gene expression and the loss of FMRP protein. Two hallmark cellular manifestations of the loss of

FMRP in brain tissue are (i) changes in dendritic spine morphology related to altered cytoskeletal remodeling and (ii) the increased rate of mRNA translation resulting from the loss of translational repressor function of FMRP. We adopted CRISPR- and siRNA-based approaches to achieve robust gene ablation in cultured primary neurons. Single *Fmr1* directed guide RNA transduced into rat hippocampal neurons by lentivirus alongside the SpCas9 resulted in efficient gene inactivation, with 77% of *Fmr1* gene copies acquiring a damaging lesion as assessed by Surveyor nuclease assay and confirmed by deep sequencing and >80% reduction of Fmrp protein as measured by ICC and immunoblotting by DIV21. Treatment of hippocampal neurons with 1μM Accell siRNA on DIV1 also resulted in robust (80-90%) reduction of *Fmr1* expression on DIV16 as measured by RT-qPCR as well as by ICC and immunoblotting. The Accell siRNA modality of Fmrp depletion was more reproducible and was therefore chosen for gene replacement experiments. Using a plate-based fluorescent noncanonical amino acid tagging (FUNCAT) assay, we found that inactivation of *Fmr1* in rat hippocampal neurons in culture results in elevation of the rate of mRNA translation. In addition, it caused an increased phosphorylation of the actin depolymerizing factor cofilin (pS3) and its regulators LIMK (pT508) and Slingshot L1 (pS978). Both cellular phenotypes were reversed by reintroduction of the human *FMR1* by recombinant AAV8 transduction. Using this *in vitro* primary neuron gene eviction and transplacement system, we are assessing the impact of rare *FMR1* mutations found in psychiatric disease patients on FMRP function. Our data show that the hallmark FXS cellular phenotypes can be studied in the plate based systems amenable for high throughput approaches.

**Title:** Role of Cdh1-APC as a regulator of FMRP and protein synthesis at the synapse

**Authors: *A. VALDEZ**[1], A. LAI[2], G. J. BASSELL[2]
[1]Cell Biol., [2]Emory Univ., Atlanta, GA

**Abstract:** For learning and memory to occur, neurons synthesize synaptic proteins in response to stimulation. This process of protein synthesis is tightly regulated to ensure that the optimal amount of proteins is made to strengthen or weaken the connection between two neurons. One of

the ways that cells regulate this process is ubiquitination, a mechanism by which proteins are targeted for degradation through the attachment of a smaller protein, ubiquitin, to specific amino acid residues. Disrupted ubiquitination can lead to multiple debilitating forms of human disease, such as a neurodevelopmental disorder known as Angelman Syndrome and several genetic forms of Autism Spectrum Disorder. Dysregulated ubiquitination may be a shared mechanism amongst other neurodevelopmental diseases.
One neurodevelopmental disease with no FDA-approved treatment is Fragile X Syndrome (FXS). Patients with FXS experience a wide variety of symptoms such as severe intellectual disability, sensory disorders, hyperactivity, reproductive issues, and seizures. FXS is caused by the loss of one protein, the Fragile X Mental Retardation Protein (FMRP). Despite lacking only FMRP, symptoms of FXS are complex and multifaceted. This suggests that FMRP must play a vital role in multiple cellular processes. FMRP has been observed to repress mRNA translation; however, it is unclear how the repressive activity of FMRP is regulated.
Neuronal stimulation has been shown to increase the ubiquitination of FMRP. This suggests that ubiquitination may be a mechanism of regulating the repressive activity of FMRP. Here we demonstrate that the Cdh1 subunit of the E3-ubiquitin ligase anaphase-promoting complex (APC) associates with FMRP, and thus may play a role in ubiquitinating FMRP. Mass spectrometry analysis reveals that Cdh1 interacts with known components of FMRP granules, such as FXR1. FMRP granules have been observed to induce translational repression. Thus, this data suggests a novel function of Cdh1 as a translational regulator through the association of FMRP granules beyond its well-characterized role in ubiquitination during mitosis. The biological relevance of this data is emphasized as expression of Cdh1-APC increases steady-state protein synthesis.
Our data identify a novel role of Cdh1-APC as a regulator of translation and support the novel hypothesis that ubiquitination serves as a dynamic mechanism to regulate FMRP.

**Abstract: Background:** Fragile X syndrome (FXS) is a genetic condition affecting neurodevelopment. Humans with FXS down to 6 months old demonstrate abnormal white matter microstructure[1]. A previous *ex vivo* diffusion weighted MRI (dMRI) study found delayed cerebellar myelination in neonatal FXS mice[2]. We aim to acquire high-resolution *in vivo* dMRI scans using wild type (WT) and *FMR1* knockout (KO) mice to identify connectivity patterns in the living neonatal mouse brain for selected regions of interest (ROI) to correlate with published human dMRI data. This preclinical tool will further contribute to our understanding of FXS neurodevelopment. **Methods:** P5 & p10 *FMR1* KO and WT male mice (n=3-5 mice/age group) were used. Anesthesia protocols were optimized for p5 & p10 mice using 45 mg/kg and 70 mg/kg of ketamine respectively plus 0.9 mg/kg dexmedetomidine. DTI used a Bruker 7T MRI with a CryoProbe. We customized an imaging setup and protocol to accommodate the limited possible scan time and small scan area inherent to imaging p5 mice. We used a segmented 3D dMRI Echoplanar Imaging (EPI) sequence at resolution 0.44 x 0.47 x 0.36 mm, TE = 24.9 ms, TR = 600 ms, 2 segments, 1 average, b = 1000 s/mm$^2$, 25 diffusion directions, 3 b = 0 s/mm$^2$ images, diffusion pulse duration of $\delta$ = 4 ms, a diffusion separation of $\Delta$ = 10 ms (total scan time of 35 mins). Fractional anisotropy (FA) and mean diffusivity (MD) values at 3 ROIs (cortex, caudoputamen, and thalamus) were quantified using FSLView. **Results & Discussion:** FA and MD values were compared (table 1). No significant differences were found in p10 mice. In p5 mice, KO mice had significantly lower FA values (thalamus) and higher MD values (cortex & caudoputamen)—consistent with decreased FA values in the thalamus of human FXS infants. **Conclusion:** This pilot study overcame challenges with imaging neonatal FXS mice, demonstrating significant differences in thalamus (FA) and cortex and caudoputamen (MD) regions in p5 mice. These results are consistent with recently published results in human FXS infants.

**Title:** FMRP regulates mossy fiber-granule cell synaptic plasticity by modulating the Cav3-Kv4 complex

**Authors: *X. ZHAN**[1], H. ASMARA[1], N. CHEN[2], G. SAHU[3], C. SZALAY[3], F. ZHANG[4], G. W. ZAMPONI[4], R. W. TURNER[3]

**Abstract:** The excitability of cerebellar granule cells is strongly regulated by an ion channel complex consisting of Cav3 (T-type) calcium and Kv4 (A-type) potassium channels (Cav3-Kv4). Our previous studies found that long-term potentiation of mossy fiber input to granule cells involves a dramatic increase in postsynaptic excitability through a reduction in A-type current invoked by a hyperpolarizing shift in steady-state inactivation (Vh) of Kv4. This study examined

how regulation of Cav3 and Kv4 channels could contribute to disruption of synaptic plasticity in a Fragile X Syndrome (FXS) mouse model. We found that mossy fiber LTP and the associated left-shift in Kv4 Vh is absent in FMRP-/- mice but rescued by infusing FMRP(1-298) through the patch recording electrode *in vitro*. FMRP was found to co-immunoprecipitate (coIP) with Cav3.1 and Kv4.3 with an association close enough to support FRET in tsA-201 cells. Introducing a short N-terminal fragment of FMRP either through the recording electrode or by bath applying a tat-FMRP construct left-shifted the Vh of either Cav3.1 or Kv4.3 expressed in tsA-201 cells, and the Cav3-Kv4 Vh in granule cells *in vitro*. Moreover, tail vein injection of tat-FMRP into FMRP-/- mice promoted widespread uptake into neurons across the CNS within 1 hr. Behavioral tests reveal a concentration-dependent reduction of hyperactivity in the Open Field test, and restoration of syllable duration in ultrasonic recordings of vocalizations between male and female FMRP-/- mice. These findings are important in revealing a previously unrecognized association between FMRP and Cav3 calcium channels that affects the properties of a Cav3-Kv4 complex at the plasma membrane level to control synaptic plasticity. Early behavioral results with tat-FMRP introduction in vivo suggest a new therapeutic approach to reduce aberrant behavioral symptoms of Fragile X Syndrome. **Title:** Pupil fluctuations track deficits in perceptual learning in Fragile X Syndrome mice

**Authors: *G. CHAUDHARI**, A. NEWADKAR, B. TODISCO, D. DE ALBA, A. GOEL, C. PORTERA-CAILLIAU
UCLA, Los Angeles, CA

**Abstract:** Fragile X Syndrome (FXS), a leading inherited form of mental impairment and single-gene cause of autism, is a complex disorder with a wide variety of symptoms, including learning impairment, atypical sensory processing, hyperarousal, and hyperactivity. In this study, we

sought to determine if these symptoms are interrelated and, specifically, whether hyperactivity and hyperarousal contribute to learning disability in a mouse model of FXS. We used a go/no-go visual discrimination task for head-restrained mice that requires them to preferentially lick for a water reward in response to a preferred visual stimulus, namely gratings drifting in one of two orthogonal orientations. We discovered that wild-type (WT) mice learn to associate the preferred stimulus with the water reward within 4 sessions, whereas *Fmr1* knockout (*Fmr1*$^{-/-}$) mice take significantly longer to master the task. Inspired by a recent study showing that WT mice slow down for the preferred visual stimulus, we hypothesized that *Fmr1*$^{-/-}$ mice's hyperactivity might affect their ability to modulate their running speed, thus impairing their ability to discriminate between the orientations. Using a custom MATLAB video analysis algorithm, we found that there were no differences between the absolute running speeds of *Fmr1*$^{-/-}$ and WT mice, both before and after learning the task (before: 50 ± 8 cm/s vs. 48 ± 6 cm/s, p=0.86; after: 61 ± 6 cm/s vs. 59 ± 8 cm/s, p=0.82). However, after learning the task both groups of mice exhibited a significant reduction in running speed when presented with the preferred stimulus. This suggests that *Fmr1*$^{-/-}$ mice are not hyperactive in this paradigm and that locomotion does not contribute to the learning deficit in *Fmr1*$^{-/-}$ mice as they too learn to slow down for the preferred stimulus. Next, we examined the role of hyperarousal in task performance. Recent studies suggest that changes in pupil size in mice reflect different brain states and correlate with the activity of excitatory and inhibitory neuron subtypes. Hence, we hypothesized that persistent hyperarousal in *Fmr1*$^{-/-}$ mice, reflected by enlarged pupil size, impairs their visual discrimination. We used an infrared camera coupled with custom MATLAB code to monitor pupil dynamics of *Fmr1*$^{-/-}$ and WT mice during both the basic visual discrimination task and a modified task, in which auditory and visual distractors are presented at random. The latter paradigm shows that, whereas the performance of WT mice is unaffected by sensory distractors, *Fmr1*$^{-/-}$ mice that have learned the basic task can no longer discriminate in the presence of distractors. We will present data on the effects of distractors on pupil size during the task in both genotypes.

**Abstract:** Fragile X syndrome is caused by loss of function of the gene encoding Fragile X mental retardation protein (FMRP), an RNA-binding protein. Loss of FMRP leads to abnormally elevated protein synthesis and high survival rates of neurons in the brain. This is associated with excessive numbers of neurons, immature synapses and aberrant synaptic plasticity. There is a significant elevation in levels of Bcl-xL, the anti-apoptotic mitochondrial protein. Bcl-xL targets to mitochondria and depletion of Bcl-xL disrupts mitochondrial membrane potential and decreases ATP content of neurons. We now show that there is a close functional relationship between FMRP, Bcl-xL and mitochondria and that absence of FMRP alters mitochondrial structure and function, causing a proton leak across the inner mitochondrial membrane, resulting in inefficient mitochondrial respiration and decreased ATP production. We also find that the elevated levels of protein translation in FMRP KO mouse neurons can be reduced by treatment with two specific modulators of the ATP synthase, which closes an inner membrane leak within the ATP synthase c-subunit, increasing the efficiency of mitochondrial metabolism. One of these modulators also increases LTP in FMRP KO mouse hippocampal slice recordings. We suggest that FMRP is not only an mRNA binding protein but also normalizes the association between the ribosome and the mitochondria. This relationship is crucial for correct synaptic development and plasticity.

**Title:** Abnormal neuronal exosomal miRNA signaling to astroglia contributes to glutamate transporter GLT1 dysregulation in FXS mouse models

**Authors: *Y. MEN**, J. YELICK, S. JIN, Y. YANG
Neurosci., Tufts Univ., Boston, MA

**Abstract:** Fragile X syndrome (FXS) is a neurodevelopmental disorder caused by the loss-of-function of fragile X mental retardation protein (FMRP). We previously showed that astroglial glutamate transporter subtype GLT1 and glutamate uptake is significantly reduced in cortex of $Fmr1^{-/y}$ mice, leading to dysregulated extracellular glutamate homeostasis and enhanced neuronal excitability. We also showed that the reduced GLT1 expression is resulted from the decreased mGluR5 expression and signaling in Fmr1-deficient astrocytes. Here, we uncovered an exciting new pathway, the exosome-mediated transfer of miR-124 from neurons to astroglia, that up-regulates GLT1 expression. In this pathway, neuron-specific miR-124 as well as a number of other miRNAs are selectively and abundantly packed into neuronal exosomes and transferred into astroglia. Transferred miR-124 significantly up-regulates GLT1 protein expression by suppressing GLT1-inhibiting downstream miR-132 and miR-218. In addition, exosomally transferred miR-124 also suppresses the expression of miR-128 which binds to mGluR5 mRNA and decreases its protein expression in astrocytes. We found that the levels of miR-124 are increased 15 fold in wild type (WT) astrocytes co-cultured with WT neurons compared to that in WT astrocyte cultures alone without altering the levels of pri-miR-124, the precursor of miR-124. In contrast, miR-124 levels in Fmr1 KO astrocytes co-cultured with wild type neurons are increased only 6 fold when compared to that in Fmr1 KO astrocytes alone. Interestingly, expression levels of both primary miR-124 (pri-miR-124) and the mature miR-124 are increased 6 fold in Fmr1-deficient astrocytes alone compared to that in WT astrocytes alone. These results suggest an increased basal endogenous miR-124 transcription in Fmr1 KO astrocytes alone while the transferred miR-124 levels from neurons to Fmr1 KO astrocytes are substantially reduced. We also found that downstream miR-128 levels are increased 19 fold, corresponding to the reduced mGluR5 levels observed in Fmr1 KO astrocytes, while miR-132 and miR-218 levels in Fmr1 KO astrocytes are not altered. Exogenously introduced miR-124 is sufficient to suppress miR-128 and restores GLT1 expression. Our findings reveal a potential role of miRNA-mediated pathological mechanisms in the GLT1 dysregulation in mouse models of FXS, which may identify new modulators to restore normal extracellular glutamate environment and attenuate FXS symptoms.

**Abstract:** Fragile X syndrome (FXS) is a common genetic cause of autism spectrum disorder (ASD) and intellectual disability that results from silencing of the *FMR1* gene, resulting in the loss of its protein product, fragile X mental retardation protein (FMRP). FMRP is an mRNA binding protein with functions in mRNA transport, localization, and translation. It is well known that mRNA translation is altered in FXS and many studies strongly link this dysregulated translation to the pathophysiology of FXS. The function of FMRP in excitatory synapse morphology and function has been widely studied in *Fmr1* KO mouse, a rodent model of FXS. In contrast, the function of FMRP in GABAergic neurons has been less characterized. Both pre- and post synaptic components of the GABAergic system are dysregulated in *Fmr1* KO mice, where multiple GABA receptor subunits and synthesizing enzymes show altered expression in several brain regions. In addition, alterations in inhibitory neurotransmission were found in *Fmr1* KO mice in a number brain regions including amygdala, hippocampus, and cortex. Inhibitory neurotransmission plays a fundamental role in shaping circuit development and function, and imbalances between excitatory and inhibitory transmission have been implicated in ASD. The consequence of FMRP deletion in different interneuron subtypes and their specific contributions to behavioral deficits observed in *Fmr1* KO mice have not been examined. Using Cre -lox recombinase technology, we generated mice with cell type-specific deletion of *Fmr1* in parvalbumin (PV)- and somatostatin (SOM)-expressing interneurons, two of the major interneuron subtypes in the central nervous system. To elucidate the complex interaction between GABAergic dysfunction and behavioral phenotypes in FXS, we assessed anxiety-like behaviors, motor function, memory, repetitive and social behaviors in *PV-Fmr1*$^{-/y}$ *SOM-Fmr1*$^{-/y}$ mice. Our preliminary findings suggest novel, cell type-specific functions for FMRP in distinct behavioral features associated with this neurodevelopmental disorder.

**Abstract:** Fragile X syndrome (FXS) is the most frequent form of heritable intellectual disability and autism. Autophagy is a catabolic process of programmed degradation and recycling of proteins and cellular components *via* the lysosomal pathway. However, a role for autophagy in the pathophysiology of Fragile X syndrome is, as yet, unclear. Here we show that autophagic flux, a functional readout of autophagy, and biochemical markers of autophagy are downregulated in hippocampal neurons of Fragile X mice. We further show that enhanced mTOR complex 1 (mTORC1) activity and translocation of Raptor, a defining component of mTORC1, to the lysosome coincides with and is causally related to reduced autophagy. Activation of autophagy by delivery of shRNA to Raptor directly into the CA1 of living mice *via* the lentivirus expression system corrects aberrant spine structure, synaptic plasticity and cognition in Fragile X mice. Finally, we show that postsynaptic density protein (PSD-95) and Activity-regulated cytoskeletal-associated protein (Arc), synaptic proteins implicated in spine structure and synaptic plasticity, respectively, are elevated in neurons lacking FMRP and are degraded, at least in part *via* the lysosomal/autophagy pathway. Activation of autophagy corrects PSD-95 and Arc abundance, identifying a potential mechanism by which downregulated autophagy is causally related to the Fragile X phenotype and reveals a previously unappreciated role for autophagy in the synaptic and cognitive deficits associated with Fragile X syndrome.

**Title:** Genetic rescue of fragile X by conditional knockdown of Rictor

**Authors: *S. ROUDABUSH**, J. YAN, J.-Y. HWANG, B. COURT-VAZQUEZ, R. S. ZUKIN
Neurosci., Albert Einstein Col. of Med., Bronx, NY

**Abstract:** Fragile X syndrome (FXS) is the most common heritable form of intellectual disabilities and the leading genetic cause of autism. The neuroanatomical hallmark of Fragile X is an increased density of immature spines, a factor thought to underlie synaptic dysfunction and impaired cognition in Fragile X mice. Our laboratory identified cofilin, an actin depolymerizing agent that regulates spine structure, and its upstream effector Rac1, a Rho GTPase and identified target of FMRP in *Drosophila,* factors critical to spine abnormalities and cognitive dysfunction, to be dysregulated in Fragile X mice. Whereas a role for overactivated mTORC1 signaling in pathophysiology of Fragile X syndrome is well-established, a role for aberrant mTORC2 signaling is, as yet, unclear. Because mTORC2 is upstream of Rac/cofilin signaling and actin polymerization, we hypothesized that genetic reduction of Rictor, a defining component of mTORC2 and binding partner critical to mTOR function and stability, might rescue synaptic defects in Fragile X mice. Because Rictor-null mice are embryonically-lethal, we created *Fmr1* KO mice in which *Rictor* could be conditionally knocked out by means of CRISPR/Cas9 technology and the Cre-loxP system, *Fmr1* KO *Rictor* cKO. In preliminary experiments, we showed that delivery of lentivirus synapsin-Cre into the somatosensory cortex of neonatal Rictor cKO mice successfully knocked out Rictor protein. We further showed that conditional knockout of Rictor in Fragile X mice restored components of Rac/PAK and cofilin signaling to near wild-type values. Preliminary findings indicate that cKO of *Rictor* in layer V of the somatosensory cortex of juvenile/neonatal *Fmr1* KO mice is sufficient to rescue aberrant dendritic spine morphology and density, as assessed by dual DiI and immunofluorescence labeling. Future studies will determine whether cKO of Rictor can rescue aberrant synaptic plasticity and behavioral phenotypes in FXS mice.

**Title:** Cell-specific deletion of Fmr1 from excitatory neurons increases MMP-9 activity and contributes to abnormal development of mouse auditory cortex

**Authors: *M. RAIS**[1], A. PALACIOS[1], X. SHUAI[1], O. POPA[1], K. A. RAZAK[2], I. M. ETHELL[1]
[1]Biomed. Sci., [2]Psychology, Univ. of California, Riverside, Riverside, CA

**Abstract:** Fragile X Syndrome (FXS), a genetic condition that is linked to autism, is characterized by intellectual disabilities, language deficiencies, behavioral challenges and auditory processing deficits. The *Fmr1* knockout (KO) mouse model replicates most of these associated behavioral and auditory processing deficits. We recently showed that elevated levels of Matrix Metalloproteinase-9 (MMP-9) contribute to the hyper-responsiveness of auditory cortex in *Fmr1* KO mice by affecting perineuronal net (PNN) formation around parvalbumin (PV)-expressing inhibitory interneurons. We also showed that genetic reduction of MMP-9 levels restores PNN formation around PV cells and normalizes auditory responses. However, how different cell types contribute to elevated MMP-9 levels and impaired development of PV cells and PNNs seen in *Fmr1* KO mice is not known. Increased cortical excitability (UP state) is present with deletion of *Fmr1* only from excitatory neurons, suggesting that FMRP expression in excitatory cortical neurons is required for normal cortical responses. In this study, we show that cell-specific deletion of *Fmr1* from excitatory neurons also affects PV and PNN development and MMP-9 activity in mouse auditory cortex. This was achieved through Cre-mediated deletion of floxed *Fmr1* gene in excitatory neurons of forebrain using Nex1 ($Cre^{Nex1}$) promoter. At P21, PV cell density and PV/PNN co-localization were significantly reduced in L2-3 and L4 auditory cortex of conditional KO mice, suggesting that these deficits develop during the early postnatal period. PNNs around PV cells also remained impaired in the adult auditory cortex of conditional KO mice. Furthermore, MMP-9 activity was also significantly increased in the adult auditory cortex of $Cre^{Nex1}/Fmr1^{Flox}$ KO mice compared to WT. Together, these findings suggest that *Fmr1* deletion from excitatory neurons may contribute to impaired development of PV expressing inhibitory interneurons via MMP-9-dependent regulation of PNNs, leading to abnormal auditory processing.

**Abstract:** Fragile X syndrome (FXS) is a neurodevelopmental disorder that causes intellectual disability and is the most common known cause of autism. Studies using the mouse model of FXS (Fmr1 KO) have uncovered synaptic deficits including alterations in several forms of synaptic plasticity. CA1 hippocampal long-term potentiation (LTP) is still observed in Fmr1 KO mice, but there is evidence that the threshold for LTP induction is elevated. Metaplasticity, the "plasticity of synaptic plasticity", sets the state dependence of synapses to be either more or less likely to undergo LTP after a "priming" stimulus. Importantly, this priming induced change in LTP threshold is relevant to memory consolidation. However, it is not known if this important form of plasticity is altered in FXS mice. We found that priming of synapses with low frequency stimulation suppresses subsequent induction of LTP in the CA1 region of the hippocampus as previously described. This NMDA receptor-dependent metaplasticity was enhanced in Fmr1 KO mice. There was no significant difference in the relative NMDA receptor component of transmission in Fmr1 KO mice. Based upon the known alteration in the voltage gated potassium channel Kv4.2, a key molecule for LTP induction, we hypothesized that this important K+ channel might contribute to the altered metaplasticity in CA1 neurons in Fmr1 KO mice,. Consistent with this hypothesis, the enhanced metaplasticity in Fmr1 KO mice was restored by treatment of the slices with heteropodatoxin, a selective blocker of Kv4.2. Therefore, our results indicate that 1) Priming stimuli trigger modulation of Kv4.2 in CA1 neurons in NMDA receptor dependent manner, which results in LTP inhibition 2) The ability of NMDA receptor activation during priming to modulate Kv4.2 activity is altered in Fmr1 KO mice. This study provides novel insight into the mechanisms that underlie changes in the threshold for synaptic plasticity in FXS and may provide potential therapeutic targets for cognitive deficits linked with this disorder.

**Abstract:** Fragile X syndrome (FXS) is the result of a mutation on the FMR1 gene and is the leading heritable cause of cognitive disability[1]. Recently, research has implicated gamma-aminobutyric acid (GABA) dysfunction in learning, memory and normal neuronal function[2,3,4]. Magnetic Resonance Spectroscopy (MRS) allows for in vivo quantification of neurotransmitters to study disease state. Understanding the differences in neuro-metabolites such as GABA can be crucial in the development of precision medicine for patients with FXS. A total of 5 participants (age 24.6 ± 2.7 years) enrolled in the study, 3 young adult males with FXS and 2 young adult males with idiopathic intellectual delay (matched on age and IQ). A comprehensive neuropsychology battery of assessments for cognitive function (Stanford-Binet Intelligent Scales), adaptive skills (Vineland-II) and autism spectrum symptoms (ADOS-2) were completed. MRS data was acquired on a GE MR750 3T scanner using MEGA-SPECIAL sequence for GABA editing with TE= 80ms, TR=2s, 10 min acquisition[5]. This study presents a preliminary analysis of GABA/Creatine ratios and intellectual impairment. Using MRS, we quantify GABA/Creatine levels for potential differences between FXS and IDD participants. The current study is a first of its kind to quantify neuronal information in the population of FXS. Findings may indicate GABA levels correlate with behavioral measures of inhibition and predict atypical information processing. The quantification and analysis of GABA in FXS can suggest a disruption in inhibitory signaling in the brain and lead to a translational path for precision medicine.

**Abstract:** Calsyntenin-1 (CLSTN1), a transmembrane cargo-docking protein of the cadherin superfamily localized in the postsynaptic membrane, is important for dendritic spine maturation during postnatal development. It was previously identified as one of the targets of fragile X mental retardation protein (FMRP). FMRP loss-of-function causes fragile X syndrome (FXS) and autistic features. However, the implication of CLSTN1 in dendritic spine abnormalities and the underlying neuropathologic processes in FXS remain to be investigated. In this study, using a transgenic mouse model and in vitro approach, we demonstrated that CLSTN1 mediates the dendritic redistribution of neuron-specific intercellular adhesion molecule-5 (ICAM5, telencephalin), subsequently affecting the maturation of dendritic spines in *Fmr1* KO mice, an animal model of FXS. We found that CLSTN1 protein is reduced in the postnatal brains of *Fmr1*

KO mice and that this reduction correlates with increased ICAM5 levels on the surface of synapses and excessive filopodia-like spines. Normalization of CLSTN1 levels in *Fmr1* KO neurons reduces ICAM5 expression on the surface of synapses and rescues impaired dendritic spine phenotypes. Using virus-mediated neural morphology labeling, we further found that normalization of CLSTN1 in the dentate gyrus in *Fmr1* KO mice restores the abnormal dendritic spine morphology of granule cells, and further improves spatial memory, fear memory and social memory. To investigate the mechanistic link between CLSTN1 and ICAM5, we conducted in vitro experiments and found that CLSTN1 immunoprecipitates, co-localizes, and co-transports with ICAM5 in neurons. In conclusion, this study demonstrates that CLSTN1 plays a critical role in dendritic spine formation and maturation by regulating ICAM5 redistribution in neurons. In *Fmr1* KO mice, CLSTN1 dysregulation contributes to excessive dendritic ICAM5 distribution and promotes abnormal spine formation and maturation. Thus, CLSTN1 may serve as a potential biomarker as well as therapeutic target for FXS.

**Title:** Mismatch between synapse elimination and synapse consolidation during early development in a mouse model of fragile X syndrome

**Authors: *X. WU**, Y. LIU, H. WANG
Institude of Neuroscience, Zhejiang Univ., Zhejiang, China

**Abstract:** Synapse refinement, a process of elimination the unwanted synapses and consolidation of wanted ones, plays a crucial role in the early development of central nervous system. However, if this process was disrupted by either genetic mutations or environmental changes, is thought to be involved in many developmental disorders including autism. Loss of fragile X mental retardation protein (FMRP) in human causes intellectual disability and accompanies with features of autism such as problems with social interactions and delayed

speech. Although previous studies have shown that FMRP deficits cause seriously impaired synaptic plasticity, the role of this protein in developmental synapse refinement has not been investigated yet. Using whole cell patch recording in acute slices from fragile X mental retardation 1 gene knockout (*Fmr1* KO) mice, we explored the developmental synapse elimination and synapse consolidation respectively at the VPm relay synapse in the somatosensory system. We found the loss of FMRP did not affect synaptic connectivity at P7-8, but caused a decrease in the strength of the synapse, as indicated by very small evoked AMPAR-EPSCs and NMDAR-EPSCs in Fmr1-KO mice. Later at P12-13, the synaptic properties became comparable between WT and Fmr1-KO mice, but the synapse elimination was disrupted in the mutants. At the age of P15-P16, the synaptic connectivity returned to normal, as indicated by the majority of VPM neurons only received one Pr5 input in Fmr1-KO mice, but the synaptic strength showed a significant decrease again. Our results uncovered that synaptic elimination and synaptic strengthening do not match during development in *Fmr1* KO mice.

**Abstract:** Fragile X syndrome (FXS) is an X linked neurodevelopmental disorder related to intellectual disability and the most common monogenic cause of autism spectrum disorder. FXS results from an expansion of CGG repeat in the 5'-untranslated region of FMR1 gene, leading to the absence of fragile X mental retardation protein (FMRP), an mRNA binding protein. Recently, the absence of FMRP in astrocytes has been implicated in structural and functional synaptic deficits in FXS mouse models. However, the contribution of human astrocytes to such impairments remains unclear. To investigate whether astrocyte dysfunction contributes to the pathogenesis of FXS, we generated a human-based FXS model via differentiation of human induced pluripotent stem cells (hiPSC) to astrocytes. We observed delayed developmental

pattern from immature to the mature stage in FXS derived astrocytes with altered expression of astrocytic proteins. FXS astrocytes also have altered functional properties displaying enhanced ATP-induced calcium signaling. In ongoing experiments other canonical astrocyte function such as glutamate uptake capacity as well as regulation of synaptogenesis is being investigated. To examine the phenotypes of FXS astrocytes in vivo, we generated chimeric mouse brains by neonatal implantation of FXS and control hiPSC-derived immature astrocytes. The transplanted human astrocytes expressed the astrocyte markers, exhibited morphology distinct from the human astrocytes in culture and acquired the long and complex processes in the mouse brain 3 months post engraftment. We are currently examining the astrocyte morphologies, their distribution in different regions in the mouse brain and their effect on structural synaptic plasticity in vivo. Our studies suggest a role of human astrocytes in FXS pathogenesis and provide therapeutic targets for the personalized FXS treatment.

**Title:** Inhibition of matrix metalloproteinase-9 activity to correct auditory hypersensitivity in fragile X syndrome

**Authors: *P. PIRBHOY**[1], J. W. LOVELACE[2], T. WEN[1], K. RAZAK[2], D. K. BINDER[3], I. M. ETHELL[4]
[1]Biomed. Sci., Univ. of California, Riverside, Riverside, CA; [2]Psychology Dept., UC Riverside, Riverside, CA; [3]Univ. of California Riverside Div. of Biomed. Sci., Riverside, CA; [4]Univ. California Riverside Sch. of Med., Riverside, CA

**Abstract:** Most individuals with Fragile X Syndrome (FXS) and autism spectrum disorders (ASD) experience improper processing of sensory stimuli (McDiarmid et al., 2017). Auditory cortical neurons of *fragile X mental retardation-1* gene knock-out (*Fmr1* KO) mice exhibit abnormally sustained responses to sounds and impaired sound selectivity (Rotschafer et al., 2013). Notably, genetic reduction of matrix metalloproteinase-9 (MMP-9) rescued altered event-related potential (ERP) habituation responses in *Fmr1* KO mice implicating MMP-9 as a target for reversing auditory processing deficits in FXS (Lovelace et al., 2016). Both FXS patients and *Fmr1* KO mice exhibit high levels of MMP-9, but how this impairs sensory processing and

neuronal circuits remains unclear. To test the hypothesis that excessive activity of MMP-9 leads to increased degradation of perineuronal nets (PNNs) and altered parvalbumin (PV) interneuron development, the auditory cortex (AC) of *Fmr1* KO C57BL/6 mice and their wild-type (WT) counterparts were treated with a selective MMP-2/9 inhibitor, SB-3CT (250 µM or 25mg/kg), or vehicle at P14 or P22. Immunohistochemistry was used to determine the density of PV-positive interneurons and PNNs in the AC one day after treatment. Results revealed enhanced PNN formation in layer 4 of the AC in *Fmr1* KO mice treated with SB-3CT at P14 compared to saline-treated *Fmr1* KO mice. To determine whether enhanced PNN formation following treatment of *Fmr1* KO mice with the MMP-9 inhibitor reverses auditory processing deficits we measured resting state and evoked neuronal oscillations in freely moving mice implanted with electroencephalography (EEG) electrodes. Results show that acute treatment of SB-3CT (25mg/kg) reduces excessive resting gamma power and normalizes sound-evoked responses in *Fmr1* KO mice compared to vehicle. Together, results reveal that inhibition of MMP-9 may serve as a potential therapeutic to ameliorate auditory cortical processing deficits in FXS.

**Abstract:** Fragile X Syndrome (FXS), the most common cause of heritable intellectual disability and autism spectrum disorder, is associated with a wide range of debilitating symptoms, such as sensory hypersensitivity. Foundational studies in a mouse model of FXS, the *FMR1* KO, suggest that an impaired cortical excitatory/inhibitory (E/I) balance may underlie symptoms associated with FXS. The E/I balance would be expected to depend on homeostatic plasticity mechanisms, which act to stabilize network activity levels. One type of homeostatic plasticity is homeostatic intrinsic plasticity (HIP), which regulates the expression of voltage-gated ion channels to maintain a stable membrane excitability (e.g. through Na channel insertion following spike

blockade). FMRP has previously been shown to regulate a subset of ion channels, some of which overlap with ion channels known to be involved in HIP. Surprisingly, there have been no prior studies of whether HIP is intact in the *FMR1* KO cortex. Here we show that some, but not all, aspects of HIP are intact in ~ DIV12 primary cortical excitatory neurons following 48 hr activity deprivation with TTX (Na channel blocker) and APV (NMDA receptor blocker). We show that in KO and WT control basal conditions, there is an equal proportion of neurons that spike once (single-spiking) or more than once (multi-spiking). Following TTX/APV, all WT neurons become multi-spikers. However, this conversion fails to occur in the KO, suggesting a loss of HIP function in KO neurons. On the other hand, we observed a greater increase in firing rate in KO neurons compared to WT when we measured the action potential firing frequency of the multi-spiking neurons following TTX/APV. This finding suggests a gain of HIP function specific to the multi-spiking neurons. These findings were recapitulated these findings following 48 hr activity reduction using the AMPA receptor antagonist NBQX. The recovery of network-wide activity patterns was tested following NBQX using multi-electrode arrays. Surprisingly, our preliminary findings suggest that KO networks recover activity similarly to WT despite altered expression of HIP. Together, these results highlight the importance of HIP mechanisms in establishing the homeostatic capacity of WT and KO networks, but suggest homeostasis is achieved using different mechanisms in the KO. Ongoing work is testing how altered HIP regulation of ion channels may underlie the loss and gain of HIP function in *FMR1* KO neurons.

Ctr. for Biol. Sci., Bangalore, India

**Abstract:** Fragile X syndrome (FXS) is a common form of heritable intellectual disability and autism spectrum disorder caused by the loss of FMRP. Some of the key symptoms associated with FXS are social anxiety, abnormal emotional behaviour as well as mood disorders. Similarly, studies using animal models of FXS, including both the mouse and the recently generated rat model, have also revealed changes in fear and anxiety behaviours. Fronto-amygdala circuitry has been strongly implicated in emotional regulation and its disruption has been associated with anxiety-related disorders. Therefore, we aimed to determine if neuronal function and plasticity in medial prefrontal cortex (mPFC) and basolateral amygdala (BLA), as well as their interactions are altered, potentially explaining the deficits in fear learning and expression in a novel rat model of FXS.

Here, we show that mGluR-dependent long-term potentiation (LTP) at both cortical and thalamic inputs to the lateral amygdala are absent in *Fmr1* KO rats. We also observed age-dependent LTP deficits in the prelimbic area of mPFC. Finally, we used retrograde tracers to identify a neuronal subpopulation in layer 5 mPFC that projects to the BLA. Whole-cell *in vitro* electrophysiology recordings revealed these cells are hypoexcitable in the absence of FMRP, due at least in part, to a significant shortening of the axon initial segment, the site of action potential initiation. This effect on cellular excitability was not observed in the subpopulation of mPFC layer 5 neurons that project to the contralateral mPFC. Conversely, principal neurons in the BLA that project to the mPFC exhibited strong hyperexcitability compared to control neurons. These data reveal that the loss of FMRP results in alterations in the subnetworks that mediate fronto-amygdala transmission which may have significant effects on how these circuits process fear information.

**Abstract:** Identification of comparable biomarkers in humans and validated animal models will facilitate pre-clinical to clinical therapeutic pipelines to treat neurodevelopmental disorders. Fragile X Syndrome (FXS) is a leading known genetic cause of intellectual disability with symptoms that include increased anxiety, social and sensory processing deficits. Recent EEG studies in humans with FXS have identified neural oscillation deficits that include enhanced resting state gamma power and reduced inter-trial coherence of sound evoked gamma oscillations. To determine if analogous phenotypes are present in an animal model of FXS, we recorded EEGs in awake, freely moving *Fmr1* knock out (KO) mice using similar stimuli as in the human studies. We report remarkably similar neural oscillation phenotypes in the *Fmr1* KO mouse including enhanced resting state gamma power and reduced evoked gamma synchronization. These deficits suggest a form of enhanced 'resting state noise' that interferes with the ability of the circuit to mount a synchronized response to sensory input, predicting specific sensory and cognitive deficits in FXS. These observed deficits are either reduced or completely rescued after pharmacological treatment which include acute (1 day) or chronic (10 day) treatment with Minocycline. We also report on the effectiveness of acute and chronic CTEP on these same deficits. The abnormal gamma oscillations are consistent with parvalbumin neuron and perineuronal net deficits seen in the *Fmr1* KO mouse auditory cortex indicating that the EEG biomarkers are not only clinically relevant, with evidence of pharmacological intervention, but could also be used to probe cellular and circuit mechanisms of sensory hypersensitivity in FXS.

**Abstract:** Animal models of Fragile-X syndrome (FXS) show the presence of imbalance between excitatory and inhibitory intracortical mechanisms. This imbalance is thought to be at the root of several features typical of the disorder, such as anxiety, seizures, hypersensitivity, and hyperactivity. Preclinical studies show that Minocycline and Lovastatin have positive impacts on neurophysiological markers of the disorder, including neuronal hyperexcitability, while open label clinical studies show improvement in hyperactivity and anxiety. Here, for the first time, we assessed the effects of a 20-weeks pharmacological intervention combining Lovastatin and Minocycline (LOVAmix trial) on the main inhibitory and excitatory circuits using transcranial magnetic stimulation (TMS) in 16 patients with FXS. We measured the resting motor threshold (rMT), short interval intracortical inhibition (SICI), long interval intracortical inhibition (LICI), cortical silent period (CSP), and intracortical facilitation (ICF). Before treatment, individuals with FXS presented significantly altered SICI, LICI, and ICF compared to age and sex matched controls. Preliminary analyses show that LOVAmix intervention normalized SICI in FXS, implying an improvement in GABAa mediated inhibition. These results suggest that combined therapy with Lovastatin and Minocycline is a promising approach to correct the neurophysiological alterations involved in cortical hyperexcitability in FXS.

**Authors: *M. CIAMPOLI**, P. PORCEDDU, A. MISTO, A. M. REGGIANI
Drug Discovery Develop. (D3), Inst. Italiano Di Tecnologia, Genova, Italy

**Abstract:** Fragile X syndrome (FXS) is a neurodevelopmental disorder, resulting from the loss of expression of the fragile X mental retardation (FMR1) gene. Individuals affected by FXS display many behavioral problems, including hyperactivity, cognitive impairment and autistic-like behaviors. The focus of our study was to understand more on the biological mechanism involved in FXS. To do that we initiated by progressing the behavioral characterization of FMR1 KO mice, a widely used experimental model to mimic FXS in rodents since they carry the same mutation as in the human disease. Key FXS associated phenotypes were investigated, i.e.

locomotor activity, sensorimotor gating, cognitive abilities and social behavior. Moreover, since our mice are derived from FVB genetic background the comparison was made with respect to corresponding wild type (WT) of such a strain. Our main findings were that FMR1 KO mice have significantly increased level of hyperactivity in the open field test, altered startle responses and strong sociability deficits as shown by the reduced social interaction attitude when they meet an unknown mouse. In contrast, a very mild cognitive deficit was observed by using different specific behavioral test.Hardly anything is known about the pathological mechanisms leading to FXS symptoms and we focused our interest on the glycogen synthase kinase 3 beta (GSK-3β) system since there is growing evidence showing an increased activity of this kinase in the mouse model of FXS. GSK-3β regulates a variety of developmental processes, such as neurogenesis, glycogenesis, cell migration, cell morphology and axonogenesis through interaction with a variety of signaling pathways. The possible link with FXS could be that FMRP is known to play a critical role in adult hippocampal neurogenesis and regulation of adult neural stem cell fate by modulating the translation of GSK-3β. Therefore, we decided to test the GSK3β hypothesis in our characterized FMR1 KO mice. We chronically treated FMR1 KO mice with a GSK-3β inhibitor (TDZD-8) and we looked at the effect on the behavioral phenotypes development. Highly remarkably we found that GSK-3β inhibitor is able to rescue the different behavioral alterations typical of FMR1 KO mice.These findings strongly suggested a role of GSK-3β in the specific behavioral patterns associated with FXS.

**Abstract:** Fragile X Syndrome (FXS) is a neurodevelopmental disorder that is the leading monogenic cause of autism spectrum disorder and a frequent form of inherited intellectual disability. FXS is caused by mutations in the Fragile X mental retardation 1 (*FMR1*) gene. In most cases, the mutation is an expansion of a microsatellite CGG triplet repeat, which leads to suppression of the expression of the fragile X mental retardation protein (FMRP), an RNA-binding protein involved in multiple aspects of mRNA metabolism. In some cases, individuals with FXS carry a point mutation in FMR1. Interestingly, we found that the previously published *Fmr1* knockout rat model of FXS expresses a transcript with a deletion of the KH1 domain, an RNA-binding domain where one of the few known point mutations associated with FXS is found. This deletion of the Fmrp-KH1 domain leads to attention deficits in both males and females, reminiscent of those observed in individuals with FXS. Deletion of the KH1 domain also leads to alterations in the transcriptional profiles within the medial prefrontal cortex (mPFC), which are of potential translational value for FXS, and deficits to white matter integrity in the neocortex and subcortical regions, measured with diffusion tensor imaging. These findings indicate that attentional testing and magnetic resonance imaging might be reliable cross-species tools for investigating the pathophysiology of FXS and potential readouts for pharmacotherapy testing.

**Title:** Amino acid starvation: Differential response to DHPG stimulation in hippocampal slices from WT and Fmr1 KO mice

**Authors: S. COOKE**, J. RUSSIN, I. LOUTAEV, *C. B. SMITH
Section on Neuroadapatation and Protein Metabolism, NIH, NIMH-SNPM, Bethesda, MD

**Abstract:** Fragile X syndrome (FXS) is the most common inherited form of intellectual disability, resulting from loss of the protein FMRP. Although the origin of FXS is known, the cellular and molecular consequences of this loss are still being uncovered. As FMRP is an RNA-binding protein, an impairment in protein synthesis is hypothesized to be a core phenotype. We developed an *in vitro* method to measure rates of protein synthesis in hippocampal slices with [$^{3}$H]leucine as a tracer. Preliminary results show no differences in protein synthesis between WT

and *Fmr1* KO mice, despite previous observations *in vivo* (Qin et al., *J Neurosci* 25:5087, 2005) and *in vitro* (Osterweil et al., *J Neurosci* 30:15616, 2010). Our protocol differs from other *in vitro* methods through inclusion of a full complement of amino acids in the incubation medium. Amino acid starvation (AAS) has been shown to have widespread, powerful effects on activation and translation of proteins involved in regulating protein synthesis. We used Western blotting to measure phosphorylation and abundance of signaling molecules following mGluR5 stimulation (100 μM DHPG, 5 min) during amino acid repletion (AAR) and AAS. The most striking results were found with proteins p-p70S6k, p-eIF2α, and p-Akt (Ser 473). In AAR conditions, p-p70S6k increased (50%) with DHPG treatment in WT but not in *Fmr1* KO. This finding is consistent with protein synthesis dependence of mGluR5-activated LTD (Huber et al., *Science* 288:1254, 2000) in WT but not in *Fmr1* KO (Nosyreva & Huber, *J Neurophys* 95:3291, 2006). In contrast, DHPG increased p-p70S6k (60%) in *Fmr1* KO, but not in WT, under AAS conditions. Following DHPG treatment, p-eIF2α tended to decrease (20%) in WT and significantly increased (40%) in *Fmr1* KO under AAR and was unaffected by DHPG under AAS. These genotype-specific differences in phosphorylation of eIF2α under AAR and AAS may point to a deficiency in this important regulatory site of protein synthesis in *Fmr1* KO mice. Lastly, p-Akt was not affected by DHPG in either genotype under either condition, whereas in both genotypes levels of p-Akt were significantly elevated by AAS, regardless of DHPG stimulation. Elevated phosphorylation of Akt in response to AAS illustrates the potential for AAS to alter the activity of proteins involved in cellular growth pathways. No known defects in whole body amino acid metabolism have been reported in FXS, making AAR the physiologically relevant condition for its study. The response of hippocampal slices to amino acid conditions provides a new domain for understanding the consequences of FMRP loss in cellular signaling pathways.

**Title:** FMRP-NBEA-PKA pathway actin cytoskeleton misregulation in a fragile X syndrome model

**Authors: *J. C. SEARS**, K. S. BROADIE
Vanderbilt Univ., Nashville, TN

**Abstract:** Fragile X syndrome (FXS) is the leading monogenic cause of autism and intellectual disability, resulting from loss of Fragile X Mental Retardation Protein (FMRP) encoded by the *Fmr1* gene. FMRP acts as a repressor of protein translation during activity-dependent synapse refinement in early-use critical periods. FMRP loss causes neural circuit hyperexcitation and hypoinhibition. Here, we employ the *Drosophila* FXS model to explore molecular mechanisms underlying these defects within the central brain Mushroom Body (MB) learning and memory circuit. We first discovered FMRP binds the mRNA transcript for Neurobeachin (NBEA; *Drosophila* Rugose(Rg)), with protein levels increased in the disease model. NBEA/Rg is an A-Kinase Anchoring Protein that regulates neuronal PKA localization/activity and modulates short-term memory formation. In parallel, we discovered striking neuronal actin cytoskeleton alterations during the early-use critical period in the FXS disease model, with increased filamentous-actin (F-actin) in MB axon lobes. Proposing a FMRP-Rugose-PKA-actin pathway, we hypothesize Rg gain-of-function (GOF) should phenocopy FMRP loss-of-function (LOF). Consistently, Rg GOF increases F-actin in MB axon lobes, and correcting Rg levels in the FXS disease model prevents the F-actin defect. Thus, elevated Rg is sufficient to increase axonal F-actin, and Rg is necessary for F-actin accumulation in the disease state. We hypothesized this mechanism operates via PKA activity, and so tested if modulating PKA would phenocopy Rg GOF and FMRP LOF. Consistently, over-expression of the PKA catalytic subunit causes a striking F-actin increase in MB axon lobes. Using a PKA activity assay with brain homogenates, we find ~2-fold increased PKA activity in the FXS disease model, comparable to the effect of PKA catalytic subunit over-expression. Moreover, correcting Rg levels in the FXS model prevents this elevated PKA activity phenotype, indicating that Rg is necessary for the observed PKA hyperactivity. Ongoing experiments are testing this new pathway both in downstream and feedback signaling mechanisms, and in single MB neurons. Taken together, our data indicate hyperactive PKA activity through a loss of FMRP-Rugose regulation in the FXS disease state, resulting in excessive F-actin accumulation in learning and memory center neurons during the critical period. To ensure rigor, sample sizes of at least 10 brains per group in imaging experiments were used, dissections/protein isolations were conducted on the same day, and female/male numbers were kept constant. When possible, analyses were conducted blind, and compared groups were labeled simultaneously.

**Abstract:** Fragile X syndrome (FXS) is the most common genetic cause of autism and intellectual disability. FXS is associated with a loss-of-function mutation in the Fragile X mental retardation (*Fmr1)* gene. The *Fmr1* knock out (KO) mice display the core deficits of FXS, including sensory hypersensitivity and abnormal cortical processing. Our previous study revealed abnormal responses to sound in the developing auditory cortex (AC) of *Fmr1* KO mice during the critical period plasticity (CPP) window, a postnatal window of circuit re-organization driven by sensory input. We also observed a delayed development of parvalbumin (PV) interneurons and perineuronal net (PNN) formation around GABAergic cells, suggesting that the auditory processing deficits may arise from altered CPP during development. To test whether developmental plasticity is abnormal in *Fmr1* KO mice, KO and WT mice were exposed to a 14 kHz tone during CPP (from P9 to P20). Control WT and KO mice were raised in the same sound-attenuated chamber from P9 until P20 without the exposure to 14 kHz tone. We obtained *in vivo* event related potentials recordings from AC of control and sound-exposed P21-P23 WT and KO mice. Significant changes in response amplitude evoked by 14 kHz tone were observed between control and sound-exposed *Fmr1* KO groups. We also performed dendritic spine analysis in L2/3 and L5/6 AC in control and sound-exposed P21 WT and KO mice. Spine density was found to be higher in AC of sound-unexposed *Fmr1* KO mice compared to WT; however it decreased dramatically in both groups following sound exposure. Immunohistochemical analysis also showed a reduced PV and PNN cell density in P21 *Fmr1* KO mice compared to WT. However, sound exposure lead to increased PV cell density in *Fmr1* KO mice, but no change in WT mice. Our studies provide a novel mechanistic insight into the auditory processing deficits in FXS and suggest a developmental period for therapeutic applications.

**Abstract:** Fragile X syndrome (FXS) is the most common form of inherited intellectual disability and the leading genetic cause of autism spectrum disorder. Symptoms include hyperactivity, social phobia, impaired cognition, and repetitive/compulsive behaviors. FXS is caused by a repeating CGG mutation in the fragile X mental retardation 1 (*FMR1*) gene leading to a decrease in fragile X mental retardation protein (FMRP). FMRP is highly expressed in neurons, especially in dendritic spines, the primary site of synaptic connections. Neocortical neurons from FXS patients and *Fmr1* knock-out (KO) mice have an increased density of abnormally elongated dendritic spines, suggesting that the decrease of FMRP is linked to abnormal spine development, leading to alterations in synaptic transmission. The striatum is the input nucleus of the basal ganglia, a group of subcortical brain regions implicated in voluntary motor control and learning. Although basal ganglia dysfunction has been linked to repetitive/compulsive behaviors, few studies have investigated the spine morphology of striatal spiny projection (SP) neurons in FXS. In this study we performed two-photon laser scanning imaging of fluorescently labeled SP neurons from male and female WT and *Fmr1* KO mice (approximately 3 weeks of age). Image series in the z-plane of proximal and distal dendrites from SP neurons were used to count and classify dendritic spines into distinct subtypes based on shape and overall length. *Fmr1* KO mice displayed a reduced population frequency of mature, mushroom-type spines on SP neurons compared to WT controls. In addition, *Fmr1* KO mice had a lower density of total spine and mushroom-type spines on SP neurons compared to WT controls. Based on the altered dendritic spine morphology seen in this study, we hypothesize that SP neurons from *Fmr1* KO mice may also possess alterations in excitatory synaptic transmission.

**Abstract:** Fragile X syndrome (FXS) is the primary hereditary cause of autism spectrum disorder and intellectual disability. Recent clinical trials have highlighted the need for objective outcome measures to quantify response to treatment, including neuroimaging techniques such as resting-state functional magnetic resonance imaging (rs-fMRI) to assess potential changes in cerebral functioning. Here, we report the preliminary results of 11 participants who took part in the LOVAmix trial, the first clinical trial investigating the effects of a combined pharmacological intervention (lovastatin + minocycline) for patients with FXS. Preliminary analyses show that the intervention modulates connectivity within the salience network, a circuit at the interface of other networks that play a crucial role in task switching. These results demonstrate the feasibility of using rs-fMRI as an objective outcome measure in clinical research with FXS patients, and suggest that the combined administration of lovastatin and minocycline modifies brain circuits related to core domains of cognitive dysfunctions that are characteristic of the condition.

**Abstract:** Fragile X syndrome (FXS) is a neurodevelopmental disorder caused by a single genetic mutation in the Fragile X mental retardation 1 (*FMR1*) gene. In addition to behavioral

and physiological symptoms, evidence has suggested that individuals with FXS may have altered immune function. In the present study, we investigated how *Fmr1* knockout (KO) mice would respond to an innate immune stimulus by administering a single injection of the bacterial mimetic lipopolysaccharide (LPS) (0.33mg/kg, i.p.) or 0.9% physiological saline. Four hours after injections, brains were dissected, followed by RNA isolation and qRT-PCR on hippocampal tissue. As expected, we found LPS significantly increased proinflammatory cytokines in *Fmr1* KO and wild type (WT) mice (IL-1beta, TNF-alpha, IL-6, MCP-1), with no effect on anti-inflammatory cytokine IL-10. Additionally, *Fmr1* KO mice given LPS had trending elevations in proinflammatory cytokine expression compared to WT LPS mice. A separate cohort of mice were tested in a burrowing paradigm with a single injection of LPS or saline prior to the testing phase, however, no differences were detected between genotypes in the behavioral sickness response following an immune stimulus. Twenty-four hours following injections, we examined cytokine expression again to determine whether differences detected at 4hr. post-LPS injections were similarly altered at 24hrs. This study provides insight into whether dysregulated immunity could be playing a broader role in the pathophysiology of FXS.

**Abstract:** Previous work has supported the role of omega-3 fatty acids in the attenuation of the behavioral phenotype of the male *Fmr1* knockout mouse model. Given the association of earlier interventions with better prognoses in children with neurodevelopmental disorders, this study aims to expand upon the current knowledge through the inclusion of a prenatal treatment of omega-3 fatty acids. In the present study, male FVB/129 *Fmr1* wildtype and female *Fmr1* heterozygous breeding pairs were assigned to one of three diet conditions one week prior to pairing: standard lab chow, EPA/DHA enriched chow, and a diet controlling for the fat increase. On postnatal day (PD) 9, isolation-induced ultrasonic vocalizations were recorded from pups.

Upon reaching PD60, the same subjects were tested in several behavioral assays, including open field, elevated plus maze, social partition, nose poke assay, delay fear conditioning, and pre-pulse inhibition. Preliminary analyses of the results indicate that prenatal dietary treatment with omega-3 fatty acids reduces hyperactivity, normalizes anxiety levels and enhances fear learning in the delay fear conditioning task in adulthood. To date, clinical trials for children with neurodevelopmental disorders have been largely ineffective, and studies suggest most parents of these children will try at least one alternative therapy during their child's lifetime. As such, studies like these are important for assessing the impact of such an intervention on the development of autistic behaviors.

**Abstract:** Fragile X Syndrome (FXS) is the most common inherited intellectual disability. This neurological condition is caused by silencing of the Fmr1 gene, which encodes the Fragile X Mental Retardation Protein (FMRP). FMRP is an RNA-binding protein that has been shown to repress the translation of a large number of mRNAs, including many of which encode proteins that are important for synaptic structure and function. The excessive protein synthesis induced by lack of FMRP in the hippocampus has been associated with an abnormal number of immature dendritic spines, and deficits in synaptic plasticity. Within this context, we have previously reported that a dysfunction in N-methyl-D-aspartate receptors (NMDARs) in the hippocampal dentate gyrus (DG) is associated with some of the behavioral changes induced by the lack of FMRP. Since NMDARs contribute to dendritic arborization during neuronal development, the present study investigated whether the hypofunction of these receptors is associated with

alterations in dendritic complexity in the hippocampal DG in Fmr1 KO mice. This subregion of the hippocampus is constantly producing new neurons in the adult brain, which migrate from its deeper layer (subgranular zone) to its granule cell layer (GCL). Here, we examined how the lack of FMRP affects NMDAR function in two subpopulations of neurons: those with a single primary dendrite that reside in the inner portion of the GCL (more immature), and those that present multiple primary dendrites and are located in the outer portion of the GCL (more mature). Our findings demonstrate that neurons with both a single primary dendrite and multiple primary dendrites from Fmr1 KO mice present a reduction in NMDAR excitatory postsynaptic currents (EPSCs) and a higher level of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPAR)/NMDAR ratio in comparison with their wild-type counterparts. However, we only found a significant change in dendritic arborization of neurons with multiple primary dendrites. Our study indicates the NMDAR-associated dendritic atrophy in Fmr1 KO mice affects a specific subpopulation of GCL neurons, that may represent a more mature neuronal phenotype.

**Title:** Genome-wide measurement of mRNA translation in fragile X syndrome

**Authors: *S. ARYAL**, F. LONGO, E. KLANN
Ctr. for Neural Sci., New York Univ., New York, NY

**Abstract:** Fragile X syndrome (FXS) is the most prevalent inherited form of intellectual disability and the leading monogenic cause of autism. FXS is caused by loss of expression of the fragile X mental retardation protein (FMRP), an mRNA-binding protein whose primary function is to regulate translation in neurons. Correspondingly, mouse models of FXS exhibit increased steady-state protein synthesis in multiple brain regions. Precise control of translation is especially critical in neurons because rapid *de novo* protein synthesis is required for long-lasting synaptic plasticity, which is impaired in FXS mice. Indeed, there is widespread agreement that aberrant translation underlies a majority of the phenotypes, including autism-like behaviors, exhibited by FXS model mice. Consistent with these observations, genetic deletion of the translation-stimulating p70 S6 kinase 1 (S6K1) rescues a range of phenotypes, including

excessive translation, aberrant synaptic plasticity, and autism-like behaviors in FXS model mice. In this study, we sought to determine the identities of the messenger RNAs that exhibit eccentric translation in FXS model mice brains, and to investigate whether genetic deletion of S6K1 normalized their altered synthesis to levels comparable to those in wild-type (WT) littermates. Toward this end, we carried out ribosome profiling on cortical lysates of ~ P30 WT, *Fmr1* knockout (KO), *Rps6kb1*(S6K1) KO, and double knockout (DKO) mice. Ribosome profiling uses deep sequencing of ribosome-protected mRNA fragments to identify precise positions of translating ribosomes on individual mRNAs. We used DeSeq2 on quality-controlled sequencing datasets to identify mRNAs that registered differential normalized ribosome footprint counts across the four genotypes.
To our surprise, we observed that the majority of genes with differential ribosome loading have decreased overall ribosome footprint counts in FXS. One possible explanation for these results is that the loss of FMRP causes ribosomes to elongate at increased velocities, which in turn decreases the number of ribosomes bound to FMRP-regulated mRNAs at steady-state, ultimately reducing ribosome loading. Indeed, using a novel biochemical method that measures the number of translating ribosomes remaining after defined periods of runoff elongation, we observed excessive elongation in primary cortical neurons derived from FXS model mice. We are currently conducting ribosome profiling after multiple time-points of runoff elongation to identify mRNAs that exhibit excessive elongation in FXS. Our findings reveal systems-level insights on translational dysregulation in the cortex of FXS model mice.

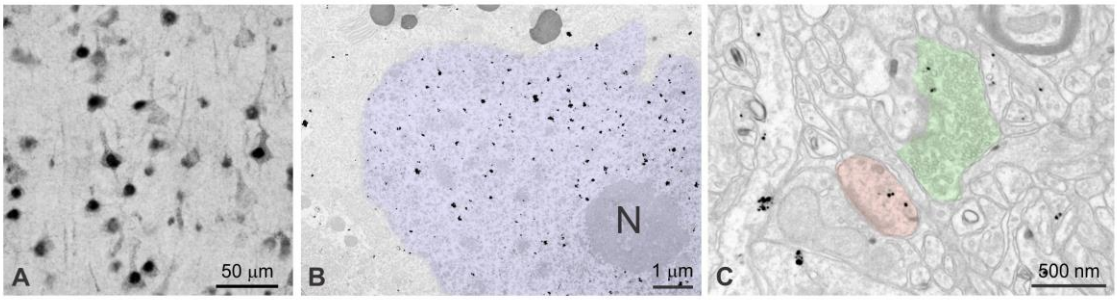
**Abstract:** Loss of the E3 ubquitin ligase UBE3A causes Angelman syndrome, whereas excess UBE3A activity (through gene duplication or gain-of-function mutation) greatly increases the risk for autism. Despite this strong association with neurodevelopmental disorders, the functional role of UBE3A in the brain is still unclear, and its cellular and subcellular organization in the human brain is almost completely unknown. We used light and electron microscopic immunohistochemistry to study the distribution of UBE3A in in the adult human cerebral cortex. We demonstrate here that UBE3A is expressed throughout the layers of cortex. It is present at high levels in both excitatory and GABAergic neurons, and at lower levels also in glial cells. We find that UBE3A in neurons has a broad, but nonuniform, subcellular distribution, concentrating preferentially in axon terminals, and in euchromatin-rich domains within the nucleus (see figure). UBE3A in terminals is likely to help regulate transmitter release at individual synapses, consistent with published evidence in a mouse model. In contrast, we speculate that by regulating gene activity, UBE3A in the nucleus may exert cell-wide effects. By identifying the subcellular compartments in which UBE3A concentrates, our data provide insight into the diverse functional capacities of this E3 ligase in the neocortex, which may help to illuminate mechanisms of human neurodevelopmental disease.



A, UBE3A concentrates in neuronal nuclei; B, immunogold particles associate with euchromatin but not the nucleolus (N); C, signal is also visible in axon terminals (green) and dendritic spines (pink).

**Abstract:** Background: Rett syndrome is a neurodevelopmental disorder characterized by cognitive impairment, motor dyspraxia and seizures which develop during early childhood in girls. MeCP2, the gene mutated in Rett syndrome, is an important mediator of synaptic development and is essential in regulating neuronal homeostatic synaptic plasticity. Clinical reports disclose that patients with Rett syndrome suffer from gastrointestinal (GI) dysmotility. We hypothesize that this could be due to impaired synaptic function in the enteric nervous system (ENS).
Methods: We have shown by immunohistochemistry that MeCP2 is present in neurons within the GI tract of humans and mice. We then carried out in vivo studies to determine whether MeCP2 knockout mice reproduced the GI dysmotility seen in Rett syndrome. Following this, homeostatic synaptic plasticity was induced in mouse enteric neuronal cultures by exposure to an excitatory stimulus (45mM KCl). The expression of the inhibitory neurotransmitter precursor nitric oxide synthase was then measured, an increase in expression being indicative of plasticity. This same experiment was performed on enteric neuronal cultures derived from MeCP2 knockout mice to determine if plasticity is altered in these neurons.
Results: MeCP2 knockout mice reproduced the GI dysmotility observed in Rett syndrome. We found that control enteric neuronal cultures underwent homeostatic synaptic plasticity in response to a prolonged excitatory stimulation. However, enteric neurons cultured from MeCP2 KO mice failed to show this induction of plasticity.
Conclusions: MeCP2 plays an important role in proper GI motility. Neurotransmitter imbalances likely mediate the GI pathology seen in Rett syndrome. These imbalances may be due to dysfunction in homeostatic plasticity mechanisms.

**Abstract:** Creatine (Cr) transporter (CrT) deficiency is an orphan disorder (CTD, OMIM #300352) characterized by intellectual disability, epilepsy and autistic-like behavior. Epilepsy is one of the symptoms with the greatest impact on everyday life of patients and families. Animal models are crucial tools to analyze disease mechanisms and to develop new therapeutic strategies. Four murine models of CTD are available so far. However, they have been analyzed only at the behavioral, neurochemical and anatomical level. To expand our knowledge about the face validity of the murine model, we monitored brain excitability and seizure susceptibility in the CrT knockout mice using video-EEG recording sessions. Our data show that CrT loss-of-function results in higher susceptibility to kainic acid (KA)-induced seizures, as assessed both at behavioral and electrophysiological level. Accordingly, we detected a prominent reduction of parvalbuminergic synapses in the cerebral cortex. This activity allowed us to fill a substantial gap in the current literature and to provide a more comprehensive set of normative data for the evaluation of potential therapeutic approaches. In addition, since CTD patients show impaired activity of cerebral cortex, we monitored visual responses in CrT ko mice throughout the disorder progression using longitudinal transcranial intrinsic optical signal (IOS) imaging and visual evoked potential (VEP) recordings. A peculiar increase of IOS and VEP response was detected in CrT ko mice, indicating that integrated visual assessment could be used as a classifying biomarker for CTD diagnosis and treatment assessment with high reliability. Importantly, VEP recordings and IOS imaging can be readily applied to humans, increasing the translational value of the visual biomarker.

**Abstract:** Insufficient thyroid hormone (TH) during development results in permanent neurological deficits. These deficits are the result of neuroanatomical defects that include smaller brain, fewer parvalbumin neurons, and hypomyelination. Interestingly, insufficient insulin-like growth factor 1 (Igf-1) during development results in similar neuroanatomical defects to those reported for developmental hypothyroidism. Thyroid hormone is known to indirectly influence serum Igf-1 levels through its regulation of pituitary growth hormone (GH) secretion which stimulates hepatic Igf-1 production. Our lab and others have observed decreases of local brain-derived Igf-1 in the developing hypothyroid mouse brain. This observation suggests that deficits associated with low TH during development may be the result of altered brain-derived Igf-1. Considering this, we sought to determine whether ectopically expressing Igf-1 in the developing brain could rescue neuroanatomical defects associated with low TH. To accomplish this, the tet-off transgenic system was used where mice harboring the tetracycline transactivator protein driven by the human GFAP promoter (tTA-GFAP) were crossed with mice containing the human Igf-1cDNA under the control the TET response element (Igf1-pTRE) transgene. Double transgenic (dTg) offspring carrying both the tTA-GFAP and Igf1-TRE genes overexpress Igf-1 specifically in brain astrocytes. Timed-pregnant mice were treated with thyroid gland inhibitors from embryonic day 14.5 (E14.5) until postnatal day 14 (P14) to induce a hypothyroid state in pups. At P14, pups were weighed and sacrificed, trunk blood was collected, and brains were dissected, weighed, and immediately frozen. Hippocampal structure, known to be disrupted by developmental hypothyroidism, was assessed by fluorescent imaging using DAPI staining. Our initial results indicate that ectopic expression of Igf-1 in the brain (dTg mice) rescues hypothyroidism-induced reductions in brain weight without increasing body weight. In addition, the ectopic expression of Igf-1 restored hypothyroidism-induced perturbations in dentate gyrus size. Ongoing studies are using quantitative real-time PCR on micro-dissected cortical and hippocampal samples to quantify myelin associated glycoprotein and parvalbumin mRNAs. Taken together, our findings support the idea that ectopic brain-derived Igf-1 rescues neuroanatomical defects caused by hypothyroidism and implicates TH in the regulation of brain Igf-1.

**Abstract:** Angelman syndrome (AS) is a severe neurodevelopmental genetic disorder characterized by motor incoordination, absence of speech, epilepsy, intellectual disability, and autistic behaviors. Approximately 70% of AS patients harbor a maternal deletion in chromosomal region 15q11-q13 and ~15% of these patients bear mutations in the *UBE3A* gene. Notably, AS patients with maternal deletion of 15q11-q13 also have haploinsufficiency in a cluster of GABA receptor subunit genes (*GABRB3*, *GABRA5*, *GABRG3*) and their symptoms are typically more severe than in patients carrying only a *UBE3A* mutation. We have previously characterized two different lines of AS-like mutant mice that harbor an exonic deletion in the *Ube3a* gene ($Ube3a^{m-/p+)}$ or have a 1.6 Mb deletion from *Ube3a* through *Gabrb3* ($UGD^{m-/p+}$). Both lines of AS-like mutant mice recapitulate the major clinical features of AS patients including a robust impairment in motor performance. Despite substantial progress in understanding the molecular basis of AS, it remains a significant challenge to develop effective pharmacological therapies for the disorder. A recent study has shown that tonic inhibition is specifically decreased in cerebellar granule cells of $Ube3a^{m-/p+}$ mice and this impairment is believed to contribute to impaired motor function. Recently, novel synthetic neurosteroid positive allosteric modulators (PAMs) of $GABA_A$ receptors have been described that have potent effects on both synaptic and extrasynaptic receptors (SGE-516) and preferential effects on extrasynaptic receptors (SGE-872). We hypothesized that SGE-872 would enhance tonic currents in cerebellar granule cells and correct the motor dysfunction in an AS mouse model. We performed whole-cell voltage clamp recordings in cerebellar brain slices and behavioral analyses in the AS $UGD^{m-/p+}$ mouse model treated with SGE-872 and SGE-516, both *in vitro* and *in vivo*. Tonic $GABA_A$ receptor-mediated currents were evaluated by application of bicuculline in cerebellar granule cell brain slice preparations. We found that $GABA_A$-receptor mediated tonic

current ($I_{tonic}$) is decreased in both UGD $^{m-/p+}$ and Ube3a$^{m-/p+}$ mice compared with wild-type mice. Pre-incubation of cerebellar slices in SGE-872 corrected the tonic current defects in UGD $^{m-/p+}$ mice. Both acute treatment with SGE-872 (i.p.) in adulthood and chronic treatment with chow containing SGE-516 beginning at weaning partially corrected the impaired motor performance on the rotarod with UGD $^{m-/p+}$ mice. These data suggest a role for GABAergic dysfunction in the motor phenotypes in AS and support the potential use of GABAergic neurosteroids for the treatment of the disorder.

**Abstract:** Williams syndrome (WS) is a rare neurodevelopmental disorder caused by a hemideletion of approximately 25-28 genes at 7q11.23. Its unusual social and cognitive phenotype is most notably characterized by the disinhibition of social behavior, in addition to reduced global IQ, with a relative sparing of language ability. Increased social approach behavior in WS may represent a unique deficit in the ability to inhibit responses to specifically social stimuli, which may be rooted in part in abnormalities of frontostriatal circuitry. Here, we examined the density of excitatory cholinergic and inhibitory parvalbumin-positive interneurons in the striatum of seven postmortem cases with WS and age-, sex-, and hemisphere-matched controls. Previous research has suggested that the selective ablation of cholinergic interneurons in mice led to significant increases in exploratory social behavior toward novel conspecifics. Interestingly, we found a significant reduction in the density of cholinergic interneurons in the medial caudate nucleus, an important region receiving cortical afferents from the orbitofrontal and ventromedial prefrontal cortex in circuitry involved in language and reward systems. This pattern of decreased cholinergic interneuron density in WS is contrasted by findings in other

disorders, including Tourette syndrome and schizophrenia, where unique patterns of decreased cholinergic interneuron density are also found. Taken together with findings from neuroimaging, differences in the brains of individuals with WS at both the macro- and microstructural level further indicate a role for frontostriatal dysfunction in the disorder's distinctive behavioral phenotype.

**Abstract:** The amygdala is an important site of reorganization in recent human evolution, particularly in the lateral nucleus, which is larger in humans and contains significantly more neurons than would be predicted for an ape brain of its size. The amygdala is critically involved in the processing of social stimuli and reward, and is a site of impairment in many disorders of social cognition. Williams syndrome (WS) is a rare neurodevelopmental disorder characterized by unusual hypersociality and disinhibition of social behavior, as well as atypical features of elaborated language use, in addition to visuospatial deficits and moderate intellectual impairment. Unlike many other disorders of social cognition, WS is characterized by a well-described genetic etiology, involving the hemideletion of 25-28 genes in a region of the seventh chromosome known to be a site of recent adaptive selection in the genome. Interestingly, segmental duplications of the deleted region in WS have been noted in a subset of cases of Autism Spectrum Disorder (ASD). Our research has found a significantly greater number of neurons in the lateral nucleus of the amygdala in WS as compared to typically-developing subjects, in contrast to findings of decreased neuron number in this region in ASD. We have

additionally utilized immunohistochemical staining methods in conjunction with unbiased stereological methods in a sample of seven postmortem subjects with WS and age-, sex-, and hemisphere- matched typically developing subjects to quantify the density of parvalbumin-positive interneurons in the amygdala. We suggest that modifications to the amygdala's microcircuitry in WS, and particularly imbalances in the ratio of excitatory neurons to inhibitory interneurons, may contribute to increased drive for social engagement, reduced threat detection, and social disinhibition characteristic of the disorder.

**Title:** A stereological study of glia density in the cortex in Williams syndrome

**Authors: *L. WILDER**[1], K. HANSON[1], C. HORTON LEW[1], C. BROWN[2], D. CUEVAS[1], D. GREINER[1], K. GROENIGER[1], U. BELLUGI[3], K. SEMENDEFERI[1]
[1]Univ. California San Diego, La Jolla, CA; [2]UCSB Psychological and Brain Sci., Santa Barbara, CA; [3]The Salk Inst. LCN-B, La Jolla, CA

**Abstract:** Williams Syndrome (WS) is a rare neurodevelopmental disorder, resulting from a hemideletion of approximately 25-28 genes on chromosome band 7q11.23. It is characterized by a specific and well defined cognitive and behavioral phenotype, including anxiety and altered social behavior, specifically hypersociability and lack of social inhibition. Investigation of neuroanatomical alterations in WS provides an excellent opportunity to study the links between genes, brain and behavior. Our previous postmortem histological studies of WS revealed decreased neuron density in the prefrontal cortex (PFC), layer V/VI in the orbitofrontal cortex in particular (Lew et al. 2017a), increased neuron number in the lateral nucleus of the amygdala (Lew et al. 2017b), and increased glia density in the caudate nucleus of the striatum, with increased oligodendrocyte density in the medial caudate (Hanson et al. 2017). These findings suggest abnormalities in frontostriatal and frontoamygdala circuits, which may underlie the anxiety and atypical social behavior observed in WS.
In the present study, we used five adult WS subjects and five typically developing controls,

matched for age, sex, and hemisphere, to examine glia distribution in the cortex. We targeted five Brodmann areas (BA 25, 10, 3, 4, and 18) to determine if differences in glia density, and oligodendrocyte density specifically, are restricted to frontostriatal regions. Blocks of tissue containing each cortical area were cut at either 40um (BA 25) or 60um (BA 10, 3, 4, and 18), and stained for Nissl substance. Cell density for all glia, and also for oligodendrocytes, was estimated with StereoInvestigator software for infragranular (V/VI) and supragranular layers (II/III). Glial cells were distinguished from neurons by their lack of stained cytoplasm surrounding the nucleus. Oligodendrocytes were identified by their small, round shape, darkly stained euchromatin, and distribution of nuclear heterochromatin (García-Cabezas et al. 2016). Preliminary results demonstrate the greatest increase in density, in both oligodendrocytes and other glia, in WS in BA 25, 3, and 4, and a smaller increase oligodendrocyte density, but not density of other glial cells, in BA 10 and 18. These increases in glia density were observed in all layers examined. Oligodendrocyte density demonstrated a layer specific pattern, with the greatest increases found in layers V/VI, in all cortical areas examined. These results suggest that neuroanatomical alterations in WS are not limited to particular cortical areas, and that increases in oligodendrocyte density may be a systemic feature of the disorder.

**Abstract:** Prader-Willi syndrome (PWS) is a genomic imprinted disorder that is characterized by brain developmental, behavioral and metabolic abnormalities. *Snord116* is a small nuclear RNA that controls the expression of many genes, including different clock genes in the suprachiasmatic nucleous. *Snord116* is also a main regulator of sleep symptoms associated with PWS. Here, we analyzed the effects of the loss of paternal expression of *Snord116* in the circadian rhythms of mice during light-dark (LD) and dark-dark (DD) where they express the

capability of entrainment and free-running respect to external events, respectively. We found that loss of paternal expression of *Snord116* in mice alters the circadian period during free-running, when the animals run according to their internal clock. In particular, mutant mice present with a reduced shortening of their circadian period in DD in comparison to their wild-type littermates. On the other hand, the circadian period during LD shows an unalterated circadian rhythm in mutants compared to wild-type mice. Our study indicates that *Snord116* is involved in the regulation of circadian rhythms in mice and points out a new endophenotype for pre-clinical investigation into the pathomechanisms of PWS. Moreover, this research promotes the knowledge of how imprinted genes can contribute to the alteration of circadian rhythms.

**Title:** Spatiotemporal tracking of human neurodevelopmental genes with cerebral organoids

**Authors: *D. SEN**
Chem. and Biomolecular Engin., North Carolina State Univ., Raleigh, NC

**Abstract:** Epigenetic mechanisms play essential roles in mammalian neurodevelopment. Genomic imprinting is a process causing the mono-allelic expression of a gene in a parental origin specific manner, and it is controlled by a hierarchy of epigenetic events. Although they are small in number, many imprinted genes are expressed in the human brain and hold important roles in development and disease. As a key example, the imprinted gene UBE3A is an important nexus in neurodevelopment and complex brain disorders where deletion of the maternal or paternal alleles of UBE3A differentially leads to Angelman Syndrome or Prader-Willi Syndrome, respectively. In addition, duplication of maternal UBE3A occurs in some forms of Autism Spectrum Disorder. These three diseases share some common neurological comorbidities strongly suggesting UBE3A's role in neural function; yet, it is still unclear when, where, and how UBE3A is regulating or disrupting normal neurodevelopment or adult brain function. Therefore, mapping the spatiotemporal localization of UBE3A expression in neurons and other cell types in the brain could provide key insights into the underlying mechanisms of UBE3A-related disorders and suggest key cell types and brain regions for further study. However, due to technical and ethical limitations, such maps have yet to be generated in humans. Here we aim to

map UBE3A expression throughout early prenatal brain development by using human cerebral organoids. Human cerebral organoids are model systems that exhibit most cell types of the human brain as well as polarized tissue structures, and have been temporally correlated with early fetal neurodevelopment. Through this human system, we connect molecular processes to tissue-level properties by spatiotemporally mapping UBE3A. This map suggests several specific brain regions, cell types, developmental time windows, and mechanistic hypotheses to pursue in understanding UBE3A's role in the human brain and in neurodevelopmental disorders.

**Title:** Selective α1-NaKA inhibition rescues hippocampal CA1 activity dependent calcium dynamics and hippocampal deficits in a mouse model of Angelman syndrome

**Authors: *P. RAYI**, H. KAPHZAN
Univ. of Haifa, Haifa, Israel

**Abstract:** We previously showed that increased expression of alpha1 subunit of Na/K-ATPase (α1-NaKA) is the precipitating event actuating the hippocampal LTP deficits, AIS abnormalities in CA1 pyramidal neurons (PNs) and memory impairment in Angelman Syndrome (AS) mice (Kaphzan et al., 2011). However, the mechanistic role of α1-NaKA in AS pathophysiology is not fully understood. Because NaKA is known to affect excitability and modify Calcium ($Ca^{+2}$) dynamics, we hypothesized that activity dependent $Ca^{+2}$ dynamics in CA1 PNs in AS mice is altered, and thus induces the observed hippocampal deficits. Hence, we aimed to: 1. Determine the activity dependent $Ca^{+2}$ dynamics in CA1 PNs in AS mice. 2. Determine whether the pharmacological inhibition of α1-NaKA pump activity will normalize this aberrant AS mice activity dependent $Ca^{+2}$ dynamics, and subsequently rescue any of the hippocampal dependent deficits.
**Results:** *Ex-vivo* 2-Photon calcium imaging in secondary apical dendrites of CA1 PNs showed a faster $Ca^{+2}$ evacuation and lower peak $Ca^{+2}$ levels compared to their WT littermates. Moreover, inhibition of α1-NaKA pump activity with Marinobufagenin (MBG) normalized this aberrant activity dependent $Ca^{+2}$ dynamics in the AS mice. Furthermore, our results show that MBG treatment rescues the LTP deficits observed in the CA3-CA1 pathway of AS mice, and whole-

cell recordings showed normalization of the increased excitability of hippocampal CA1 cells in AS mice. Finally, we show that chronic inhibition of α1-NaKA by MBG (10 μg/Kg/day) using osmotic mini-pumps rescued the spatial learning deficits of AS mice seen in the Morris water maze test. Taken together, our study brings new insights into the aberrant $Ca^{+2}$ dynamics in AS mice. Additionally, these results suggest the use of pharmacological α1-NaKA inhibition as a therapeutic strategy for alleviating AS hippocampal deficits.

**Title:** A novel cyclic peptide facilitates learning and memory in Angelman syndrome

**Authors: *J. MARSHALL**, K. LAU, M. RIOULT-PEDOTTI, M. YAO, C. MARINO, P. MIGANI
Dept Molec Pharmacol & Biot, Brown Univ., Providence, RI

**Abstract:** Angelman syndrome (AS), is a severe cognitive disorder caused by loss of expression of the maternally inherited allele of the Ube3A gene. The Ube3A gene encodes an ubiquitin ligase that regulates synaptic strength, learning, and memory. Using biochemical, electrophysiological and mouse behavioral methods we explore the efficacy of a novel compound, CN2097, to treat Angelman syndrome. Our studies in an Angelman syndrome (AS) mouse model, suggest that the reported reduction in alpha-$Ca^{2+}$/calmodulin-dependent kinase II (αCaMKII) activity that produces learning deficits, is the result of defective BDNF signaling. Brain-derived neurotrophic factor (BDNF) plays a key role in long-lasting increases in synaptic strength (long-term potentiation; LTP), a synaptic basis of learning and memory. We found that the impaired LTP observed in the Angelman mouse model occurs because of a reduction in the interaction between TrkB and the synaptic scaffold protein PSD-95, leading to attenuated BDNF-induced CaMKII and PI3K (Akt/mTOR) signaling. We designed a novel cyclic peptide, CN2097, that binds with high affinity to the PDZ domains of PSD-95 to enhance the association of PSD-95 with TrkB and restore signaling that is sufficient to reduce the LTP impairment observed in the CA1 region of the hippocampus. Assessing behavioral paradigms, we found that CN2097 restored contextual fear memory and improved rotarod performance in AS mice. These studies demonstrate that CN2097 can rescue deficits in CaMKII and Akt signaling and reverse the LTP impairment to ameliorate learning deficits. The use of drugs based on enhancing BDNF-

TrkB signaling provide a novel treatment approach that has the potential to lead to the first effective therapy for Angelman syndrome.

**Title:** Small molecule inhibitors of G9a reactivate the maternal PWS locus genes in Prader-Will-syndrome patient derived neural stem cells and differentiated neurons

**Authors: *H. WU**[1], C. NG[1], V. VILLEGAS[1], S. CHAMBERLAIN, 02139[2], A. M. CACACE[3]
[1]Fulcrum Therapeut., Cambridge, MA; [2]Univ. of Connecticut Hlth. Ctr., Farmington, CT; [3]FULCRUM Therapeut., Cambridge, MA

**Abstract:** Prader-Willi syndrome (PWS) is a congenital developmental disorder in which boys and girls present with developmental delays, including muscle hypotonia, short stature at infancy, intellectual impairment and various behavioral problems during childhood. Most PWS patients exhibit poor feeding habits and lose appetite control, leading to obesity and type II diabetes. This combination of traits indicates dysfunction of the neuroendocrine system. In healthy individuals, the maternal copies of genes situated on chromosome 15q11-q13 are silenced by hypermethylation and repressive histone modulation of the PWS imprinting center (IC). Because the vast majority of PWS patients have genetic deletions on their paternal chromosome 15q11-q13, there is loss of gene expression including SNORD116, SNORD115 snoRNA clusters, SNURPN, SNURF, NDN and MAGLE2 (PWS genes). A recent report demonstrated that inhibition of the epigenetic enzyme G9a (also known as EHMT2) by small molecules could reactivate SNORD116 and other PWS genes in both PWS patient fibroblasts and a PWS mouse model (Kim et al., 2016). This is consistent with the key role that G9a, a histone methyltransferase, plays in catalyzing H3K9 dimethylation at the maternal PWS IC to silence PWS genes. However, it is not known if inhibition of G9a could have similar impact on PWS neural progenitors and neurons, the cell types of direct pathophysiological relevance for PWS.
In this study, we derived neural progenitor cells (NPCs) and NGN2-induced glutamatergic neurons from induced pluripotent stem cells from a PWS patient with a ~ 5.1 Mb deletion on the paternal PWS locus (PWS1-7). We found that 1 uM 5-azacytidine reactivated maternal SNORD116 and other PWS genes to ~20%-100% of a WT control line (MCH2-10) in NPCs but has no effect in neurons. This is consistent with the hypothesis that the antagonizing effect of

DNA methylation for 5-azacytidine is only limited to mitotic cells. Multiple small molecule inhibitors of G9a reactivate maternal PWS genes in a dose dependent manner from 0.1 uM to 3 uM in both NPCs and neurons, albeit less effectively in neurons. Interestingly, G9a inhibition does not induce the methylation of the maternal PWS IC, indicating that disruption of the histone repressive complex alone is sufficient to drive an open chromatin state of the IC that leads to PWS gene reactivation. Finally, we found that GNRH1 and HTR2C, the downstream genes impacted by the deleted PWS genes in neurons, are partially rescued by G9a inhibitors. Using disease relevant cellular models, this study provided *in vitro* support for potential epigenetic intervention as an approach to PWS treatment.

**Abstract:** Angelman syndrome (AS) is a neurodevelopmental disorder characterized by motor deficits, seizures, and some autistic-like behaviors. AS stems from dysfunction of the maternally-imprinted *UBE3A* gene, with the paternal copy silenced. Located on human chromosome 15q11.2, *UBE3A* encodes for ubiquitin-protein ligase E3A that acts in the ubiquitination pathway to identify substrates for degradation in the proteasome. *UBE3A* also appears necessary for the maturation of neural circuits and experience-dependent plasticity in the cerebral cortex. Over the last several years, mouse models with a full or conditional deletion of the maternally-imprinted *Ube3a* mouse-homolog have been used to study the mechanisms and behavioral phenotypes associated with AS. These studies suggest that a loss of the *UBE3A* protein results in up-regulation or down-regulation of many other genes involved in key cellular pathways (e.g.,

cellular signaling, regulation of cell death, and neurogenesis). Although several research groups have conducted extensive behavioral phenotyping on the transgenic *Ube3a* model (using various background strains), findings to date do not provide particular insight on the profound language disabilities associated with AS. Our lab has built upon evidence that auditory processing deficits can be linked to speech and language delays, and early indices of rapid auditory processing can predict later language outcomes in typically developing and at-risk human populations, specifically to develop comparable tasks for use in mouse models. We also use vocalization analysis, an area where other labs have already shown atypical results in the *Ube3a* KO mouse. Finally, we can tap cognitive and memory processing particularly relevant to language (e.g., sequential and rule learning) as well. The current results show behavioral features of a transgenic mouse model with a dysfunction of the maternally-imprinted *UBE3A* mouse-homolog (*Ube3a*$^{m-/p+}$), using tasks that might specifically relate (in humans) to atypical language abilities (rapid auditory processing, processing of conspecific ultrasonic communications, complex sequential processing, rule learning). We also present data from social-communication and related tasks to validate the autistic-like phenotype as seen in AS, as well as tactile and repetitive behavioral assessments. Overall, we expect AS mice to show a pattern of specific acoustic and sensory processing deficits, as well as learning impairments, that could contribute to the language phenotype in humans with AS.

**Title:** Microglia regulates molecular factors related to brain arteriovenous malformation in endothelial cells

**Authors: *E. PARK**[1], P. R. CHEN[2], E. KIM[1]
[1]Dept. of Neurosurg., UT Hlth. Sci. Ctr. at Houston, Houston, TX; [2]Dept. of Neurosurg., UT Hlth. Sci. Ctr. at Houston, Mem. Hermann Texas Med. Ctr., Houston, TX

**Abstract:** Brain arteriovenous malformation (bAVM) is a congenital disease caused by abnormal development of the capillary network connecting arteries and veins in the brain. It often leads to cerebral hemorrhage in young patients however the underlying molecular mechanism is not clear yet. Endothelial dysfunction is representative pathology of bAVM and angiogenic molecular factors have been related to the focal bAVM formation. On the other hand,

previous studies have shown immune cells including microglia are highly distributed around endothelium of blood vessel in human bAVM. It suggests the interaction between endothelial cells and microglia is critical in the bAVM pathology. Therefore we determined if microglia regulate molecular factors related to bAVM in endothelial cells. We stimulated BV2 microglia cell line with soluble endoglin (sENG) which is expressed in endothelial cells and elevated in human bAVM, and the conditioned media (CM) from sENG-treated BV2 cells (BV2-CM) treated to mouse primary endothelial cells. Real time quantitative-PCR exhibits increased mRNA expression of inflammatory cytokines (TNFα and IL-6) and angiogenic mediators (MMP-9 and VEGF-A) in BV2 cells by sENG treatment. Endothelial cells incubated with sENG-treated BV2-CM significantly increased molecular factors (Notch-1 and TGF-β) that have been related to bAVM formation. To test if the effect is related to pro-inflammatory activation of microglia, the BV2 cells were stimulated with lipopolysaccharide (LPS) and the CM was treated to endothelial cells. LPS induced inflammatory cytokines (TNFα and IL-6) and angiogenic mediators (MMP-9 and VEGF-A) in BV2 cells and the LPS-treated BV2-CM significantly increased TGF-β and VEGF-A in endothelial cells, but not increased Notch-1 which is induced in sENG-treated BV2-CM. The results suggest that microglia may interact closely with endothelial cell in the bAVM pathology with different route of inflammation.

**Title:** Temperament, language and social development in infants and toddlers with agenesis of the corpus collosum

**Authors: *J. TURNER**[1], J. ELISON[2], S. SUNG[2], R. ADOLPHS[1], L. K. PAUL[1]
[1]Dept. of Neurosci., Caltech, Pasadena, CA; [2]Univ. of Minnesota, Minneapolis, MN

**Abstract:** Approximately 1 in 2000 infants under age 1 are diagnosed with agenesis of the corpus callosum (AgCC) annually in the United States. Accumulating evidence suggests that CC development is critically involved in the emergence of behavioral and cognitive skills during the first two years of life, that structural abnormalities of the CC are associated with a variety of neurodevelopmental disorders, and ~30% of individuals with AgCC later show phenotypic features consistent with an autism spectrum disorder. With modern availability of high-resolution

ultrasound imaging, an increasing number of AgCC cases are being identified in utero, making it imperative to provide data that can guide medical and psychological support to infants with AgCC.
Longitudinal behavior ratings of children with AgCC, acquired at ~ 6, 12, 18 and 24 months of age, were compared with ratings of normative comparison children (HC), using Infant Behavior Questionnaire-Revised (AgCC=17, HC=18), MacArthur-Bates Communicative Development Inventories (AgCC=9, HC=34) and Video-Referenced Rating of Reciprocal Social Behavior 2.3 (AgCC=16, HC=80).
*Temperament:* Positive and negative emotionality ratings were similar in AgCC and control groups at 6 months. By 12 months, both emotionality ratings had increased minimally in the AgCC group and increased significantly in control children, resulting in significantly lower emotionality scores in AgCC at 12 months. Groups did not differ in duration of orienting at either 6 or 12 months.
*Language Development:* Gesture use was lower in AgCC than controls at 12, 18 and 24 months, despite similar rates of age-related improvement. In contrast, groups had similar total vocabulary scores at 12 months, but vocabulary expansion was slower in the AgCC group with resulting in significantly smaller vocabulary by 24 months.
*Social Skills:* At 18 months, the AgCC group was significantly more atypical than the control group. Although the AgCC group exhibited more marked improvement than the control group over time, their social skills remained somewhat more atypical than the control group at 24 months.
These findings suggest that interventions for children with AgCC should target emotional expression during the first year of life and language development during the second year.

**Title:** Effects of Ube3a overexpression in sprague dawley rats

**Authors: *A. W. NENNINGER**, M. M. PETERS, E. J. WEEBER, K. R. NASH
Mol. Pharmacol. and Physiol., Univ. of South Florida, Tampa, FL

**Abstract:** Angelman syndrome (AS) is a disease characterized by severe intellectual disability, speech and movement problems, abnormal personality, seizures, and disrupted LTP. Interruption in expression or function of the paternally imprinted Ube3a gene is thought to be the sole cause

in many cases of AS. The Ube3a gene encodes a member of the HECT domain containing E3 ubiquitin ligases. Ube3a has been shown to interact with a number of proteins in the CNS in addition to functioning as a ubiquitin ligase and coactivator of steroid receptors. Due to this single gene alteration and lack of changes in brain structure during development it is believed that a gene therapy approach could offer a therapeutic treatment. We have previously shown that introduction of the full length Ube3a gene using Adeno-associated virus (rAAV) using stereotactic surgery recovers the deficits present in AS mouse and rat models. Although gene therapy is a promising potential treatment there is some concern that supraphysiological levels of Ube3a may cause a separate set of cognitive deficits. This evidence comes from studies of a syndrome closely related to AS known as chromosome 15q11.2-13.1 duplication syndrome, or Dup15q. This syndrome results from a duplication of the region containing the UBE3A gene resulting in increased levels of the Ube3a protein. Therefore, to investigate the effects of overexpression of Ube3a 2 month old sprague dawley rats were injected with rAAV either expressing Ube3a or GFP as a control. After aging the rats for 3 months, behavioral tests including Morris water maze, novel object, rotarod, fear conditioning and digi-gait were performed. We also present electrophysiological characterization of these rats.

**Abstract:** The RNA helicase *DDX6* is a member of the DEAD-box protein family and plays vital roles in RNA metabolism processes such as translational repression, decapping and RNA decay. Previous *in vitro* and lower *in vivo* models have implicated altered *DDX6* in cellular dysfunction but clinical consequences and pathogenesis in humans have not yet been described. Here we report the identification of multiple unrelated patients carrying *de novo* missense mutations in *DDX6,* all presenting with non-epileptic intellectual disability (ID), developmental delay (DD), microcephaly and overlapping dysmorphic features of unknown etiology. All missense variants reside in exon 11 which encodes the highly-conserved C-terminal RecA domain of *DDX6,* involved in RNA binding, helicase activity and protein partner binding. Comprehensive *in vitro* functional studies performed on *DDX6* p.Arg373Gln and p.Cys390Arg variants demonstrated that both mutations lead to significant defects in P-body assembly and interactions with protein partners involved in translation repression (and mRNA degradation). Additionally, study of patient-derived fibroblasts carrying the p.Cys390Arg mutation demonstrated a significant reduction in total P-body number when compared to an unrelated age-matched control individual. Transcriptomic studies revealed among the genes up-regulated in patient cells an enrichment of mRNA excluded from P-bodies, targets of *DDX6,* and in mRNA encoding protein involved in regulation of translation. Two additional patients with *de novo* mutations affecting the same or adjacent amino acid to p.Cys390 were also identified. Collectively, our clinical and molecular data define a novel role for *DDX6* mutations in human neurodevelopmental dysfunction and confirm the implication of this gene in an autosomal dominant form of intellectual disability with developmental delay and dysmorphic features.

**Title:** Automated motor outcomes in genetic models of ubiquitin protein ligase E3A gene (UBE3A) mediated neurodevelopmental disorders

**Authors: *M. C. PRIDE**, J. L. SILVERMAN
UC Davis Sch. of Med., Sacramento, CA

**Abstract:** Clinically-relevant outcome measures are required to demonstrate the test utility of innovative drug designs (like gene therapy or stem cells), as well as to validate other traditional medicinal therapies that may be in the drug discovery pipeline by biotechnological and pharmaceutical companies. However, a major rate-limiting step, is that sophisticated, well-validated, tools that provide precise, translationally relevant (i.e., the same measures in animal models and human patients) outcome parameters are underdeveloped. Our studies utilized automated treadmill walking and pressure sensitive equipment to allow for the collection of a substantial number of quantitative motor parameters such as gait, coordination, stride length, stance width, and pressure of feet (~paws). These innovative quantifiable outcomes revealed 30 metrics of posture, gait and locomotion, stride length, force development, loading, symmetry, and gait variability. Each of these measures are analogous to those being collected by clinics at the MIND Institute, Baylor and UCLA for rare genetic neurodevelopmental disorders characterized by developmental delay and ataxia, such as Angelman and Dup15q Syndromes. Both of these genetic disorders have substantial characteristic motor dysfunction. We collected digital paw prints of each of the four limbs assessed by the Mouse Specifics software. Our studies revealed mutant mice had deficits in numerous parameters on the treadmill assay, including stride and swing length, as well as in the other more commonly used motor assays. Advantages for our focused study on motor phenotypes resulting from *Ube3a* deletion or overexpression are the a) strong correlation between motor and social communication abilities, b) motor is highly translatable between preclinical models and human studies, making associated outcome measures extremely useful in a clinical trial, and c) these motor markers could all be used as preclinical screening outcomes for therapeutic development.

**Abstract:** Angelman Syndrome (AS) is a genetically inherited neurodevelopmental disorder characterized by impaired cognitive development, lack of speech, seizures, and motor ataxia. The genetic cause for AS is usually due to a *de novo* deletion of the maternal *UBE3A* gene. Additionally, brain-specific postnatal imprinting of the intact paternal *UBE3A* gene results in complete loss of UBE3A in mature neurons due to the presence of a long antisense transcript driven by the neighboring *SNURF/SNRPN* promoter. Our group has previously shown reactivation of the paternally silent *Ube3a* gene in the brains of a mouse model of AS following i.p. injection of a KRAB-fused Zinc Finger artificial transcription factor (S1K) targeted to the *Snurf/Snrpn* promoter. This treatment effectively silenced expression of the antisense transcript, allowing paternal UBE3A to be expressed. As an alternative delivery method, we have engineered S1K-secreting bone-derived mesenchymal stem cells (MSC). The ability of MSC to transfer larger molecules such as organelles are suggestive of their potential usefulness as delivery vehicles for artificial transcription factors such as zinc fingers.
Here we show a series of *in-vitro* and *in-vivo* AS model experiments that demonstrate highly efficient *Ube3a* reactivation by the reprogrammed MSCs. We engineered mouse MSCs to secrete S1K as confirmed by uptake into Neuro2a cells with MSC-S1K conditioned media via fluorescent microscopy. We then bilaterally transplanted MSC-S1K into the hippocampus of 8-week old *Ube3a:YFP* reporter mice. Brains were examined at 3-, 6-, and 10- weeks following transplantation. Interestingly, we observed significant reactivation of the silenced *Ube3a:YFP* gene compared to controls via IHC and western blotting in the hippocampus, cerebellum, and

cortex 3-weeks following transplantation and stable reactivation up to 6-weeks. Additionally, in vivo experiments comprehensively characterized the functional effect of MSC-S1K in E6:AP AS mice. Compared to wild type littermate controls and sham transplanted MSC, we measured for improvements in behavioral phenotypes reported in previous reports of AS mice and in unpublished findings of our collaborators (using gross and fine motor skills assays (e.g., open field, beam walking, rotarod, DigiGAIT); learning and memory assays (e.g., novel object recognition, spontaneous alternation, contextual and cued fear conditioning); and polyspike analysis via electroencephalography (EEG). We report the first-of-its-kind use of MSCs as a delivery platform for epigenetic modifiers in neurologic disease – expanding the therapeutic potential of both systems for future genetic diseases.

**Title:** Expression of UBE3A via lentivector delivery in hematopoietic stem cells to treat Angelman syndrome

**Authors: *J. L. SILVERMAN**[1,3], A. A. ADHIKARI[3,1], N. A. COPPING[3,1], R. D. LEE[1], J. R. BEEGLE[2], H. NELSON[2], H. O'GEEN[3], D. J. SEGAL[3], J. S. ANDERSON[2]
[2]Intrnl. Med., [1]UC Davis Sch. of Med., Sacramento, CA; [3]Psychiatry and Behavioral Sci., MIND Inst., Sacramento, CA

**Abstract:** The ubiquitin protein ligase E3A gene (*UBE3A*) encodes for enzyme responsible in the ubiquitination of target substrates for degradation, spanning almost all cell types. A deletion or mutation in *UBE3A* causes Angelman syndrome (AS), a neurodevelopmental genetic disorder associated with severe cognitive impairments, poor motor coordination, and epilepsy. One of our laboratory's goals is to develop a hematopoietic stem cell (HSC) gene therapy to deliver an artificial transcription factor (Bailus et al., 2016) for the treatment of AS. To evaluate the use of

HSC therapy as a treatment option for AS, we have generated lentiviral vectors expressing modified Ube3a proteins that contain both secretion signals and single amino acid changes which create N-glycan sites for increased cell uptake. We have also generated immune deficient mouse models of AS, lacking either *Rag1, IL2,* and/or *Rag2* genes, that are capable of receiving HSCs to evaluate the efficacy of the lentiviral vector transduced cells. *In vitro* experiments confirmed expression of the modified Ube3a proteins in human HSCs and their immune cell progeny. We evaluated the ability of the modified Ube3a proteins to function properly by ubiquitination of target proteins. *In vivo* experiments generated and characterized novel mouse models of AS with maternally inherited deletions of *Ube3a* and that are capable of transplantation of human CD34+ HSC. We comprehensively characterized the immune deficient *Rag1-/-*, *IL2-/-* and *Rag2-/-* mice to ensure that there were no confounding effects of immunodeficiency compared to control C57BL/6J prior to transplantation with HSCs. We measured behavioral phenotypes reported in previous *Ube3a*$^{m-/p+}$ models (Jiang et al., 2010; Born et al., 2017) using anxiety-like behavior assays (e.g., elevated plus-maze); motor assays (e.g., open field, beam walking, rotarod); learning and memory assays (e.g., novel object recognition, spontaneous alternation, contextual and cued fear conditioning); and seizure threshold assays (measuring seizure severity and latency to first jerk post-pentylenetetrazole-induced seizures). In the *Rag1-/-* and *IL2-/-* mice, we did not find any pronounced anxiety-like phenotypes, motor deficits, or global learning/memory phenotypes; however, we did observe deficits in novel object recognition. Taken together, our data show that an Ube3a lentiviral vector-transduced human CD34+ HSC gene therapy could be a possible safe and efficacious delivery method for gene therapeutics in AS. Future directions will be to transplant Ube3a lentiviral vectors in our humanized mouse model and to evaluate its efficacy and safety as a therapeutic.

Sci. Ctr., Toronto, ON, Canada

**Abstract: Background**: Gilles de la Tourette syndrome (GTS) is a disorder characterized by motor and vocal tics. Although by definition the onset of GTS is before age 18 year, clinical trials of deep brain stimulation (DBS) have been conducted only in adults. Using individual participant data (IPD) meta-analysis methodology, the current study investigated the safety and efficacy of DBS as a treatment for GTS in children and youth. **Methods**: A systematic review with no date or language restrictions was performed according to the PRISMA statement. From 843 articles screened, the IPD of 58 children and youth (ages 12-21) extracted from 21 articles were collected and analysed. A mixed-effects univariable analysis followed by multivariable hierarchical regression were performed using change in the Yale Global Tic Severity Scale (YGTSS) score as primary outcome and reported measures of comorbidities as secondary outcomes. **Results**: Our results showed an average improvement of 57.5 ± 24.6% across studies on the YGTSS. We also found that comorbid depression and stimulation pulse width each correlated negatively with outcome ($p<0.05$). In patients with less severe GTS, greater improvements were evident following thalamic stimulation. Over one-quarter (n=16, 27.6%) of participants experienced side effects, the majority of which were minor. **Conclusion**: DBS in the pediatric population may be an effective option with a moderate safety profile for treatment of GTS in carefully selected children and youth. Large prospective studies with long-term follow-up are necessary to understand how DBS influences tic symptoms and may alter the natural course of GTS in children.

**Title:** Cyclin-dependent kinase 5 regulates dopamine transporter surface expression and internalization, clues to understand the dopaminergic system of p35 knock-out mice

**Authors: *G. FERNANDEZ**, M. MARI, F. KRAPACHER, G. PAGLINI
INIMEC-CONICET-UNC, Cordoba, Argentina

**Abstract:** Dopamine transporter (DAT) catalyzed the Dopamine (DA) reuptake from the synaptic cleft. This process is the major regulator of dopamine signaling strength, limiting pre and postsynaptic DA receptors activation. Desregulation in DA signaling is common in a broad of psychiatric Disorders such as Parkinson disease, Schizophrenia, Attention Deficit hyperactivity Disorder (ADHD), etc. Therefore, DAT has been one of the most studied proteins in order to understand the neurobiology mechanism underlying these disorders. Previous studies from our lab have demonstrated that transgenic mice lacking p35 protein (p35KO), the specific activator of Cyclin dependent kinase 5 (Cdk5) exhibit behaviors resemble those described in animal models of ADHD. p35 KO mice display hyperactivity which is reverted by Methylphenidate and d-Amphetamine, drugs targeting DAT. Although we have shown that p35KO mice have an altered Dopaminergic system, the trafficking and activity of Dopamine Transporter (DAT) still remain unknown. In this work we studied the implications of Cdk5 inhibition in DAT expression and trafficking in P35KO mice and N2a cell line. Through Biotinylation assay, we observed that p35KO mice have a normal DAT expression levels in Striatum synaptosomes but the superficial expression of the transporter is diminished in these mice. On the other hand, using the antibody feeding method, we demonstrated that, in N2a cell line, the genetically and pharmacologically inhibition of Cdk5 augment the constitutive endocytosis rate of DAT. These results suggest that Cdk5 activity modulates DAT trafficking from the plasma membrane, and its superficial levels. These findings may help us to elucidate DAT function in the hyperdopaminergic system of p35KO animal, model of ADHD.

**Title:** Targeted deletion of latrophilin-3 in Sprague-Dawley rats results in hyperactivity and reduced anxiety-like behavior: A new model of ADHD

**Authors: *S. L. REGAN**
Neurosci. Program, Univ. of Cincinnati, Cincinnati, OH

**Abstract:** Attention deficit hyperactivity disorder (ADHD) is a persistent developmental disorder characterized by inattention, impulsivity, and hyperactivity. ADHD is partially heritable, with monozygotic twin concordance of 70-80%. Recently, Latrophilin-3 (*LPHN3)* polymorphisms have been associated with a subtype of ADHD, but how it translates to ADHD is unknown. We created a null mutant of *Lphn3* in Sprague Dawley rats using CRISPR/Cas9 to excise exon-3. We compared wildtype (WT) and knockout (KO) progeny of het x het crossings using home-cage activity, elevated zero maze, and the acoustic startle response. We also assessed monoamines, mRNA expression, and protein levels. *Lphn3* KO rats were hyperactive as adolescents and adults in the home-cage test, showed decreased anxiety in the elevated zero-maze, and had increased acoustic startle responses compared with WT. Norepinephrine was increased in the hippocampus and HVA was increased in the neostriatum. Increased protein levels were found for the dopamine transporter (DAT) in neostriatum. The L*phn3* KO rat offers a new approach to understanding variant LPHN3 leads to ADHD and may help elucidate the CNS function of this poorly understood adhesion protein. (Supported by a grant from the L.I.F.E. Foundation.)

**Title:** Cognitive training combining numerosity with visual perception promotes arithmetic fluency in children with dyscalculia

**Authors: *D. CHENG**[1,2], X. ZHOU[2], Q. XIAO[3]
[1]Dept. of Pediatric Neurol., Capital Inst. of Pediatrics, Beijing City, China; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China; [3]Dept. of Specialty, Beijing Chinese Language and Culture Col., Beijing, China

**Abstract:** Developmental dyscalculia (DD) is a disorder in the development of mathematical abilities that afflicts approximately 5% of school-age children. Although the effect of numerosity

training on symbolic mathematics performance have been proved, the mechanisms underlying this effect remain unclear. The goal of the current study was to test the hypothesis that numerosity training (with an apple-collecting computer game) enhances arithmetic fluency through the improvement of visual perception. 96 children with developmental dyscalculia (DD) were identified Chinese primary school children and they were randomly divided into the interventional group and the control group. The interventional group received training with an apple-collecting game, whereas the control group received an English dictation task. Children were tested in cognitive and mathematical abilities before and after 8days of training, 15 minutes per day, and four months later. Results showed that the interventional group showed significant improvement in simple subtraction, numerosity comparison, and figure matching, but not in mental rotation and sentence completion, whereas the control group did not show significant improvements in any areas. Analysis of covariance further showed that the improvements in numerosity and arithmetic performance could be accounted for by the improvement in figure matching (a measure of visual perceptual ability). The results suggest that numerosity training with an apple-collecting computer game enhances arithmetic fluency in DD children by improving their visual perceptual ability.

**Title:** Multigenerational transmission of developmental nicotine exposure-induced ADHD-like phenotypes is modulated by the D397N polymorphism of CHRNA5 in adolescent mice

**Authors: *J. M. BUCK**[1], J. A. STITZEL[2], H. C. O'NEILL[3]
[1]Integrative Physiol. and Neuroscience; Inst. for Behavioral Genet., [2]Inst. Behav Genet., Univ. of Colorado Boulder, Boulder, CO; [3]Univ. of Colorado Boulder Inst. for Behavioral Genet., Boulder, CO

**Abstract:** Developmental nicotine (NIC) exposure (DNE) is associated with increased NIC use and ADHD, a neurodevelopmental disorder characterized by inattention, impulsivity, hyperactivity and sleep disturbances, increased amplitude of rest-wake activity rhythms, eveningness, and increased NIC use. The alpha-5 nicotinic acetylcholine receptor (nAChR) subunit (CHRNA5) is important for ADHD-relevant phenotypes such as attentional behaviors, and constitutive knockout of CHRNA5 alters the effects of DNE on neuronal morphology. The human D398N polymorphism of CHRNA5 is associated with increased risk for NIC dependence and has been shown to alter the function of ADHD-implicated neuronal populations in-vitro. We have previously demonstrated that DNE elicits multigenerational NIC preference, ADHD-like hyperactivity and risk-taking, and aberrant rhythmicity of home cage (HC) activity in wild-type mice. However, no previous research has explored the potential role of the D397N polymorphism (mouse equivalent of the D398N polymorphism in humans) in the transmission of DNE-induced ADHD-like phenotypes. We thus characterized the behavioral and rhythmometric consequences of DNE in the F1 (D F1 NIC and N F1 NIC) and F2 (D F2 NIC and N F2 NIC) generation adolescent offspring of D397 and N397 mice exposed to NIC prior to and throughout breeding. To this end, we assessed HC activity rhythms as well as open field (OF) activity and risk-taking behaviors at baseline (BL) and in response to voluntary NIC consumption and withdrawal (WD). D397 and N397 DNE mice exhibit a multigenerational predisposition to NIC consumption, HC hyperactivity during the inactive phase at BL, and increased risk-taking behaviors in the OF at BL. However, only D F2 NIC and N F1 NIC mice display active phase HC hyperactivity and hyperactivity in the OF at BL. Similarly, only D F2 NIC and N F1 NIC mice exhibit anomalous rhythmicity of HC activity, including increased MESOR, global amplitude, and orthophase estimates, which indicate general hyperactivity, increased magnitude

of daily variation in activity, and phase-delayed peak activity which resembles eveningess, respectively. Collectively, these data suggest that the D397N polymorphism exerts an apparent lineage-switching effect on the multigenerational transmission of certain ADHD-like phenotypes, wherein only second-generation D397 and first-generation N397 adolescent DNE progeny display the entire spectrum of ADHD-like phenotypes assessed. Taken together, our findings underscore the need for human research exploring the multigenerational link between DNE and ADHD and warrant consideration of the role of the D398N polymorphism therein.

**Title:** Atypical attentional bias to emotional faces in children with ADHD

**Authors: J.-H. SONG**[1], N. KWON[1], *S.-Y. KIM[2]
[2]Dept. of Psychology, [1]Duksung Women's Univ., Seoul, Korea, Republic of

**Abstract:** Emotional faces involuntarily bias attention regardless of one’s current goal possibly due to its ecological value. Recent studies showed that involuntary attentional bias to negative emotion was positively related to one’s level of anxiety in neurotypical adults, whereas children with typical development (TD) did not show the modulation effects. Children with ADHD often report high levels of anxiety as well as atypical attentional functions. However, it has been unspecified whether children with ADHD would also show attentional bias to emotional faces. Thus, we investigated 1) whether task-irrelevant emotional faces can bias attention in children with ADHD, and 2) effects of anxiety levels on the attentional bias to threats in ADHD. In Study 1, 20 children with ADHD (mean age (M) = 13.2) and 26 children with TD (M = 13.4) performed a task to detect an orientation of red “T” (a target) presented at the upper right position on the computer screen. While performing the task, a distractor (either a picture of angry face or place) appeared for 4 seconds and disappeared for 5-8 seconds. Attentional capture effects (ACE) were defined by RT differences between targets presented with onset of a distractor (T1) and targets without distractors (TBaseline). Attentional holding effects (AHE) were defined by how long the ACE lasted (e.g., until T2, T3, or T4, where “T2” was defined by targets appearing 2 seconds after the onset of a distractor). A three-way ANOVA with Group (TD/ADHD), Emotion (Angry/Neutral), and Order (T1/T2/T3/T4/TBaseline) showed significant 3-way interaction, driven by significant ACE in TD [Angry: $t(25)=6.65$, $p<.001$; Place :

*t*(25)=6.33, *p*<.001]. However, ACE was not significant by either distractor in ADHD. In study 2, 21 children with ADHD (M = 12.6) and 25 children with TD (M = 12.6) performed the same task as in the Study 1, but distractors were all faces (i.e., Angry face/Neutral face). The same three-way ANOVA and subsequent post-hoc analyses revealed that TD showed ACE by both faces [Angry: *t*(24)=7.22, *p*<.001; Neutral : *t*(24)=4.95, *p*<.001], whereas ADHD showed ACE only by angry faces [*t*(20)=2.85, *p*<.01]. Notably, correlation analyses with ACE, state anxiety, and trait anxiety in ADHD revealed a significant positive correlation between the magnitude of ACE and levels of trait anxiety [*r*=.606, *p*<.01]. Overall, our findings suggest that ADHD reveal atypical mechanisms of attentional bias to emotional faces, and their attentional orienting functions are modulated by their anxiety levels rather than ecological values of external stimulus. Upcoming neuroimaging studies will help to elucidate underlying neural mechanisms of attentional bias to threats in ADHD.

**Title:** Improving working memory by applying the newly designed story grammar marker in children with specificlanguage impairmentof northern Taiwan

**Authors: H.-C. YANG**[1], D.-X. LIN[1], C.-M. YANG[2], D.-H. HUANG[2], D.-Y. HSU[2], *S.-M. WENG[1]
[1]Dept. of Speech Language Pathology and Audiol., Fac. of Natl. Taipei Univ. of Nursing A, Taipei, Taiwan; [2]Dept. of Industrial Design, Ming Chi Univ. of Technol., New Taipei city, Taiwan

**Abstract:** Specific language impairment (SLI) is diagnosed as delayed or abnormal language development in kids without apparent pathologic mechanisms, such as poor neurodevelopment, physical abnormality of the speech apparatus, autism spectrum disorder, apraxia, acquired brain damage or hearing loss, etc. Previous studies have shown the link between working memory (WM) and language development in young children with SLI. Most SLI cases have deficits in both verbal short-term and WM, and with limited abilities to simultaneously store and process verbal information that may also constrain their acquisition of linguistic skills. Hence, intensive WM training may be effective for enhancing the weakest aspects of short-term memory in children with SLI; WM training may also be of value as the aim of developing compensatory therapeutic strategies for SLI. Since telling stories puts a tremendous load on WM, especially for children been found to have difficulties with oral language expression and organization, story

grammar marker (SGM) which reduces the load on WM by externalizing the global structure and sequence of components in stories might be introduced for improving WM in SLI kids. Here we introduced a newly designed pyramidal shape SGM consists all elements of traditional SGM and we recruited twenty SLI kids aged from 7 to 12 years old to be randomized distributed into two groups with either traditional or newly designed pyramidal shape SGM for WM training for 4 weeks. Our data showed this newly designed pyramidal shape SGM has equivalent effects on WM training as traditional one and also the advantage as an user-friendly tool for its toy-like interface design.

**Title:** Early development of speech network before birth and their prediction to language performance of 2 years later

**Authors: *M. ZHU**, Y. LIU, Y. HE
State Key Lab. of Cognitive Neurosci. and, Beijing, China

**Abstract:** Resting-state functional connectivity (RSFC) approaches offer a novel tool to delineate functional networks in the brain. The aims of the present study were: 1) to explore the task-based hierarchical speech-processing networks on adults in a non-task resting state and how the networks emerge and change on babies before birth; 2) to find the relationship between the network properties before birth and the language performance at 2 years old. With three cohorts of participants - 105 adult participants from HCP, 20 full-term neonates from dHCP, and 40 preterm neonates with 31-42 weeks gestational age, we examined their intrinsic functional connectivity pattern by defining networks based on six regions of interest (ROI). The results confirmed that the resting functional connectivity patterns on adults were also organized in a hierarchical way, which corresponding to the levels of acoustic input, phonemic analysis and articulation, semantic processing and information integration. The similarity of each network on neonates to adults decreased from low to high-level networks. We also found that the functional connectivity between the cortex of HG and mSTS and that of primary motor and inferior frontal gyrus increased with gestational age. Moreover, multivariate pattern analysis using support vector regression revealed that the language performance of 2 years old could be predicted by the functional connectivity strength within some language networks. Collectively, we highlighted the

hierarchical language network in human brain and the relatively development order in the very early age.

**Title:** The effects of methylphenidate on verbal creativity, verbal fluency, and problem-solving abilities in individuals with attention deficit hyperactivity disorder

**Authors: *B. M. KILLE**[1], B. J. FERGUSON[2], M. M. MCBRIDE[2], D. C. WANG[2], D. Q. BEVERSDORF[3]
[1]Psychological Sci., Univ. of Missouri, Columbia, MO; [2]Thompson Ctr. For Autism, Columbia, MO; [3]Dept Radiol, Neurol, Psychol Sci, DGS of INP, Univ. of Missouri Columbia, Columbia, MO

**Abstract:** Creativity, or the ability to generate ideas that are both novel and useful, is associated with a decreased signal-to-noise ratio in the brain that results in defocused attention. Reductions in attention are the hallmark of attention deficit hyperactivity disorder (ADHD), which may facilitate divergent thinking that is essential to the creative process. One of the most common treatments for ADHD is methylphenidate (MPH), a psychostimulant that targets the dopamine and noradrenergic systems, which increases attention in ADHD. However, the effects of MPH on convergent and divergent thinking in ADHD are unclear. Therefore, the present study examined effects of MPH on convergent and divergent thinking in individuals with ADHD. Participants (N=9, range=18-40, mean age=26.3, SD=7.01, 3 females, all Caucasian) with a diagnosis of ADHD and who are currently taking MPH for their ADHD were recruited for this ongoing study. Participants attended one session while on their MPH and another where they withheld their MPH. During both sessions, participants completed problem-solving tasks (anagrams, compound remote associates) letter & category fluency assessments, and the Verbal Torrance Test for Creative Thinking (V-TTCT). Initial analyses indicate significant reductions in solution latency time for the anagrams task ($p = 0.008$), and significant increases in originality on the V-TTCT ($p = 0.049$) for the MPH session. Furthermore, trends toward significance were revealed for flexibility and the total battery score on the V-TTCT. Thus, initial results from this ongoing

study suggest that MPH may increase some domains of verbal creativity and problem-solving abilities in those with ADHD.

**Title:** Vibrotactile adaptation and Weber's Law in children with Tourette syndrome

**Authors: Ü. EŞEN**[1], H. DOKTUR[2], D. YıLDıZ[2], C. TANıDıR[3], M. TOMMERDAHL[4], *B. GUCLU[1]
[1]Bogazici Univ., Istanbul, Turkey; [2]Bakirkoy Res. and Training Hosp. for Psychiatry, Neurol. and Neurosurg., İstanbul, Turkey; [3]İstanbul Gelişim Univ., İstanbul, Turkey; [4]Dept. of Biomed. Engin., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

**Abstract:** Tourette syndrome (TS) is a developmental neuropsychiatric disorder which is characterized by multiple motor tics along with at least one vocal tic present at least for one year. It was previously suggested that neurotransmission, especially regarding the inhibitory neurotransmitter γ-aminobutyric acid (GABA), is altered in patients with TS and neuroanatomical changes such as increased volume in dorsal prefrontal and parieto-occipital brain regions were documented. According to these findings, the chronic tics and premonitory urges are thought to be due to hyperexcitability caused by reduced GABA concentrations; and TS patients do not adapt to vibrotactile stimuli as much as healthy controls. In the current study, we aim to extend the GABAergic dysfunction hypothesis by testing vibrotactile intensity/amplitude discrimination with and without adaptation based on different standard and adapting stimuli. Twenty-nine TS patients (age range: 9-17, 7 female, 22 male) participated in psychophysical experiments. Vibrotactile stimuli (25 Hz, duration: 0.5 s) generated by a portable device (CM-4, Cortical Metrics) were applied on the fingertips of the participants. The test battery consisted of measuring choice reaction time (amplitude: 200 μm), dynamic detection threshold (amplitude ramp: 2 μm/s), static detection threshold, amplitude discrimination, and amplitude discrimination with single site adaptation (adapting duration: 1 s). Our analyses show that the dynamic thresholds were still higher than the static thresholds (averages 11 μm vs. 8 μm; $p<0.001$) indicating some adaptation due to ramping subthreshold stimuli. ANOVA was performed on difference limen (DL) values with standard stimulus amplitude (levels: 50, 100,

200 µm) and adapting stimulus amplitude (levels: 0, 100, 300 µm) as factors. DL values increased as a function of the standard stimulus amplitude as predicted by the Weber's Law ($p<0.001$), and there was a main effect of adaptation by increasing DLs ($p<0.001$). However, there was also a significant interaction between the amplitudes of the standard and adapting stimuli ($p=0.014$). Increasing the adapting stimulus amplitude did not cause an additional increase in DLs. These preliminary data suggest that reduced adaptation due to GABAergic dysfunction in TS may be more prominent at higher adapting stimulus levels. We are currently studying normal children to characterize their vibrotactile discrimination capacity for comparison with the TS group.

**Title:** Probing neuronal and molecular underpinnings of language-related disorders using human stem cell-derived neuronal networks

**Authors: *M. V. ANIJS**[1], F. M. S. DE VRIJ[2], S. A. KUSHNER[2], S. C. VERNES[3,4]
[1]Neurogenetics of Vocal Communication, Max Planck Inst. For Psycholinguistics, Nijmegen, Netherlands; [2]Dept. of Psychiatry, Erasmus MC, Rotterdam, Netherlands; [3]Neurogenetics of Vocal Communication, Max Planck Inst. for Psycholinguistics, Nijmegen, Netherlands; [4]Donders Ctr. for Cognitive Neuroimaging, Nijmegen, Netherlands

**Abstract:** Human language is a fascinating and complex trait and the genetics of related disorders can help us to identify its underlying biological processes. Given that language is unique to humans, species-specific neurogenetic mechanisms are likely involved, highlighting the importance of studying language-related genes such as *CNTNAP2* in human model systems. To do this, we have generated electrophysiologically mature neuronal networks from human stem cells. The differentiation protocol that we use generates forebrain neural progenitor cells from stem cells that subsequently give rise to both neurons and astrocytes in a consistent 60:40 ratio. The resulting neuronal networks include neurons representative of both upper and deep cortical layers and we have demonstrated the activity and connectivity of the networks by calcium imaging. We aim to understand the neuronal phenotypes observed in neuronal networks

derived from normal ‘wild-type’ cells and compare these with isogenic lines carrying CRISPR/Cas9-induced mutations in key language-related genes. We are developing lines that allow to investigate consequences of coding mutations (e.g. in the *CNTNAP2* gene) and non-coding mutations (e.g. in microRNAs or 3'UTR regulatory sequences). These models also allow interrogation of the underlying molecular state of the differentiated human neurons and how these pathways are perturbed in mutant-derived networks. In our molecular studies, we place a particular focus on the role of microRNAs, since they are important modulators of gene regulation, have evolved relatively rapidly, and have been implicated in several neurodevelopmental disorders such as autism and specific language impairment. To understand not only the genes, but also the related microRNA regulatory pathways important for normal network function, we are profiling total and small RNA expression patterns across neuronal differentiation and network development. This work will demonstrate molecular pathways involved in normal network development and function. Integrating these findings with equivalent studies in isogenic mutant-derived networks will provide new insight on how coding and non-coding mutations lead to disrupted neuronal development/function and ultimately language-related disorders.
Taken together these investigations will connect known language-related genes via shared pathways and implicate new players in neuronal network development and language-related disorders. In this way, we will gain a more complete understanding of the genetic components of neuronal development that underpin language, with the potential of detecting processes that are unique to our species.

[5]Microbiology and Immunol., [6]Pharmacol. and Toxicology, [7]Indiana Clin. and Translational Sci. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN

**Abstract:** Neurofibromatosis type 1 (NF1) is an autosomal dominant disease with mutation in one copy of the NF1 gene and has a prevalence of approximately 1 in 3000 individuals. Children with NF1 suffer from a significant incidence of learning disabilities and cognitive difficulties associated with symptoms of attention deficit hyperactivity disorder (ADHD). Even though approximately 40-60% of children with NF1 meet criteria for ADHD, very few preclinical studies, if any, have investigated alterations in impulsivity and risk-taking behavior. Mice with deletion of a single *Nf1* gene (*$Nf1^{+/-}$mice)* recapitulate many of the phenotypes of NF1 patients. Therefore, we compared wild type (WT) and *$Nf1^{+/-}$* mouse strains to investigate differences in impulsivity, risk-taking, and locomotor activity using the delayed discounting task (DDT), cliff avoidance reaction (CAR) test, and open field. For DDT, mice were trained to differentiate between a small and large reward in a t-maze. Once criteria were met, a 10 s or 20 s delay was administered prior to the large reward. *$Nf1^{+/-}$* mice choose a higher percentage of smaller rewards when both 10 s and 20 s delays were administered compared to WT mice, suggesting *$Nf1^{+/-}$* mice are more impulsive. When treated with the alpha-2A adrenergic receptor agonist guanfacine (0.3 mg/kg, i.p.) daily across the six day testing phase of DDT, *$Nf1^{+/-}$* mice exhibited decreased impulsive choice by waiting for the larger, delayed reward. In the CAR test, mice were placed on an elevated, circular platform for 60 min. *$Nf1^{+/-}$* mice exhibited increased risk-taking and impulsivity compared to WT mice in the CAR test by repetitively entering the outer edge of the platform where they risk falling. Treatment with guanfacine ameliorated deficits in behavioral inhibition by reducing the amount of exploration *$Nf1^{+/-}$* mice made along the outer edge of the platform. In addition, *$Nf1^{+/-}$* mice exhibited increased distance travelled and mean speed compared to WT controls in a 1 hr open field test. Hyperactivity in *$Nf1^{+/-}$* mice was reduced with guanfacine pre-treatment. Overall, our study confirms that *$Nf1^{+/-}$* mice exhibit an ADHD phenotype. These data suggest that *$Nf1^{+/-}$* mice can be used to identify drug targets and alterations in neural circuitry associated with symptoms of ADHD.

**Title:** Altered gray matter volumes in language-associated regions in children with developmental language disorder and speech sound disorder

**Authors: *F. KURTH**[1], E. LUDERS[1,2], L. PIGDON[2], G. CONTI-RAMSDEN[3,2], S. REILLY[2,4], A. T. MORGAN[2]

**Abstract:** Developmental language disorder (DLD) and speech sound disorder (SSD) are common, and although scientific evidence for structural and functional alterations in DLD / SSD is accumulating, current neuroimaging studies provide an incongruent picture. Here, we hypothesized that children affected by DLD and SSD present with gray matter (or gray matter asymmetry) aberrations in brain areas associated with language processing compared to typically developing (TD) children. To assess this hypothesis, we enhanced MRI-based information with microscopically defined cytoarchitectonic probabilities of Broca's area (BA 45, BA 44) as well as an auditory area (TE 3.0). Left and right gray matter volumes in addition to gray matter volume asymmetry were investigated in 18 children with SSD, 13 children with DLD, and 18 TD children within these regions of interest. We observed significantly larger gray matter volumes in right BA 45 in DLD compared to TD children and also compared to SSD children. These findings suggest an altered development of language processing areas, specifically BA 45, in children with DLD that is in agreement with previous interpretations of procedural deficits. Furthermore, we detected a larger rightward gray matter asymmetry in BA 45 in children with DLD and with SSD compared to TD children, albeit only on a trend level. This may suggest an altered hemispheric lateralization of language processing in DLD and SSD consistent with previous reports.

**Abstract:** Attention Deficit Hyperactivity Disorder (ADHD) causes impaired visuospatial working memory (VWM), which primarily maps to the prefrontal cortex. However, little is known about the synaptic processes underlying cognitive loss in ADHD, or those ultimately involved in the preventive effect observed through theclinical use of Atomoxetine (ATX). To investigate the plasticity underlying ADHD related cognitive loss, and that potentially involved in the preventive action of Atomoxetine. Allocentric VWM was assessed, as well as the dendritic spine number and proportional density on pyramidal neurons in the prefrontal cerebral cortex layer III of neonatal 6-hydroxydopamine-lesioned rats. The effect of acute ATX treatment was also assessed at 28 days of age. 6-OHDA induced lesions produced increased motor activity and a loss ofVWM, concomitant with a reduction in thin spine density. ATX administration reversed cognitive loss, in conjunction with a decrease in thin spines and an increase in mushroom spines. A reduction in the proportion of spines involved in learning in hyperactive animals could account for the loss in cognitive function observed. Considering thin spine density was also reduced after ATX administration, we hypothesized that the restoration in cognitive function recorded could be brought about by an increase in memory related mushroom spines.

**Abstract:** AIDA-1, the product of the gene *ANKS1B*, is a synaptic protein previously implicated in amyloid precursor protein processing and nuclear function. Previous work in our lab demonstrated that AIDA-1 regulates the synaptic localization of the NMDA receptor subunit GluN2B, and that postnatal deletion of AIDA-1 impairs synaptic plasticity and reduces anxiety-like behaviors in mice. Published studies link *ANKS1B* to neuropsychiatric diseases, including autism spectrum disorder (ASD) and schizophrenia. We recently identified several families harboring heterozygous deletions in the *ANKS1B* gene detected by chromosome microarray. Probands suffer from diverse conditions including ASD, attention-deficit hyperactivity disorder, speech apraxia, and motor impairments. Using blood samples from two of these families, we confirmed the presence of the heterozygous deletion by quantitative PCR and reprogrammed peripheral mononuclear cells to generate human induced pluripotent stem cells (hiPSCs). To model the functional and behavioral implications of embryonic loss of AIDA-1, we generated an animal model by crossing AIDA-1 floxed mice to a Nestin-Cre mouse line. In several cohorts of conditional heterozygous AIDA-1 mice, behavioral analysis reveals reduced anxiety, increased startle response and reduced prepulse inhibition, reduced sociability, and impaired fine motor function compared to littermate Nestin-Cre controls. To probe the mechanisms by which AIDA-1 regulates neuronal function, we immunoprecipitated AIDA-1 from mouse brain lysates and identified the AIDA-1 interactome using tandem mass tag-based quantitative mass spectrometry. Our analyses revealed proteins involved in ER to Golgi transport, endosomal recycling, and small GTPase regulation. We are currently characterizing induced neurons from proband and control hiPSCs using imaging, biochemical analyses, and functional electrophysiology. Moreover, we are testing neural substrates in AIDA-1 heterozygous mice to identify the cellular and synaptic dysfunction underlying behaviors relevant to neuropsychiatric disease.

**Abstract:** Reading disorder (RD, a.k.a. Dyslexia) is a specific learning disability that affects reading. If learning disabilities remain untreated, a child may experience long term social and emotional problems which influence future success in all aspects of their lives. Early detection and intervention will help to close the gap between typically developing and reading impaired children in acquiring reading skills. The complete explanation of a complex neurodevelopmental disorder requires an understanding across multiple levels, including, but not limited to, cognition, behavior, and genetics. Although our understanding and treatment for dyslexia has greatly increased in the last 20 years, a significant percentage of children with dyslexia are either identified too late, or have a specific manifestation of the disorder that is not understood well enough to design and deliver a successful remediation. This outcome is exacerbated when the child is non-native speaker. Research examining the connection among genetic, cognitive and behavioral aspects of reading disorder offers promise for early identification and intervention to successfully address specific phenotypes of RD. Recently we demonstrated the animal models of dyslexia (i.e. genetic models based on candidate dyslexia susceptibility genes) and children with specific reading impairment show a common deficit on a virtual Hebb-Williams maze. This deficit is consistent across language orthographies (i.e. transparent and non-transparent languages). In this study we examined the link between maze performance, phonological processing, family history of dyslexia, and genetic risk in a longitudinal study. We examined reading ability and maze performance at 5-6 and 8-9 years of age and determined whether early reading measures, maze performance or genetic risk is a better predictor of reading ability by the third-grade.

**Abstract:** Attention deficit hyperactivity disorder (ADHD) is a heterogeneous neurodevelopmental disorder with a devastating impact on the quality of life of millions of children, adolescents and adults. While ADHD is thought to be highly heritable and its etiology largely unknown, it is likely to involve a combination of environmental factors and the contribution of multiple genes defects. To understand the molecular underpinnings of ADHD, we hypothesize that 3D neuralized structures (organoids) derived from patient-specific induced pluripotent stem cells (iPSCs) can be used as a potential platform. In particular, the Prefrontal Cortex (PFC) is emerging to be of central relevance to the neural pathways of ADHD, as it connects extensively to sensory and motor cortices, as well as to the basal ganglia and cerebellum. These areas are intricately interconnected and modulated by a mesh of neurons that in ADHD display heavy deficits in dopaminergic and noradrenergic transmission. Thus, it is critical to understand the molecular influences modulating PFC's function in order to develop novel medications for patients afflicted with the disorder. We have started to generate and characterize iPSCs-derived cortical organoids from ADHD patients and healthy siblings controls to study the molecular and cellular differences in corticogenesis between diseased and control brains. Particularly, we propose that the root cause of the PFC's smaller structure involves a limited progenitor pool and impaired radial migration. To achieve these long-term goals, we used our novel and non-viral reprogramming methods to generate high quality control and ADHD-iPSCs lines to optimize in vitro organoid generation, and apply this technology to fusion organoid models. Our approach will facilitate examination of how disease risk is translated at the cellular and tissue levels through comparative studies of processes such as progenitor cell proliferation, migration and connectivity during development.

**Abstract:** Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder characterized by attention disabilities, hyperactivity and impulsiveness. Neuroimaging studies have shown alterations in several brain regions in children and adults with ADHD, including the hippocampus and internal and external capsule. ADHD is considered multifactorial and involves genetics and environmental factors. Additionally, gut micro-organisms (i.e., the gut microbiota) might contribute to the pathobiology of ADHD because a divergent microbiota is found in people with ADHD compared to healthy controls. Increasing evidence suggests a role for the gut micro-organisms in neurodevelopment, including brain function and structure. Therefore we hypothesize that the gut microbiota from persons with ADHD might influence brain function and structure similar to what has been reported in ADHD. In this confirmatory, double-blind and randomized study we investigated the impact of the gut microbiota on behavior and brain structure/function by colonizing young male germ-free wild-type C57BL/6JOlaHsd mice with microbiota from three human males with ADHD and three male age-matched healthy controls. Mice (n=14 per experimental group) were housed in gnotobiotic isolators, in which the behavioral tests were conducted as well. Linear discriminant analysis effect size (LEfSe) showed that nineteen bacterial genera were significantly different between the ADHD and control mice. In addition, a significant difference in β-diversity between the mice colonized with ADHD or control microbiota was found. Mice colonized with ADHD microbiota did not differ in locomotion activity, but were more anxious than control mice in the open field test. In the larger human sample (n=135 with ADHD and n=134 controls) we also found a positive correlation between ADHD scores and anxiety scores. Colonization with ADHD-microbiota affected brain structure as well: increased functional connectivity between right motor cortex and right visual cortex and differences in DTI measures in hippocampus (decreased FA and increased MD and RD) and right internal capsule (decreased FA and increased RD) as obtained with an 11.7 T Bruker MR scanner. This study demonstrates that ADHD microbiota is able to induce anxiety and brain structure abnormalities in mice that are similar to alterations found in humans with ADHD. Our data also suggests that the microbiota might be a potential target in alleviating

ADHD symptoms. The microbial composition can be manipulated by diet, therefore nutritional interventions could be a promising therapy to mitigate ADHD symptoms.

**Title:** Multimodal imaging of occipitotemporal cortex in children with dyslexia

**Authors: *C. WANG**, M. MANDELLI, C. WATSON, E. CAVERZASI, M. GORNO-TEMPINI
Neurol., Univ. of California San Francisco, San Francisco, CA

**Abstract:** Individuals with developmental dyslexia have been demonstrated to show atypical neural response to printed words and faces, but the nature of those abnormal processes remains unclear. To explore the possible mechanisms, we acquired neuropsychological measures and multimodal imaging data from 25 children with dyslexia (age mean = 12.6 years, SD = 2.2) and 16 age-matched typically developing controls (age mean = 12.2 years, SD = 1.7) to investigate neural response during implicit tasks with words and cartoon faces in dyslexics and the related structural characteristics. In a cluster in the left occipitotemporal cortex showing the strongest word selectivity in controls, dyslexics showed reduced activation and lack of gradient in word response relative to controls. In the same area, the neural response for faces was greater than for words in both controls and dyslexics. Furthermore, analyses of high-resolution structural anatomy also revealed gyrification abnormalities of this region in a sub-group of dyslexic children. Our findings suggest that children with dyslexia show a complex pattern of functional and structural abnormality in the occipitotemporal cortex.

**Title:** Genetic polymorphisms of HTR1A and -1B and serotonin transporter binding measured by PET allow for accurate classification of ADHD: An imaging-genetics machine learning model

**Authors: *A. KAUTZKY**[1], T. VANICEK[2], H. SIGURDARDOTTIR[2], C. PHILIPPE[2], G. M. JAMES[2], G. S. KRANZ[2], G. GRYGLEWSKI[3], T. TRAUB-WEIDINGER[2], M. MITTERHAUSER[2], W. WADSAK[2], K. PAPAGEORGIOU[2], M. HACKER[2], S. KASPER[2], R. LANZENBERGER[2]
[1]Med. Univ. of Vienna, Wien, Austria; [2]Med. Univ. of Vienna, Vienna, Austria; [3]Med. Univ. of Vienna, Medical University of Vienna, Austria

**Abstract:** Objective: High heritability rates above 70% have been reported for ADHD. While the norepinephrine and dopamine transporters represent a main treatment target for attention deficit and hyperactivity disorder (ADHD), single nucleotide polymorphisms (SNPs) associated with serotonergic transmission might impact ADHD etiology and pathology [1]. Here, we strove for a multivariate prediction model for ADHD based on SNPs as well as SERT binding potential ($BP_{ND}$) measured with [$^{11}$C]DASB and positron emission tomography (PET).
Methods: 16 patients with ADHD and 18 healthy control subjects (HC) were scanned by PET and genotyped for 30 SNPs within *SLC6A4, HTR1A, HTR1B, HTR2A* and *TPH2* genes using Sequenom iPLEX. The collective and the genotyping technique has been described previously [2, 3]. 18 cortical and subcortical regions of interest (ROI) were defined. The cerebellum was used as reference region for computation of $BP_{ND}$. 18 cortical and subcortical regions of interest (ROI) were defined. RandomForest (RF) was used to select the most informative set of predictors in a nested cross-validation approach [4]. The inner loop was used for model optimization, the outer loop for validation.
Results. Variable selection produced consistent results and highlighted the putamen, anterior cingulate cortex and midbrain ROI as well as SNPs rs1328684 of *HTR2A* and rs130058 of *HTR1B* as most discriminative between HC and ADHD patients. Mostly, the feature selection algorithm chose 2-3 predictors for optimal performance. The mean accuracy for the validation sets across the ten repeats was 0.81 (±0.05) and the models yielded balanced sensitivity and specificity.
Conclusion. A prediction accuracy above 0.8 allows for clinically relevant classification. Therefore, our results advocate the relevance of the two SNPs within *HTR2A* and *HTR1A* genes and epistasis within these genes in ADHD and might contribute to the generation of a

multimodal, imaging- and genetics-based classification tool for ADHD. Regarding the high rates of co-morbidities and difficult differential diagnosis in this disorder, a reliable classification model would be of significant clinical value.

**Title:** Brain and behavioral consequences of developmental nicotine exposure in a GAD67-GFP mouse model

**Authors: *M. M. MARTIN**, M. X. TRUPIANO, D. M. MCCARTHY, P. G. BHIDE
Biomed. Sci., Florida State Univ., Tallahassee, FL

**Abstract:** Cigarette smoking during pregnancy is a major public health concern because it can have detrimental effects on both the mother and her child. For example, developmental nicotine exposure (DNE) is associated with increased risk for ADHD, conduct disorder, aggression, learning disabilities, depression, and epilepsy. The GABA neurotransmitter system is known to be altered in many of these developmental disorders raising the possibility that DNE may target the GABA system in the developing brain. Here we examined the effects of DNE on the GABA system using a GAD67-GFP knock-in mouse model. Female mice were exposed to plain drinking water or water containing nicotine (200 µg/ml) beginning 3 weeks prior to conception and continuing throughout pregnancy and up to 3-weeks postpartum when the offspring were weaned. We found that DNE produces a significant increase in the number of GABA neurons in the intermediate and marginal zones of the dorsal forebrain in 15-day old embryos, suggesting that DNE alters the GABA neuron migration from the basal to the dorsal forebrain. Since perturbation of developmental pathways can lead to lasting changes in the mature brain and

behavior, we examined behavioral phenotypes as well as the number and location of GABA and non-GABA neurons in the prefrontal and medial prefrontal cortex in the adult mouse brain. We found significant changes in the behavioral phenotype (deficits in working memory and impaired approach-avoidance behavior) as well as significant changes in neuron numbers suggesting long-term behavioral and structural consequences of developmental nicotine exposure.

**Title:** Norbinaltorphimine, a selective κ-opioid receptor antagonist, alleviates behavioral and neurotransmitter phenotypes in a mouse model of attention deficit hyperactivity disorder

**Authors: L. ZHANG**[1], J. BIEDERMAN[2], T. J. SPENCER[2], K. L. JAUNARAJS[3], D. G. STANDAERT[3], D. M. MCCARTHY[1], *P. G. BHIDE[1]
[1]Biomed. Sci., Florida State Univ. Col. of Med., Tallahassee, FL; [2]Psychiatry, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA; [3]Neurol., Univ. of Alabama at Birmingham, Birmingham, AL

**Abstract:** Kappa opioid receptor (KOR) antagonists improve stress resilience and have therapeutic potential in mood disorders and drug addiction. However, whether they can alleviate non-stress related neurobehavioral deficits is not known. Since KORs negatively regulate dopamine and noradrenaline release from synaptic terminals, KOR antagonists have the potential to alleviate the frontal cortical hypo-dopaminergic state associated with attention deficit hyperactivity disorder (ADHD), and provide therapeutic benefit. To test this possibility, we administered norbinaltorphimine (nor-BNI; 20 mg/kg; i.p.) to a perinatal nicotine exposure (PNE) mouse model of ADHD. The PNE mouse is an excellent ADHD model because it shows significant decreases in frontal cortical dopamine and noradrenaline content, and attention and working memory deficits. Following a single nor-BNI administration to the PNE mice, we assayed frontal cortical dopamine and noradrenaline levels by *in vivo* microdialysis and HPLC at 30 min intervals over a 48 hr period. We observed two dopamine peaks at 3 and 5 hr post nor-BNI, and two noradrenaline peaks at 4 and 6 hr post nor-BNI. Additionally, the nor-BNI administration significantly improved attention and working memory in the PNE mice at 2.5 and

5.5 hr post nor-BNI. By 24 hr after the nor-BNI administration, both the behavioral parameters returned to pre-nor-BNI levels. These observations suggest that nor-BNI produces bi-phasic elevation of dopamine and noradrenaline levels in the frontal cortex that begin approximately 2-3 hr after the nor-BNI administration and last up to 24 hr. Nor-BNI produces significant improvements in attention and working memory in the PNE mouse model. The improvements are evident up to 5.5 hr after the single nor-BNI administration but not at 24 hr. In summary, our data suggest that nor-BNI may have therapeutic potential for ADHD related phenotypes, and enlarge the neuropsychiatric landscape in which KOR antagonists may have clinical benefit.

**Title:** A selective κ-opioid receptor antagonist alleviates behavioral phenotypes in Fmr1 knockout mouse

**Authors: *D. M. MC CARTHY**[1], M. TRUPIANO[1], E. CARRAZANA[2], L. ZHANG[1], J. BIEDERMAN[3], T. J. SPENCER[3], P. G. BHIDE[1]
[1]Biomed. Sciences, Col. of Med., Florida State Univ., Tallahassee, FL; [2]Avekshan LLC, Alachua, FL; [3]Psychiatry, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA

**Abstract:** Fragile X mental retardation syndrome (FX) is an inherited condition that causes a range of developmental disabilities, including delayed speech and language development, mild to moderate intellectual disability, anxiety, attention deficit, hyperactivity, communication and social deficits associated with autism spectrum disorder, and seizures FX is the result of a mutation in the Fragile X mental retardation 1 (*FMR1*) gene. The mutation expands a DNA segment, known as the CGG triplet repeat, beyond its normal range of 5 to 40 repeats. An expansion in the 55-200 range constitutes a premutation, whereas an expansion beyond 200 repeats causes a full mutation or FX. FX is the number one inherited cause of intellectual disabilities, and the most common known cause of autism worldwide. Therefore, new methods for the treatment are needed. We examined spontaneous locomotor activity, attention, anxiety, social interaction and cliff avoidance reflex in the *Fmr1* knockout mouse (B6.129P2-*Fmr1*$^{tm1Cgr}$/J). Adult male and female *Fmr1* knockout mice showed hyperactivity, impaired social

interaction (tube test), increased time in the open arms of the elevated plus maze and impaired cliff avoidance reflex. We have shown that the selective kappa opioid receptor antagonist norbinaltorphimine (nor-BNI) attenuates hyperactivity in a developmental nicotine exposure mouse model and increases frontal cortical dopamine and noradrenaline levels (Zhang *et al*, 2018 Soc. Neurosci. Abstr.). Since the phenotypes observed in the *Fmr1* knockout mouse could be mediated at least in part via impaired frontal cortical monoamine neurotransmitter signaling mechanisms, we examined the effects of nor-BNI on the behavioral phenotypes in the *Fmr1* knockout mouse. A single administration of nor-BNI (20mg/kg; i.p.) significantly reduced hyperactivity in male *Fmr1* knockout mice and partially rescued impaired social interaction in the tube test in both males and females. Our observations suggest that nor-BNI can alleviate behavioral phenotypes in the *Fmr1* knockout mouse and that it could have therapeutic potential in management of FX.

**Abstract:** The estimated worldwide prevalence of Attention-Deficit/Hyperactivity Disorder (ADHD) is approximately 1.2% to 7.3%. The etiopathogenesis of this disorder remains controversial, although symptoms are well characterized: hyperactivity, impulsivity and inattention. Given its role in the regulation of high-level executive functions, consensus interpretation considers hypofrontality is critical in the emergence of ADHD. Adolescent male rats were subjected to chronic unpredictable mild stress for 3 consecutive weeks starting from the post-weaning phase. The stress procedure was a combination of a series of unpleasant situations, repeated over the week. The control rats were handled daily but were not subjected to any stress. Then the rats were exposed to a series of behavioral experiments. A set of rats were sacrificed immediately after the stress procedure and the prelimbic pyramidal neurons were tested electrophysiologically. Another set of rats were used for in vivo brain imaging using Functional Magnetic Resonance imaging technology. Stressed rats exhibited an attenuated corticosterone

response to acute stress compared to control mates. They spent a significantly higher time exploring the open arms of the elevated plus maze and travelled longer distances in the open field test indicating a disinhibited behavior. They also displayed higher number of premature responses and a lower number of correct responses on the 5-Choice Serial Reaction Time Task reflecting a motor impulsivity. They displayed higher number of premature responses on the Differential Reinforcement of Low rate responding and showed increased delay discounting, reflecting a cognitive impulsivity as well, behaviors partially restored following DREADD activation of the Prelimbic Cortex. They demonstrated a lower number of correct responses on the cognitive flexibility task, higher motivation and compulsivity for saccharine and increased preference for cocaine as compared to saccharine. Finally, the stress procedure also decreased *ex vivo* intrinsic excitability of deep layer pyramidal neurons in the prelimbic cortex of the rats as evidenced by a higher threshold for inducing action potential, a lower input resistance and a higher action potential latency, observations also confirmed using fMRI analyses. In brief, we have successfully developed a preclinical model of ADHD after subjecting adolescent rats to chronic mild stress. This model shows the behavioral hallmarks of ADHD, namely, disinhibition, hyperactivity, impulsivity and inattention, that correlates with decreased excitability of pyramidal neurons of the prelimbic cortex.

**Title:** Ghrelin selectively inhibits CaV3.3 subtype of low voltage activated Ca2+channels

**Authors: *E. R. MUSTAFA**, S. CORDISCO GONZALEZ, S. S. ROGRIGUEZ, J. RAINGO
Multidisciplinary Inst. of Cell Biol., La Plata, Argentina

**Abstract:** Voltage-gated $Ca^{2+}$ ($Ca_V$) channels are instrumental in coupling changes in membrane voltage to $Ca^{2+}$ influx that, in turn, regulates numerous critical neuronal functions. In particular, low voltage activated $Ca^{2+}$ channels ($Ca_V3$) are involved in the generation of burst firing and pacemaker activity. Knowing that G-protein coupled receptors can modulate $Ca_V3$ activity, here we investigated the ghrelin effect on $Ca_V3$ currents through its receptor, GHSR. Previously, we have showed that ghrelin evoked GHSR activity inhibits high voltage activated $Ca_V$, particularly $Ca_V2.1$ and $Ca_V2.2$. Whole cell patch recordings on transfected tsA201 cells reveal that

activation of GHSR by ghrelin application has an inhibitory effect on $Ca_V3.3$ currents but no effect either on $Ca_V3.1$ or $Ca_V3.2$. Application of ghrelin has no impact on $Ca_V3.3$ voltage dependency parameters ($V_{1/2}$ and *k* of activation and $V_{rev}$). On the other hand, ghrelin accelerates the $Ca_V3.3$ activation and inactivation kinetics at hyperpolarized voltages (from -40 to -20 mV), while the kinetics of recovery from inactivation remains similar to control values. Based on this data, we hypothesized that ghrelin application could reduce the calcium entry by $Ca_V3.3$ channels in response to physiologically relevant stimuli, such as action potentials. In order to study the isolated efficacy of $Ca_V3.3$ to calcium entry during action potential train we measure $Ca^{2+}$ currents using a hippocampal CA1 neuron firing recording as a voltage command in tsA201 cells expressing $Ca_V3.3$ and GHSR. We found that ghrelin reduces the calcium entry through $Ca_V3.3$ evoked by this stimulation paradigm. Similar to previous reports, $Ca_V3.3$ displayed current facilitation, and we found that this phenomenon is slightly reduced by ghrelin application. Next, we explore the signaling cascade implied in the effect of ghrelin on $Ca_V3.3$ and we found that co-expression of a $G_q$ dominant negative mutant or co-expression of the regulator of G-protein signaling 2 (RGS2, an effector antagonist for $G_{q/11}$) completely occlude the inhibitory actions of ghrelin on $Ca_V3.3$. The data presented here allow us ascribing a ghrelin control of the firing activity in neurons expressing GHSR and $Ca_V3.3$, but further experiments are necessary to explore this possibility.

**Title:** Leptin promotes cellular differentiation and increases ionic currents in cells of neuroblastoma n1e115

**Authors: *B. DOMINGUEZ MANCERA**, R. I. VERGARA-REYES, P. CERVANTES-ACOSTA, A. HERNANDEZ-BELTRAN, M. BARRIENTOS-MORALES
Univ. Veracruzana, Dept Fisiología, Veracruz, Mexico

**Abstract:** The study of the development and neural function has been favored with the establishment and use of cell lines such as N1E-115 (neuroblastoma), which proliferates unlimitedly and develops neurites when is exposed to different agents. To determine the chronic effect (48-72 hrs) of the anorexigenic hormone Leptin -LEP- on N1E-115 cells, it was applied alone or in combination with Dimethylsulfoxide - $Me_2SO$- (agent promoting the development of neurites). Cells were grown at in Dulbecco's modified Eagle's medium (DMEM) containing

0.12% with 10% fetal calf serum. The cultures were maintained under a humidified atmosphere containing 5% $CO_2$. After the cultures were in confluent phase, cells were trypsinized and seeded at a density of 5 X $10^5$ per 35 mm dish in 2 ml of growth medium. The treatments were Control, LEP (10nM), $Me_2SO$ (1.5%) and LEP (10nM) + $Me_2SO$ (1.5%). The cells were subjected to electrophysiological study with the Patch clamp technique in Whole Cell Recording; cells with capacitance higher than 40 pF were used. The statistical analysis was by one-way ANOVA and the post hoc comparisons were by Tukey ($p<0.05$). The results show that the cells maintained in standard culture medium (DMEM + SFB10%) without treatment, do not show neuritic development; LEP, $Me_2SO$ and LEP + $Me_2SO$ stimulate cells to produce neurites and neural networks. An increase in inward (1.4 folds) and outward currents (1.3 folds) is observed in the analysis of total currents in LEP treated cells, LEP + $Me_2SO$, and in cells treated with $Me_2SO$ respect to the control value (~2 nA inward and ~1.5 nA outward currents). The inwards currents ($Ca^{2+}$, $Na^+$) increased ($p <0.05$) ~ 1.5 ± 0.5 folds in the three treatments; as well as the neuritic development with respect to the control. In conclusion, Leptin promotes differentiation and electrical activity.

**Title:** Neural voltage-independent regulation of voltage-gated calcium channels in pancreatic β-cells

**Authors: *D. E. GARCIA-DIAZ**, I. ARENAS, J. GARDUÑO, J. BRAVO-MARTÍNEZ, L. DE LA CRUZ
Dept. de Fisiología, Facultad de Medicina, Univ. Nacional Autónoma de México, Ciudad DE Mexico, Mexico

**Abstract:** The islets of Langerhans are innervated by sympathetic and parasympathetic terminals. Voltage-independent regulation of calcium channels is crucial for intracellular calcium concentration and insulin secretion. Voltage-gated calcium (CaV) channels are regulated by G proteins via voltage-dependent and independent mechanisms. Phosphatidylinositol-4,5-bisphosphate ($PIP_2$) is a membrane phosphoinositide feasibly regulating the activity of ion

channels and transporters. $PIP_2$ has been hypothesized to be responsible for voltage-independent regulation of CaV channels. However, whether CaV channels are regulated by $PIP_2$ in pancreatic β-cells, it is still scarcely understood. At present, $PIP_2$ depletion through activation of a muscarinic pathway induced by oxotremorine methiodide (Oxo-M) can be readily performed to assess voltage-independent regulation in pancreatic β-cells. Conversely, noradrenaline (NA), a voltage-dependent Gβγ activator, can be applied to detach voltage-dependent regulation by means of a prepulse paradigm. Therefore, the purpose of this study was to investigate the voltage-independent regulation of CaV channels, by cholinergic and adrenergic receptor activation in pancreatic β-cells of the rat. By using patch clamping and biochemical methods we recorded CaV currents and separated voltage-independent and voltage-dependent counterparts. CaV current amplitude was inhibited by activation of the muscarinic receptor 1 ($M_1R$) in the absence of kinetic changes. Oxo-M-induced inhibition exhibited the hallmarks of voltage-independent regulation and did not involve PKC activation. This inhibition was mimicked or occluded by diC8-$PIP_2$ dialysis supporting mediation of native $PIP_2$ into the plasma membrane. On the other hand, both NA exposure and cell dialysis with GTPγS, a nonspecific activator of G proteins, significantly inhibited CaV current in pancreatic β-cells. Interestingly, this inhibition persisted despite of a strong depolarizing prepulse. Taking together, CaV channels in rat pancreatic β-cells are regulated mostly by a voltage-insensitive mechanism. However, further experiments should be addressed to elucidate the nature of a double-controlled inhibition of CaV channels exerted by the autonomic nervous system on pancreatic β-cells.

**Title:** Dopamine receptor type 1 modulates $Ca_V2.2$ current density

**Authors: *J. RAINGO**, C. CHOU-FREED, V. MARTINEZ DAMONTE, S. RODRIGUEZ, C. MCCARTHY
Multidisciplinary Inst. of Cell Biol. (IMBICE), La Plata, Argentina

**Abstract:** D1R interacts with $Ca_V2.2$ and modulates its trafficking to the plasma membrane. This effect has been shown to regulate $Ca_V2.2$ density at postsynaptic sites in the prefrontal cortex (Kisilevsky et al. 2008). Here we studied the cellular mechanisms involved in $Ca_V2.2$ regulation by D1R using a heterologous expression system. We manipulated the concentration of transfected $Ca_V2.2$ and YFP-tagged D1R cDNA in HEK293t cells and measured D1R expression levels by fluorescence signal. There was a linear correlation between the amount of D1R transfected and YFP signal level, as expected. We recorded whole-cell calcium currents in cells expressing $Ca_V2.2$, its auxiliary subunits and increasing concentrations of D1R. We found a positive correlation between $Ca_V2.2$ current density and D1R expression levels at low D1R/$Ca_V2.2$ cDNA molar ratios (D1R/$Ca_V2.2$ MR) ($Ca_V2.2$ alone= 79.31 ± 11.04 pA/pF, 0.1 D1R/$Ca_V2.2$ MR= 114.3 ± 9.42 pA/pF; P=0.023). Moreover, this effect was occluded by Cholero Toxin, a Gs protein inhibitor. To evaluate if this effect was due to an increase in functional channels at the plasma membrane, we measured total charge movement during ON gating current evoked by steps from -100 mV to the reversal potential. We found that the charge movement increased from 7.6 ± 1.2 fC/pF ($Ca_V2.2$ alone) to 12.6 ± 0.22 fC/pF (0.1 D1R/$Ca_V2.2$ MR). At D1R cDNA concentrations above 0.1 D1R/$Ca_V2.2$ MR, the $Ca_V2.2$ current density was reduced, reaching values below the control condition without D1R ($Ca_V2.2$ alone= 79.31 ± 11.04, 1 D1R/$Ca_V2.2$ MR= 43.35 ± 4.88 pA/pF; P=0.0008). This current reduction was insensitive to Cholero Toxin. We hypothesized that high D1R expression levels could promote the formation of D1R homodimers. We therefore assayed the effect of adding equimolar cDNA concentrations of other receptors that are able to form heterodimers with D1R (ghrelin receptor and D2R) and found that this maneuver occluded the calcium current increase. Finally, we compared the acute inhibitory effect of dopamine mediated activation of D1R on $Ca_V2.2$ currents. We found a shift in the EC50 (3.28 ± 0.32 µM at 0.1 D1R/$Ca_V2.2$ MR versus 0.79 ± 1.5 µM at 1 D1R/$Ca_V2.2$ MR) without changes in the maximum inhibitory effect (~50 % of inhibition). This result suggests that D1R expression level impacts its activation mode. In summary, we found a biphasic effect of D1R co-expression on $Ca_V2.2$ current: at low D1R expression levels, a stimulation of traffic that implicates Gs protein activity, and in contrast, at high D1R expression levels, a reduction in current and increased sensitivity to dopamine-mediated inhibition, possibly due to the formation of D1R dimers and involving a different signaling pathway.

**Title:** Cell-specific epigenetic modification of the CACNA1B gene in nociceptors controls calcium channel function in normal and neuropathic pain

**Authors: *E. J. LOPEZ SOTO**, D. LIPSCOMBE
Dept. of Neurosci., Brown Univ., Providence, RI

**Abstract:** Voltage-gated $Ca_V2.2$ calcium channels control transmission of noxious stimuli at nociceptor terminals in dorsal horn spinal cord. $Ca_V2.2$ channels are the targets of many drugs and neurotransmitters that activate G-protein coupled receptors to down regulate nociception. Nociceptors express a unique form of the $Ca_V2.2$ channel, through cell-specific pre-mRNA splicing, which influences the sensitivity of $Ca_V2.2$ channels to inhibition by mu-opioid receptors. Here, we elucidate the mechanism of cell-specific selection of *CACNA1B* exon 37a during alternative pre-mRNA splicing. The multi-zinc finger DNA binding protein CCCTC-binding factor (CTCF) is a master regulator of gene expression. A few reports, based on studies in non-neuronal cell lines, suggest that CTCF may also promote exon recognition of weak splice junctions. Based on publicly available ChIP-seq data, we identify that CTCF binds a region of *CACNA1B* close to exon 37a in several (although not all) human and mouse cell lines. By electrophoretic mobility shift assay, we confirm that recombinant CTCF binds a 60 bp region in exon 37a of Cacna1b, but not the neighboring homologous exon 37b. We have applied several methods, *in vitro* and *in vivo* using cell lines and neurons from mouse dorsal root ganglia (DRG), to show that CTCF promotes Cacna1b exon 37a inclusion in Trpv1-lineage neurons during pre-mRNA splicing. Using the DRG-derived F11 cell line as a model we show: 1) by ChIP-qPCR, that CTCF binds in exon 37a of Cacna1b *in vivo*, but not in exon 37b; 2) CTCF overexpression increases, and CTCF siRNA knockdown decreases exon 37a inclusion; 3) pharmacological inhibition of gDNA methylation (58.75 ± 6.644 % reduction as measured by 5-mC DNA ELISA) results in a 2.0 ± 0.1 fold-increase in exon 37a expression, an increase in CTCF binding to exon 37a, and a decrease in 5-mC in exon 37a; 4) siRNA knockdown of DNA methyltransferase DNMT3a, but not DNMT1 or DNMT3b, promotes exon 37a inclusion; 5) active DNA demethylating enzymes TET1 and TET2, but not TET3, when overexpressed, increase exon 37a inclusion. *In vivo*, we show that DRG Trpv1-lineage neurons, but not Trpv1-negative neurons, express exon 37a, have less 5-mC in locus 37a compared to DRG neurons that do not express Trpv1. Additionally, we find that in a peripheral nerve injury model, known to alter global methylation, exon 37a inclusion is reduced. Collectively, our results show that cell specific epigenetic factors change alternative splicing exon selection in Cacna1b gene, thereby regulating transmission of nociceptive information in the primary afferent pain pathway in normal and neuropathic pain.

**Title:** $PIP_2$ depletion inhibits N-type $Ca^{2+}$ channels in acutely dissociated oxytocin neurons of rat supraoptic nucleus

**Authors: *M. KIRCHNER**, W. E. ARMSTRONG, R. C. FOEHRING
Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

**Abstract:** Oxytocin (OT) and vasopressin (VP) neurons of supraoptic nucleus express high-voltage-activated L-, N-, P/Q-, and R-type $Ca^{2+}$ channels that prompt transmitter release, intracellular signaling, and plasticity. These channels also serve a critical role in triggering the $Ca^{2+}$-dependent afterhyperpolarization (AHP) activated during repetitive firing. Previous work from our lab has demonstrated that the second messenger phosphoinositol PtdIns(4,5)P2 ($PIP_2$) is required for AHP generation in OT, but not VP neurons. Depletion of $PIP_2$ results in AHP abolishment, lowered somatic $[Ca^{2+}]_i$, and decreased whole-cell $Ca^{2+}$ currents. Furthermore, we determined the AHP was reduced after blocking N-type channels, but not after blocking L, P/Q, or R channel types in OT neurons. To determine the mechanism by which $PIP_2$ modulates $Ca^{2+}$ channels, we studied isolated $Ca^{2+}$ currents in voltage clamp from acutely dissociated supraoptic neurons using Wistar-Kyoto rats containing the OXT-mRFP1 fusion transgene to label OT neurons (Yoichi Ueta, Kitakyushu, Japan). Wortmannin, a compound that obstructs $PIP_2$ production by targeting the rate-limiting enzyme PI4Kα, significantly inhibited whole cell $Ca^{2+}$ currents in OT but not VP neurons. This effect was abolished when cells were supplemented intracellularly with the $PIP_2$ analogue, di$C_8$-$PIP_2$. Wortmannin also caused a hyperpolarizing 4.6 mV shift in the voltage activation curve, but this shift did not account for the total inhibition of the current. Activation and deactivation time constants were unaffected. When isolating N-type $Ca^{2+}$ currents with 5 μM nifedipine (L-type), 0.5 μM agatoxin-IVA (P/Q-type), and 0.3 μM SNX-482 (R-type), wortmannin significantly inhibited the isolated N-type current, but had little effect when examining the reciprocal family of $Ca^{2+}$ currents available after only N-type channels were blocked using 1 μM conotoxin GVIA. The results suggest that $PIP_2$ selectively and constitutively modulates N-type channels in OT neurons, which are in turn coupled to $Ca^{2+}$-dependent AHPs.

**Abstract:** Calcium entry mediated by L-type voltage gated calcium channels (Cav1 family) plays a vital role in controlling the firing pattern of hippocampal pyramidal neurons. We recently found that Cav1.3 functionally couples with the intermediate conductance calcium-activated potassium channel (KCa3.1) to contribute to a long lasting slow afterhyperpolarization (sAHP) that determines the pattern of spike discharge in pyramidal cells (Sahu et al., 2017, PMID 29038242). IsAHP in pyramidal neurons is preferentially activated by Cav1.3 calcium entry and accentuated by Cav1.3 facilitation. However, the full range of molecular mechanisms that support IsAHP generation over a 10 sec time span has not been determined. We employed Stochastic Optical Reconstruction super resolution microscopy (STORM) and patch clamp recordings to define the relationship between Cav1.3, KCa3.1 and ryanodine receptor 2 (RyR2) calcium release channels. STORM in total internal reflection fluorescence (TIRF) mode (30-40 nm precision) revealed a close apposition between Cav1.3 and KCa3.1 channels when expressed in tsA-201 cells or as native channels in cultured hippocampal pyramidal cells. Cav1.3 and KCa3.1 channels were observed throughout neuronal somata and dendrites in isolation or as distinct clusters in close apposition. Similarly, clustered patterns were reliably detected between Cav1.3 and RyR2 and between KCa3.1 and RyR2, suggesting a tri-protein complex. In a separate set of experiments IsAHP-like tail currents were recorded in tsA-201 cells expressing Cav1.3 and KCa3.1 following a 0 mV depolarizing step (100 msec). The IsAHP-like outward tail current was blocked after internal perfusion with 200 µM ryanodine and potentiated after perfusion with 10 mM caffeine, which decreases or increases RyR-mediated store calcium release, respectively. Removing extracellular calcium further blocked KCa3.1-mediated tail currents, indicating that Cav1.3 -mediated calcium entry is required for inducing RyR2-mediated calcium release that prolongs the IsAHP.
These data establish a close functional coupling among Cav1.3, KCa3.1 and RyR2 channels as a

tri-protein complex, where calcium entry through Cav1.3 channels results in a long lasting KCa3.1-mediated component of the sAHP by activating RyR2.

**Title:** L-type calcium channels cooperate with NMDA receptors to signal to the nucleus

**Authors: *N. MANDELBERG**[1], B. LI[2], S. D. SUN[3], R. W. TSIEN[1]
[1]New York Univ. Sch. of Med., New York, NY; [2]Zhongshan Sch. of Med., Sun Yat-Sen Univ., Guangzhou City, China; [3]Ctr. for Neural Sci., New York Univ., New York, NY

**Abstract:** Neurons and synapses are plastic, with the remarkable ability to change their physiology based on the inputs they receive. Excitation-transcription (E-T) coupling refers to the control of gene transcription by electrical activity across the cell membrane – the process by which a neuron translates external inputs into a language that the nucleus can understand. The transcription factor calcium- and cAMP response element binding protein (CREB) is a well-studied linchpin of E-T coupling in neurons, and its role in learning and memory has been firmly established across organisms. L-type voltage-gated calcium channels ($Ca_V1$) play a disproportionally large role in CREB-mediated E-T coupling because of their privileged relationship with downstream signaling molecules. While plasticity can exhibit remarkable synapse specificity, the role of E-T coupling in linking specific synapses, rather than whole-cell somatic events, to the nucleus remains poorly understood. Specifically, it is unknown where in the neuron $Ca_V1$-mediated E-T coupling is initiated, and how $Ca_V1$ channels cooperate with other mediators of E-T coupling.
Recent work from our lab has suggested that $Ca_V1$ channels signal not only through calcium flux, but also via a voltage-dependent conformational change (VDC) that synergizes with calcium signals. This synergy extends to both the calcium flux through the channel itself, but also through *N*-methyl-D-aspartate receptors (NMDARs), raising the possibility of local cooperation between $Ca_V1$ channels and other synaptic calcium sources. We show that quantal

events in the absence of whole-cell spikes can influence CREB, suggesting that localized, synaptic stimuli are capable reaching the nucleus. We have also begun to explore the spatial profile of $Ca_V1$ influence on nuclear events by restricting the activation of $Ca_V1$ to specific portions of the neuron during stimulation. To determine how $Ca_V1$ channels and NMDA receptors could synergistically contribute to neuronal E-T coupling, we pharmacologically isolated $Ca_V1$ VDC and ionic flux from NMDA receptors. We provide evidence that NMDA receptor stimulation works with $Ca_V1$ VDC to activate neuronal CREB, and that this synergy is exaggerated in a model of Timothy Syndrome, a genetic form of autism spectrum disorder. Furthermore, we used different calcium chelators to show that this functional relationship is based on a close spatial relationship. Together, these results suggest that $Ca_V1$ channels can exert control over neuronal transcription from the dendrite based on local signals that interact not only with downstream signaling partners, but also other channels at the dendritic spine.

**Abstract:** Calmodulin (CaM) is an important signalling molecule that regulates high voltage-activated calcium channels and second messenger cascades that activate CaM kinases and gene transcription. Calcium channels of the Cav3 family (T-type) mediate low threshold calcium influx, but were not believed to interact with CaM. We reported a constitutive association between CaM and the Cav3.1 channel at rest that is lost through an activity- and Cav3 calcium-dependent CaM dissociation, followed by activation of αCaMKII (Asmara, PMID 28800734). Recent work has revealed a Cav3.1 channel-dependent LTP of parallel fiber input to Purkinje

cells that we find can be triggered by optogenetic stimulation of ChR2 expressed in relation to promotor activity of parvalbumin or L7 in Purkinje cells in in vitro tissue slices. We used a theta-burst pattern of light pulses (470 nm) over 5 min (25 Hz for 200 ms at 1 Hz) to trigger a ChR2-mediated depolarization in Purkinje cells to selectively evoke Cav3 calcium influx in the presence of high voltage-activated calcium channel blockers. Slices were fixed to detect immunolabel for phosphorylation sites specific to either αCaMKII or CaMKIV from a condition of rest or 5 min after an LTP-inducing optogenetic burst pattern. We further examined phosphorylation of CREB using antibodies specific to phosphorylation at site serine 133 (αCaMKII-mediated) and serine 142 (αCaMKII or CaMKIV-mediated). We found under resting conditions that Purkinje cells in lobule IX / X exhibit a higher level of activated CaMKIV than αCaMKII, with membrane optogenetic stimulation increasing immunolabel intensity for αCaMKII but not CaMKIV. Optogenetic stimulation further triggered nuclear CREB activation, as signified by immunolabel for CREB Ser-133 and Ser-142. Phosphorylation of αCaMKII and CREB Ser-133 were blocked by the Cav3 channel blocker TTA-P2 (1 μM), but not CaMKIV and CREB Ser-142. Together these results indicate that Cav3 calcium influx is sufficient to trigger αCaMKII and phosphorylation of CREB Ser-133. Cav3-mediated calcium influx thus differentially regulates αCaMKII and CaMKIV levels during activation of a signaling cascade that triggers CREB in Purkinje cells following stimuli capable of activating long term plasticity of parallel fiber input.

**Title:** CaBP1 regulates $Ca_v1$ L-type $Ca^{2+}$ channels and their coupling to neurite growth and gene transcription in mouse spiral ganglion neurons

**Authors: *A. LEE**[1], T. YANG[2], J.-E. CHOI[2], D. SOH[2], K. TOBIN[2], M.-L. JOINER[2], M. HANSEN[2]
[1]Mol. Physiol. & Biophys, [2]Univ. of Iowa, Iowa City, IA

**Abstract:** CaBP1 is a $Ca^{2+}$ binding protein that is widely expressed in neurons in the brain, retina, and cochlea. In heterologous expression systems, CaBP1 interacts with and regulates voltage-gated $Ca_v$ $Ca^{2+}$ channels but whether this is the case in neurons is unknown. Here, we investigated the cellular functions of CaBP1 in cochlear spiral ganglion neurons (SGNs), which express high levels of CaBP1. Consistent with the role of CaBP1 as a suppressor of $Ca^{2+}$-dependent inactivation (CDI) of $Ca_v1$ (L-type) channels, $Ca_v1$ currents underwent greater CDI in SGNs from mice lacking CaBP1 (C-KO) than in wild-type (WT) SGNs. The coupling of $Ca_v1$ channels to downstream signaling pathways was also disrupted in C-KO SGNs. Activity-dependent repression of neurite growth was significantly blunted and unresponsive to Cav1 antagonists in C-KO SGNs in contrast to WT SGNs. Moreover, $Ca_v1$-mediated $Ca^{2+}$ signals and phosphorylation of cAMP-response element binding protein were reduced in C-KO SGNs compared to WT SGNs. Our findings establish a role for CaBP1 as an essential regulator of $Ca_v1$ channels in SGNs and their coupling to downstream pathways controlling activity-dependent transcription and neurite growth.

**Abstract:** Determining the roles of proteins present in the synaptic terminal of the retina is essential to further efforts to prevent and cure blindness. $Ca_v1.4$ is a photoreceptor specific, voltage-gated calcium channel clustered at the presynaptic active zone or 'ribbon'. $Ca^{2+}$ influx via $Ca_v1.4$ is essential for communication across the first visual synapse. $Ca_v1.4$ channels are also required for synaptic development, but the mechanism for this aspect of $Ca_v1.4$ function is unknown. We used *in vivo* electroporation to transiently express $Ca_v1.4$ in a subset of $Ca_v1.4$ KO

rods and demonstrated rescue of synaptogenesis using morphological markers, electrophysiological recordings of bipolar neurons, and a behavioral assay for vision. We designed a complimentary pair of $Ca_v1.4$ mutants lacking the ability to conduct $Ca^{2+}$, and found that either could rescue pre-synaptic development of $Ca_v1.4$ KO rods but post-synaptic development was incomplete. We propose that $Ca_v1.4$ serves two roles in synaptogenesis; as a scaffold to organize development of the pre-synaptic ribbon complex, and as a mediator of $Ca^{2+}$ signaling to complete the process. The scaffolding role of $Ca_v1.4$ may serve as a primer to ensure that structural framework is in place prior to the requirement for dynamic $Ca^{2+}$ signaling in response to changing lighting conditions.

**Title:** Effect of isoflurane on axonal endoplasmic reticulum $Ca^{2+}$dynamics in hippocampal neurons

**Authors: *V. OSMAN**[1], H. C. HEMMINGS, Jr.[2]
[1]Dept. of Pharmacol., [2]Dept. of Pharmacology, Dept. of Anesthesia, Weill Cornell Med., New York, NY

**Abstract:** General anesthetics are essential to modern medicine, but despite their widespread clinical use, their precise cellular and molecular mechanisms of action remain unclear. Anesthetics depress synaptic transmission with both pre- and post-synaptic effects including inhibition of activity-dependent $Ca^{2+}$ influx into the presynaptic nerve terminal. However, the principal presynaptic sites of action upstream of $Ca^{2+}$ entry are unknown. Axonal endoplasmic reticulum (ER) $Ca^{2+}$ controls presynaptic $Ca^{2+}$ through sequestration, and decreased ER $Ca^{2+}$ has been linked to a reduction in presynaptic $Ca^{2+}$ influx. ER $Ca^{2+}$ efflux and influx mechanisms are essential for $Ca^{2+}$ regulation and provide possible targets for anesthetic action. **Isoflurane, a common volatile anesthetic, inhibits presynaptic $Ca^{2+}$ entry and synaptic vesicle (SV) exocytosis, which we hypothesize involves effects on ER $Ca^{2+}$ dynamics**. Primary cultures of rat hippocampal neurons were used to test isoflurane-induced changes in ER $Ca^{2+}$ concentration using fluorescent biosensors and pharmacological modulators of ER $Ca^{2+}$ regulators. This project

will further our understanding of isoflurane's neuronal mechanisms of action. Ultimately, this understanding will aid in the development of more-selective anesthetics decreasing patient risk.

**Title:** Functional modulation of the Cav3.1 calcium channel by alternative splicing at the C-terminus

**Authors: *R. WANG**, Z. WANG, F. SHAKOLA, E. KALONTAR, M. HOSSAIN, Y. YU, M. RUGGIU
Biol. Dept., St. John's Univ., Jamaica, NY

**Abstract:** The CACNA1G gene encodes for Cav3.1, the alpha-1G subunit of a low-voltage-activated T-type calcium channel, which plays crucial roles in cardiac and smooth muscle cells and neurons by influencing the transmembrane potentials and regulating intracellular $Ca^{2+}$ signaling. Heterozygous missense mutations in the CACNA1G gene cause spinocerebellar ataxia-42 (SCA42), and mice that are null for this gene are unable to generate spike-and-wave discharges in thalamocortical relay neurons in response to GABA-B receptor activation, a hallmark of absence seizure. Different splice variants of Cav3.1 have been described, and alternative splicing of Cav3.1 channel transcripts can alter channel kinetics, localization, and cytosolic $Ca^{2+}$ trafficking, which create a complex and diverse system of electrical conduction and signal transduction. In this work, we analyze the function of two exons, termed E34 and E35, that are alternatively spliced *in vivo* in all possible combinations. These exons are found immediately after domain IV in the intracellular C-terminus, but their function is still largely unknown. To examine the physiological properties of these splice variants, we recorded channel activity with two-electrode voltage clamp on *Xenopus* oocytes injected with mRNAs corresponding to specific splice variants. Our data show that the Cav3.1 variants that include either or both E34 or E35 produce much larger channel currents than that of the variant skipping both exons, suggesting that the protein sequences encoded by E34 and E35 may facilitate the channel trafficking, or increase the channel open probability or signal channel conductance. We also analyzed the expression of these C-terminal splicing variants by RT-PCR in the mouse. The results show that E34 and E35 are preferentially included in nerve tissue postnatally, while they

are mostly skipped in embryonic tissues. By generating minigene constructs, we investigated the mechanism of E34 and E35 splicing regulation in a cell line, and tested whether specific splicing factors contribute to their inclusion and/or skipping. Taken together, our data indicate that the alternative splicing at exon 34 and 35 of Cav3.1 may regulate neuron excitability and modulate the intrinsic firing pattern by changing the $Ca^{2+}$ influx through the channel.

**Abstract:** Ultrasound brain stimulation shows great potential for probing brain function and treating brain disorders with unique advantages as both noninvasive and good spatiotemporal resolution. However, it lacks cellular selectivity which is critical for precisely targeting neurons for understanding brain functions and treating brain dysfunction. Nano-scale gas vesicles, with a gene encoded biogenic ultrasound responsive protein structure, can scatter sound waves and thereby produce ultrasound contrast which is considered as the GFP in ultrasound. We wondered that whether the oscillations of nano-scale gas vesicles can localize acoustic energy to induce targeted perturbations to the selected neurons. Here we report our findings on nano-scale gas vesicle enabled acoustic sensitivity both in vitro and ex vivo. In cellular level, the nano-scale gas vesicles were targeted to different domains of various membrane proteins such as Piezo1, TRPV1, CFTR etc, as well as simply mixing with the cells in the solution. Calcium imaging on primary culture neurons and CHO cells were utilized to characterize the performance of nano-scale gas vesicles to ultrasound stimulation. Our results show nano-scale gas vesicles can enhance the effects of what low-intensity ultrasound activates primary culture neurons, whereas the neurons would keep silent at the absence of nano-scale gas vesicles under the same ultrasound stimulation. In addition, cell targeting experiments showed different responses when

targeting to different domains of the same mechanosensitive ion channels. Finally, this effect was tested in brain slices targeted by RGD to integrin. Similar result was also observed in the ex vivo experiment, demonstrating a novel targeting strategy for ultrasound brain stimulation. Collectively, we demonstrated a novel targeting strategy for ultrasound stimulation with gene encoded nano-scale gas vesicles. It is a promising tool in targeting neurons on account of combining noninvasive, good spatiotemporal resolution of ultrasonic stimulation and enhancement effect plus good biocompatibility of nano-scale gas vesicles together.

**Authors: *C. K. LANKFORD**[1], J. HOUTMAN[2], S. BAKER[1]
[1]Biochem., [2]Microbiology and Immunol., Univ. of Iowa, Iowa City, IA

**Abstract:** Hyperpolarization activated HCN1 channels function to control neuronal excitability and timing and are abundantly expressed in the cortex, hippocampus, cerebellum, brainstem, and retina. HCN1 dysregulation in these systems can result in hyperexcitability as well as saturation of downstream neural circuits. HCN1 activity has been shown to be modulated by multiple factors with dopamine, neuropeptide Y, and nitric oxide signaling all resulting in reduced HCN1 activity. It has also been shown that phosphorylation by protein kinase C reduces HCN1 activity by downregulating the number of channels at the cell surface. The mechanism underlying this controlled HCN1 downregulation remains poorly understood. We recently identified an interaction between HCN1 and the 14-3-3 family of proteins, a highly conserved family of phosphopeptide binding proteins abundantly expressed in the brain. We hypothesize that 14-3-3 binding is involved in the phosphorylation dependent downregulation of HCN1. To test this hypothesis, we mapped the 14-3-3 binding site on HCN1 and determined that a site near the C-terminus serves as the principle site for 14-3-3 recruitment. Loss of this site significantly disrupts the 14-3-3/HCN1 interaction as assessed by co-immunoprecipitation and results in an increase in the steady-state levels of HCN1 in a heterologous expression system. Pulse-chase experiments using SNAP-tag labeled HCN1 revealed that loss of 14-3-3 binding extends the half-life of HCN1. These results suggest that 14-3-3 binding is involved in HCN1 turnover.

**Title:** $I_H$ current modulates bicuculline-induced increased in rebound excitation of vta da neuron

**Authors: *K. Y. BOSQUE CORDERO**[1], R. VÁZQUEZ-TORRES[2], C. A. JIMENEZ-RIVERA[3]
[1]Biol. Dept., Univ. of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico; [2]Physiol. Dept., Univ. of Puerto Rico, San Juan, PR; [3]Physiol., Univ. of Puerto Rico, Physiol. Dept., San Juan, PR

**Abstract:** The hyperpolarization-activated cation current ($I_h$) is a major determinant of neuronal intrinsic excitability in many cells including dopaminergic neurons of the Ventral Tegmental Area (VTA DA). In contrast to other cellular conductances, the $I_h$ current is activated by hyperpolarizing voltage steps to potentials negative to -55 mV. $I_h$ current modulates the electrophysiological properties of neurons in the Mesocorticolimbic (MCL) system. Neuroadaptations in this network are hypothesized to trigger drug addiction. Rebound excitation is the increase in firing rate following hyperpolarizing inputs. Changes in the intrinsic properties of the cell related to rebound excitation are still poorly understood. We used ZD7288 (ZD)(an $I_h$ blocker) in whole cell patch-clamp recordings to evaluate rebound excitation in VTA DA neurons. Rat brain slices were also incubated with bicuculline (BIC) (30 or 120 minutes) as a mechanism to enhance excitability and promote rebound excitation through GABAergic disinhibition. In addition the effect of ZD in the increase rebound excitation after BIC treatment was investigated. It was found that ZD administration reduced rebound excitation in naïve slices. After 30 minutes of BIC incubation there was a significant increase in the number of action potentials (AP) within the rebound excitation (No BIC, AP 1±0.22 vs. BIC 30 minutes, AP 18±11) and a 69% $I_h$ reduction (No BIC, -465pA vs. BIC 30 minutes, -144pA, ****p<0000.1) with a left shift in the activation curve. There was a reduction in rebound excitation after 2 hours BIC incubation but it was still enhanced compared to control (No BIC AP 1±0.22 vs. BIC 120 min AP 5±1.4). A 25% $I_h$ current reduction was found with no apparent change in the

activation curve after BIC treatment (No BIC, -465pA vs. BIC 120 minutes, -351pA, *p>0.01). ZD administration reduced the rebound excitation of 2-hour BIC treated slices to baseline level (No BIC AP 1±0.22 compared to BIC 120 minutes +ZD AP 1±0.4). Taken together, our data suggest that the $I_h$ current may play an important role in the modulation of rebound excitation and in drug-induced excitability in the MCL system.

**Title:** Activation of group-I mGluR receptors increases $I_h$ in mouse MNTB neurons

**Authors: *A. B. CORREA**, C. KUSHMERICK
Dept. of Physiol. and Biophysics, Univ. Federal De Minas Gerais, Belo Horizonte, Brazil

**Abstract:** Metabotropic glutamate receptors play physiological roles in the control of neuronal excitability, modulation of synaptic transmission and regulation of synaptic efficacy. These receptors can be classified into three groups according to their structure and signaling pathways. Group-I is composed of the isoforms $mGlu_1$ and $mGlu_5$ that couple through the G protein $G\alpha_q$. Activation of postsynaptic Group-I mGluR receptors generates an inward (depolarizing) current in mouse Medial Nucleus of the Trapezoid Body (MNTB) neurons through an unknown mechanism. Here, we investigated the contribution of HCN channels to the inward current activated by the Group-I mGluR agonist (S)-3,5-dihydroxyphenylglycine (DHPG, 10 μM) in mouse MNTB neurons from C57BL wildtype (WT) or $mGlu_5$ knockout (KO) animals. Brainstem slices containing the MNTB were obtained from juvenile mice (p20-30) and membrane currents were measured under whole-cell voltage clamp at 33-34 °C. HCN current ($I_h$) was measured as the difference between the steady-state and instantaneous currents evoked by voltage steps from -60 mV to different test potentials. To calculate conductance, we measured the reversal potential of $I_h$ as the intersection of the I-V relationship of tail currents obtained with or without prior depolarization to -120 mV. No significant differences were observed between WT and $mGlu_5$ KO MNTB neurons for $I_h$ current amplitudes or maximum conductance ($G_{max}$). Application of DHPG did not affect the midpoint or the steepness of the $I_h$ activation curve, but

significantly increased $G_{max}$ by 9.1%. The effect of DHPG to increase $I_h$ was not significantly different in WT vs. $mGlu_5$ KO animals. We conclude that $I_h$ contributes to the inward current evoked by DHPG in the MNTB neurons from WT and $mGlu_5$ KO mice.

**Abstract:** Imbalance in excitatory and inhibitory activity (E/I imbalance) has been linked to the pathophysiology underlying several neuropsychiatric disorders, such as epilepsy and schizophrenia. Genetic studies have linked hyperpolarization-activated cyclic nucleotide-gated (HCN) channels to both disorders. More recent studies have linked improper trafficking of the channels to the neuronal cell surface to depression, overall making it an attractive drug target. HCN channels are believed to have multiple functions on neuronal activity and are expressed in both excitatory and inhibitory neurons with different subcellular localization. However, the exact distribution between specific cell populations and how this distribution effects the overall E/I balance is still unclear. Using in situ hybridization in primary cortical cultures, we confirm that HCN1 is expressed in both GABAergic and glutamatergic neurons, although only in a subpopulation of each cell type. To further address this, in situ hybridization as well as immunocytochemistry combined with various cell specific markers is applied. Besides, we aim at studying the effect of HCN inhibition on neuronal activation looking at c-fos induction, both in individual cell types and at the overall network level.

**Title:** Reduced seizure propensity and enhanced function of hyperpolarization-activated cyclic nucleotide channels (HCN) in mice deficient in striatal enriched protein phosphatase (STEP)

**Authors: *S. JANG**, H. CHUNG
Dept. of Mol. and Integrative Physiology, Neurosci. Program, Univ. of Illinois at Urbana-Champaign, Urbana, IL

**Abstract:** STriatal Enriched Protein Phosphatase (STEP) is a brain specific tyrosine phosphatase that regulates Hebbian and homeostatic plasticity by negatively regulating NMDA- and AMPA-subtype glutamate receptors at excitatory synapses. Previously, our lab reported that prolonged manipulation of hippocampal network activity changes STEP61 expression and activity, resulting in modulating synaptic weight against altered network activity in a homeostatic manner. Despite a well-established role of STEP61 in regulating synaptic activity, it is unclear whether STEP regulates the function of other ion channels that contribute to intrinsic excitability of hippocampal neurons. Our findings show that (1) STEP knock-out (KO) mice display prolonged latency to convulsion, reduced cumulative seizure scores, and decreased death rate following I.P injection of Kainic acid (30 mg/kg), suggesting that STEP KO mice are resistant to Kainic acid-induced status epilepticus (SE). In electrophysiology experiment, (2) lack of STEP leads to elevated voltage sag (mV), rebound potential (mV), hyperpolarization-induced inward currents (pA) and tail currents (pA) in hippocampal neurons located at CA2 regions where STEP61 is highly enriched in wild-type (WT) mice. Consistently, (3) acute inhibition of endogenous STEP activity into cultured hippocampal neurons enhances Ih (pA) and voltage sag (mV). (4) Lastly, over-expression of STEP WT gene into CHO cells transfected with HCN2 gene leads to reduction of the total expression of HCN2 channels and Ih currents while STEP expression is not altered. Taken together, STEP is a negative modulator for the function of HCN channels, contributing to determining the severity of SE following i.p injection of KA.

**Title:** A unique subcellular distribution of HCN channels accelerates action potential propagation in GABAergic interneuron axons

**Authors: *F. C. ROTH**, J. F. STORM, H. HU
Div. of Physiol., Univ. of Oslo, Inst. of Basic Med. Sci., Oslo, Norway

**Abstract:** Fast-spiking parvalbumin-expressing basket cells ($PV^+$-BCs) produce rapid feedforward and feedback inhibition in cortical neuronal networks and play a key role in a wide range of higher brain functions. These operations critically depend on a complex axonal signaling machinery that translates action potentials (APs) initiated in the proximal axon to a highly divergent GABAergic synaptic output with minimal temporal delay. In many types of axons, repetitive firing produces afterhyperpolarizations (AHPs) that slow down AP propagation. By contrast, our previous direct recordings from rat $PV^+$-BC axons revealed a stable AP propagation velocity during high-frequency repetitive firing, but the underlying mechanism remains unclear. We propose that hyperpolarization-activated cyclic nucleotide-gated (HCN) channels in $PV^+$-BC axons reduce the AHP and are a critical determinant of axonal AP propagation velocity during sustained firing. To test this idea, we performed simultaneous soma-axon recordings in rat hippocampal $PV^+$-BCs with the confocal targeted patch-clamp method to measure the latency between somatic and axonal APs during long trains of APs at 20 Hz, which mimic the activity pattern of $PV^+$-BCs during locomotion in rodents. Under control conditions, the latency remained nearly constant during the AP train. Bath application of the HCN channel blocker ZD7288 increased the latency of all axonal APs in the train and unmasked a large slow AHP. Interestingly, the AP latency increased progressively during repetitive firing in the presence of ZD7288 (n = 8), suggesting that HCN channels are critical for maintaining high AP propagation velocity during repetitive firing in $PV^+$-BC axons. In close agreement, ZD72288 also prolonged temporal delays between presynaptic APs in $PV^+$-BCs and inhibitory postsynaptic currents in dentate gyrus granule cells (n = 7). Together, these results imply a high density of HCN channels in the interneuron axon. To directly test this idea, we mapped the HCN channel subcellular distribution in $PV^+$-BCs with outside-out patches. In stark contrast to pyramidal neurons, HCN channels in $PV^+$-BCs were confined to the axon (median density 11.0 pS $\mu m^{-2}$, 50 patches) and almost undetectable at the soma and dendrites (5 and 6 patches,

respectively). Simulations with simplified BC compartmental models suggest that this unique HCN channel distribution increases axonal AP propagation velocity by counterbalancing AHPs during repetitive firing.

**Title:** Downregulation of HCN channels in mouse hippocampal neurons by virus delivered gene-interfering tools

**Authors: *M. DEUTSCH**[1], A. GÜNTHER[2], A. BAUMANN[1]
[1]Inst. of Complex Systems (ICS-4), Res. Ctr. Juelich, Juelich, Germany; [2]Brain Sci. Inst., RIKEN, Wako, Japan

**Abstract:** Pacemaker ion channels, also known as hyperpolarization- and cyclic nucleotide-gated (HCN) ion channels, are expressed in a wide range of neuronal tissue. On the cellular level they contribute to the regulation of the resting membrane potential, integration of synaptic input at the dendrites, regulation of presynaptic neurotransmitter release, as well as generation of rhythmic activity. Thus HCN-channel dysfunction or altered gene expression levels might lead to several pathologic conditions like epilepsy, neuropathic pain, Parkinson´s disease or an age-related decline in the working memory. To investigate consequences of HCN-channel dysfunctions in single neurons and neuronal networks, we interfered with HCN-channel expression.
Therefore, we specifically targeted the different channel isoforms using two independent gene-interfering techniques. First, we took advantage of a cell-autonomous RNA-interference process. It mediates the breakdown of target mRNA by the application of short-hairpin RNAs. As a second approach we used an enzymatically inactive Cas9 variant. This protein binds specifically to transcriptional start regions of *hcn* genes, thereby directly interfering with the gene transcription. Both techniques were delivered to hippocampal neurons by recombinant adenoassociated viruses. We monitored the specificity and efficacy of *hcn* gene knockdown by immunological, and quantitative PCR assays. By electrophysiological recordings of virus transduced neurons we validated changes of neuronal activity. The knowledge achieved by these experiments provides further insight in HCN-channel functions, in particular their contribution to the activity of neuronal networks.

**Title:** Chronic inflammation increases SUMOylation of the hyperpolarization activated cyclic nucleotide gated channel 2 (HCN2), which mediates the hyperpolarization activated current ($I_h$), is altered in rat dorsal root ganglion (DRG) neurons

**Authors: *L. A. FORSTER**[1], L. A. JANSEN[2], V. RYU[2], A. Z. MURPHY[1], D. J. BARO[2]
[1]Neurosci. Inst., [2]Biol., Georgia State Univ., Atlanta, GA

**Abstract:** Previous studies showed that injection of Complete Freund's Adjuvant (CFA) into a rodent's paw elicited inflammatory pain behavior that lasted for 14 days. Chronic inflammatory pain was prevented by genetic ablation of HCN2 from primary sensory afferent neurons in the DRG. Immunohistochemistry (IHC) on sectioned lumbar 4-6 (L4-6) DRG from injected animals showed that HCN2 immunoreactivity (IR) in ipsilateral relative to contralateral DRG increased at post-injection (pi) days 1 and 7 but not 4. *In vivo* DRG recordings showed that $I_h$ and the number of cells expressing $I_h$ was increased at days 5-7. We interpreted these data to mean that multiple mechanisms acted over distinct time courses to produce a persistent HCN2 mediated increase in primary sensory afferent neuron $I_h$. We are testing the hypothesis that HCN2 SUMOylation is altered during chronic pain. Small Ubiquitin like Modifiers (SUMO) are peptides that are post-translationally added to lysine residues in target proteins to alter protein-protein interactions. Previously, we have shown HCN2 channels are SUMOylated in the mouse nervous system. Increased HCN2 SUMOylation is associated with increased HCN2 surface expression and $I_h$. SUMOylation likely regulates HCN2 interactions with auxiliary proteins that control channel surface expression and stability. Using proximity ligation assays (PLA), SUMOylated HCN2 channels were visualized as fluorescent puncta that varied in size from 1-45 pixels. Control experiments showed that the number of puncta/DRG neuron was significantly increased in positive (antibodies included) vs negative (antibodies omitted) sections (t-test $p=0.019$). In order to examine changes in HCN2 IR and SUMOylation in adult male rats, CFA was injected into one hindpaw and L4-6 DRG were obtained at 1d and 3d pi and sectioned at 20 µm. At 1d pi IR increased in all small (<30µm), medium (30-40 µm) and large (>40 µm) diameter neurons ipsilateral relative to contralateral levels (n=1 rat), and the number of small cells expressing HCN2 increased by 55%. We are currently examining HCN2 SUMOylation at 1d pi. At 3d pi, IR intensity was the same in ipsilateral and contralateral DRG, and the number of neurons expressing HCN2 was increased by 87% in small diameter neurons and was unchanged

in medium and large diameter neurons. SUMOylation was significantly increased in small but not medium or large diameter neurons from ipsilateral vs. contralateral DRG at 3d pi. Puncta size was not significantly different, however, the average number of puncta/cell increased by 78% (n=1 rat). In sum, our work suggests that HCN2 SUMOylation is increased in primary sensory afferent neurons during chronic inflammatory pain.

**Title:** TRIP8b phosphorylation is altered in epilepsy and affects HCN1 channel binding

**Authors: *K. FOOTE**[1], R. J. HEUERMANN[1], J. S. TRIMMER[3], G. T. SWANSON[2], D. M. CHETKOVICH[4]
[1]Neurol., [2]Pharmacol., Northwestern Univ., Chicago, IL; [3]Neurobiology, Physiol. & Behavior, Univ. of California, Davis, Davis, CA; [4]Neurol., Vanderbilt Univ., Nashville, TN

**Abstract:** Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are expressed within the distal dendrites of CA1 pyramidal neurons in the hippocampus, where they reduce dendritic integration and dampen neuronal excitability. Channel gating and trafficking is modulated by direct interactions with an auxiliary subunit, tetratricopeptide repeat-containing Rab8b-interacting protein (TRIP8b). Interactions between hippocampal TRIP8b and HCN1 are reduced in animal models of temporal lobe epilepsy (TLE), leading to a redistribution of HCN1 away from the distal dendrites of CA1 pyramidal neurons. The mechanistic basis for decreased association of TRIP8b and HCN1 in models of TLE is unknown. In this project, we test the hypothesis that the phosphorylation state of TRIP8 modulates the affinity of the auxiliary protein for HCN1 and that dephosphorylation contributes to TLE-associated redistribution of channels. We first carried out mass spectrometry analysis to identify relevant phosphorylation sites on TRIP8b. Our data confirmed the phosphorylation of previously published residues, as well as identified novel sites. We then generated rats with kainic acid-induced seizures and identified six phosphorylation sites on TRIP8b that are modulated after seizures. At least one of these residues is located in a region of TRIP8b that influences HCN channel function. In order to study the significance of individual phosphorylation sites, we performed cell-based assays such as co-immunoprecipitation and fluorescence polarization. Our results demonstrate that the

phosphorylation state of TRIP8b impacts the binding interaction between TRIP8b and HCN1 channels. We propose that reestablishing the phosphorylation state of TRIP8b in epilepsy will aid in restoring HCN channel properties in the epileptic hippocampus.

**Title:** Locus coeruleus activation inhibits HCN currents via alpha 2 adrenergic receptor in mesencephalic trigeminal neurons

**Authors: *J. WON**[1], S. OH[2], Y. KANG[3]
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Sch. of Dent, Seoul Nat'l Univ., Seoul, Korea, Republic of; [3]Osaka Univ. Grad. Sch. Dent., Osaka, Japan

**Abstract:** Masticatory function is coordinated by trigeminal proprioceptive inputs relayed by the mesencephalic trigeminal nucleus (MTN) neurons, which are exceptional in that they are located in the central nervous system. MTN neurons are known to show rigorous hyperpolarization induced-inward current ($I_h$) through HCN channels to control resting membrane potential, membrane resonance, and firing patterns of MTN neurons. Despite these important roles, how HCN channels are intrinsically regulated has not been elucidated. As MTN neurons receive projections from the noradrenergic locus coeruleus (LC) neurons, we investigated whether noradrenergic inputs inhibit HCN current in MTN neurons by using patch clamp analysis combined with pharmacological approaches. When MTN neurons were exposed to a2AR agonist guanabenz (GBZ), $I_h$ was significantly reduced in a dose dependent manner. This inhibition was blocked by atipamezole, an a2AR antagonist. The reduction in $I_h$ was insensitive to barium, an inward rectifying potassium channel blocker, implying that the affected $I_h$ is mainly HCN current. The activation curve of GBZ sensitive current was similar to those of sensitive to ZD7288, indicating that the affected $I_h$ is indeed from HCN channel. GBZ also induced negative shifting of the activation curve of HCN currents ($I_{HCN}$). $I_{HCN}$ inhibition was reversed by a2A AR specific blocker BRL44408, and immunohistochemical analysis further confirmed the molecular expression of a2A AR expression in MTN neurons. As DiI-labeled MTN neurons were found to receive projections from TH-positive LC neurons by immunohistochemical analysis, we

activated either multiple or single LC neurons to see if $I_{HCN}$ are reduced in adjacent MTN neurons. Microstimulation and single LC neuron firing resulted in increase of intracellular calcium in LC neurons, which was accompanied by inhibition of $I_{HCN\ in}$ MTN neurons. The inhibition of $I_{HCN}$ was positively correlated to the firing frequency of LC neurons. Our results suggest that noradrenergic input induces $I_{HCN}$ inhibition in MTN neurons. These results indicate that LC activation due to exogenic factors may alter the excitability of MTN neurons, which can lead to altered proprioceptive transmission from the masticatory system and masticatory dysfunctions.

**Title:** Coding of information in live neuronal networks reconstructed from the hippocampus

**Authors: D. POLI**[1], Y. S. VAKILNA[1], T. B. DEMARSE[2], *B. C. WHEELER[3], G. J. BREWER[4]
[1]Biomed. Engin., Univ. of California Irvine, Irvine, CA; [2]Neurol., Univ. of North Carolina, Chapel Hill, NC; [3]Bioengineering, Univ. of California San Diego, LA Jolla, CA; [4]MIND Inst. and Biomed. Engin., UC Irvine, Irvine, CA

**Abstract:** Our goal is to determinate the nature of information coding and transmission between hippocampal regions (the circuit comprised of the dentate gyrus (DG), CA3, CA1, and entorhinal cortex) to bridge the gap in understanding between the synaptic (molecular) and macroscopic (EEG or fMRI) levels. We reconstruct the trisynaptic circuit in vitro, culturing neurons dissociated from the hippocampal subregions on a multichamber device over a micro-electrode array (MEA). Micro-tunnels connect the compartments allowing axonal growth but not somata migration. We found DG axons spontaneously form connections to and drive input-dependent repeatable motifs of activity in CA3 reminiscent of in vivo network topology (Bhattacharya et al., Front. Neural Circuits, 2016). We also observed that strong axonal inputs transmitted via micro-tunnels in the native feed-forward direction (e.g., from EC into DG) evoked more target activity than that induced by feed-back propagation during site specific electrical stimulation in individual chambers (Poli et al., EMBEC & NBC, 2017). Further, the sparse temporal-spatial pattern of the highest spike rates evoked by stimulation sites in DG region at 3-5 recording sites coupled to CA3 neuron specifically coded information identifying the stimulation sources

induced in the opposite chamber. (Poli et al., Front. Neural Circuits, 2017). Functions ascribed to the hippocampal sub-regions for encoding pattern separation of the EC axonal inputs transmitted into the dentate gyrus (DG) via micro-tunnels and pattern completion from DG into the CA3 region intrinsically emerged from the networks and were passed on to downstream subregions (Poli et al., Journal of Neural Engineering, 2018). The development of the multichamber system provides a new paradigm for directly measuring axonal communication and spiking within all sub-regions simultaneously with regional specificity. Feed-forward and feedback connectivity were inferred from the direction of spike times within tunnels over two electrodes. The proportions of feed-forward and feed-back varied by subregion as did the spike dynamics. Low frequency delta, theta and gamma oscillations emerged from the networks, surprisingly robust in the axons between subregions. Thus, each stage of the hippocampal trisynaptic loop provides detailed data for understanding hippocampal computation.

**Title:** From local to global signaling in olfactory bulb granule cell dendrites

**Authors: *M. MÜLLER**[1], O. BOSCH[1], V. DARIA[2], V. EGGER[1]
[1]Univ. Regensburg, Regensburg, Germany; [2]The Australian Natl. Univ., Canberra, Australia

**Abstract:** The inhibitory axonless olfactory bulb granule cells (GCs) form reciprocal dendrodendritic synapses with mitral and tufted cells (MTCs), the main projection neurons of the olfactory bulb (OB), via large spines. These synapses mediate self inhibition of and lateral inhibition between MTCs and are substantially involved in odor signal processing. GC dendrites are highly excitable in multiple ways: Synaptic inputs to individual GC spines can generate $Na^+$ spikes that are localized to the spine head, and stronger activation results in globally propagating dendritic signals that encompass both low-threshold $Ca^{2+}$ spikes (LTS) and $Na^+$ spikes.
To optimally investigate the transition from local to global signaling, we implemented a holographic two-photon uncaging system which allows simultaneous photostimulation of multiple spines in 3D in acute brain slices. We first tested the function of the holographic system via photolysis of caged glutamate at spines along basal dendrites of cortical pyramidal cells (PC) in juvenile rat brain slices. Cells were recorded from and filled with calcium-sensitive

fluorescent dye (OGB-1) via somatic patch pipettes.
Next, we investigated the conditions for $Na^+$ spike generation. Although GC resting potentials are hyperpolarized compared to PCs by approx. -10 mV, their $Na^+$ spike threshold potential requires similar numbers of simultaneously activated spines (9 ± 2, n = 24 in 23 GCs vs 10 ± 1, n = 7 in 4 PCs). Within the subthreshold regime GCs can display both sub- and supralinear integration of inputs, depending on the relative distance between the stimulated spines and their proximity to the mitral cell layer. As to low-threshold $Ca^{2+}$ spikes, activation of a significantly lower number of spines already suffices to elicit dendritic $Ca^{2+}$ transients as detected by two-photon $Ca^{2+}$ imaging in dendritic sections remote from the stimulated spines (5 ± 2 spines, n = 24 in 23 GCs, $P < 0.001$ vs $Na^+$ spike). We show that these $Ca^{2+}$ signals are able to propagate far along the dendrite and thus might correspond to the previously observed LTS. Occasionally, the somatic membrane potential showed so-called spikelets that indicate dendritic $Na^+$ spikes (n = 4 GCs).
These findings highlight the broad computational power of GC dendrites and elucidate the precise conditions underlying the transition from local to global signaling.

**Title:** Inhibitory control of the prefrontal cortex by the claustrum

**Authors: *J. C. JACKSON**[1], M. M. KARNANI[2], B. V. ZEMELMAN[3], D. BURDAKOV[2], A. K. LEE[4]
[1]Ashburn, VA; [2]The Francis Crick Inst., London, United Kingdom; [3]Ctr. for Learning and Memory, Univ. of Texas, Austin, TX; [4]HHMI Janelia Res. Campus, Ashburn, VA

**Abstract:** The claustrum is a small subcortical nucleus that has extensive excitatory connections with many cortical areas. While the anatomical connectivity from the claustrum to the cortex has been studied intensively, the physiological effect and underlying circuit mechanisms of claustrocortical communication remain elusive. Here we show that the claustrum provides strong, widespread, and long-lasting feedforward inhibition of the prefrontal cortex (PFC) sufficient to silence ongoing neural activity. This claustrocortical feedforward inhibition was predominantly mediated by interneurons containing neuropeptide Y, and to a lesser extent those containing parvalbumin. Therefore, in contrast to other long-range excitatory inputs to the PFC,

the claustrocortical pathway is designed to provide overall inhibition of cortical activity. This unique circuit organization allows the claustrum to rapidly and powerfully suppress cortical networks and suggests a distinct role for the claustrum in regulating cognitive processes in prefrontal circuits.

**Title:** *In vivo* evidence of spatio-temporal spike pattern propagation in feedforward network of vibrissal primary somatosensory cortex

**Authors: *H. JANG**, J. KWAG
Dept. of Brain and Cognitive Engin., Korea Univ., Seoul, Korea, Republic of

**Abstract:** Spikes transduced from whisker movement in the vibrissal primary somatosensory cortex (vS1) *in vivo* have spatio-temporally complex spike patterns composed of neural codes such as rate code (firing rate) and temporal code (precise spike timing) to encode somatosensory information. For such information to be useful, *in vivo* complex spike pattern should be preserved in the downstream neurons across layers of canonical feedforward network (FFN, Layer (L)4->L2/3->L5->L6). To directly investigate whether whisker-evoked spatio-temporally complex spikes can propagate across the canonical FFN, single-unit activities were recorded from L1 to L6 of vS1 using a multi-electrode probe (NeuroNexus) during 3s whisker stimulation (12 Hz) in anesthetized mice. The propagation of *in vivo* spike pattern was quantified by analyzing the coherence and instantaneous similarity between spike patterns in L4, the main recipient of sensory inputs, and that in other downstream layers (L2/3, L5, and L6) of the canonical FFN. Through coherence analysis, we found that a subset of downstream units in L2/3, L5, and L6 preserved *in vivo* spike pattern of L4, indicating reliable propagation of whisker-evoked *in vivo* spike pattern. To further investigate whether rate and temporal structure of the spike pattern were propagated, we analyzed the instantaneous firing rate and instantaneous similarity and found that both rate and temporal structure of spikes were preserved in

downstream layers. Our results demonstrate for the first time that the whisker-evoked neural codes propagate across the canonical FFN of vS1, suggesting that such propagation of neural code might serve as a key mechanism for somatosensory information processing.

**Title:** Involvement of hilar mossy cells in the functional coupling between CA3 and dentate gyrus during sharp wave-ripple activity

**Authors: *A. SWAMINATHAN**[1], I. WICHERT[2], D. SCHMITZ[1,2,3,4,5], N. MAIER[1]
[1]Neurosci. Res. Center, Charité Universitäts, Berlin, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Berlin, Germany; [3]Berlin Inst. of Hlth., Berlin, Germany; [4]Ctr. for Neurodegenerative Dis. Berlin, Berlin, Germany; [5]Einstein Ctr. for Neurosciences, Berlin, Germany

**Abstract:** The dentate gyrus (DG) is considered as the hippocampal input gate for the information arriving from the entorhinal cortex. Embedded into the DG network are two excitatory cell types – granule cells, which project to the CA3, and hilar mossy cells (MCs), which receive input from both, granule cells and feedback projections from CA3 pyramidal cells (PCs). Postsynaptic targets of MC projections include granule cells and various interneurons in both the same and in the contralateral hemisphere of the brain. The role of MCs during rhythmic population activity, and in particular during sharp-wave/ripple complexes (SWRs), has remained largely unexplored. SWRs are prominent field events in the hippocampus during slow wave sleep and quiet wakefulness, and they are involved in memory consolidation and future planning. We used an *in vitro* approach to investigate MC activity and -activation during SWRs. With simultaneous CA3 field potential– and cell-attached recordings from MCs we find that a significant fraction of MCs (47%) is recruited into the active neuronal network during SWRs. Moreover, MCs receive pronounced, compound ripple-associated synaptic input where both excitatory and inhibitory components are phase-coherent with and delayed to the CA3 ripple. Finally, we demonstrate that a significant fraction (66%) of tested granule cells receive SWR-associated excitatory inputs that are delayed compared to MCs, indicating an indirect activation of granule cells by CA3 PCs via MCs. Together, our data suggest a role for MCs in the

distribution of SWR-associated synaptic activity from the CA3 area onto diverse targets in the ipsi- and contralateral DG network.

**Title:** Identifying avalanches in simulated mouse primary motor cortex (M1)

**Authors: *D. W. DOHERTY**[1], S. DURA-BERNAL[2], S. A. NEYMOTIN[3], W. W. LYTTON[4]
[1]SUNY Downstate Med. Ctr., Pittsburgh, PA; [2]Physiol. and Pharmacol., State Univ. of New York Downstate Med. Ctr., Brooklyn, NY; [3]Dept. Neurosci., Brown Univ., Providence, RI; [4]SUNY Downstate, Brooklyn, NY

**Abstract:** Connectivity among the neurons participating in avalanches recorded in vitro and in vivo has been unknown. We set out to observe avalanches in a realistic simulation of a cortical column from the mouse primary motor cortex (M1) and to investigate mechanisms underlying the generation of avalanches. We applied sustained 0.23nA current to a 40um x 1350um x 40um volume of a 300um x 1350um x 40um simulated cortical column. About 2.2s after stimulus onset, self-sustained asynchronous irregular (AI) activity appeared. We binned spikes into 1ms bins during AI activity and found no gaps in spiking when all of neurons were included. We decided to look for avalanches in populations by cell type. Using the same stimulus protocol, Pyramidal Tract neurons in layer 5B (PT5B) were responsive only after the onset of AI activity across the simulated cortical column. PT5B activity in raster plots resembled avalanches so we binned PT5B responses into 1ms bins and computed avalanches as continuous activity every millisecond from one neuron to next until activity stoped for 1ms or more. The PT5B population power law value was -1.97 from 7.2s of AI activity. The total number of avalanches observed was 1,122 and the longest duration was 50ms.We applied 0.22nA for 5s to the simulated cortical column in the same manner as above to see if PT5B avalanches remained if the stimulus was turned off. AI activity appeared at 8s or 3s after the stimulus was turned off. PT5B responses were placed into 1ms bins from a 2s period resulting in 249 avalanches, 32ms longest duration avalanche, and power law value of -2.22. The same experiment with 180s runtime resulted in 172s of AI activity, 27,938 avalanches, 50ms longest duration avalanche, and power law value of -2.74. Avalanche number 4 shown in the accompanying diagram has a duration of 6ms (from 8,514ms to 8,519ms) and size of 15 unique neurons. The red lines in the diagram show direct

connections between the PT5B neurons. Our ability to record from every neuron in our simulated M1 enables us to investigate connectivity underlying avalanche activity in normal and diseased brain.

**Title:** Peak activation of the CA2 subregion of the hippocampus precedes peak activation of CA3 following perforant-path stimulation

**Authors: *C. A. WILHITE**[1], R. S. WITTE[2], S. L. COWEN[3]
[1]Physiological Sci., [2]Med. Imaging, [3]Psychology, The Univ. of Arizona, Tucson, AZ

**Abstract:** Episodic memory formation requires accurate information processing by the entorhinal-hippocampal network. Recent studies using single recording electrodes in guinea pigs and in slice preparation have shown that the CA2 subregion of the hippocampus receives direct input from the entorhinal cortex (EC), indicating a distinct role of CA2 in the processing of signals within the entorhinal-hippocampal circuit. Here we used multiple penetrations of high-density silicon probes to analyze evoked potentials and current source density (CSD) in the hippocampus of an anesthetized rat. Penetrations were performed across the entire transverse axis of three cross-sections of the dorsal hippocampus, and local-field measurements were acquired in response to electrical stimulation of the medial entorhinal afferents (medial perforant-path). We found that the peak of the CSD response in CA2 preceded the peak response in distal CA3 (Student's *t* test, $p < 0.001$, $d > 1.0$, $n = 10$ trials) across all sections. Cross-correlation measures between regions revealed a > 1 ms lag between the peak source in CA2 and the peak source in distal CA3 across all sections. Furthermore, this lag in time of the peak CSD between CA2 and distal CA3 was larger at low (300 µA) compared to high (750 µA) stimulation intensities. Lastly, the amplitude of the peak CSD in CA2 was larger than the peak CSD in distal CA3 for low and high stimulation intensities ($p < 0.001$, $d > 1.0$) across all sections. Such fast and robust activation of CA2 upon stimulation of the entorhinal afferents *in vivo* supports the claim that information processing in CA2 may occur in parallel with the classical trisynaptic circuit (EC --> DG --> CA3 --> CA1). Further studies are needed to determine whether these CA2 activation patterns are behaviorally significant in the waking animal.

**Title:** Visuomotor planning increases the magnitude of synaptically-mediated evoked potentials in macaque frontal cortex during optogenetic stimulation in parietal cortex

**Authors: *B. FERRENTINO**[1], R. A. SHEWCRAFT[1], B. PESARAN[2]
[1]Ctr. for Neural Sci., [2]New York Univ., New York, NY

**Abstract:** The frontoparietal pathway plays a role in flexible, cognitive behaviors such as attention, decision making, and movement planning. Coherent neuronal dynamics in frontal and parietal cortex vary with task demands. Furthermore, frontoparietal networks are both functionally and anatomically connected in primates. Additionally, we have shown evidence of effective connectivity in frontoparietal circuits from measurements taken in frontal cortex during optogenetic stimulation of posterior parietal cortex. However, whether behaviorally driven changes in frontal cortical dynamics result from changes in frontoparietal effective connectivity is unknown. Here we optogenetically stimulate PPC while simultaneously recording from frontal cortex in an awake macaque during both reach and saccade tasks and quiet sitting without controlled behavior and show that frontoparietal effective connectivity varies across conditions. We implanted one rhesus macaque with a semi-chronic, 96-channel array of movable electrodes placed over frontal cortex. We also added a chamber system over PPC, allowing for injection of AAV-hSyn-ChR2(h134R)-EYFP. We stimulated PPC with 500 ms long pulse trains of 10 ms wide pulses at a rate of 20 pulses/s with Poisson distribution. We performed stimulation during the delay period of a delayed reach and delayed saccade tasks and while the animal was sitting quietly without being engaged in an explicit task. To assess how frontoparietal effective connectivity changes with task engagement, we compared the stimulation-pulse-triggered, synaptically-mediated evoked potentials in frontal cortex across both conditions. We found that stimulation of the superior parietal lobule generated synaptically-mediated evoked potentials in frontal cortex on 34 of 96 total electrodes. The driven responses were located in motor cortex, consistent with known anatomical and functional connectivity of frontoparietal circuits. The amplitude of pulse-triggered evoked potentials in the frontal cortex significantly changed by -23.01 - 834.19% on 12 out of 34 electrodes with evoked potentials when synaptic input from PPC arrived during the delay period of the task compared to quiet rest ($p<0.05$; permutation test). This increase in evoked response magnitude across a large-scale circuit suggests that effective connectivity of the frontoparietal network is strengthened when the subject is engaged in preparing a visually guided movement.

**Abstract:** Genetically encoded voltage indicators (GEVIs) enable longitudinal monitoring of neuronal circuit dynamics of identified cell populations. GEVI's membrane delimited signals arise largely from the neuropil where dendritic and axonal membranes of many cells intermingle, hence optical signals from densely-labeled neuronal processes cannot be allocated to individual neurons. It was previously established that optical signals arising from population imaging with externaly applied voltage-sensitive dyes do not report neuronal action potentials, but rather they report compound synaptic potentials. Optical signals in GEVI-labelled animals are also dominated by synaptic potentials. Here, we take advantage of the synaptic-potential-bias in GEVI optical recordings to analyze the synaptic connectivity of subplate neurons of developing cerebral cortex. Subplate neurons are the oldest and most mature (pioneer) cortical cells residing in a transient subplate zone. The zone is transient because the entire zone with subplate neurons disappears after birth. During the in utero development, before cortical layers 4, 3 and 2 have been formed, the subplate neurons are thought to receive and nurture young thalamocortical projections. In neonatal (P02-P06) mice, we analyzed the spread of synaptically-evoked depolarization across the subplate zone using synaptic stimulations delivered in three characteristic locations: A) white matter; B) subplate zone and C) cortical plate (where migrating neurons assume their positions at this age). The multi-site experimental measurements are analyzed to determine the strength and spatial propagation of synaptic inputs projecting from cortical plate into the subplate zone and compare it against those projecting from the white matter into the subplate zone (putative thalamocortical). We discuss the use of GEVI brain slice imaging as an experimental tools for dissection of brain circuits. Support, MH109091.

**Abstract:** Slow waves (high power waveforms 0.5-2 Hz for at least one cycle) [SW] are a defining feature of EEG for NREM sleep, occurring more frequently with increasing sleep depth - none being observed during epochs of NREM1, while >20% of NREM3 epochs consist of SW activity. The SW is related to neuronal activity, whereby one phase of the oscillation is associated with neuronal quiescence, and the other an increase in neuronal activity, referred to as down- and up-states, respectively. Spindles (high power waveforms 10-16 Hz lasting several cycles) are another prominent feature of sleep during NREM2-3. Not only are both of these waveforms characteristic of sleep, but increases in the occurrence of SWs and/or spindles are associated with improvements in memory, and similarly the relative occurrence of these waveforms decreases with age and in subjects with various cognitive disorders. Furthermore, there is a strong temporal coupling between these two waveforms whereby spindles tend to occur during the up-state of SWs. Interestingly, the more synchronized spindles are to the up-states the better memory dependent task performance is, and likewise, this phase-locking becomes less synchronized with age. Studies have also revealed that each waveform exhibits a spatial structure, propagating as traveling waves with preferred directions. In this respect, the spindle has been shown to occur primarily as a rotational wave beginning in the temporal lobe and spiraling in a posterior-to-anterior fashion towards the frontal lobe. In contrast, while the topographical structural of the SW has been studied in less detail, it is often characterized as propagating in the reverse - anterior-to-posterior - direction. Given the importance of SW-spindle phase-locking it seems counter-intuitive that these waveforms should propagate along opposite trajectories, so to investigate how these waves might be decoupled in space, and yet still be synchronized in time, we present a method to compare the propagation of these waveforms. We hypothesize, that during instances of SW-spindle coupling, an extended portion of brain becomes transiently synchronized in a SW downstate propagating in an anterior-to-posterior manner; this SW is then focally disrupted at the distal wavefront by a spindle, while the down-state is prolonged in more anterior regions until the spindle reaches its location.

**Title:** Input-specific synaptic location and function of the alpha5 GABAA receptor subunit in the mouse CA1 hippocampal neurons

**Authors: *S. AMALYAN**, E. MAGNIN, R. FRANCAVILLA, L. DAVID, L. TOPOLNIK
Biochem., Univ. Laval, Quebec, QC, Canada

**Abstract:** Hippocampus-dependent memory and learning processes are coordinated by GABAergic inhibition, which is provided by a heterogeneous population of interneurons via activation of specific sub-types of GABA receptors. The alpha5-$GABA_AR$ subunit (α5-$GABA_AR$) is highly expressed in the hippocampus of the mouse, monkey and human brain. It has been reported that, in the CA1 pyramidal cells, this subunit is predominantly located at extrasynaptic sites, where it is responsible for the generation of tonic inhibitory conductance. However, little is known about the synaptic expression of the α5-$GABA_AR$ and its location site-specific function. We examined the cell- and synapse-specific distribution of the α5-$GABA_AR$ in the CA1 stratum oriens/alveus (O/A) using a combination of immunohistochemistry, whole-cell patch-clamp recordings, and optogenetic stimulation in hippocampal slices. In addition, the input-specific role of the α5-$GABA_AR$ in spatial learning and anxiety-related behavior was studied using behavioral testing. Using optogenetic activation of distinct inhibitory inputs to O/A interneurons, we demonstrate that the vasoactive intestinal peptide (VIP+) and calretinin (CR+)-expressing inputs are sensitive to the α5-$GABA_AR$ inverse agonists (L-655,708 and MRK-016). These results were validated by immunohistochemical labeling, showing that the α5-$GABA_AR$ subunit was preferentially targeted to the inhibitory synapses made by the VIP+ and CR+ inputs onto somatostatin (SOM+)-expressing interneurons. In contrast, synapses made by the parvalbumin (PV+)-positive inhibitory inputs to O/A interneurons showed no or little α5-$GABA_AR$. Finally, chemogenetic silencing of VIP+ inputs showed that the α5-$GABA_AR$ expressed at this input is dispensable for spatial learning but may play a role in the anxiety-like behavior. In summary, our results show that the α5-$GABA_AR$ subunit exhibits a cell- and input-specific expression in the CA1 hippocampus, being mainly expressed in SOM+ interneurons and targeted to synapses formed by the VIP+ and CR+ inputs. Furthermore, phasic inhibition via VIP+ input to interneurons plays a predominant role in the regulation of the anxiety-like behavior, whereas the α5-$GABA_AR$ subunit tonic inhibition may control spatial learning.

**Abstract:** In the hippocampus, a highly specialized population of interneuron-specific (IS) inhibitory cells coordinates the activity of local inhibitory circuits. While disinhibition is thought to play a critical role in hippocampal learning, the contribution of IS cells to network activity remains unclear. Here we reveal the synaptic properties of CA1 type 3 vasoactive intestinal peptide/calretinin-co-expressing IS cells (IS3) and demonstrate their recruitment during different network states in awake mice. Using patch-clamp recordings and two-photon glutamate uncaging, we found that IS3 cells fire spikes in response to repetitive or spatially clustered excitatory inputs. In particular, both the Schaffer collateral and the temporoammonic pathways could drive IS3 cell firing in vitro. Using synaptic models of these layer-specific inputs and a computational IS3 cell model with in vivo-like levels of synaptic activity, we predicted that IS3 cells could be driven to spike rhythmically during theta oscillations, as well as transiently during sharp-wave ripples. We also predicted inhibitory populations that could reduce or silence IS3 cell recruitment during these network states. Furthermore, two-photon calcium imaging in awake mice revealed a range of IS3 cell activities across the behavioral states. As a rule, somatic calcium transients (CaTs) increased with locomotion, often at specific running speeds, which persisted across recording sessions. In addition, significant CaTs were detected during immobility but not coupled to sharp-wave ripples. Thus, while synaptic properties of IS3 cells are predicted to generate a particular output, additional factors may modulate the cell recruitment during different behavioral and network states.

**Title:** Hippocampal long-range VIP-GABAergic neurons projecting to subiculum comprise a heterogeneous population of cells that may coordinate contextual learning

**Authors: *R. FRANCAVILLA**, X. LUO, E. MUNOZ, O. CAMIRÉ, L. TOPOLNIK
CHUQ, Quebec, QC, Canada

**Abstract:** The formation and recall of cognitive representations require fast coordinated communication among multiple cortical areas. Interestingly, anatomical data point to the existence of long-range GABAergic circuit elements that could account for cross-regional disinhibition between the hippocampus and functionally connected regions. Despite their potentially important role in coordinating rhythmic activity among relevant brain areas, very little is known about the cell types, their connectivity and their functional role in hippocampus-dependent memory. Here, using a combination of retrograde tracing, anatomical analysis, and optogenetics we have identified several distinct types of hippocampal GABAergic cell projecting to subiculum that express vasoactive intestinal peptide (VIP-LRPs). First, retrograde tracing using *cre*- and combinatorial *cre-/flp*-dependent strategies showed that VIP-LRPs represent a heterogeneous population with cells located in different CA1 hippocampal layers and expressing different markers such as *m2* muscarinic receptor, calretinin and enkephalin. Channelrhodopsin2-based mapping of VIP-LRP targets revealed that these cells are interneuron-selective in the CA1 region but target both pyramidal cells and interneurons in the subiculum. To further study their functional role in hippocampus-dependent memory, such as the novel object recognition task and the contextual fear conditioning, we applied the optogenetic antidromic activation of VIP-LRPs validated in vitro to in vivo experiments. Our data showed that activation of VIP-LRPs had no impact on the recognition memory but impaired the fear learning in the context-dependent manner. Together, these results identify the VIP-LRP neurons as a heterogeneous cellular population, which, through its region- and target-specific innervation, may control the information flow along the hippocampo-subicular axis and coordinate mnemonic processing associated with contextual learning.

**Abstract:** **Background:** During sleep, the electrophysiological activity of the hippocampus and the medial prefrontal cortex (mPFC) becomes coordinated, which is likely a physiological basis for the transition of short-term memory into long term storage. The hippocampus sends direct but limited excitatory afferents to the mPFC although no direct feedback connections from the mPFC to hippocampus have yet been described and no reliable brain functions can be executed without feedback activity. The ***nucleus reuniens*** of the ventral midline thalamus receives mPFC afferents and projects to the hippocampus, suggesting that it may serve as a conduit for mPFC control of hippocampal activity during sleep. Therefore, we hypothesized that the cortical slow oscillation in mPFC could drive synaptic activity in reuniens neurons. **Methods:** Using sharp glass micropipettes and tungsten microelectrodes, we obtained intracellular recordings of identified reuniens neurons together with local field potential recordings of the mPFC and the hippocampus in mice anesthetized with ketamine-xylazine. **Results:** All recorded reuniens neurons revealed membrane potential depolarization with progressive buildup of synaptic activities during the active states of the mPFC slow oscillation. During these states, the recordings of most reuniens neurons displayed sharp rising depolarizing events, likely driver EPSPs occasionally accompanied with spikes. **Conclusions:** The results confirm our hypothesis that the cortical slow oscillation effectively drives neurons of the nucleus reuniens of the thalamus. The cortical drive to the reuniens is likely the main source of frontal cortical activity mediating feedback to the hippocampal formation during the slow oscillation.

**Authors: *G. D. DUMONT, ESQ**[1], B. S. GUTKIN[2]
[1]Ecole Normale Superieure, Paris, France; [2]Group For Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France

**Abstract:** Macroscopic oscillations of different brain regions show multiple phase relations that are persistent across time. Such *phase locking* is believed to be implicated in a number of cognitive functions and is key to the so-called Communication Through Coherence (CTC) theory for neural information transfer. Multiple cellular level mechanisms influence the network dynamic and structure the macroscopic firing patterns.
Key question to identify the biophysical neuronal and synaptic properties that permit such motifs to arise and how the different coherence states determine the communication between the neural circuits.
We use a semi-analytic modeling approach to investigate the emergence of phase locking within two bidirectionally delayed-coupled spiking circuits with global gamma band oscillations. Internally the circuits consist of excitatory and inhibitory quadratic integrate and fire cells coupled synaptically in an all-to-all fashion. The circuits can show global the pyramidal-interneuron (PING) or interneuron gamma (ING) rhythms. Multiple circuits can also be intercoupled together with reciprocal synaptic connections with variable delays and targeting excitatory and/or inhibitory neurons.
Using mean-field approach together with an exact reduction method, we break down each spiking gamma network into a low dimensional nonlinear system. We then derive the macroscopic phase resetting-curves (mPRCs) that determine how the phase of the global oscillation responds to incoming perturbations. We find that depending on the gamma type (PING or ING) and perturbation target (excitatory of inhibitory neurons), the mPRC can be either class I (purely positive) or class II (by-phasic).
Hence we show analytically how incoming excitation can either promote spiking (advancing the phase) or retard the global oscillation.
We then study the emergence of macroscopic coherence states (phase locking) of two weakly

synaptically-coupled gamma-networks by deriving a phase equation for the coupled system. This phase equation links the synaptic mechanisms to the coherence state of the system; notably the determinant part played by the delay and coupling strength in the emergent variety of coherence modes. We show that the delay is a necessary condition for symmetry breaking, i.e. a non-symmetric phase shift between the macroscopic oscillations and that the effect is controlled by the synaptic weights of the pyramidal neurons. Using this analysis we find that a whole host of phase-locking relationships can exist, depending on the coupling strength and delay, potentially giving an explanation to the experimentally observed variety of gamma phase-locking modes.

**Title:** Measured connectivity of bursting neuronal networks with and without inhibition

**Authors: *H. LEMKE**, A. NANTWI, T. NGUYEN
The Col. of New Jersey, Ewing, NJ

**Abstract:** Neuronal networks in dissociated cultures spontaneously generate synchronous activity known as network bursting, which is characterized by the firing of nearly all neurons every 30−100 seconds. There has been much research directed toward understanding the initiation of bursts, as well as the role of underlying network topology. Previously, we used a novel approach [1] that combines laser scanning photostimulation (LSPS) with calcium (Ca) imaging of a large cell-population to directly measure the functional connectivity of bursting neuronal networks. This approach permits rapid mapping of excitatory connections in networks consisting of 150-200 neurons and 1500-2000 connections. From these connectivity maps, various network properties are extracted.
In the present study, we used this approach to explore the role of inhibitory connections in network bursting. Bursting activity was recorded for 5 minutes before mapping the connectivity of 60 neurons. Next, bicuculline, a $GABA_A$ receptor antagonist, was added to the bath to block inhibitory connections. Activity was recorded for ten minutes, after which connectivity was mapped again. In accord with other reports, we observed that with the addition of bicuculline, fluorescence amplitudes increased while bursting rates decreased (see Fig. 1a and 1b). Analysis of connectivity maps (see Fig. 1c and 1d) revealed that both the number of excitatory connections and the average degree increased. Interestingly, the modularity coefficient and clustering coefficient stayed relatively the same, suggesting that community structure does not depend on network type.

[1] Nguyen T., O'Connor K., Sheth K., Bolle N.: Mapping functional connectivity of bursting neuronal networks. Applied Network Science 2(15), 1-15 Figure 1. Network bursting of a neuronal network composed of (a) both excitatory and inhibitory connections and (b) only excitatory connections (40 µM bicuculline added). Scale bars: delta F/F= 10%(vertical), 50 sec (horizontal). Corresponding connectivity maps (c) with and (d) without inhibition. Scale bar: 200 µm.

**Title:** Spike-timing-dependent plasticity effect on the temporal patterns of neural synchronization

**Authors: J. ZIRKLE**[1], *L. L. RUBCHINSKY[2,1]
[1]Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

**Abstract:** Synchronization of neural activity has been associated with several neural functions. Abnormalities of neural synchrony may underlie different neurological and neuropsychiatric diseases. Neural synchrony in the brain at rest is usually very variable and intermittent. Experimental studies of neural synchrony in different neural systems report a feature which appears to be universal: the intervals of desynchronized activity are predominantly very short (although they may be more or less numerous, which affects average synchrony). This kind of short desynchronization dynamics was conjectured to potentially facilitate efficient creation and break-up of functional synchronized neural assemblies.

Cellular, synaptic, and network mechanisms of the short desynchronizations dynamics are not fully understood. In this study we use computational neuroscience methods to investigate the effects of spike-timing-dependent plasticity (STDP) on the temporal patterns of synchronization. We employed a minimal network of two simple conductance-based model neurons mutually connected via excitatory STDP synapses. The dynamics of this model network was subjected to the time-series analysis methods used in prior experimental studies.
We found that STDP may alter synchronized dynamics in the network in several ways depending on the time-scale of action of plasticity. However, in general, the action of STDP tends to promote dynamics with short desynchronizations similar to those observed in experiments. Complex interplay of the cellular and synaptic dynamics may lead to the activity-dependent adjustment of synaptic strength in such a way as to facilitate short desynchronizations in the activity of synaptically coupled intermittently synchronized neurons.

**Abstract:** Pathological alterations in the balance between excitation and inhibition have been suspected for a long time to be responsible for aberrant neuronal processing in adult cortical circuits. Accordingly recent publications have proposed the implication of defective inhibition in the etiology of various pathologies including epilepsy, depression, schizophrenia and autism. In vitro experiments have suggested that defective function of the K-Cl co-transporter KCC2 was responsible for a reversed polarity of GABAergic synaptic transmission from inhibitory to excitatory, participating in epileptogenesis in animal models as well as in human epileptic tissue. However, this hypothesis is not clearly demonstrated in vivo. Treatment with the diuretic

bumetanide, which also reduces the accumulation of $Cl^-$ ions in neurons through the inhibition of NKCC1, was found to reduce seizures in epileptic animal models. But first, the relevance of in vitro assessment of the polarity (i.e. excitatory vs inhibitory) of GABAergic transmission for the in vivo condition has been put into question. And second, bumetanide has a limited bio-availability in the brain due to poor blood brain barrier penetration, and it is therefore unclear if its action was indeed due to a restoration of neuronal $Cl^-$ gradient. In order to test the hypothesis of excitatory GABAergic transmission in epilepsy with a direct approach in vivo, we use multi-site silicon probe recordings and investigate the mono-synaptic interactions between pyramidal cells and interneurons in the hippocampus of adult mice in vivo, after induction of seizures by injection of the convulsant kainic acid (KA). Our preliminary results suggest that the perisomatic GABAergic inhibition of pyramidal cells is indeed deficient in a subset of neurons and KA-treated mice. Therefore, excitatory effects of GABA might not be a general phenomenon in epilepsy, but rather affect the synaptic transmission between specific neuronal populations in cortical circuits, which may have serious implications for the identification of therapeutical targets against epilepsy.

**Abstract:** Sleep spindles are waxing and waning 10-16 Hz neural oscillations that last for 0.5-2 s during non-REM sleep. These network events are associated with memory consolidation but little information is available regarding how they may coordinate unit activity to facilitate

plasticity. We investigated whether sleep spindles modulate unit activity with timing that may facilitate spike-timing dependent plasticity, a mechanism that leads to long-term potentiation when the pre-synaptic spike occurs 25 ms before the post-synaptic spike. We analyzed local field potentials and unit activity in human intracranial microelectrode recordings. Spikes were sorted into units, which were then classified as putative excitatory, inhibitory, or multi-units based on waveforms, autocorrelation, and burstiness. We found that during sleep spindles there is a phase-dependent upregulation of unit spiking that varies across cell types. Furthermore, we discovered that during sleep spindles a given unit pair is more likely to fire within the 25 ms window that facilitates spike-timing dependent plasticity, and that this effect is not explained simply by the increased firing rate. Together, these results may suggest that sleep spindles modulate unit activity in an organized manner to facilitate spike-timing dependent plasticity, a critical neuronal mechanism underlying memory consolidation.

**Abstract:** We summarize our theoretical and computational work that addresses mechanisms responsible for initiation, maintenance and suppressing of spontaneous population activity in cortical networks. The models are primarily motivated by in vitro studies, however the examined mechanisms have more general implications. Three aspects of this work are emphasized: 1) a framework connecting properties of neuronal morphology with graph theoretic concepts of connectivity, 2) a study examining effects of structured connectivity to spontaneous activity in neuronal population, 3) the most recent work integrating these previous results with more detailed models and experimental data. Part 1) describes our work on structural organization of

connectivity, deriving the relation between morphometric properties of individual neurons and the graph theoretic description of network structure both in approximative models with mean-field-type characterization of neuron morphology (Aćimović et. al, 2015) and models with statistically accurate neuronal morphology (Aćimović et. al, 2011). Starting from a homogeneous population, we show how neurite morphology alone constrains the connectivity. More recent analysis also considers non-homogeneities that lead to structures like hub networks and networks containing clusters of strongly coupled neurons. Part 2) incorporates these models of connectivity into spiking neuronal networks to examine the effect of structured connectivity on network activity. The activity consists of spontaneous network bursts (e.g. like those recorded in dissociated in vitro cultures), the periods of intensive synchronized activity spreading across neuronal population, separated by low-activity intervals. Network bursts are quantified by their frequency and internal structure. Our previous work (see Mäki-Marttunen et. al; 2013) examines how connectivity and neuronal model complexity affect internal burst structure. Our recent unpublished work includes the properties of connectivity that support bursting initiation. Part 3), our most recent study, combines these previous results with more precise description of neuronal dynamics and suitable model fitting protocols to quantitatively reproduce statistics of experimental data. The role of cellular model complexity, short-term presynaptic activity, the contribution of most common glutamatergic and GABAergic synaptic receptors, as well as the details of network connectivity are included in the model. The obtained results are discussed and compared to the relevant models from the literature summarized in our recent publication (Manninen et. al, 2018).

**Abstract:** The acetylcholine system plays important behavior function including learning & memory and attention. Basal forebrain cholinergic neurons are the major source of cortical acetylcholine; its projection is widely projected and form different types of synapse with the cortical neurons. We combined with in vivo optogenetics and multi-channel electrophysiological techniques, selective specific regulation of basal forebrain cholinergic neuron activity in transgenic CHAT-Cre mice, while using multi-electrophysiological techniques to record medial prefrontal cortex neurons activities and field potential oscillations. We first Identified three different types of the cholinergic modulated cortex neurons types: excited pyramid neurons, inhibited interneurons and excited interneurons based on the cortical neurons response when the light stimuli of the BF cholinergic neurons. The cortical neurons responses modulated by the acetylcholine release were also state dependent only present during wake state not in sleep stage. Further analysis demonstrated that the excited interneurons response only occurs during high 30-100Hz Gamma oscillations. Our data provide the general neuronal mechanism that how the cortical neuron ensembles modulated by the acetylcholine release during different states in free moving animals. Suggestion that the gamma oscillation is the gate of the interneuron activation of the acetylcholine release in mPFC.

**Abstract:** The hippocampal theta oscillation typically occurs during exploratory behaviours and REM sleep and has been linked to learning and memory. The medial septal region of the basal forebrain has been identified as responsible for theta generation. According to the leading theory, rhythmically active individual 'pacemaker' cells, firing at their own frequencies, are synchronized to a common frequency and thus give rise to the hippocampal theta. However, experiments in which multiple septal neurons were recorded concurrently are rare and therefore the mechanisms of septal theta synchronization are still debated.
To address this, we aimed to decipher the network mechanisms of rhythm genesis in the medial septal circuit by analysing multiple simultaneously recorded medial septal neurons from an anesthetized rodent model of hippocampal theta oscillation including both rats and mice. Anaesthetized mouse recordings were performed with state-of-the-art high density silicon probes. Additional recordings were performed in awake drug-free mice. We analysed the emergence of theta-synchrony evoked by sensory stimulation (anesthetized) or forming spontaneously (awake) within the medial septal network. A group of medial septal neurons showed theta rhythmic firing irrespective of the dominant hippocampal oscillation and exhibited increased phase synchrony during theta (putative 'pacemaker' neurons), sustaining their original frequency. This contradicts to the aforementioned theory of frequency-synchronization of septal units as a key mechanism underlying theta generation. As an alternative, increased timing precision of action potentials within the theta cycle may be responsible for the observed stronger synchrony. A second group of neurons fired synchronously at lower delta frequencies while a third group of cells followed the dominant hippocampal oscillation.
To better understand the roles of the different rhythmicity groups described above, we also built a minimal network model. The building blocks were neurons that exhibited rhythmic activity in either delta or theta frequency range and showed a characteristic H-current known to be expressed by septal pacemaker neurons. We showed that a minimal network model of inhibitory pacemaker neurons and excitatory 'follower' neurons can capture multiple features of the septal theta generating network.

**Title:** Neuronal population activity underlying difference of spontaneous wakefulness and anesthesia network dynamics in layer 2/3 somatosensory cortex

**Authors: *B. RAHSEPAR**, J. NOUEIHED, F. R. FERNANDEZ, J. A. WHITE
Biomed. Engin., Boston Univ., Boston, MA

**Abstract:** Although the behavioral effects of anesthetics are obvious, the neuronal network mechanisms underlying this difference remain elusive. To understand how network activity is changed under anesthesia compared to spontaneous awake state, we imaged calcium dynamics of different neuronal populations in layer 2/3 of mouse somatosensory cortex in both states. Our preliminary data shows that firing rate of excitatory cells are significantly lower under Ketamine-Xylazine anesthesia whereas the maximum cross-correlations between the neurons are significantly higher. From an information theory perspective, the decorrelation observed during wakefulness may maximize the information that the population of the neurons could encode neuronal activity during waking and sensory processing periods. Our goal is to track calcium activity using two-photon microscopy in excitatory and inhibitory neurons simultaneously during wakefulness and under anesthesia. The calcium activity will be used to investigate how changes in the firing properties of these two population contributes to enhanced cross-correlation between neurons under anesthesia. By tracking both the output in both cells types, our hope is to elucidate the mechanisms decorrelating neuronal spike activity during wakefulness.

**Abstract:** While the mechanism of general anesthetics have been detailed at the molecular level, a systems-level description is largely lacking. It remains unknown if top-down or bottom-up processing is affected differently in anesthesia, or even if subcortical structures may play an initiating role in the transition across conscious states. We utilized a non-human primate model of general anesthesia to investigate how various cortical and subcortical networks mediate the transition into and out of anesthesia-induced unconsciousness. We simultaneously recorded local field potential (LFP) and spiking activity from chronic multielectrode arrays in prefrontal (PFC), posterior parietal, and auditory cortex, as well as from probes in the thalamus of two monkeys during intravenous administration of the GABAergic anesthetic propofol. In line with previous work, loss of consciousness (LOC) was followed by global decreases in spike rates and widespread cortical slow (0.1 - 1.2 Hz) oscillations—a hallmark of GABA-modulating anesthetics. However, not all brain regions were affected contemporaneously. PFC was the most sensitive to drug onset with beta power increasing across multiple PFC regions soon after propofol administration. This beta oscillation was tightly coherent between PFC and thalamus. This coupling was specific to particular thalamic subnuclei. On the other hand, slow oscillations appeared first and most prominently in parietal cortices. They moved anteriorly to frontal cortex during induction into LOC. Remarkably, different cortical areas simultaneously exhibited differentiated depths of anesthesia. Burst suppression, a marker of deep anesthesia, was present in parietal and temporal cortices while frontal cortex was in a lighter stage characterized by cross-frequency coupling of slow oscillations with high frequency activity. During regaining of consciousness (ROC), cortical areas exhibited a different sequence in returning to the conscious state. Whereas PFC was the first region to be affected during induction, it was the last area to return to pre-induction state, in terms of LFP power and spiking responses to auditory and somatosensory stimuli. Overall, these data suggest that general anesthetics such as propofol impact the brain in a highly structured manner and disrupt higher cognitive areas quite differently from sensory areas.

**Title:** Disproportional local field potential and GCaAMP-6 signals of hippocampal neuronal population activities

**Authors: *P. LI**[1,2], A. CACCAVANO[3], S. VICINI[4], J.-Y. WU[2]
[1]Pediatrics, Sun Yat-Sen Mem. Hospital,Sun Yat-Sen Univ., Guangdong, China; [2]Neurosci., [3]Interdisciplinary Program in Neurosci., Georgetown Univ., Washington, DC; [4]Dept Parmacology & Physiol., Georgetown Univ. Med. Ctr., Washington, DC

**Abstract:** We compared the local field potential (LFP) and GCaAMP-6 fluorescent signals in mouse hippocampal slices. During spontaneous sharp wave ripples (SWRs) and carbachol induced theta oscillations, the LFP amplitude was similar but the GCaMP-6 signal was disproportionally large, by a factor of 80. The LFP signal of the SWRs was about 50 μV in the striatum radiatum of CA1 (Fig 1, top black trace), and the GCaAMP-6 signal of the same tissue was about 0.3% (dF/F, 470nm excitation, 520 nm emission, measured as a population summation from an area of 60 μm in diameter by a 20x objective and a photodiode array, Fig 1 top red trace). When the tissue was perfused with 60 μM carbachol, the SWRs stopped and were replaced by episodic theta oscillations. The amplitude of the episodic oscillation was ~100 μV (Fig 1 bottom black trace), and the GCaAMP-6 signal was disproportionally large, about 26% of dF/F (Fig 1 bottom red trace). We used C57BL/6J-Tg (Thy1-GCaMP6f) GP5.5Dkim/J. mice (Jax 024276) mouse and the Ca signals are presumably reflecting neuronal Ca influx. SWRs and carbachol induced oscillations represent two active states in the hippocampus, both comprised of large numbers of moderately depolarized neurons with sparse spiking. Our data suggest that the LFP and GCaAMP population signals were not linearly correlated during population neuronal events.

**Authors: *S. H. BITZENHOFER**, J. A. PÖPPLAU, I. L. HANGANU-OPATZ
Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

**Abstract:** Coordinated activity in neuronal networks shapes the refinement of cortical networks during brain development. Thereby, it is critical for the maturation of cognitive and behavioral abilities. Dysfunction of early network activity disturbs the maturation of cortical networks, leading to life-long disruptions of cortical function and the emergence of neurodevelopmental disorders. We elucidated the layer-specific cellular mechanisms underlying rhythmic activity in the developing prefrontal cortex with a combination of in utero electroporation, optogenetics and electrophysiology. We show that optogenetic activation of layer 2/3 pyramidal cells in the prefrontal cortex induces rhythmic spiking and drives local network activity in beta frequency at neonatal age. Furthermore, we show that the frequency of this driven activity increases with age driving activity in gamma frequency in juvenile mice. Chronic stimulation of layer 2/3 pyramidal cells during early postnatal development alters the functional maturation of cortical networks and disrupts behavioral abilities at older age.

**Abstract:** Although sleep and general anesthesia are prominent states of reduced arousal, it remains unclear if they share a common mechanism. So far, comparative research mostly focused on oscillatory dynamics like slow waves which can be observed during non-rapid eye movement (NREM) sleep and under general anesthesia with propofol. However, it is unclear how reduced arousal level is mediated during rapid eye movement (REM) sleep where no such oscillations are present. For this study, we utilized the spectral slope as an electrophysiological metric of non-oscillatory neural activity to delineate wakefulness from states of reduced arousal. The spectral slope represents the decay of the electrophysiological power spectrum in log-log space and is thought to index the local balance between excitation and inhibition. Here, we demonstrate in four independent datasets including scalp EEG and intracranial EEG that the spectral slope tracks arousal levels in both NREM and REM sleep as well as under general anesthesia with high temporal precision. For anesthesia, we found a significant decrease in spectral slope with departure from wakefulness in both EEG and intracranial EEG, evident in the majority of electrodes. These results confirm that anesthesia is a global brain state of increased inhibition. Moreover, we also observed decreased slope values in NREM and REM sleep compared to wakefulness in both recording groups - compatible with a higher rate of inhibition in sleep. In the scalp EEG the main effect of slope was concentrated around frontal electrodes F3, Fz, F4 consistent with a focus in medial prefrontal cortex. Consequently, the intracranial regions that were driving this effect were localized in medial prefrontal cortex and medial temporal lobe structures. When training a classifier to differentiate between sleep stages, both spectral slope and slow oscillation power performed comparatively well when differentiating NREM sleep from wakefulness. When discriminating between REM and wake, however, the spectral slope showed a significantly better performance of 79.06 % ± 3.10 (mean ± SEM; $p = 0.002$) compared to slow oscillation power (59.95 % ± 2.19; chance level: 50%). These findings indicate that enhanced inhibition might be the underlying principle of reduced arousal states, emphasize the role of non-oscillatory dynamics in brain activity and thus, resolve the paradox of decreased arousal during REM sleep.

**Title:** Distinct activity patterns in neuromodulatory centers are associated with differential modulation of cortical low and high gamma oscillations

**Authors: *N. K. TOTAH**, S. VAN KEULEN, N. LOGOTHETIS, O. ESCHENKO
Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany

**Abstract:** Neuromodulatory systems are thought to gate cortical neuronal excitability – a generalized state consisting of high frequency (20 to 200 Hz) local field potential (LFP) oscillations. Stimulating neuromodulatory centers evokes a non-specific response across all components of the excited cortical state (beta and gamma band LFP oscillations). The non-specificity of neuromodulation is at odds with the fact that neuromodulators regulate distinct cognitive functions that are affiliated with different cortical LFP oscillations. For example, various dopamine and norepinephrine-dependent cognitive functions (e.g., working memory, spatial navigation, and top-down attention) are each accompanied by power increases within different LFP frequency bands. How can neuromodulators contribute to cognitive processes associated with different LFP frequency bands if they non-specifically modulate cortical LFP? Here, rather than perturbing neuromodulatory systems with stimulation, we recorded spontaneous unit activity from two primary sources of cortical neuromodulators (the noradrenergic locus coeruleus, LC, and dopaminergic ventral tegmental area, VTA) and correlated it with LFP power fluctuations in the prefrontal, visual, and somatosensory cortex of urethane-anesthetized rats. We found that neuromodulatory population spike rate rhythmically fluctuates at 1 – 2 Hz (delta band) in both LC and VTA. But, in the LC, an additional 5 – 7 Hz (theta band) fluctuation of spike rate occurred. While neuromodulatory delta oscillations non-specifically regulated the power of all cortical LFP oscillations over 20 Hz, theta spike rate oscillations were exclusively associated with cortical high gamma band (60 – 200 Hz) activity. As LC population spiking rhythmically rose and fell, two types of LC single units (characterized by narrow or wide action potentials) fired in phasic opposition, potentially providing differential cortical state regulation. Our results demonstrate that the noradrenergic system is a unique neuromodulatory center that can affect specific cortical activity patterns, rather than merely gate a generalized state of cortical excitability.

**Title:** Enhanced cerebello-cortical coherence of local field potentials during patterned stimulation of the cerebellar vermis

**Authors: *S. TREMBLAY**[1], C. A. CHAPMAN[2], R. COURTEMANCHE[1]
[1]Exercise Science/CSBN, [2]Psychology/CSBN, Concordia Univ., Montreal, QC, Canada

**Abstract:** The cerebellum is involved in sensorimotor, cognitive and emotional functions through cerebello-cerebral connectivity. Non-invasive cerebellar neurostimulation has been used to treat neurological disorders and has positive functional effects on frontal oscillations, cognition, and mood. Here, we explored the effects of rhythmic cerebellar stimulation at various frequencies on oscillations and coherence across a cerebello-cortical network in the rat. We predicted that slow frequencies (< 30 Hz) would synchronize large networks, and that faster frequencies (> 30 Hz) would synchronize more local networks. In addition, 25 Hz cerebellar stimulation has been shown to modulate prefrontal gamma activity. We therefore hypothesized that cerebellar stimulation in the theta and beta ranges would be effective in modulating rhythmic activity in the prefrontal cortex. Local field potentials (LFPs) were recorded continuously with bipolar electrodes in the lateral cerebellum (crus I/II), and in both hemispheres of the prefrontal cortex (frontal association cortex), in three adult male Sprague-Dawley rats anesthetized with urethane. Stimulation patterns were delivered to the cerebellar vermis in a randomized order: single pulses (0.2 Hz), and repeated pulses at 1 Hz (delta), 4 Hz (theta), 25 Hz (beta), and 50 Hz (gamma). Coherence between sites, in seven frequency bands (covering 0.1 Hz to 200 Hz), was analyzed before, during, immediately after, and 30 sec after stimulation. The effects of stimulation frequency and intensity were analyzed using a repeated measures ANOVA for each coherence comparison (Cb-Cx, Cx-Cx). Beta-frequency stimulation had the strongest enhancing effect on Cb-Cx coherence (in 8-14 and 14-30 Hz bands) and Cx-Cx coherence (80-200 Hz), with a main effect of stimulation in each of the three rats. Few studies have looked at the effects of cerebellar stimulation on oscillations and coherence across cerebello-cerebral networks. We have found here that cerebellar beta-frequency stimulation can drive synchronization of large cerebellar-cerebral and cerebral-cerebral networks. The present results could provide basic mechanisms underlying the therapeutic effects of cerebellar stimulation by promoting large-scale synchronization of neural networks.

**Abstract:** A prominent feature of brain activity is the presence of oscillations in neuronal recordings. Interactions between brain rhythms have been demonstrated at different space and time scales, and are believed to play an important role in neuronal communication. One such interactions is the cross-frequency coupling (CFC) between the phase of the theta rhythm and the amplitude of gamma oscillations in the hippocampus. However, how this idea copes with the co-existence of multiple theta rhythm generators and layer-specific gamma oscillations is not yet understood.
We used multichannel silicon recordings in freely exploring animals and source separation tools to analyse theta and gamma oscillations in CA1 and the dentate gyrus originating in CA3 and entorhinal cortex (EC) layers II and III. Synchronization between theta generators was computed, showing epochs of high and low theta coherence, supporting the idea of several rhythms coexisting in the hippocampus. An increase of the theta frequency was found in the activity generated in the EC correlated with higher synchronization, but not in CA3, suggesting that EC neurons have an active role binding the rhythms of different populations.
Moreover, the interaction between layer-specific gamma oscillations and theta rhythms was measured through CFC analysis, finding the strongest coupling between signals with the same origin and during events of high theta synchronization. In order to investigate the directionality

of these interactions, systematic analysis of cross-frequency directionality was performed, indicating that the higher frequencies drive the theta oscillation in each layer.
These results suggest that layer- and band-specific gamma-oscillations coordinate theta rhythms. This mechanism may explain how anatomically distributed computations, organized in theta waves, can be bound together.

**Title:** Toward cellular-based explanations of LFP theta-gamma rhythm generation in the hippocampus

**Authors: A. CHATZIKALYMNIOU**[1,2], *F. K. SKINNER[1,3]
[1]Krembil Res. Institute, Univ. Hlth. Network, Toronto, ON, Canada; [2]Physiol., [3]Med. (Neurology), Physiol., Univ. of Toronto, Toronto, ON, Canada

**Abstract:** One of the most studied examples of cross-frequency coupling (CFC) in the rodent hippocampus, is phase-amplitude coupling (PAC) of theta and gamma rhythms. CFC has been implicated in various cognitive roles and specific CFC changes may be an early biomarker for neurological disease. However, underlying cellular-based mechanisms are difficult to determine. In large part, this is due to CFC analyses being performed using population activity recordings such as local field potentials (LFPs), and cellular contributions to LFPs are challenging to determine. These challenges arise because of the many overlapping pathways and multiple cellular subtypes that exist to influence PAC in LFPs. To obtain a cellular-based understanding of theta-gamma PAC, we are leveraging insights from existing simple (Ferguson et al. 2017, 4 (4) ENEURO.0131-17.2017) and detailed (Bezaire et al. 2016, eLife Sciences 5, e18566) models that are connected to a whole hippocampus preparation. The simple models provide an explanation for theta rhythm generation as dependent on spike-frequency adaptation and post-inhibitory rebound but only include fast-firing parvalbumin (PV+) interneuron types and pyramidal (PYR) cells and ad-hoc LFP representations. The detailed models include PYR cells and 8 different interneuron subtypes, produce theta-gamma rhythms using biophysical LFP models, and show that only some interneuron subtypes contribute to theta power. However,

mechanistic explanations of theta/gamma generation still need to be developed. We use a MATLAB-based program, SimTracker (Bezaire et al. 2016 bioRxiv 81927), to design, execute, organize, and analyze the simulations. From analyses of the existing detailed models, we find that the removal of connections from PV+ basket cells or PYR cells, but not other cell types, lead to a tripling of LFP gamma at ~30 Hz and ~70 Hz power respectively. Further, we have developed reduced versions of the detailed models and we find that they also exhibit theta-gamma rhythms. These reduced models increase computational efficiency and allow us to perform many sets of biophysical LFP simulations. Analysis of these simulations allows us to extract explanations using insights from the simple models. Subsequently, we can explain how extra-hippocampal inputs from medial septum and entorhinal cortex modulate PAC in the hippocampus and possibly predict critical balances for CFC disease biomarkers.

**Abstract:** Transcranial magnetic stimulation (TMS) to the dorsolateral prefrontal cortex (PFC) is currently clinically administered as a non-invasive neuromodulation tool for the treatment of depression. Nonetheless, basic mechanisms underlying TMS effects on prefrontal neural circuitry are largely unknown. Several studies have investigated TMS effects using non-invasive imaging modalities such as electroencephalography (EEG). However, EEG suffers from low signal to noise ratio and low spatial specify due to volume conduction. Therefore, in our study we investigate the effect of prefrontal TMS in a non-human primate model with implanted depth electrodes arrays spanning the left hemisphere from frontal to occipital brain regions. This allows us to record neural activity from the stimulation region and connected brain areas with high spatiotemporal resolution. Several sessions of single-pulse TMS to the prefrontal cortex together with baseline as control condition were recorded (monkey under anesthesia). Data preprocessing involved removal of TMS artifacts such as pulse artifact and muscle activity. Neural activity

could be fully recovered at least 10 ms after stimulation. As shown in fig 1, we found decreased power shortly after the stimulus and recovery in low frequency oscillations (2-4 Hz) roughly one second after offset. This effect was strongest in prefrontal electrodes. In conclusion, we provide evidence that TMS is modulating intrinsic brain activity under anesthesia through the suppression of low frequency oscillations. Future research will involve investigating the effect of changing TMS parameters in further detail. Our research can lead to a better understanding on how TMS affects neural activity in the prefrontal cortex and eventually more efficient treatment protocols to a variety of disorders such as depression.

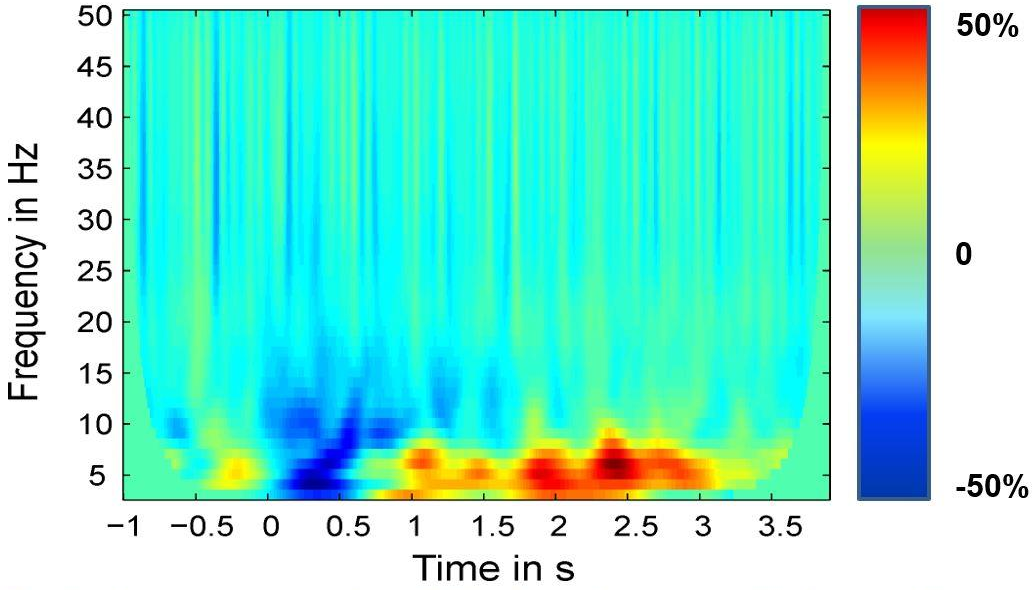

*Fig 1. Time-frequency response to single-pulse TMS (applied every 5s, average over 500 pulses) to the PFC contrasted to no-stimulation baseline shows reduced neural activity and recovery afterward for low frequency oscillations with respect to stimulus.*

**Title:** Evaluating phase-synchrony dynamics in epilepsy patients using EMD-based mean-phase coherence analysis

**Authors: *S. FARAHMAND**, T. SOBAYO, D. J. MOGUL
Biomed. Engin., Illinois Inst. of Technol., Chicago, IL

**Abstract:** Spatiotemporal synchrony dynamics between neuronal populations play an important role in decoding complicated brain functions such as in normal cognitive processing as well as during pathological conditions such as epileptic seizures. It has been widely shown that the synchrony level can be altered in several neurological disorders such as epilepsy, which itself may promote epileptic seizures. Therefore, evaluating synchrony dynamics may not only reveal crucial components essential to clinical EEG interpretation but may also provide a key insight into the dynamics of seizures as they evolve. A variety of mathematical methods have been proposed to identify the instantaneous synchrony changes among neuronal networks in the brain. However, many of them rely on several assumptions regarding properties of brain electrophysiological signals that render them inappropriate for this purpose: cross-correlation, Fourier spectrum-based coherence, wavelet methods, and mutual information measures are among them. These methods, while useful, suffer from assumptions of time-series linearity and/or stationarity, and may possibly detect spurious levels of synchrony as a result of utilizing bivariate measures, while original signals themselves may consist of several oscillatory components. Furthermore, it has been shown that phase synchronization can be detected among non-linear, coupled, chaotic oscillators even if their amplitudes are not synchronized. Therefore, it is crucial to employ non-linear methods to measure instantaneous phase-synchrony changes. Empirical mode decomposition (EMD) provides localized time-frequency representation of a signal via adaptively decomposing it into a finite group of narrowband, oscillatory components without making any assumptions of its linearity and stationarity features. This study reports on developing a non-linear, adaptive, analytical methodology that merges the EMD, Hilbert transform, mean-phase coherence analysis, and eigenvalue decomposition technique to evaluate the dynamical evolution of phase-synchrony in three epilepsy patients with temporal lobe epilepsy and one patient with frontal lobe epilepsy. Although a different phase-synchrony dynamics was detected between both types of epilepsy, the synchrony levels achieved a maximum at seizure offset during the ictal periods as seizures evolved. This result suggests that hypersynchronization of the epileptic network may be an essential self-regulatory mechanism by which the brain terminates seizures.

**Title:** Loudness effects on the spectral composition of stimulus-related activity in the macaque auditory cortex

**Authors: *Y. KAJIKAWA**[1], J. J. ORZYK[1], C. E. SCHROEDER[2]
[1]Nathan Kline Inst., Orangeburg, NY; [2]Nathan Kline Inst. - Translational Neurosci. Div., Columbia Univ. Col. of Physicians and Surgeons, Orangeburg, NY

**Abstract:** Brain signals often exhibit prominent power/amplitude in particular frequency bands, as indexed by spectrotemporal decompositions of both ongoing and event-related activity. Specific frequencies of ongoing activity have been linked to a number of behavioral and cognitive conditions. For sensory responses, spectral analyses have mostly been applied to responses at higher stimulus intensities. Resulting frequency compositions usually include both "evoked" components (those clearly phase-locked to stimulation) and "induced" components (those that are poorly phase-locked to stimuli). However, the magnitude and timing of sensory responses depend on the strength of sensory stimuli (e.g. sound level, cutaneous indentation pressure, visual contrast and brightness). When stimuli are weak, sensory responses are both smaller and slower. Similarly, the spectral composition of sensory responses is likely to be dependent on the stimulus strength, and there is some evidence for this idea. We examined how the spectrotemporal patterns of auditory cortical responses to broad-band noise changed depending on the sound intensity in awake macaques. We indexed the spectral composition of stimulus-related activity using both field potentials and current source density. At high stimulus intensities, evoked responses occur with brief onset peaks with broad band characteristics, followed by slower temporal components with lower frequency composition. At lower stimulus intensities, evoked responses occurred with similar but blunt peak patterns, and corresponding spectrotemporal peaks both delayed and limited to lower frequency bands. Induced (poorly phase-locked) components' spectral composition was defined by single trial spectral decomposition followed by averaging of resultants across trials. At high stimulus intensities, induced activity generally began with a spectral peak at ~150 Hz and rapidly shifted down to ~60 Hz within 50 ms. At lower stimulus intensities the spectral peak of trials-asynchronous peak started at lower frequencies with more delays, even after accounting for the delay of the evoked response peak components. Thus, both evoked and induced response components may change their frequency bands depending on the sensory input strength in sensory cortex.

**Title:** Slow-wave oscillations in cultured neuronal networks reflect bursting and single spiking

**Authors: *S. THEISS**[1], S. ILLES[2]
[1]Inst. of Clin. Neurosci., Univ. of Duesseldorf, Duesseldorf, Germany; [2]The Sahlgrenska Academy, Univ. of Gothenburg, Goeteborg, Sweden

**Abstract:** Microelectrodes implanted in human or animal brain tissue record electrophysiological signals from neurons. These signals have two components: slowly varying local field potentials (LFP), associated with the spatial average of many sub-threshold post-synaptic currents (“input”), and multi-unit activity in form of action potentials (MUA, spikes, “output”). In two-dimensional neuronal cultures, so far only spike-bursts have been associated with LFPs (Leondopoulos et al, J Neural Eng. 2012). In order to examine this input-output relationship, we cultured networks of 1—5 x $10^5$ cortical, hippocampal or striatal neurons from P0 rats on planar microelectrode arrays (MEAs) with 60 electrodes (30 µm diameter, 200 µm distance, Multichannel Systems, Germany). Using the MEA2100 system, we obtained stable 30-minute recordings of both slow extracellular voltage fluctuations above 0.1 Hz and spike activity corresponding to neuronal action potentials. To control for potential phase shifts between spikes and slow waves, we carefully applied linear-phase FIR filters, down-sampled the data from 25 kHz to 1 kHz and verified that spikes were only minimally distorted or time shifted. Conversely, spikes did not distort low frequency signals obtained by band-pass filtering. We calculated normalized power spectral densities of 6-minute long segments using the Welch method with an 8.2-second long sliding window of 8,192 points, 50% overlap and a frequency resolution of 0.12 Hz. In each of the traditional delta (1—4 Hz), theta (4—11 Hz), beta (11—30 Hz) and gamma (30—55 Hz) frequency bands, we aggregated spectral power and determined spike-phase histograms reflecting the percentage of spikes at a specific phase of slow wave activity. After approximately 3 weeks in vitro, networks developed synaptically mediated spontaneous spiking activity organized in synchronous network bursts that were associated with slow LFP oscillations at the respective bursts frequency. Power spectral densities showed clear peaks at the network burst rates. However, after pharmacologically suppressing synaptically mediated synchronous network bursting, neurons on several electrodes exhibited tonic spike firing at individual but constant frequencies. These tonic single spikes preferentially occurred at the rising flanks of

same-frequency gamma oscillations. In conclusion, cultured networks exhibited slow delta and theta LFP oscillations corresponding to synaptically mediated burst events, but also gamma oscillations at the precise frequency of tonic single spike firing in the absence of network bursts. These results may have relevance for the interpretation of DBS electrode signals.

**Abstract:** It is known that brain activity can persist for minutes or even return in mammals after a cardiac arrest of limited duration. At the same time, other observations have shown the possibility to fully recover cognition after longer times (up to 40 min). This suggests that what happens to the brain after cardiac arrest is mostly unknown. Recordings of brain activity around cardiac arrest have been typically conducted by using electroencephalography or electrocorticography that record neural activity as relatively large voltage fluctuations from sensors located outside the brain. From these measures, smaller electrophysiological phenomena cannot be detected. To bridge this gap, we recorded intraparenchymal local field potentials (LFPs) by means of a multi-electrode array (MEA) in the frontal cortex of a male monkey, during a standard euthanasian procedure. The LFPs were recorded starting from a deep sedated state (induction by Ketamine; mixture Isoflurane/Oxygen to effect), displaying supra-threshold fluctuations well after the cardiorespiratory arrest caused by the intravascular bolus injection. Cardiac activity was also recorded. We found that cortical LFPs displayed a regime of burst suppression by the anesthesia, followed by a strong drop-down once cardiac arrest occurred. However, after few minutes, bursts of LFPs distributed and coordinated across the MEA, emerged sparse in time up to about 120 minutes, each displaying a peak of power at 1-3 Hz in the Fourier spectrograms. Although confined to a single subject, our results show that the dying brain can still show signs of electrophysiological activity: a persisting excitability of the cortical tissue occurring after some minutes of apparent silence. We think that this finding stimulates fundamental scientific, ethical and clinical questions.

**Title:** Only sub-gamma coherence predicts long-range, parietal-frontal effective connectivity in macaques

**Authors: *R. SHEWCRAFT**[1], B. PESARAN[2]
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]New York Univ. Ctr. for Neural Sci., New York, NY

**Abstract:** Coherent neural activity plays a role in flexible behaviors that require hand-eye coordination (Dean 2012), attentional control (Buschman & Miller 2007), visual perception (Womelsdorf 2006), working memory (Pesaran 2002) and decision making (Wong 2016). The causal relationship between coherent neuronal dynamics and inter-regional interactions has not been previously examined. Here we optogenetically stimulate neurons in the posterior parietal cortex while simultaneously recording spike-field activity in the frontal cortex to provide causal evidence of functional connections. We then compare parietal-frontal functional connectivity, measured by LFP coherence, with causally determined maps of parietal-frontal effective connectivity. We injected AAV5-hSyn-ChR2(h134r) in the PPC of two rhesus macaques and measured synaptically driven responses to optogenetic stimulation on an array of 96 electrodes implanted over frontal cortex. The electrodes covered approximately 180 $mm^2$ of cortical surface. We also implanted a single electrode at the stimulation site in PPC. We measured LFP activity on all electrodes during a baseline period prior to stimulation. We also measured synaptically mediated LFP responses in frontal cortex that were driven by stimulation in PPC. We used 1 s long pulse trains, with 10 ms wide pulses and Poisson distributed inter-pulse intervals with a mean rate of 20 pulses/s. We estimated functional connectivity by computing the coherence between the PPC electrode and each frontal electrode during the baseline period. Larger stimulation-driven responses in frontal cortex may be due to greater synaptic connectivity with the stimulation site. Therefore, we quantified the strength of synaptic interaction as the maximum Z-score of the pulse-triggered evoked potential at each frontal site. Next, we compared the functional connectivity with the stimulation-based effective connectivity by computing Spearman's rank correlation coefficient ($\rho$) across all electrodes. In each animal,

coherence at frequencies below 35 Hz was significantly and positively correlated with evoked potential magnitude (p < 0.05, FWER corrected). Coherence at 35-100 Hz was not positively correlated with synaptic interactions. Furthermore, we found animal specific frequency structure. For Monkey H, the correlation had peaks at 5 Hz ($\rho$=0.70) and 14 Hz ($\rho$=0.57), with a trough at 11 Hz ($\rho$=0.40). Monkey J had peaks at 4 Hz ($\rho$=0.38) and 25 Hz ($\rho$=0.26), with a trough at 15 Hz ($\rho$=0.0). These results show that neural coherence measures the strength of synaptic interactions between populations of PPC neurons and individual frontal neurons.

**Title:** Investigating the ventral hippocampal-prefrontal anxiety circuit: Sexual dimorphisms and effects of estrous stage

**Authors: *K. J. SCHOEPFER**[1], A. A. WILBER[2], W. WU[3], M. KABBAJ[1]
[1]Biomed. Sci., [2]Psychology, [3]Statistics, Florida State Univ., Tallahassee, FL

**Abstract:** Synchronized oscillations in the local field potentials (LFPs) between interconnected brain structures are hypothesized to play a role in the regions' communications. In mice and rats, the ventral hippocampus (vHPC) monosynaptically projects to the medial prefrontal cortex (mPFC) ipsilaterally and bilaterally. As members of the corticolimbic system, the vHPC and mPFC serve to update and evaluate internal and external cues to assign a behaviorally-relevant emotional valence to the environment. Anxiety is a naturally-occurring adaptive response to potential threat. Inappropriate overrepresentation of the anxiety response can classify an anxiety disorder. Women are ~60% likelier than men to be diagnosed with an anxiety disorder, yet possible neural correlates to this sex difference have not been explored. In females, natural cycling of the gonadal hormones estradiol (E2) and progesterone (P4) dynamically modifies the expression of anxiety-like behavior in rodents, electrical excitability of HPC and mPFC pyramidal cells, and HPC-mPFC functional connectivity in women. This suggests a role for the hormonal milieu to act on the vHPC-mPFC circuit to regulate anxiety expression. Phase-locked theta (4-12 Hz) oscillations between the vHPC and mPFC have been shown to directly underlie innate anxiety-like behaviors in male rodents. Surprisingly, however, the vHPC-mPFC circuit's role in anxiety-like behavior remains to be investigated in females. Here, we aim to determine how the vHPC-mPFC circuit differs between both sexes of rat and identify the degree of female

estrous stage modulation therein. Rodents are implanted with electrodes in vHPC CA1, prelimbic mPFC, infralimbic mPFC, and dorsal HPC (dHPC) CA1 (as a negative control) and are acclimatized to a square arena. LFPs are recorded daily in this familiar arena, and theta parameters are analyzed as a function of sex and of estrous stage. Rodents are then recorded on the elevated plus maze (EPM), a validated behavioral test for innate anxiety-like behavior; females are tested either in diestrus (low E2/P4) or proestrus (high E2/P4) stages. We predict that between vHPC-mPFC (but not dHPC), theta coherence, theta power correlations, and EPM zone-specific LFP profiles may exhibit sexual dimorphisms which are most polarized in high-E2 female estrous states. This project aims to extrapolate a validated electrophysiological endophenotype of innate anxiety-like behavior (vHPC-mPFC theta synchrony) in males to both sexes. Results are expected to delineate sexual dimorphisms and similarities in a functional neural circuit that mediates innate anxiety expression.

**Title:** Auditory evoked neural responses in the auditory cortex of the cat during slow wave sleep and anesthesia

**Authors: *D. A. HORVATH**[1,2,3], A. JUHASZ[2], R. FIATH[1,2], K. TOTH[1], G. KARMOS[2], I. ULBERT[1,2]
[1]RCNS HAS, Budapest, Hungary; [2]Fac. of Information Technol. and Bionics, Pazmany Peter Catholic Universtiy, Budapest, Hungary; [3]Sch. of PhD Studies, Semmelweis Univ., Budapest, Hungary

**Abstract:** Aims
Changes of auditory cortical evoked potentials depending on vigilance are well known. However, the underlying cellular and circuit level processes are still unclear. We aimed to characterize single unit firing properties in relationship to the sleep slow wave (SW) phase.
Methods
We implanted chronically metal linear array multielectrodes into the auditory cortex (AC) of cats. We recorded spontaneous local field potential (LFP), multiunit and single unit activity and the same signals evoked by single or pairs of clicks from the AC of freely moving and behaving

animals. To describe the firing properties of single units related to the SWs, we detected the LFP phase of the SWs and computed the preferred phase for firing of each single unit using circular statistics. We also characterized the extracellularly recorded and separated single units based on their firing autocorrelograms and waveform properties. We determined the cortical layer for each extracellularly recorded single unit based on the current source density (CSD) diagram of the click evoked average responses.
Results
We found that while both putative principal cells and interneurons prefer to fire at the initial phase of the up state, circular statistics reveals that interneurons are more locked to the up-state phase than principal cells. Adding the cortical layer of each single unit to the data analysis revealed that neurons in the different cortical layers have different preferred firing phases during the SW.
Conclusions
We can conclude that each cortical neuronal type has its own contribution the SW recorded in naturally sleeping cats.

**Title:** Decreased phase amplitude coupling across laminar hippocampal CA1 following traumatic brain injury

**Authors: *C. COTTONE**, K. GAGNON, C. ADAM, M. SERGISON, H.-C. I. CHEN, A. ULYANOVA, J. A. WOLF
Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Traumatic brain injury (TBI) is caused by mechanical insults to the head, often resulting in prolonged or permanent brain dysfunction including disruption of cognitive functions. The hippocampus is one of the most studied brain regions following TBI due to its central role in short-term and spatial memory and its demonstrated vulnerability during TBI. We hypothesize that TBI may disrupt the timing between ensembles of neurons in these networks, and that this may underlie aspects of post-TBI cognitive dysfunction. Preliminary results demonstrated that TBI leads to a disruption of oscillatory organization in the hippocampus and

dysfunctional entrainment to theta, potentially due to a compensatory response to loss of afferent input due to axonal injury. Cross-frequency coupling (CFC) and spike-local field potential (LFP) entrainment may support the organization of these neurons assembles and are present during a range of cognitive functions, including learning and memory. While CFC and spike-LFP interactions have been studied in detail both within a brain region and across brain regions, little is known about their short-range interactions within the laminar architecture of the hippocampus and how they may be affected following TBI. Using 64-channel silicon probes, we simultaneously recorded laminar hippocampal field structure and CA1 neurons in behaving rats during an open field paradigm. Recordings were divided into moving and non-moving periods, and then phase-amplitude coupling (PAC) was calculated for every possible pair of channels using the 1-20 Hz band as the phase of the lower frequency oscillation and 1-300 Hz band as the power of the coupled higher frequency oscillation (64x64 permutations). The entrainment of the neurons was calculated for each single neuron's firing properties, with every channel's local field potential oscillations on the laminar probe for each frequency in 1-300 Hz band. As such, we can now visualize to which frequencies the cell is attuned, as well as where these oscillations are located in the laminar structure. Results show a reduction in PAC in injured subjects relative to sham, predominantly between radiatum and pyramidal layers in theta-gamma and delta-theta-ripple coupling, thus reflecting a loss of encoding synchrony between CA1-CA3 (low gamma (~ 30-60 Hz)), EC-CA1 (high gamma (~ 60-110 Hz)) and a disruption of the Sharp waves-ripples (~ 140-240 Hz) generation. One interpretation of these results is that laminar afferent inputs into CA1, both from CA3 and entorhinal cortex, are no longer properly coupled to lower frequencies, leading to disrupted entrainment and the consequent disruption of neuron ensemble formation.

**Title:** Reactivity of prefrontal and thalamic spontaneous oscillations to hippocampal high-frequency stimulation

**Authors: *L. S. BUENO-JUNIOR**, R. N. RUGGIERO, J. P. LEITE
Ribeirao Preto Med. Sch., Univ. of Sao Paulo, Ribeirao Preto, Brazil

**Abstract:** Rodent synaptic plasticity experiments are traditionally focused on stereotyped responses - field postsynaptic potentials (fPSPs) - evoked by afferent electrical stimuli at innocuous frequencies (e.g., 0.05 or 0.1 Hz). Through measuring a given feature of fPSPs, such as amplitude or slope, one can analyze how they react to conditioning manipulations, for example high-frequency stimulation (HFS). A less common approach is to evaluate how spontaneous oscillations between fPSPs react to HFS. This approach is the one we report here. In chronically implanted rats, we examined local field potentials (LFP) in 8-second inter-stimulus epochs before and after HFS. Also unlike most of the literature, we probed a three-node circuit: the stimulated area, i.e., hippocampus (intermediate CA1/subiculum), and two recorded areas, i.e., medial prefrontal cortex (mPFC) and mediodorsal thalamus (MD), allowing functional connectivity measures. Ongoing analyses indicate a long-lasting (>2 h) increase in power spectral densities across low- and high-gamma frequencies after HFS, both in the mPFC and MD. In addition, these areas showed stronger power and coherence around a 6 Hz-peaked theta activity, but this effect was specific to the initial 3 minutes after HFS. These preliminary findings may reflect the different stages of fPSP long-term potentiation, which requires further analysis. Considering that electroencephalography is increasingly used for monitoring the effects of deep-brain stimulation in humans, future studies like the present one could further explore spontaneous oscillations in their relationship with synaptic plasticity, both in health and disease.

**Title:** Transcranial static magnetic field stimulation of the dorsolateral prefrontal cortex has region specific effects on neural oscillations

**Authors: *A. G. SHEFFIELD**[1], S. AHN[2], S. ALAGAPAN[3], F. FROHLICH[4]
[1]UNC Chapel Hill, Chapel Hill, NC; [2]Dept. of Psychiatry, UNC at Chapel Hill, Chapel Hill, NC; [3]Psychiatry, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [4]Psychiatry, Univ. of North Carolina, Chapel Hill, NC

**Abstract:** Transcranial static magnetic field stimulation (tSMS) is a novel non-invasive brain stimulation technique that has been shown to locally increase alpha oscillations in the parietal and occipital cortex. We investigated if tSMS locally increased alpha oscillations in the left or right prefrontal cortex, as the balance of left/right prefrontal alpha oscillations (frontal alpha asymmetry) has been linked to emotional processing and mood disorders. Therefore, altering frontal alpha asymmetry with tSMS may serve as a novel treatment to psychiatric diseases. We performed a crossover, double-blind, sham-controlled pilot study to assess the effects of prefrontal tSMS on neural oscillations. The DLPFC was chosen as the site of stimulation as frontal alpha asymmetry has been localized to this region. 24 right-handed healthy participants were recruited and received left DLPFC tSMS, right DLPFC tSMS, and sham tSMS in a randomized order. EEG data were recorded using a 128-channel Hydrocel Geodesic Sensor Net and Netamps 410 amplifier (EGI Inc., Eugene, OR). EEG data were collected before (2 minutes eyes-closed, 2 minutes eyes-open), during (10 minutes eyes-open), and after (2 minutes eyes-open) stimulation. After standard signal preprocessing, power spectral density (PSD) was computed by Welch's method with a 2-second window and a 12.5% overlap resulting in a PSD with 0.5 Hz resolution. Alpha was defined as 2 Hz on either side of the individual alpha frequency (IAF), and exploratory analyses were performed for the fixed frequency bands delta (1-4 Hz), theta (4-8 Hz), alpha (8-12 Hz), beta (12-30 Hz), and gamma (30-50 Hz). Frequency power during- and post-stimulation were log-normalized to the eyes-open pre-stimulation period. Finally, channels were grouped and averaged for 8 locations for statistical analysis: left/right frontal, temporal, parietal, and occipital. In contrast to our hypothesis, neither left nor right tSMS locally increased frontal alpha oscillations. However, IAF alpha oscillations were higher in occipital cortex relative to other brain regions during left DLPFC tSMS. Both left and right DLPFC tSMS increased post-stimulation global theta oscillations relative to sham, with a greater increase in response to right stimulation. Beta oscillations in the left hemisphere increased post-stimulation for left and right DLPFC tSMS compared to sham. We concluded that DLPFC tSMS modulated the network oscillations in regions distant from the location of stimulation and that tSMS has region specific effects on neural oscillations.

**Title:** Entrainment of alpha oscillations by transcranial alternating current stimulation in the ferret

**Authors: *E. NEGAHBANI**[1], I. M. STITT[1], S. RADTKE-SCHULLER[1], T. DOAN[6], M. DANNHAUER[6], A. V. PETERCHEV[6,7,8], F. FROHLICH[1,2,3,4,5]

**Abstract:** Despite the growing number of applications of transcranial alternating current stimulation (tACS), the underlying mechanisms remain largely unknown due to the lack of technical feasibility of simultaneous electroencephalography (EEG) and tACS. Previously, our simulations showed that tACS entrains neuronal firing and that the entrainment depends on the match of stimulation frequency to the endogenous frequency as a function of stimulation amplitude (Arnold tongue). Yet, experimental confirmation has been lacking. Here, we tested the hypothesis that tACS modulates alpha oscillations by entraining single neurons as described by the Arnold tongue. We used the head-fixed ferret (*Mustela putorius furo*) as the animal model since it displays robust thalamo-cortical alpha oscillations.
We implanted multielectrode arrays in a 3-node thalamocortical network including the lateral posterior (LP)/Pulvinar nuclear complex of the thalamus, the posterior parietal cortex (PPC) and the primary visual cortex (VC, area 17). tACS electrodes were placed on the left frontal (above the eye) and the medial occipital regions. Animals (n = 3) received 12 stimulation sessions, each including 54 stimulation trials drawn randomly from combination of 6 different amplitudes (all subthreshold) and 9 frequencies (centered on the individual endogenous alpha frequency). We also developed a computer model of the distribution of the tACS electric field in the ferret head to guide and validate the stimulation protocol.
Neurons at PPC and VC but not LP/Pulvinar phase synchronized to the tACS waveform as characterized by Arnold tongues centered on the endogenous peak frequency (~ 14 Hz), thus confirming the predictions of the computational models. tACS synchronized the PPC neurons stronger than the ones in VC. Further delineation indicated that tACS synchronized the narrow-spiking neurons more strongly than wide-spiking neurons in both PPC and VC. Further analysis showed that narrow spiking neurons were also more strongly phase-locked to the endogenous oscillations.
Together, our results represent the first in-vivo demonstration of entrainment of alpha oscillations by tACS that is characterized by an Arnold tongue. This experimental confirmation of the theoretical predictions from computational modeling paves the way for future, mechanistic investigations of how tACS modulates network oscillations, including how plasticity enables effects of tACS to be maintained after stimulation.

**Abstract:** Synchronized activity in the fronto-parietal network plays a crucial role in attention and other cognitive functions, and is disrupted in schizophrenia and other psychiatric disorders. Recent studies have begun to investigate the development of fronto-parietal functional interactions. However, these studies use EEG or fMRI, two methods which are limited by their spatio-temporal resolution. To fill the knowledge gap between very early network activity patterns in local networks[1] and the mature network synchronization patterns that are linked to cognitive function, we performed microelectrode electrophysiological recordings in developing ferrets (*Mustela putorius furo*), an altricial animal model system with a long history in the study of development. We implanted multielectrode arrays into the frontal (prefrontal and premotor, PFC/PMC) and posterior parietal cortex (PPC) for simultaneous recordings of single-units and local filed potentials (LFPs). We recorded from freely-moving animals from postnatal day 26 to 77 (P26-P77). To probe functionally and translationally relevant network activity patterns, we used an auditory oddball test which is commonly used to detect pathologically altered network activation in schizophrenia.
A total of fourteen sessions were recorded from seven animals. Coherence analysis revealed that, similar to a previous finding in adult ferrets during a sustained attention task[2], the LFP signals in PFC/PMC and PPC were synchronized in theta band (4-8 Hz) during the oddball test as early as P26. The theta coherence was higher in trials with the deviant tone compared to trials with the standard tone (t-test, $p < 0.05$, $n = 14$ sessions). The action potentials in both brain regions were phase-locked to the LFP in the theta band; and the phase-locking value was higher for the deviant than the standard tone (PFC/PMC, $p < 0.01$, $n = 160$ single-units; PPC, $p < 0.05$, $n = 37$). When assessed as a function of age, the enhancement of theta coherence by the deviant tone

became shorter in duration and less delayed to the tone onset.
Together, our results suggest that fronto-parietal interactions track circuit maturation and may represent an attractive target for future network-based interventions during development for the prevention and treatment of neuropsychiatric disorders.

**Title:** Characterizing social and cognitive development in nrem sleep and risk for asd

**Authors: *J. PAGE**[1], C. LUSTENBERGER[2], F. FROHLICH[3]
[1]Frank Porter Graham Child Develop. Institute, U, Chapel Hill, NC; [2]ETH Mobile Hlth. Systems Lab., Zurich, Switzerland; [3]Psychiatry, Univ. of North Carolina, Chapel Hill, NC

**Abstract:** Early childhood is characterized by rapid development and pronounced changes in both early brain function and learning. Both are thought to be fostered by sleep [1], specifically non-rapid eye movement (NREM) sleep. NREM sleep is characterized by the presence of slow wave activity (SWA) and sleep spindles (10-16 Hz) [2], which are related to intelligence and general learning traits in adults, school aged children [3], and cognitive and social development in infants/toddlers [4]. Sleep spindle characteristics are widely studied in young adults and school aged children, and show clear developmental changes [5]. Furthermore, spindle features are altered in several neurodevelopmental disorders, such as autism spectrum disorder (ASD) in both adults [6] and children [7]. Sleep spindles may, therefore, represent a useful biomarker to distinguish typical from atypical development. However, the topographical and spectral

characteristics of sleep spindles has yet to be examined in infants/toddlers with risk for autism and moreover it is unknown how these features are associated with outcomes of early cognitive and social development.To do address this gap, we conducted a study to characterize the topography of sleep spindles in 12 - 30 month typically developing (TD) infants/toddlers and risk for ASD (meeting diagnostic criteria based on the ADOS-2) and examined associations with cognitive and social development. Here, we report preliminary nap data in TD and ASD group with high density electroencephalogram (hdEEG, 128 electrodes) and associations with cognitive and social development. Initial findings show decreased spectra power in theta (4-7 Hz), slow (10-12Hz) and fast (14-16Hz) spindles, and increased beta (20-25Hz) activity, in infants/toddlers in the ASD group. Infants/toddlers at-risk of ASD showed negative correlations with theta, slow and fast spindles, and beta on measures of cognitive and social development. Autism severity was negatively correlated with frontal sleep spindles, and positively correlated with beta oscillations. Thus, participants with increased symptom severity showed decreased spindles and increased beta activity. These findings suggest an important role of network dynamics of NREM sleep in cortical maturation and the associated development of both cognitive functioning and risk for neurodevelopmental disorders.

**Title:** Target engagement of alpha oscillations by transcranial alternating current stimulation (tacs) in patients with chronic low back pain

**Authors: *J. PRIM**[1,6], S. AHN[2,6], M. ALEXANDER[2,6], M. DAVILA[2], K. MCCULLOCH[1], F. FROHLICH[2,6,3,4,5]
[1]Allied Hlth. Sci., [2]Psychiatry, [3]Neurol., [4]Neurosci., [5]Cell Biol. and Physiol., Univ. of North Carolina, Chapel Hill, NC; [6]Carolina Ctr. for Neurostimulation, Chapel Hill, NC

**Abstract:** Chronic low back pain (LBP) is the second most prevalent cause of disability in US adults. Although extensively studied, current therapeutic options for chronic pain are limited. The development of a new, safe, scientifically-supported, low-cost treatment for chronic pain is imperative for helping the millions of people with chronic pain who suffer from physical handicaps and common psychiatric comorbidities such as opioid addictions and depression. Chronic pain ultimately is a disorder of the central nervous system, which is manifested in aberrant activity patterns such as network oscillations in the thalamo-cortical system. We hypothesized that transcranial alternating current stimulation (tACS), which is a non-invasive brain stimulation tool developed to modulate brain rhythms, can be used as a treatment option in patients with LBP by modulating abnormal neuronal activity. Here, we evaluated the efficacy and feasibility of tACS in 20 patients with LBP by conducting a double-blind, randomized, placebo-controlled cross-over single site study. We hypothesized that 10Hz-tACS would modulate abnormal alpha oscillations and automatic nervous system (ANS) regulation resulting in pain relief. We applied a single session of 10Hz-tACS for 40 minutes and recorded electroencephalography (EEG) and heart rate variability (HRV). We measured pain severity assessed by the Defense and Veterans Pain Rating Scale (DVPRS), Pressure Pain Threshold (PPT), and Oswestry Disability Index (ODI). Changes in alpha oscillations from EEG data and high frequency component (HF) (known as respiratory sinus arrhythmia) from HRV data were presented as primary outcomes. Changes in pain severity were secondary outcomes.
We found that baseline alpha oscillations were negatively correlated with pain severity ($p$<0.05, FDR corrected). and 10Hz-tACS enhanced alpha oscillations in the somatosensory region ($p$<0.05, FDR corrected). Importantly, the enhancement of alpha oscillations were significantly correlated with pain relief (normalized pain changes) in the frontal and somatosensory regions ($p$<0.05, FDR corrected) in the active tACS condition while no correlation was seen in the condition. We found a significant treatment effect in the HF of HRV (Linear mixed-effects model, $F(1,56)=8.61$, $p<.01$) and a negative correlation between HF and pain severity ($r=-0.47$, $p<.01$). There was a treatment effect using the nonparametric signed rank test for normalized pain changes. These findings suggest that 10Hz-tACS could be a network-level approach for treating patients with LBP. Further studies with larger sample sizes are needed to better understand the effect of tACS on chronic pain.

**Title:** Physiological correlates of the ANS and HPA-axis in active and passive music therapy interventions

**Authors: *T. MCPHERSON**[1,2], D. BERGER[1], S. ALAGAPAN[1,2], F. FROHLICH[1,2,3,4,5]
[1]Psychiatry, [2]Carolina Ctr. for Neurostimulation, [3]Neurol., [4]Neurosci. Ctr., [5]Cell Biol. and Physiol., Univ. of North Carolina, Chapel Hill, NC

**Abstract:** Music therapy (MT) is an innovate multicomponent intervention that has been shown to treat major depressive disorder (MDD), yet specific components that drive efficacy remain unknown. Rhythm has emerged as a component that is hypothesized to be critical for MT. Active MT requires patients to engage rhythmically with music, embodying a pulse by coordinating their playing with the music. In contrast, passive MT only requires patients to listen to music, omitting the sensorimotor engagement that is central to active MT. This differential impact of rhythmic engagement in MT interventions remains unexplored. Dysregulation of the autonomic nervous system (ANS) and the hypothalamic-pituitary-adrenal (HPA) axis have been implicated in MDD. MT has been shown to modulate heart rate variability (HRV) and stress hormone levels, physiological correlates of the ANS and HPA-axis, respectively, suggesting that MDD could be treated with MT. Here we contrasted the effects of active and passive MT interventions to examine the differential impact of rhythmic engagement on the ANS and HPA-axis in healthy control participants.Healthy participants (N=16) participated in both an active and a passive 40 minute MT intervention session on separate days spaced at least one-week apart. HRV recordings and saliva samples were collected both before and after each intervention session. The high frequency component (HF) and the low frequency divided high frequency components (LF/HF) were calculated (HRV markers of parasympathetic and sympathetic ANS activation, respectively) and saliva samples were analyzed for alpha-amylase and cortisol (endocrine markers of the sympathetic ANS and HPA-axis, respectively). Normalized change scores over the duration of the interventions—log(post/pre)—were calculated for each correlate. ANOVA of change rate was used to compare the effects of session order (1st and 2nd) and condition (active and passive) on these change scores. A main effect was found for condition in LF/HF

(F(1,27)=8.206, p=0.00783, ηp2=0.227), where active MT decreased LF/HF power (mean change, -0.3872), while passive MT increased LF/HF power (mean change, 0.3731). There was no effect of condition for alpha-amylase (F(1,27)=1.216, p=0.280, ηp2=0.0416), cortisol (F(1,27)=0.054, p=0.817, ηp2=0.00194), or HF (F(1,27)=0.004, p=0.952, ηp2=0.000132). These results indicate that MT effectively targets the ANS and suggests that differences in rhythmic engagement between active and passive MT leads to a differential modulation of the sympathetic ANS.

**Abstract:** Neural oscillations are a fundamental mechanism that organizes the temporal relationship of activity patterns in large-scale brain networks. Several psychiatric disorders have been associated impairment of neural oscillations [1]. In particular, patients with schizophrenia exhibit impaired neural oscillations involved in sensory and cognitive processing [2]. Therefore, strategies to target and modulate impaired neural oscillations may serve both as tool to investigate the causal relationship between oscillation abnormalities and symptom manifestations and, ultimately, to treat patients by restoring physiological oscillation dynamics. Transcranial

alternating current stimulation (tACS) is a non-invasive brain stimulation modality that applies oscillating electrical currents to the brain via scalp electrodes. A single session of tACS enhances posterior alpha oscillations (8-12 Hz) in healthy humans [3]. Yet, it has remained unknown if tACS, and in particular repeated application of tACS, can alter or modulate network in disorders associated with dysfunction of neural oscillations such as schizophrenia.
In this study, we performed a randomized, double-blind, sham-controlled clinical trial to contrast tACS with transcranial direct current stimulation (tDCS) and sham (i.e., placebo) stimulation in 22 schizophrenia patients with auditory hallucinations. Clinical results were recently reported in a separate paper [4]. We used high-density electroencephalography to investigate if a five-day, twice-daily 10Hz-tACS protocol enhances alpha oscillations and modulates network dynamics that are impaired in schizophrenia. We found that 10Hz-tACS enhanced alpha oscillations ($F$6,57=3.49, $p$=0.005) on day 5 of stimulation and modulated the strength of global functional connectivity to 10Hz. In addition, 10Hz-tACS enhanced the 40Hz auditory steady-state response (ASSR, $F$6,57 =4.20, $p$=0.001), which is impaired in patients with schizophrenia.
Importantly, clinical improvement of auditory hallucinations correlated with enhancement of alpha oscillations and the 40Hz-ASSR. Together, our findings suggest that tACS has potential as a network-level approach to modulate impaired neural oscillations related to clinical symptoms in patients with schizophrenia.

**Abstract:** Major depressive disorder (MDD) is one of the most prevalent psychiatric disorders, but existing pharmacological treatments are non-specific and associated with poor remission rates and undesirable side effects. Safer, more effective, targeted treatments are urgently needed. Here, we evaluated the efficacy and feasibility of transcranial alternating current stimulation (tACS), which we hypothesized would improve clinical symptoms by reducing alpha oscillations in the left frontal regions. (NCT02339285)25 participants were randomized to one of three arms (10Hz-tACS, 40Hz-tACS, or active sham stimulation) and received daily 40 minute sessions over five consecutive days. We measured change in clinical symptoms using the Montgomery-Åsberg Depression Rating Scale (MADRS) as the primary outcome, and change in alpha oscillations as measured by high-density electroencephalography (hdEEG) as the secondary outcome. Exploratory analyses were performed on the Hamilton Depression Rating Scale (HDRS), Beck Depression Inventory (BDI), and Montreal Cognitive Assessment (MoCA).Although there was no significant interaction between treatment condition (10Hz-tACS, 40Hz-tACS, sham) and session (baseline to four weeks after completion of treatment), exploratory analyses showed significance at 2 weeks following completion of treatment, with more participants in the 10Hz-tACS group responding to treatment as measured by the MADRS and HDRS in comparison to the 40Hz-tACS and sham groups. Furthermore, we found a significant reduction in alpha power over the left frontal regions in EEG after completion of the intervention for only the group that received 10Hz-tACS. Importantly, the treatment was safe and feasible, with the majority of patients completing all sessions and no adverse events, mania, or hypomania during the course of the study.To our knowledge, this is the first clinical trial of tACS for the treatment of MDD. Additional studies with larger sample sizes are needed to better understand the effect of tACS on depression.

**Title:** Higher-order visual thalamus orchestrates cortico-cortical synchronization during sustained attention

**Authors: *W. A. HUANG**[1,2], S. RADTKE-SCHULLER[1], Z. C. ZHOU[1,2], F. FROHLICH[1,2,3,4,5]
[1]Psychiatry, [2]Neurosci. Curriculum, [3]Neurosci. Ctr., [4]Neurol., [5]Cell Biol. and Physiol., Univ. of North Carolina, Chapel Hill, NC

**Abstract:** Sustained attention, the continuous allocation of processing resources to respond to infrequent but behaviorally relevant stimuli[1], is impaired in many psychiatric disorders and represents an important aspect of cognitive control[2]. Sustained attention requires engagement with the external world and is modulated by thalamo-cortical rhythms[3]. Despite the extensive behavioral characterization of sustained attention, very little is known about the underlying thalamo-cortical oscillations and their potential role as a stimulation target for enhancing sustained attention. Here, we studied this question by simultaneous recording from three reciprocally connected nodes in the thalamo-cortical visual circuit: pulvinar complex (lateral aspect of lateral posterior nucleus, LPl) - posterior parietal cortex (PPC) - primary visual cortex (V1) circuit, in ferrets (*Mustela putorius furo*). To probe visual sustained attention, we employed a widely used paradigm: the five-choice serial reaction time task (5-CSRTT)[4], in ferrets, as ferrets have a relatively well-developed higher-order visual thalamus. In this task, animals need to pay attention to a computer screen during a delay period with random length until a visual stimulus is presented, which the animal touches for reward. We found that (1) theta-band (4-8 Hz) functional connectivity (eg. coherence) between LPl, PPC and V1 dominates and increases during the delay period before the animal touched the correct stimulus location, (2) this functional connectivity is directed from LPl to PPC and V1, and (3) the LPl theta phase couples to the local gamma amplitude (40-80 Hz) and PPC/V1 gamma coherence (30-60 Hz). As a whole, our study determines the role of thalamic theta in coordinating cortical functional connectivity of the LPl-PPC-V1 during sustained attention and provides targets for subsequent

optogenetic circuit interrogation. Our work will ultimately provide a circuit-level mechanistic explanation on how a higher-order visual thalamic structure modulates cortical communication, and may represent a fundamental link between neural network activity and behavior.

**Title:** Pilot double-blind, placebo-controlled clinical trial of the effect of transcranial alternating current stimulation (tacs) on the stress-immune response

**Authors: *J. PARIKH**[1], S. AHN[2], M. L. ALEXANDER[2], S. ALAGAPAN[2], F. FROHLICH[2,3,4,5,6]

**Abstract:** Stress is evolutionarily important to survival; however, high levels can lead to adverse health outcomes. Stress responses are characterized by the activation of two pathways: the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic division of the autonomic nervous system (SNS). These pathways are regulated via a top-down mechanism, where reflexes in the brain produce physiological changes elsewhere in the body. Additionally, immune activity is closely related to stress, with cytokine markers reacting to SNS activation and entering a negative feedback loop with the HPA axis. This research sought to target the top-down mechanism of the stress pathways using 10Hz bifrontal Transcranial Alternating Current Stimulation (tACS) (NCT03178344).

20 participants underwent 40 minutes of tACS or an active sham condition at two separate sessions in a double-blind, randomized, crossover study design. Saliva samples were collected before and after stimulation to test for alpha amylase (indicator of SNS), cortisol (indicator of HPA axis), and a cytokine panel (indicator of immune functioning) as the primary outcomes, and change in alpha oscillations was measured by high-density electroencephalography (hdEEG) as the secondary outcome. Exploratory analyses were performed using the State-Trait Anxiety Inventory (STAI), Perceived Stress Scale (PSS), Connor-Davidson Resilience Scale (CDRISC), and the Behavioral Inhibition and Activation Scales (BIS/BAS).

Results demonstrated an effect of stimulation in reducing alpha amylase activity as well as two markers of the cytokine panel, indicating a decreased stress and immune response in the verum stimulation condition. Furthermore, exploratory analyses indicated a positive relationship between interleukin 1-beta and scores on the PSS, and a similar inverse relationship between the same cytokine marker and scores on the CDRISC, suggesting a mediating effect of resilience on responses to tACS. Finally, there were no adverse events or negative effects of verum stimulation on any of the markers, supporting other evidence of tACS as a safe and effective method for use in human populations.

This research adds to the understanding of the physiological effects of tACS, as well as provides a basis for tACS as a possible treatment for individuals with chronic stress and anxiety. To our knowledge, this is the first clinical trial exploring the effect of tACS on the stress-immune response. Additional studies involving larger sample sizes and clinical populations are needed to further expand on these findings.

**Title:** Optically-resolved posterior parietal cortex neural populations show NMDA receptor-dependent visual deviance detection

**Authors: *Z. C. ZHOU**[1,2], Y. YU[3,4], Y. LI[1], F. FROHLICH[1,5,3,4,6]
[1]Psychiatry, [2]Neurosci. Curric., [3]Cell Biol. and Physiol., [4]Neurosci. Ctr., [5]Neurol., [6]Carolina Ctr. for Neurostimulation, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

**Abstract:** Disorders such as schizophrenia and attention deficit hyperactivity disorder (ADHD) are characterized by impairments in context-dependent sensory processing (i.e., the inability to distinguish between frequent and rare stimuli) [1]. Such sensory processing impairment may arise from the lack of cognitive control from higher-order brain areas, for example, the parietal cortex which is involved in both sensory processing and stimulus history [2,3]. However, little is known about how single neuron activity gives rise to population dynamics that distinguishes if a stimulus has been present frequently or infrequently. In human electroencephalography (EEG) studies, the sensory response amplitude is modulated by the frequency of stimulus presentation, a phenomenon that is termed deviance detection (DD). To address this gap in knowledge, we recorded 2-photon calcium activity in parietal cortex of the head-fixed ferret during a visual oddball paradigm. We hypothesized that a distinct subnetwork of neurons shows DD which is impaired by blocking NMDA receptors with MK801. During the recordings, we presented to the animals drifting grating stimuli with differing motion directions. In each recording block, one stimulus was presented frequently (standard - 90% occurrence) and the other infrequently (deviant - 10%). We found that a DD effect arose from neurons that showed enhanced activity in the deviant context at trend level (2-way ANOVA; saline: 51/322 neurons, $F(2, 341) = 2.82$, $p = 0.06$); in MK801 sessions, the DD diminished (34/124 neurons, $F(2, 203) = 1.03$, $p = 0.36$). Ninety neurons were found to enhance activity to the standard context, and 57 enhanced to the deviant context. Interestingly, there was heavy overlap of these neurons that enhanced to both contexts (44 neurons); further we found that these neurons contributed the most to the DD effect. Importantly, these results suggest that the parietal cortex differentiates oddball context, and that the mechanism of such context distinction relies on NMDA-receptor function of specific subpopulations. With these findings, we hope to ultimately gain a mechanistic understanding of context-dependent cognitive deficits by bridging the gap between single neurons and population-

**Title:** Bidirectional closed-loop optogenetic control of gamma oscillations reveals their role in memory consolidation

**Authors: *V. KANTA**[1], D. PARE[2], D. B. HEADLEY[3]
[1]Rutgers, the State Univ. of New Jersey, Newark, NJ; [2]Rutgers Univ. Newark, Newark, NJ; [3]Rutgers, The State Univ. of New Jersey, Newark, NJ

**Abstract:** Gamma oscillations are local field potential (LFP) fluctuations between 30-100 Hz that occur throughout the brain. They are thought to coordinate neuronal interactions not only locally, but also between regions. Testing the role of gamma oscillations had so far not been possible because previously available techniques did not allow for up- or down-regulation of gamma without substantial off-target effects. Here, we introduce a novel approach for detecting and modulating spontaneous gamma oscillations. Specifically, we achieved real-time control over these oscillations by combining optogenetics with programmable multi-channel signal processors, known as “field programmable gate arrays” (FPGAs). Unlike computers, FPGAs allow nearly instantaneous signal analysis and conditional light stimulus delivery, providing unprecedented control over fast neuronal events like gamma. This method has allowed us to track gamma burst cycles with millisecond accuracy and deliver optogenetic stimuli with both frequency and phase specificity. As a test-bed for our method, we examined whether gamma oscillations in the basolateral amygdala (BLA) mediate the facilitation of memory consolidation by emotions. It was previously shown that manipulations which increase or decrease BLA

activity after training respectively enhance or impair subsequent memory recall. Moreover, it was reported that emotionally arousing stimuli elicit prominent gamma oscillations in the BLA. We first tested whether gamma oscillations were present during the consolidation of emotional memories in Long Evans rats implanted with electrodes in the BLA. We found that the power of mid-gamma oscillations (40-70 Hz) is increased in the BLA immediately after training on aversive and appetitive spatial memory tasks, and that this increase correlates with subsequent memory strength. Next, we used our closed-loop gamma detection algorithm to deliver 2 ms light pulses either in-phase (trough) or out-of-phase (peak) with ongoing gamma. These tests were carried out in subjects that had received AAV infusions in the BLA, driving the expression of the excitatory opsin Chronos. By timing light pulses to particular oscillatory phases, we could boost or diminish oscillations, specifically in mid-gamma. When these manipulations were carried out immediately after training in a spatial task, subsequent memory strength was respectively enhanced or impaired. This study introduces a novel closed-loop optogenetic method to modulate fast oscillatory rhythms in real time. Importantly, our results directly link gamma oscillations in the BLA with the emotional modulation of memory consolidation.

**Abstract:** The basolateral nucleus of the amygdala (BL) supports a plethora of psychological processes, from emotional behaviors to memory consolidation. Recent experimental work in the lab of our collaborator has successfully developed a closed-loop real-time optogenetic control system that reliably detects and modulates gamma-oscillatory bursts in the BL with frequency and phase specificity (Kanta et al., 2017), and more importantly, that this modulation affects memory consolidation.
However, how gamma modulation affects the functioning of specific neuronal microcircuits in BL is not clear. In this study, we investigate this using a large scale biophysical computational

model of the BL. We first replicate several features of gamma oscillations seen in *in vivo* local field potential recordings from BL (Amir et al., 2018), including their spectral composition, entrainment of unit activity and spatial heterogeneity. Our network model also produces gamma as transient, several cycle long bursts, mimicking the fine structure of gamma rhythmogenesis seen *in vivo*. We then add expression of channelrhodopsin in selected neuron subpopulations, with the aim of seeking a deeper understanding of the mechanisms of optogenetic control on gamma oscillations in BL. The model is used to study various aspects of the control of oscillations including specificity, optimal conditions, and limitations.

**Abstract:** Predicting the future of a time series given past measurements is an open problem in machine learning. This is applicable to neuroscience when one wants to use statistical models to predict upcoming patterns in the local field potential (LFP) or electroencephalogram (EEG). With these models, experimenters can create closed loop control systems that provide more accurate feedback to the brain via optogenetic or transcranial magnetic stimulation. In this study, we trained different statistical models to use past values in the LFP to predict its future state. In particular, we are interested in predicting the occurrence of bursts of gamma-band activity (64-84 Hz), and the time domain values of the LFP out to 10 ms in the future. To accomplish this task, we examined the performance of four different models: autoregressive linear prediction (AR), feed forward artificial neural networks (ANN), convolutional neural networks (CNN), and recurrent neural networks (RNN). Preliminary results show that the AR model does not perform significantly better than chance in predicting gamma bursts, suggesting nonlinear dependency in the data. Averaging the raw LFP data for 50 ms prior to the burst (similar to a spike triggered average) did, however, show an interesting trend of higher mean voltage level ending with a rising slope. ANN prediction of the gamma-band filtered signal 10 ms ahead in time has an

accuracy approaching 70% on testing data, with accuracy improving to 85% with the addition of a low-pass filtered version and the raw LFP signal. We are presently exploring Long Short Term Memory (LSTM), and evolutionary learning algorithm approaches to enhance accuracy. One of our goals is to implement the best performing algorithm in a field programmable gate array (FPGA) to enhance the prediction of gamma bursts in real-time.

**Title:** Gamma oscillations in the basolateral amygdala: Regional specialization, microcircuit mechanisms, and behavioral correlates

**Authors: *D. B. HEADLEY**[1], P. KYRIAZI[2], D. PARE[3]
[1]Rutgers, The State Univ. of New Jersey, Newark, NJ; [2]Behavioral and Neural Sci., Rutgers University, The State Univ. of New Je, Newark, NJ; [3]Rutgers Univ. Newark, Newark, NJ

**Abstract:** The basolateral amygdala (BLA) is a cortical-like structure that mediates a variety of emotional behaviors. Like cortex, it generates gamma oscillations, which are local field potential (LFP) fluctuations at 30-100 Hz. In the BLA, gamma oscillations are most prominent in conditions of emotional arousal, when they coordinate the activity of fast-spiking interneurons and pyramidal cells, similarly to what has been reported in cortex. However, many properties of gamma oscillations in the BLA remain unclear. For instance, we do not know if they are similarly expressed in the basolateral (BL) and lateral (LA) nuclei, whether they coordinate local microcircuits similarly across nuclei, and if they are differentially recruited by positively or negatively valenced events. The present study explores these questions. Long Evans rats were implanted with silicon probes in the BLA to record LFPs and unit activity. They were then trained to respond to a light CS that depending on its position signaled either reward availability or an impending footshock. The footshock could be avoided passively or actively, depending on the rats' position in relation to the CS. During the inter-trial interval, spontaneous gamma oscillations were only observed in the BL nucleus (mid-gamma, ~55 Hz). Moreover, principal and fast-spiking cells in BL had substantially higher entrainment to gamma compared with those in LA. Further analyses revealed that this disparity was associated with differences in the

prevalence of fast-spiking cells and in their connectivity with principal neurons. Compared to LA, BL had a higher proportion of fast-spiking interneurons, paralleling the higher incidence of parvalbumin expressing cells in BL than LA. We also found that BL had a higher probability of connections between principal cells and fast-spiking interneurons, a connection known to be crucial for gamma genesis. During task events, mid-gamma power increased in BL and LA, particularly at the onset of the conditioned stimuli and active behaviors, such as active avoidance and reward approach. Moreover, gamma power gradually ramped up during behavioral freezing, until the rat either avoided or was shocked. Together, these results suggest that gamma oscillations are differentially expressed in BL and LA, likely because of differences in their intrinsic connectivity. Moreover, our findings indicate that gamma oscillations are similarly engaged during positively and negatively valenced stimuli or behaviors, suggesting that they act as a general mechanism for coordinating ensemble activity. This material is based upon work supported by NIMH R01 grants MH107239 and MH112505 to Denis Paré.

**Abstract:** Accumulating evidence suggested that physical exercise improves various brain function, including memory and learning, emotion and cognitive/executive functions. The multiple effects of exercise on the brain function may be due to interaction of neural activation of multiple brain regions stimulated by exercise. Furthermore, previous studies have suggested that the beneficial effects of exercise on brain functions are different depending on intensity of the exercise. Thus, it is possible that physical exercise forms exercise-specific functional brain network, which is defined by co-activation of multiple brain regions, and that the functional brain network recruited by exercise may depend on intensity of the exercise. However, the functional brain networks underlying the beneficial effects of exercise remain unclear. In the present study, we tried to identify the functional brain network recruited by acute treadmill

running at different intensities (30 min; high speed, 25 m/min; low speed, 15 m/min; control, 0 m/min) in male Wistar rats, using c-Fos immunohistochemistry and correlation analysis. We selected 23 brain regions as ROI, including cortex, limbic system, hypothalamus, and brainstem, which are regions associated with mental or motor functions. We mapped functional brain network recruited by each physical exercise, using correlation analysis to the inter-regional c-Fos expression data obtained after each exercise condition. Furthermore, we characterized properties of the functional brain networks, using graph theoretical analysis. Acute treadmill running increased c-Fos expression of motor cortex, sensory cortex, amygdala and hippocampus, regardless of exercise intensity. On other hand, high speed group showed significantly more c-Fos-positive cells in medial prefrontal cortex, the hypothalamic paraventricular nucleus, nucleus accumbens, caudate putamen and the locus ceruleus nucleus, compared to control group. Low speed group showed significantly more c-Fos-positive cells in the dorsal raphe nucleus and cingulate cortex, compared to control group. These results suggests that the effects of exercise on brain functions are different depending on intensity of the exercise. Furthermore, the functional brain network in low speed group had more connection expressing inter-regional negative correlation than that in control group, whereas the functional brain network in high speed had no connection expressing inter-regional negative correlation. These results suggest that acute physical exercise at different intensities could form intensity-specific functional brain networks.

**Abstract:** Human resting state (rs) brain activity is characterized by temporal fluctuations across variety of timescales. In the sub-second timescales, activity is characterized by neuronal

oscillations in many frequencies. In timescales of seconds to tens of minutes, scale-free fluctuations and power-law long-range temporal correlations (LRTCs) characterize the amplitude envelopes of neuronal oscillations. Scale-free dynamics and LRTCs are suggestive of critical neuronal dynamics, which endows the brains with an optimal information processing capacity. LRTCs in neuronal activity have high inter-individual variability. Twin studies have indicated a strong genetic inheritance of this variability. Cortical signal variability affects both neuronal oscillations and scale-free fluctuations. These result of changes in neuronal firing patterns which in turn are affected by dopaminergic (DA) neurotransmission. We investigated whether scale-free dynamics as evidenced by LTRCs in oscillation amplitude envelopes could be modulated by DA transmission. DA is regulated by the Catechol-O-methyltransferase (COMT, rs4680). The greatest variance in COMT activity is explained by a single nucleotide polymorphism (Val/Met) at codon 158. Val/Met substitution results in reduction in enzyme activity and higher cortical DA-levels. We hypothesized that COMT polymorphism and DA-levels could influence LRTCs and brain critical dynamics in rs oscillatory activity. We recorded rs magnetoencephalography (MEG) data from 83 healthy volunteers (18-55 years of age; 6 left-handed; 44 female), genotyped using Infinium PsychArray-24 v1.1 (Illumina). The sample consisted of 18 Val/Val, 49 Val/Met, and 16 Met/Met carriers. We estimated oscillation amplitude envelopes between 3-120 Hz for cortically source-reconstructed MEG data and used detrended fluctuation analysis (DFA) to quantify the LRTCs. The genotypes differed in brain dynamics in gamma (30-60 Hz) band. Compared to Met/Met and Val/Val homozygotes, Val/Met heterozygotes exhibited greater scaling exponents, especially in the frontal, insular, limbic, parietal and temporal regions. These genotype differences in LRTC scaling exponents were not explained by the amplitude of the gamma oscillations. As the Val allele is associated with less synaptic dopamine compared to Met allele, our data suggest that intermediate brain DA-levels are associated with the strongest LRTCs in rs oscillatory activity.

**Title:** Excitation/inhibition balance in the aMCC influences resting state activity in the CEN

**Authors: *L. V. DANYELI**[1,2,3,4], L. COLIC[1,3], D. DENZEL[6,3], F. VON DÜRING[3], L. R. DEMENESCU[3], M. LI[3,6], M. WALTER[1,2,3,6,5]
[1]Leibniz Inst. For Neurobio., Magdeburg, Germany; [2]Dept. of Psychiatry and Psychotherapy, Univ. Tübingen, Tübingen, Germany; [3]Clin. Affective Neuroimaging Lab., Magdeburg, Germany; [4]IMPRS for Cognitive and Systems Neurosci., [5]Max-Planck-Institute for Biol. Cybernetics, Tübingen, Germany; [6]Med. Fac., Univ. Magdeburg, Magdeburg, Germany

**Abstract:** *Background:* Excitation/inhibition balance can be used as a predictor not only for the functional regional response in the task-based functional magnetic resonance imaging (fMRI) but also for functional connectivity (FC) strength measured within and between networks. Previous studies reported that both Glutamate (Glu) and γ-Aminobutyric acid (GABA) levels can predict within network connectivity patterns. However, the results were inconsistent and they were mainly focused on the default mode network confirming that there is a need for more robust and extensive measurements. Therefore, we investigated whole brain associations between the main excitatory - Glu - and inhibitory neurotransmitter - GABA - with the FC of the anterior mid cingulate cortex (aMCC), a node of the salience network (SN), with a particular focus on regions of the central executive network (CEN). We additionally explored how these metabolites influence basic neuronal measurements such as fractional amplitude of low frequency fluctuation (fALFF).
*Methods*: 78 healthy subjects (39 females, age = 26.97 ± 6.53) completed a research paradigm that included a resting-state fMRI and a magnetic resonance spectroscopy (MRS) session in 7T. An MRS voxel was placed in the aMCC, and Glu, GABA and Creatine (Cr) levels were acquired using a stimulated-echo acquisition mode (STEAM) sequence. A regression analysis was conducted in SPM8 between metabolites and aMCC voxel-seed FC maps with age, sex and grey matter ratio as covariates of nuisance. Additionally, the same regression analysis was performed for fALFF. Results are reported on FWE < 0.05 cluster level significance with an initial threshold of $p < 0.001$, uncorrected.
*Results*: Glu/Cr and aMCC voxel FC showed a strong negative association in the left posterior frontal gyrus and several nodes of the visual cortex. A regionally converging positive correlation was found between fALFF and GABA/Cr in the left posterior frontal gyrus.
*Conclusion*: Both GABA and Glu levels measured in the aMCC predict the strength and the basal activity of the posterior frontal gyrus, which is a node of the CEN.

**Abstract:** In resting conditions, breathing is typically characterized by an active inspiratory phase and a passive expiratory phase. Expiration may become active through abdominal (ABD) muscle recruitment during periods of increased inspiratory requirements. This respiratory rhythm is thought to be controlled by three coupled oscillators in the ventral medulla: preBötzinger complex (preBötC) for generating inspiration, the parafacial respiratory group (pFRG) for generating active expiration, and the post-inspiratory complex (PiCo) which is thought to control the post-inspiratory phase. Although there exists abundant evidence linking preBötC activity to the generation of respiratory rhythm, research addressing the role of pFRG in ventilation and rhythm generation across sleep states is limited. Recent work in our laboratory reports the occurrence of ABD recruitment during REM sleep, despite the induction of muscle paralysis during this sleep state. This ABD recruitment was associated with a stabilization of breathing in healthy rats. Because pFRG generates active expiration through the engagement of ABD muscles, we hypothesize that the expiratory oscillator is also responsible for the ABD recruitment observed during REM sleep in healthy rats. To test this hypothesis, we inhibited and activated the pFRG oscillator using a chemogenetic approach (DREADDs) while simultaneously recording EEG, airflow, ABD and neck EMG of transfected rats across sleep/wake cycles. Our results suggest that manipulation of pFRG activity influences expiratory ABD recruitment events during REM sleep. Inhibition of pFRG significantly reduced the number of REM events with ABD recruitment, whereas activation of this oscillator resulted in an increase of the number of REM events in which ABD recruitment was observed. Interestingly, modulation of pFRG activity did not seem to affect ABD recruitment during NREM sleep. These results suggest that ABD recruitment may occur through different mechanisms across states.

**Title:** Phase-specific effects of alpha tACS on functional resting-state connectivity in the motor network

**Authors: *K. F. HEISE**, E. BOKKEN, B. KING, G. ALBOUY, D. MANTINI, S. P. SWINNEN
Dept. of Movement Sci., Katholieke Univ. Leuven, Leuven, Belgium

**Abstract: Background:** Transcranial alternating current stimulation (tACS) has been shown to modulate endogenous neural rhythms in a frequency-specific way. Our aim is to investigate whether tACS induced modulation of resting-state (RS) connectivity. To do so, tACS was applied bilaterally centred over primary motor cortex in combination with functional magnetic resonance imaging acquisitions. Our analyses specifically focused on the effect of stimulation phase on RS connectivity of the Motor Network (MN) and Default Mode Network (DMN). **Material & Methods:** 12 young (range 20-28 years of age, 4 females) healthy volunteers were tested in a double-blind cross-over design. Peri-rolandic individual alpha frequency was derived from resting-state EEG prior to MRI scanning. TACS was applied using a high-density electrode montage to homologues primary motor cortices with either 0° phase lag, 180° phase lag, or sham stimulation (order counterbalanced across subjects) during task-free MRI (eyes open). Two RS functional sequences of 5 minutes (baseline without, 2$^{nd}$ with tACS) were acquired in each session using multiband factor imaging method (TR= 1000 ms; TE= 33 ms). fMRI data was co-registered to the high-resolution T1-weighted image. 20 seeds for regions of interest (ROI) were chosen to define MN and DMN. Connectivity analysis was performed on the z-transformed correlation coefficients of each ROI pair. Baseline normalized z-scores for connectivity measures were subjected to separate linear mixed effects (LME) models for each ROI pair within subject contrasting stimulation conditions (0°, 180°, sham) modelled as fixed effect. **Results:** LME results revealed that relative changes in RS connectivity (stimulation - baseline) were significantly different for 180° phase lag compared to sham condition ($p<.01$) and for 180° phase lag compared to 0° phase lag ($p<.01$), but not for the contrast of 0° and sham. Specifically, our results show a strong relative within hemisphere increase and between hemisphere decrease in connectivity of primary motor, premotor, and somatosensory cortices but an increase in

connectivity within regions of the DMN for 180° phase lag compared to sham. Comparison of 180° to 0° phase lag condition showed a relative intrahemispheric increase in MN connectivity and a decrease in connectivity within the DMN within and between hemispheres for 180° phase lag (p-corrected <.05). **Discussion:** Our results reveal a phase-specific modulation of connectivity within the MN, in particular primary motor, somatosensory, and premotor cortices but which is also extending beyond the site of stimulation as it also affects distant connectivity patterns in the DMN.

**Title:** Characterization of excitatory and inhibitory neuron activity during up states *in vitro*: Up states are resilient to optical activation of PV neurons

**Authors: *D. V. BUONOMANO**[1], J. L. ROMERO-SOSA[2], H. MOTANIS[3]

**Abstract:** Many computations the brain performs emerge from the neural dynamics of local cortical circuits. The dynamics in these circuits are governed in part by the interaction between recurrently connected excitatory and inhibitory neurons. An example of neural dynamics that emerges from local circuits are Up states—which reflect network-wide patterns of activity. Here we examine the role of inhibition and resilience of Up states in cortical organotypic slices.Simultaneous recordings from pyramidal (Pyr) neurons and parvalbumin-positive (PV) neurons, revealed that PV neurons exhibited an intrinsic excitability profile marked by a low spike adaptation index (AI=0.01±0.01) compared to pyramidal neurons (AI=0.122±0.015), and that during Up states the firing rate of PV neurons was higher than Pyr (18±2.5 Hz) vs (7±2.2 Hz). Interestingly, $Ca^{2+}$-imaging revealed no difference in mean activity which may reflect differences in $Ca^{2+}$ buffering. Of 30 paired recordings, 12 exhibited detectable Pyr→PV connections, 8 pairs had PV→Pyr connections, and 7 pairs were reciprocally connected—thus reciprocity was present at higher than chance levels. The correlation between Pyr and PV activity during Up states was higher in reciprocally connected pairs (0.67±0.01 vs 0.82±0.008, $p<10^{-10}$). Paradoxically we observed that, on average, PV neurons fired before the Pyr neurons by

16.9±5.71ms—indicating that events driving Up states may initially preferentially activate PV neurons, or that PV neurons respond significantly quicker to these triggering events.Experimental and theoretical studies suggest that local neural circuits may store information in locally stable patterns of neural activity—i.e., neural trajectories. Critical to this hypothesis is the notion that these trajectories are robust to perturbations. We performed perturbation experiments in which PV neurons were optically activated after the initiation of spontaneous Up states. While brief optical activation of PV neurons decreased intracellularly evoked spikes, it did not change the mean duration of Up states (1.91±0.17 vs 1.99±0.19 sec).These results establish that Up states are robust to perturbations produced by broad light activation of PV neurons, and that local connectivity shapes neural dynamics—as evidenced by the increased correlation between reciprocally connected neurons. Furthermore, the presence of Up state *in vitro* reveals that the learning rules that lead to these dynamic regimes are intact, thus providing an opportunity to study how Up states emerge from local cortical circuits.

**Title:** Quantification of spine density in the rat default mode network

**Authors: *S. DAVANGER**[1], L.-M. VALENCIA-PESQUEIRA[2], R. HOLST[3]
[1]Univ. Oslo, Oslo, Norway; [2]Univ. of Oslo, Oslo, Norway; [3]Oslo Univ. Hosp., Oslo, Norway

**Abstract:** The default mode network (DMN) underlies important aspects of mental function, such as self-generated thoughts and mind wandering. These thoughts have autobiographical and social-oriented content and are important for future planning and adapting to a changing environment. In humans, the posterior and the anterior cingulate cortices are included in a set of central hubs, receiving and integrating information from other DMN areas. In rat brain, the cingulate cortex is a key DMN area. Due to the complex nature of processing and predicting events in a continuously changing social environment, we hypothesized that high computational demands on the DMN hubs are reflected in a high synaptic density. We investigated dendritic spine density of layer V cortical pyramidal neurons in 5 female rats, after Golgi staining. Imaging was performed with a Leica Microscope and Application Suite X. Images were subjected to deconvolution. Imaris software was used to produce 3D reconstructions from Z-stacks and to quantify spine density along basal dendrites. 14 cortical areas were selected for analysis and classified as belonging to the DMN, lateral cortical network (LCN; a task-positive network), or primary cortex. The cingulate cortex had the highest spine density of the 14 areas, at

1.64 spines/µm (SD: 0.55, 95% CI: 1.38 - 1.90), while primary sensory cortex (S1) and the jaw region of the primary sensory cortex (S1J) had the lowest, at 1.05 spines/µm (SD: 0.43, 95% CI: 0.83 - 1.27) and 1.03 spines/µm (SD: 0.21, 95% CI: 0.92 - 1.14), respectively. Two mixed models were estimated. The first consisted of a comparison between the cingulate cortex and all other regions. This approach showed that the spine density levels are significantly higher in the cingulate cortex with $p < 0.0005$. The second model split the non-cingulate class into three groups: the DMN, LCN and primary cortices. This model showed higher levels of the cingulate cortex spine density compared to the three groups, with $p < 0.0005$. Thus, the cingulate cortex of the DMN has the highest spine density of the rat cerebral cortex. Investigations of DMN synapses in rat brain may complement fMRI studies of functional connectivity in humans, demonstrating the neuroanatomical basis for complex neuropsychological processes.

**Title:** EEG power predicts laminar specific fMRI connectivity

**Authors: *R. SCHEERINGA**[1,2], P. KOOPMANS[3], T. VAN MOURIK[1], O. JENSEN[4], D. G. NORRIS[5], M. BONNEFOND[2]
[1]Radboud Univ. Nijmegen, Donders Inst., Nijmegen, Netherlands; [2]Lyon Neurosci. Res. Center, INSERM U1028, Univ. de Lyon, Lyon, France; [3]Erwin L. Hahn Inst. for Magnetic Resonance Imaging, Univ. of Duisburg-Essen, Essen, Germany; [4]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [5]Donders Inst., Radboud Univ., Nijmegen, Netherlands

**Abstract:** In general, feedforward anatomical connections between brain regions originate in supragranular layers of lower order regions and project to layer IV while feedback projections originate deep layers and project to both deep and superficial layers of the lower order regions. LFP recordings have related these feedforward and feedback projections to gamma and alpha-beta band synchronization respectively. With the development of high resolution fMRI we can now measure laminar level neural activity non-invasively in humans. In a recent study we related laminar fMRI activity in V1, V2 and V3 to simultaneously recorded EEG power in the alpha, beta and gamma bands. For this we used a visual attention task in which subjects had to respond to a speed increase in inward contracting gratings. A cue indicated whether a speed increase was

likely to occur, or would not occur (attention contrast). In line with invasive electrophysiology we observed that EEG gamma band power correlated positively to middle and superior cortical layers, beta power correlated negatively with deep layers while alpha power correlated negatively with BOLD in all layers. Here we reanalyze this data and explore whether fMRI based laminar specific connectivity between lower (V1/V2) and higher order (V2/V3) regions is related to frequency specific power effects. For this we first estimated the single trial BOLD amplitudes. For both 'attention on' and 'attention off' conditions we calculated laminar connectivity between all regions and layers but observed no laminar specific differences related to attention. If we, however, correlate this attention effect over subjects with attention effects in EEG power we do find laminar specificity. Gamma power correlated with connectivity strength of lower order superficial layers with all higher order layers, but especially with superficial-superficial layer connectivity. For beta we observe a negative correlation between EEG power and connectivity of higher order deep layers and all layers in the lower order region. This correlation is substantially stronger for the deep layers. This suggests gamma synchronization relates to the neural response of the entire cortical column to bottom-up input, while beta relates to how it responds to top-down input.

**Title:** The role of NMDA conductance in average firing rate shifts caused by external periodic forcing: A computational study

**Authors: *N. NOVIKOV**[1], B. GUTKIN[2]
[1]Ctr. for Cognition and Decision Making, Higher Sch. of Econ., Moscow, Russian Federation;
[2]Group for Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France

**Abstract:** Many processes occurring in the brain involve prolonged modulation of neural firing rates. The examples are working memory retention [1], motor planning [2], or sustained attention [3]. Alongside with the firing rates, neural oscillations are usually modulated. In many cases, there is a theoretical understanding of mechanisms via which the level of neural activity affects the oscillations [4]. At the same time, the effects of oscillations on the mean firing rates are less explored. However, investigation of these effects is important for understanding the functional

role of oscillations in controlling excitability of cortical regions and stability of neural representations.In the present work, we theoretically investigated the role that slow voltage-dependent NMDA currents could play in shifting the mean firing rates of an excitatory-inhibitory system in the presence of external zero-mean harmonic forcing. We analyzed a low-dimensional system with linearized neural gain functions, and non-linear NMDA conductance.
First, we provided analytical expressions that link parameters of the model with the forcing-induced shift in the average firing rates. Next, we considered a model with NMDA receptors located on the excitatory neurons only (Model 1) or both on the excitatory and the inhibitory neurons (Model 2). For both models, we used our analytical results to find the initial and the shifted (by the external forcing) time-averaged steady-states on the phase plane. We geometrically demonstrated that the excitatory firing rate shift is strongly limited by stability conditions in the Model 1, while in the Model 2 it is possible to overcome these limitations. Predictions of our phase-plane analyses were confirmed by direct numerical simulations of the corresponding models. Finally, we performed bifurcation analysis, and demonstrated that there is an optimal combination of excitatory-to-inhibitory AMPA and NMDA weights that result in the strongest possible shift of the excitatory firing rate without loss of stability.

**Title:** Optogenetic stimulation-induced plasticity of orbitofrontal-striatal circuits *in vivo*

**Authors: *S. BARISELLI**[1], A. V. KRAVITZ[2]
[1]NIDDK, NIH, Bethesda, MD; [2]NIDDK, Natl. Inst. of Hlth., Bethesda, MD

**Abstract:** The dorso-medial striatum (DMS) is a brain region at the interface between excitatory inputs, mainly from cortex and thalamus, and dopaminergic afferents to control the selection of appropriate actions. While *ex vivo* studies have provided detailed mechanistic information about cortico-striatal plasticity and its dopaminergic modulation, it is unclear how these mechanisms operate in living mice to shape on-going behavior. Thus, we studied, optogenetic-mediated theta-burst stimulation (TBS) and low-frequency stimulation on orbitofrontal cortex-evoked local field potentials (OFCe LFPs) and multi-unit neuronal activity in DMS of awake mice. We found that while TBS induced potentiation, LFS did not induce cortico-striatal plasticity. Considering that motor, compulsivity and cognitive disorders have been linked to impairments in cortico-striatal plasticity, studying circuit plasticity *in vivo* in awake mice will provide realistic insights to develop refined circuit therapies for such diseases.

**Title:** Think globally, act locally (and vice versa): The perils and neuroprotective features of topology in seizures and cognition

**Authors: *E. L. OHAYON**, A. LAM
The Green Neurosci. Lab., Neurolinx Res. Inst., San Diego, CA

**Abstract:** It has long been known that disturbances to brain anatomy can lead to seizures. Investigations of these changes have mostly centered on the properties of cells and synapses. Recently there has been increased interest in the contributions of network structure. For example, network changes following post-traumatic injury and neurodegeneration in aging can be accompanied by an increased prevalence of seizures. However, even these models miss some of the most profound implications of network structure as they are often driven by "small world" graph theory and the disproportional contribution of "hubs". Similarly, the conclusions are often based on the availability (and limitations) of current imaging data provided by MRIs, fMRIs and, more recently, tractography. Together these models correctly draw our attention to the importance of networks but can miss the relation between simple local changes and global activity. Here we illustrate through a range of computational network models how local changes can introduce a variety of unexpected and rich neural patterns. The models include large recurrent network lattices (up to 100,000 units) as well as random networks. In both cases we show how small changes in local topology can modulate system dynamics including activity persistence and the geometric features of the activity. For example, local damage -- akin to post-

traumatic injury -- can act as a "seed crystal" in a chemical lattice and generate spiral waves. These patterns, once generated, can be then be projected onto intact networks and shown to be persistent. Beyond pathology, the models suggest important roles for local and global heterogeneity in generating and maintaining the persistent activity that is so necessary for healthy cognition. The observations thus have broad implications for how we consider network topology -- both locally and globally -- in conditions such as epilepsy and Alzheimer's disease, as well as their potentially critical role in healthy development. Moreover, we demonstrate how these concepts may translate to cognitive and behavioral output through the application of embodied autonomous agents modeling.

**Abstract:** We are interested in the connectivity between regions of the brain that support goal-oriented behavior. Prior monkey behavioral experiments from our group have shown that medial temporal lobe (MTL), orbital prefrontal cortex (OFC), and ventral striatum (VS) play roles in the integration of visual and reward value information. In a preliminary study, we injected the OFC with a lentivirus virus expressing anterogradely transported green fluorescent protein (GFP and visualized strong projections to both, VS and the MTL. To identify reciprocal connections, we injected 4 x 5 µl of a retrogradely transported Lentivirus (Lenti-FuGE-syn::GFP) into the OFC of one monkey at an injection rate of 0.5 µl /min. In a second monkey, a retrogradely transported Adeno-Associated Virus (AAV-retro-hSyn-GGaMP) was injected bilaterally into VS (3 x 10 µl in the left hemisphere and 11 x 1 µl in the right hemisphere). Antibody staining for the GFP reporter expression, followed by immunohistochemistry as well as confocal microscopy revealed common regions of afferent VS and OFC projections from the basolateral amygdala (BLA), and

perirhinal cortex (PR). It also showed that area TE, in the anterior temporal lobe, projects strongly to the OFC while there were few cell projecting to the VS. Conversely, there is a dense entorhinal cortex projection to the VS but not to the OFC. In future studies we plan use a two-component retrograde virus system expressing chemogenetic receptors to examine the functional properties of the projections reported above.

**Title:** Local circuit regulation via gap junctions and self-inhibition in the locus coeruleus

**Authors: *A. M. MCKINNEY**, X. JIANG
Neurosci., Baylor Col. of Med., Houston, TX

**Abstract:** The locus coeruleus (LC) is the source of ~90% of the brain's noradrenergic projections. It participates in diverse behaviors and cognitive processes crucial for survival, including sleep/wake states, attention, and the fight/flight response, and its dysfunction is closely associated with diverse neuropsychiatric disorders such as depression, post-traumatic stress disorders, Alzheimer's disease, and autism spectrum disorders. Despite its importance, our current understanding of the LC is largely restricted to its long-range projection and diverse effects on its postsynaptic targets, though little is known about how LC neurons interact each other to coordinate their functions within the local circuit. Utilizing an *ex vivo* brain slice preparation that allows simultaneous intracellular recording of up to 8 LC neurons (targeted by expression of dopamine β-hydroxylase, DBH+), we examined the functional interactions between LC neurons at the single-cell level in order to uncover the general principles governing the functional organization of LC local circuits. Our profiling of LC neurons and their connections so far revealed several unexpected mechanisms regulating the excitability of adult LC neurons: (1) a strong (>15mV) self-inhibition lasting tens of seconds that following phasic firing and persists in the presence of the α2 adrenoreceptor blockers yohimbine and idazoxan, (2) prevalent gap junction coupling, which was previously believed to be abolished during late adolescence, and (3) that single LC neurons do not communicate with each other via ionotropic synaptic connections or α2 adrenoceptor-mediated mechanisms, as was previously reported. More LC neurons recordings are currently underway to validate these finding and uncover how molecular and genetic variation underlies the unique organization of the LC local circuits.

**Title:** Inter-hemispheric effective connectivity predicts chronic subjective fatigue and motor corticospinal excitability in stroke survivors

**Authors: *S. ONDOBAKA**, A. KUPPUSWAMY
Univ. Col. London, London, United Kingdom

**Abstract:** Chronic post-stroke fatigue (PSF) has a significant impact on stroke survivors' morbidity, disability, quality of life and mortality. Yet, it remains elusive what the neuronal mechanisms are that underlie PSF, a risk factor for development of depression in many neurological and psychiatric disorders. PSF has been associated with increased corticospinal excitability, as indexed by resting motor thresholds (RMTs). We recently proposed that PSF is a result of poor sensory attenuation, i.e. inability to withdraw attention from a sensory stream. In this study, we employed spectral dynamic causal modelling (spDCM) of resting state fMRI signals of non-depressed stroke survivors and measured their RMTs. We assessed their chronic fatigue level by using a validated and commonly used Fatigue Severity Scale (FSS-7). We reasoned that the patterns of inter-hemispheric connectivity could provide a mechanistic explanation for the inter-individual variability in chronic PSF severity and the associated corticospinal excitability. Our reasoning was motivated by the previous neuronal findings that link inter-hemispheric balance (IB; a measure of [L>R-R>L] connectivity) with both attentional control and cortical excitability. We hypothesised that the deviation from the naturally occurring left-hemisphere inhibitory dominance would be positively associated with both severity of persistent self-reported PSF and the associated corticospinal excitability.
The result from the linear regression analysis showed that the individual IB in the motor cortex (M1) predicts reported levels of chronic fatigue ($p = 3.09e^{-05}$, $R^2 = 0.673$) and corticospinal excitability ($p = 5.07e^{-04}$, $R^2 = 0.541$). We observed a positive association between L>R M1 connectivity and both FSS scores ($R^2 = 0.278$) and RMTs ($p = 0.0188$, $R^2 = 0.299$). There was a negative association between both RMTs and FSS and the strength of R>L M1 connectivity (FSS: $p = 0.0057$, $R^2 = 0.388$, RMTs: $p = 0.0379$, $R^2 = 0.242$). As previous report showed, we observed a significant correlation between the subjectively reported FSS scores and the physiologically measured RMTs ($p = 0.0026$, $R^2 = 0.443$). There was a negative association between FSS and the strength of R>L M1 connectivity ($p = 0.0057$, $R^2 = 0.388$). The findings

support the idea that the individual inter-hemispheric neural dynamics between primary motor regions influence corticospinal excitability and underpin chronic post-stroke fatigue. The strong explanatory power of resting IB dynamics make it a promising target for new intervention protocols using brain stimulation to change corticospinal excitability and ameliorate chronic fatigue symptoms.

**Title:** Cortical propagation of slow wave activity unveiled by fast line fMRI scanning and optic-fiber calcium recordings

**Authors: *F. AEDO-JURY**[1,2], M. SCHWALM[1,2], A. STROH[1,2]
[1]Inst. of Pathophysiology, [2]German Resilience Ctr., Johannes Gutenberg Univ. of Mainz, Mainz, Germany

**Abstract:** Slow-oscillation-associated slow wave activity (SWA) represents a default cortical state, occurring e.g. during deep sleep and anesthesia. Individual slow waves occur spontaneously, but can be evoked by sensory stimulation, generating a propagating wave of activity. Using optic-fiber calcium recordings in two sensory cortical areas and fMRI fast line-scanning in anesthetized rats, we explored temporal dynamics of SWA which was reliably induced and maintained by deep isoflurane anesthesia.Slow calcium waves were recorded in somatosensory (S1) and visual cortex (V1) with an optic fiber upon neural staining with the synthetic calcium indicator Oregon-Green BAPTA-1 (OGB-1). Visual stimulation was employed to induce stimulus-locked slow waves. Stimulus-induced slow calcium waves were reliably detected with characteristic delays, first in V1 and with a latency of approx. 100 ms in S1, yielding a propagation speed of approx. 50 mm/s.Line scanning fMRI (FLASH pulse sequence, TR: 50 ms, spatial resolution: 0.6 mm) revealed visually-evoked BOLD responses during SWA occurring first in the occipital lobe and exhibiting an increasing delay along the posterior-anterior axis, suggesting activity propagation from V1 towards other cortical areas with a velocity similar as determined with optic-fiber calcium recordings. Data was analyzed measuring individual voxel rise-time of the BOLD signal versus distance to V1.As previously shown in recordings of spontaneous activity by conventional multislice fMRI, during SWA BOLD

activation of the entire cortex occurs. Here we resolve the cortical propagation of slow waves using fast fMRI line scanning, while unambiguously controlling for the origin of the wave from the V1 upon visual stimulation.With this technique spatiotemporal propagation dynamics of SWA can be investigated on the mesoscale, with an imaging modality applicable both in rodents and humans. This will allow for translational studies probing SWA propagation in the context of neurological disorders in which SWA dynamics may be altered or disrupted.Thereby fMRI line scanning methods can bridge the apparent gap between the high temporal resolution of optical and electrophysiological methods and brain-wide fMRI methods, enabling a cross-scale investigation of defined neurophysiological phenomena as e.g. slow wave activity.

**Title:** Homeostasis and oscillatory modulation

**Authors: *E. PETERSON**[1], B. VOYTEK[2]
[1]Cognitive Sci., U.C. San Diego, San Diego, CA; [2]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA

**Abstract:** Neuromodulators like dopamine, serotonin, and acetylcholine alter membrane excitability, but prolonged modulation leads to homeostatic corrections. Neural oscillations also modulate excitability and can be sustained for prolonged periods, though whether oscillations also engage homeostatic mechanisms is an open empirical and theoretical question. In a series of numerical experiments, we study the interaction between homeostasis and oscillations in a feed-forward population of pyramidal cells driven by a constant stimulus, with varying levels of oscillatory modulation. We show that sustained oscillations can engage Calcium-dependent homeostatic mechanisms, to surprising effect. For example, excitatory oscillations---which typically increase excitability--begin instead to inhibit firing. In contrast, short (4-cycle) bursts of excitatory oscillations synchronize firing just as well as sustained oscillations, but return to increasing excitability. Based on these results we suggest that the stability of an oscillation in any brain area can, via homeostatic mechanisms, profoundly affect the role that an oscillation will play in shaping the neural code.

**Abstract:** Pediatric dysphagia often results in aspiration into the naso-pharynx and lungs and is associated with respiratory distress. These feeding and swallowing difficulties, and their consequences, are seen in up to 80% of children with developmental disorders including infants with DiGeorge/22q11.2 Deletion Syndrome (22q.11.2DS). The tongue, essential for the peripheral execution of swallowing as well as respiratory control, is innervated by the hypoglossal nerve (CnXII). Our initial work has found the neurobiological properties of hypoglossal motorneurons (MNs) change in *LgDel* mouse pups that carry an orthologous heterozygous deletion of 28 contiguous genes on murine chromosome 16 that are orthologues of these deleted in 22q11.2DS. We asked whether CnXII MNs that innervate key classes of extrinsic tongue muscles: protrudors move the tongue forward while retractors pull the tongue backwards, differ in their physiological properties, and potential phenotypic divergence in *LgDel* versus wild type (WT) pups. We also asked whether CnXII MNs innervating tongue protrudors and retractors receive different synaptic inputs during different phases of the fictive respiratory cycle in the two genotypes. Our current results show that retractor CnXII MNs are more dominant in *LgDel* than WT pups and have a higher firing rate during both tonic and respiratory related phasic phases. In contrast, protrudor MN activity is more prominent in WT pups and in WT, firing of protrudor MNs is increased both during and between inspiratory bursts. These observations provide a foundation for understanding the pathophysiological changes in functionally and anatomically distinct CnXII MNs and their contribution to swallowing and breathing abnormalities that occur in DiGeorge/22q11.2 Deletion Syndrome.

**Title:** Tuning cortical network state from criticality to balanced dynamics by strengthening inhibition

**Authors: *J. LI**[1], W. L. SHEW[2]
[1]Physics, Univ. of Arkansas, Fayetteville, AR; [2]Univ. of Arkansas Fayetteville, Fayetteville, AR

**Abstract:** According to many experimental observations, the neurons in cerebral cortex tend to fire independently of each other, sometimes referred to as the asynchronous state. In contrast, many other experimental observations reveal relatively coordinated and synchronous cortical population dynamics. These discrepant observations have naturally led to competing hypotheses to explain them. A commonly hypothesized explanation of asynchronous firing is that excitatory and inhibitory neurons are precisely correlated, nearly canceling each other, resulting in the so-called 'balanced state'. On the other hand, a prominent hypothesis to explain the more coordinated state is that the system operates at the tipping point of a phase transition, in a state called 'criticality'. Both hypotheses claim the same qualitative mechanism - properly balanced excitation and inhibition. Thus, natural questions arise: how are the balanced state and criticality related, how do they differ? Here we propose an answer to these questions based on investigation of a simple, network-level computational model. We found that the strength of inhibitory synapses relative to excitatory synapses can be tuned from weak to strong to generate a family of models that spans a continuum from 'criticality' to the 'balanced state'. When inhibition was strong (balanced by strong excitation) the dynamics were clearly inconsistent with predictions for criticality; avalanche distributions were not power-laws, branching functions were not flat, etc. Rather, the dynamics for strong inhibition matched expectations for the "balanced state"; perfectly canceling E and I synaptic inputs, weak pairwise correlations, synaptic strength scaling like square root of network size, etc. At criticality (weak inhibition) E and I currents were loosely balanced, pairwise correlations were higher, and synaptic strength scaled like inverse of network size. Our results reconcile two long-standing competing hypotheses and offer a possible explanation of discrepant experimental observations: neuromodulatory mechanisms that act at inhibitory synapses could cause shifts in cortical state from criticality to the balanced state, or vice versa.

**Title:** The fractal cortex: Reconciling cortical network dynamics across scales of observation

**Authors: *W. L. SHEW**[1], S. CHAKRABORTY[2], T. KNOPFEL[3], V. AGRAWAL[2]
[1]Univ. of Arkansas Fayetteville, Fayetteville, AR; [2]Univ. of Arkansas, Fayetteville, AR;
[3]Imperial Col. London, London, United Kingdom

**Abstract:** Current understanding of the cerebral cortex is synthesized from observations acquired at diverse spatial scales. How do the governing principles of cortical neural network dynamics vary when observed at different scales? As experimental tools approach larger and larger measurement volumes with finer and finer resolution, answering this question directly becomes plausible. Here we developed a systematic approach to quantify how a change in scale of observation results in an apparent change in the rules governing cortical network dynamics. We expect our methodology to be useful for studying multi-scale measurements of diverse neural systems. Here, we applied our approach in two different network-level computational models and voltage imaging measurements of mouse cortex.

Our approach was motivated by a growing number of experiments which suggest that the cortical network operates in a dynamical regime near 'ciriticality'. Here, criticality refers to the boundary between an ordered, synchronous regime and a disordered, asynchronous regime of population neural activity. Interestingly, theory suggests that, if the system operates in a dynamical regime near criticality, then the rules governing the system dynamics could manifest with a special fractal symmetry - dynamic rules that are similar across different scales of observation. Here we first confirmed this prediction in two computational models. The first model was a network of simple binary excitatory neurons. The second model included more realistic details of cortical neural networks, including adaptation, inhibitory neurons, distance-dependent connectivity, and more. To our knowledge this is the first demonstration of scale-invariance of the dynamical rules that govern a neural system at criticality.

Next, we applied our approach to analyze voltage-imaging recordings of cortical network dynamics from a mouse as it awoke from anesthesia. Because this imaging technique provided wide coverage (the dorsal surface of nearly one hemisphere) with good resolution (33 microns per pixel), we could directly resample the same data at different scales to compare how dynamical rules vary across scales. We found that the dynamical rules governing mouse cortex

exhibited a distinct shift, becoming more scale-invariant as the mouse awakens from anesthesia. Considered together with our models, this finding suggests that conscious cortex is closer to criticality than unconscious cortex.

**Title:** Cortical network dynamics exhibit longest-ranged temporal correlations for critically-balanced excitation and inhibition

**Authors: *D. A. ROISEN**, S. H. GAUTAM, W. L. SHEW
Univ. of Arkansas, Fayetteville, AR

**Abstract:** Growing experimental evidence supports the hypothesis that the cerebral cortex often operates close to a special dynamical regime, called criticality, at the tipping point between synchronous and asynchronous population neural activity. Typically, this evidence is based on the statistics of population activity, focusing on bouts of elevated collective activity called neuronal avalanches, cascades, or population events. At criticality, theory predicts that these events are very diverse in spatiotemporal size, with the probability of different event sizes following a particular power-law distribution. However, in humans it is difficult to reliably measure spatiotemporal sizes of population activity events using typical noninvasive measurement tools, which have severe limitations on spatial resolution. One alternative approach is to focus on temporal statistics of recordings with good temporal resolution (e.g. EEG and MEG). Theory predicts population dynamics with diverse temporal scales at criticality which manifest as long-range temporal correlations. Away from criticality in the asynchronous regime or synchronous regime, distributions of event sizes are expected to deviate from power-law and temporal correlations become shorter in duration.
This predicted relationship between temporal correlations and event size distributions has yet to be directly verified in experiments. Here we show, using multi-electrode recordings in rat somatosensory cortex, that power-law distributed events coincide with the longest-range temporal correlations. We generated a wide range of cortical states by pharmacologically altering inhibition. Comparing across these different cortical states, we found, that the asynchronous state (excessive inhibition) and the synchronous state (reduced inhibition) exhibit shorter range of temporal correlations and deviation from power-law event size distributions compared to the

balanced state. Our findings demonstrate that studies of long-range temporal correlations based on noninvasive human brain recordings can reveal changes in the balance of excitation and inhibition. Our results also suggest that sufficiently long-range temporal correlations are consistent with power-law distributed population events, as predicted at criticality.

**Title:** Neuronal avalanches and long-range temporal correlations at the emergence of collective oscillations: What is the relation with branching processes?

**Authors: *M. COPELLI**[1], L. DALLA PORTA[1,2]
[1]Fed. Univ. Pernambuco (UFPE), Recife, Brazil; [2]Systems Neuroscience, Inst. d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain

**Abstract:** The critical brain hypothesis has emerged in the last decades as a fruitful theoretical framework for understanding collective neuronal phenomena. Lending support to the idea that the brain operates near a phase transition, Beggs and Plenz were the first to report experimentally recorded neuronal avalanches, which are bouts of neuronal activity with both sizes (*s*) and durations (*d*) distributed according to power laws: $P(s) \sim s^{-3/2}$ and $P(d) \sim d^{-2}$. The exponents governing these distributions coincide with those of a critical branching process or, more generally, with the mean-field exponents of the directed percolation (DP) universality class, which comprises a variety of models in which a phase transition occurs between an absorbing (silent) and an active phase. This class of models, however, failed to reproduced other signatures of criticality observed experimentally, most notably long-range time correlations observed at both small (microelectrode arrays) and large (M/EEG) spatial scales. The CROS ("CRitical OScillations") model was proposed by Linkenkaer-Hansen et al. as an attempt to reproduce both classes of phenomena (avalanches and time correlations). With excitatory and inhibitory stochastic neurons locally connected in a two-dimensional disordered network, they showed that the model exhibited a transition from an active to an oscillating state. Precisely at the transition, the network activity had long-range time correlations and power-law distributed avalanches.

From the theoretical point of view, however, the model raises several questions, which we investigate here. Firstly, we introduce a tentative order parameter to better characterize the phase transition, while also simulating larger system sizes (*L=300*) than in the original results (*L=50*). Secondly, we point out that it is highly counterintuitive to have a two-dimensional system exhibiting mean-field exponents. That could be due to an insufficiently small ratio between connection range and system size (which is addressed here, again, by increasing *L*). We argue that, if the onset of oscillations in a two-dimensional network is to be reconciled with DP critical exponents, then the DP exponents for dimensionality *D=2* should also be tested. Finally, we explore parameter space in more detail around the transition line, allowing the exponents to be adjusted by a maximum-likelihood estimator (MLE) and testing whether the model satisfies other scaling relations which have been observed experimentally.

**Title:** Switching states of network connectivity in rat recordings during anaesthesia and sleep

**Authors: *W. CLAWSON**, D. BATTAGLIA, A. F. VICENTE, C. BERNARD, P. P. QUILICHINI
INSERM U1106 INS, Marseille, France

**Abstract:** Oscillations pace neuronal firing and coordinate communication between neuronal populations. However, how a given neuronal network can support different operations is still unclear. In this study, we compare 4 different global brain states: theta vs slow oscillations during anesthesia and REM vs non-REM in natural sleep through analysis of LFPs and single unit recordings in the entorhinal cortex and hippocampus in rats.
We find that changes in the dominant oscillatory state have a complex impact on neural computations. Each of the global brain states we examine can be subdivided into computing microstates and are characterized by different methods of information processing within the neural population based on firing pattern, information sharing and information storage. We show

that the global brain state modulates the temporal statistics of computing microstate switching. This results in varying levels of complexity of computational state transitions, measured through a minimum description length approach. This demonstrates that changes in the global brain state impact both the repertoire from which the computing microstates are sampled and the transitional rules between these states.

Within each computing microstate we identify functional hubs as neurons that are actively involved in specific primitive operations such as information sharing and storage. Importantly, these hubs are not simply neurons with a high firing rate but exhibit these operations as an effect of the current computing microstate. We show that different computing microstates within each global brain state lead to the recruitment of different hub neurons. Interestingly, only a few neurons are hubs during a given state but approximately 70% of all neurons can be hubs within other computing microstates. Therefore, being a functional hub is not a permanent property, but depends on the current computing microstate.

**Title:** Spatio-temporal organization of cell assemblies in nucleus reuniens during slow oscillations

**Authors: *P. P. QUILICHINI**[1], D. ANGULO-GARCIA[2], M. FERRARIS[1], A. GHESTEM[1], C. BERNARD[1]
[1]INSERM U1106 INS, Marseille, France; [2]Univ. de Cartagena, Grupo de Modelado Computacional, Inst. de Matematicas Aplicadas, Cartagena, Colombia

**Abstract:** The nucleus reuniens (NR) is an important anatomical relay between the medial prefrontal cortex (mPFC) and the hippocampus (HPC) and growing evidences suggest that it has a role in orchestrating the information flow between the HPC and the mPFC. However, the network mechanisms supporting such function are still unknown. We used silicon probe implanted in the NR, HPC and mPFC in rats during anesthesia, which reproduces some network dynamics of slow-wave sleep, to extract long-lasting stable recordings of local field potentials and large numbers of single units simultaneously. At the beginning of UP states, we identified a reliable sequential activation of NR neurons, which moreover present a spatial organization whereas this nucleus is apparently a non-layered region. Using chemical inactivation of the NR, we show that NR seemed necessary to support the sequences concurrently found in the mPFC at the onset of UP states as well as the robust generation of neuronal sequences during Sharp-Wave Ripples in the HPC. We propose that NR actively binds mPFC and HPC during slow oscillations and appears to participate to the stability of neuronal assemblies that are formed in these regions, which are known to support memory transfer/consolidation.

**Abstract:** The retina, a CNS tissue, displays numerous abnormalities in Alzheimer's disease (AD), including the presence of Aβ deposits, pTau, nerve fiber layer (NFL) thinning and retinal ganglion cell (RGC) degeneration. Yet, the possible inflammatory processes associated with the pathological hallmarks of AD in this tissue are poorly understood. We investigated retinal pathology including amyloidosis, macro- and microgliosis, and analysis of RGCs in mild cognitively impaired (MCI) and AD patients as compared to age- and gender-matched controls. We assessed load and distribution of macrogliosis (Vimentin, Müller glia), astrogliosis (GFAP, s100β), and microgliosis (Iba1) surrounding retinal Aβ (4G8 and 12F4) in predefined retinal layers and sub-geometrical regions. RGCs and various inflammatory biomarkers were further quantified. Analysis of retinal cross sections spanning from the Ora Serrata to the optic disc in the supro-temporal and inferior-nasal quadrants revealed a wide spectrum of pathological changes in retinal tissues isolated from patients as compared to controls. Aβ deposits were more abundant in inner retinal layers (~90%), with up to a 7.5-fold increase in $A\beta_{42}$ (12F4)-immunoreactive area in peripheral regions of the AD retina. Importantly, retinal Aβ burden was tightly associated with gliosis, including reactive astrocytes, activated microglia, and other infiltrating myelomonocytes. Most early observed changes were related to astrogliosis, especially noted in far peripheral regions with a 3.3-fold change in AD compared to controls. In MCI, and moreover in AD patients, S100β+ astrocytes were not confined to the inner retina but propagated into the outer layers. Vimentin-expressing Müller glias were increased by 1.7-fold in the AD retina, though not in MCI. The peripheral regions of the retina appear more sensitive to damage associated with AD than the central regions. Triggering receptor expressed on myeloid cells2 (TREM2) and immunomodulatory factor osteopontin (OPN/Spp1) expressions were also upregulated in AD retinae. Levels of retinal OPN, a neuronal intrinsic factor that can promote neuronal survival and regeneration following injury and may be involved in glial cell activation and neuroprotection, were tightly associated with retinal Aβ load. Taken together, our findings suggest the occurrence of early and progressive pathological processes related to Aβ and associated inflammation in the retina of MCI and AD patients. A better understanding of this pathology in AD patients may help in the design of novel targeted therapies to treat or prevent AD in the future.

**Abstract:** Previously, we have shown that immunomodulation with glatiramer acetate (GA) in 8-13 month old mouse models of Alzheimer's disease (AD) leads to substantial attenuation of neuropathology and preservation of synapses and cognitive function. However, adult AD mouse models have been argued to correspond to the pre-clinical human disease, presenting limited aspects of aging-related processes linked to clinical manifestations of AD. In the current study, we explored the impact of GA immunization on old, late-stage double-transgenic $APP_{SWE}/PS1_{\Delta E9}$ mice (ADtg; 21-24 months old), an age more comparable with clinical stages of the human disease. Treatment included weekly subcutaneous injections of either GA or PBS for 8 weeks, compared to age-matched naïve wild-type littermates (n=7 mice/group). Brain and retinal tissues were analyzed for soluble and insoluble amyloid-beta (Aβ) levels, inflammatory biomarkers, and synaptic integrity. In spite of the late disease stage, Aβ plaque burden was significantly reduced in the entorhinal cortices and retinae of immunized mice. Additional assessment of plaque phenotype revealed a targeted response to large- and medium-sized plaques determined by their area, length and width. These differences can be attributed to an increased recruitment of myeloid cells to sizable plaque populations. Diffused plaques were more impacted by the

immunization as compared with mature fibrillar plaques. In comparison to PBS-treated controls, brains of GA-immunized mice displayed a significant decrease in $GFAP^+$ astrogliosis. In-depth analysis of astrocyte morphology and functional biomarkers showed lower reactive astrocytes with reduced expression of glutamine synthetase (GS), an astrocyte-associated enzyme involved in degradation of extracellular synaptic glutamate, in GA-treated ADtg mice. GA immunization restored astrocyte homeostatic GS levels, comparable with levels measured in WT mice. GA also altered patterns of innate immune cells surrounding medium to large plaques. Further, analysis of synaptic density in these aged mice indicated enhanced postsynaptic PSD95 biomarker expression following GA immunization in areas of reduced Aβ pathology. This study demonstrates the specific neuroprotective effects of GA immunomodulation in old, late-stage ADtg mice and provides the foundation to translate GA for AD treatment in humans.

**Abstract: Background:** Synaptic loss accurately predicts cognitive decline in Alzheimer’s disease (AD) patients. Accumulation of soluble amyloid β-protein ($Aβ_{42}$) oligomers appears to

be detrimental to synapses, yet oligomers are difficult to study due to their constant dynamic state. Previous work has shown the feasibility to generate and study photochemically stabilized oligomers via photo-induced cross-linking of unmodified proteins (PICUP). We have further demonstrated the therapeutic effects of bone marrow (BM)-derived macrophages in partially attenuating disease progression in murine models of AD via the involvement of infiltrating macrophages in cerebral Aβ plaque clearance. **Methods**: Here, we sought to investigate the ability of BM-derived macrophages, either pre-stimulated with glatiramer acetate (GA) or genetically targeted to overexpress ACE (ACE10), to uptake and degrade $A\beta_{42}$ oligomers and preserve synapses. **Results:** Our studies indicated that peripheral immune activation in $APP_{SWE}/PS1_{\Delta E9}$ transgenic mice, either with GA or adoptive transfer of BM-monocytes, profoundly reduced cerebral Aβ burden and increased synaptic density. In postnatal day 1 cortical neurons, overnight exposure to 100nM of pure $A\beta_{42}$ fibrils, and moreover, defined and photochemically stabilized oligomers, but not monomers, triggered substantial pre-VGluT1 and post-PSD95 synaptic loss and neuritic retraction. Co-culturing primary neurons in vitro with BM-derived GA-prestimulated or ACE-overexpressing macrophages, as compared with WT macrophages, resulted in enhanced synaptic and neuritic protection as well as increased clearance of synaptotoxic $A\beta_{42}$ assemblies. Synaptic rescue by curbing oligomeric $A\beta_{42}$ species tightly correlated with macrophage anti-inflammatory phenotype, high surface expression of Scara-1, TREM-2 and CD36, and efficient extracellular Aβ degradation. **Conclusion:** Overall, our studies indicate that activated BM-derived macrophages can effectively protect neurons against the synaptotoxicity of Aβ oligomers associated with AD.

**Abstract:** In Alzheimer's disease (AD) patients, the retina displays a wide spectrum of abnormalities, including nerve fiber layer thinning, vascular changes, and retinal ganglion cell (RGC) degeneration. We previously reported the first-ever identification of key pathological hallmarks, Aβ plaques, in the retina of AD patients, including those at early stages. Other groups further demonstrated $A\beta_{1-42}$ peptides, Aβ deposits, and tauopathy in postmortem retinas of AD patients. Here, we explored novel pathological hallmarks of AD along with associated inflammation and degeneration in retinal flatmounts and cross sections and in the corresponding brain sections from mild cognitively impaired (MCI) and AD patients. The ultrastructure and presence of specific amyloid deposits in glial cells were investigated using transmission electron microscopy (TEM). We identified the existence of intracellular Aβ oligomers in cells within the innermost retinal layers of MCI and AD patients, with 2-3-fold increases in confirmed patients versus controls. We further found various pathological changes in retinal tissues of AD patients, such as retinal vascular Aβ deposits, $A\beta_{40}$- and $A\beta_{42}$-containing plaques, (p)tau, paired helical filaments (PHF) tau, and neurofibrillary tangles (NFTs). These AD-related pathologies were more abundant in the inner retina, and especially in the peripheral regions of the superior and inferior quadrants. A 4.7-fold increase in retinal $A\beta_{42}$-containing plaques was noted in the superior temporal regions of AD patients (n=8) as compared to age- and sex-matched controls (n=7; $p<0.001$, t-test). Strong associations between retinal and brain plaque load in the same set of patients were found, in particularly for the primary visual cortex and the entorhinal cortex. Inner retinal Aβ deposits were tightly associated with local inflammation, similar to brain pathology, including astrogliosis, activated microglia, and changes in other non-neuronal glial cells. TEM analysis revealed the existence of $A\beta_{42}$ deposits in certain sub-cellular compartments of Muller glial cells. These pathological changes were linked to a significant 30% retinal neuronal loss with enhanced susceptibility of a certain RGC subset. Utilizing a noninvasive retinal imaging developed by our team enabled us to monitor with high spatial resolution individual amyloid deposits and infiltrating immune cells. Our findings indicate the existence and distribution of pathological hallmarks and associated inflammation and degeneration in the inner retinae of MCI and AD patients, which provide the incentive to develop noninvasive high-resolution retinal imaging to diagnose and monitor AD.

**Title:** High fat diet exacerbates brain blood flow reductions caused by stalled capillaries in a mouse model of Alzheimer's disease

**Authors: O. BRACKO**, J. C. CRUZ HERNANDEZ, L. K. VINARCSIK, M. ALI, M. SWALLOW, J. ZHENG, B. N. NJIRU, N. NISHIMURA, *C. B. SCHAFFER

**Abstract:** Cerebral blood flow (CBF) reductions have been long observed in patients and mouse models of Alzheimer’s disease (AD). Obesity is associated with increased risk for developing AD as well as with increased severity of AD symptoms. Using *in vivo* multiphoton microscopy we have shown that ~1.6% of cortical capillaries are transiently stalled in APP/PS1 mice, leading to a ~20% reduction in CBF that can be restored by administering antibodies against the neutrophil-specific cell surface protein, Ly6G. This blood flow improvement also led to an immediate improvement in performance on spatial and working memory tasks. Wildtype (wt) mice showed a much lower rate of capillary stalling of ~0.4%. This study explores if a western high fat diet (HFD; 42% kcal fat, 42.7% kcal Carbohydrates and 15.2% Protein; Fig. 1A) exacerbates this capillary stalling phenomena in APP/PS1 mice. The number of capillary stalls was elevated in 18-month old AD mice (0.9% on control diet; 1.1% on HFD) as compared to wt (0.3% on control diet; 0.6% on HFD) (Fig. 1B). Thus, capillary stalling increased by 20%, and CBF also decreased by 27%, in both AD mice and wt mice receiving HFD compared to AD and wt mice receiving a control diet, respectively (Fig. 1C-G). AD-HFD animals displayed an enhanced motor and cognitive deficit compared to AD animals after 6 month of HFD whereas wt-HFD animals display cognitive deficits after 9 month HFD compared to wt controls. Impaired short-term memory was restored using anti-Ly6G treatment in APP-HFD animals, however deficits seen in wt-HFD animals were not (Fig. 1H). The onset of cognitive decline did not change between AD control and AD-HFD groups; however at 16 months, AD-HFD animals had larger short-term memory deficits and reduced CBF compared to AD control animals. Anti-Ly6G treatment released stalls, improved CBF to control levels and restored short-term memory deficits in AD and AD-HFD mice. We demonstrated that capillary stalling contributes to enhanced AD progression in obese APP/PS1 mice, suggesting that this mechanism isone potential link between obesity and AD risk and severity.

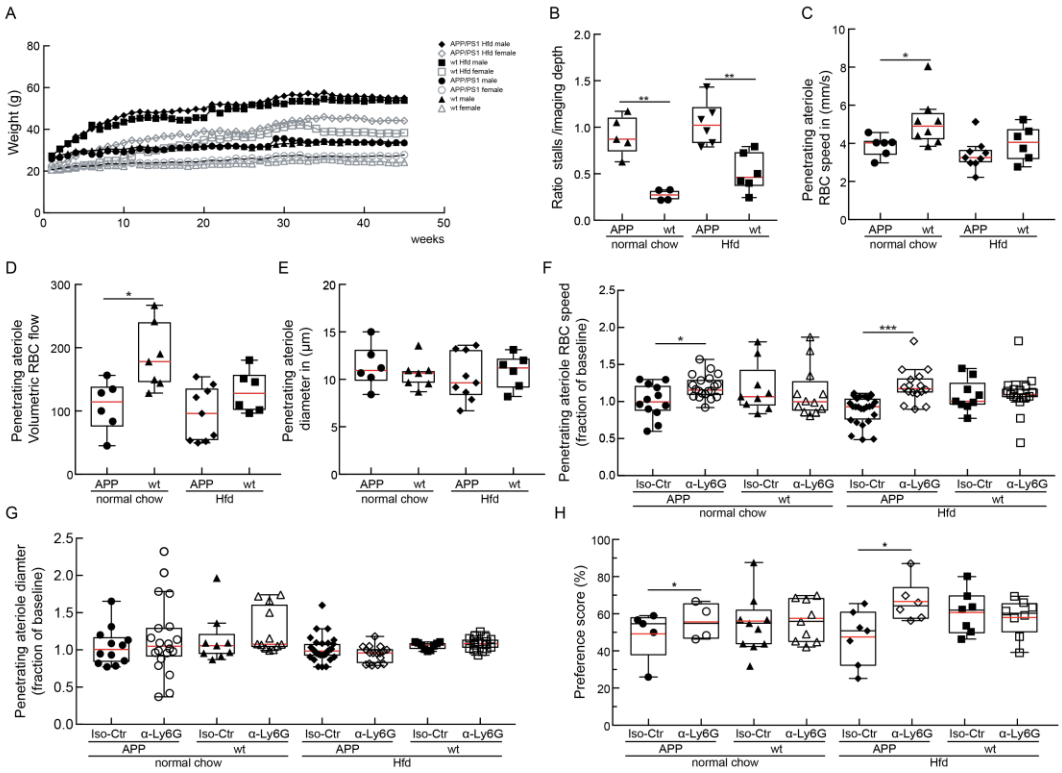

Figure 1: Stalled capillaries causing reduced CBF in AD and wt mice on a western high fat diet. (A) Graph shows the body weights of wild-type (wt) and AD mice on a HFD or normal chow. (B) Number of capillaries with stalled blood flow in AD-HFD AD, wt-HFD and wt. (C) RBC speed (D) Volumetric RBC flow and (E) diameters at 10 month of age (5-month on HFD) AD-HFD, AD, wt-HFD and wt. (F) RBC speed and (G) capillary diameter of AD-HFD, AD, wt-HFD and wt mice, measured 60-90 min after α-Ly6G or Iso-Ctr antibody administration in 13-month old mice (9 month on HFD). (H) Preference score in object replacement task for AD-HFD, AD, wt-HFD and wt mice analyzed 3-6 hr after a single administration of α-Ly6G or Iso-Ctr antibodies compared to baseline measurements.

**Title:** Time lapse tracking with intravital imaging in an Alzheimer's disease mouse model reveals highly dynamic plaques after vascular occlusions

**Authors: *Y. ZHANG**, N. NISHIMURA
Biomed. Engin., Cornell Univ., Ithaca, NY

**Abstract:** Alzheimer's disease (AD) is a common neurodegenerative disease that currently has no cure. The progression of AD is characterized by the formation of amyloid plaques consisting of amyloid-beta (Aβ). Although vascular risk factors are correlated with AD incidence and progression, previous studies conflict on how vascular occlusions alter Aβ plaque accumulation. We used two-photon microscopy to image plaque dynamics in APP/PS1 mice expressing green fluorescent protein in microglia. To model microvascular occlusions that mimic small lesions found frequently in AD patients, we injected rose bengal and irradiated with a green laser through a cranial window to occlude cortical penetrating arterioles. Vessels were labeled with Texas-Red dextran and plaques were visualized with methoxy-X04 and animals were imaged on before and after lesioning on day 1, 3, 7, and 14 (n = 3 lesions in 3 animals,12 months old). One day after the lesion, about 30% of previously existing plaques disappeared, but about half of these reappeared over the course of two weeks (Fig. a). Plaque morphologies near lesions also changed over time (Fig. c and d). Control regions on the contralateral side showed no change in pre-existing plaque numbers (Fig. b). In both the lesion and control regions, new plaques appeared within the two-week period at similar rates. From 3 to 14 days post lesion, we observed a steep increase in the number of microglia surrounding the lesion with enlarged cell bodies and short processes that were consistent with activation.
These results suggest that microvascular lesions can alter Aβ plaques, causing both appearance and disappearance in response to injury. An increase in the number of activated microglia correlated with stabilization of plaque numbers, indicating a potential role of microglia in driving plaque dynamics.

**Title:** Multi-exposure speckle imaging to measure the cerebral blood flow recovery associated with blocking leukocyte adhesion in mouse models of Alzheimer's disease

**Authors: *D. A. RIVERA**, O. BRACKO, N. NISHIMURA, C. B. SCHAFFER
Cornell Univ., Ithaca, NY

**Abstract:** Human patients and mouse models of Alzheimer's disease (AD) exhibit a cerebral blood flow (CBF) deficit of ~30%. Using two-photon excited fluorescence (2PEF) microscopy in AD mice, we recently discovered that this blood flow deficit was caused by an increased number of capillaries with stalled blood flow. Administration of antibodies against Ly6G, a cell surface protein on neutrophils, eliminated the capillary stalls and led to CBF increases of ~30% and improved performance on short term memory tasks. Measuring CBF changes with 2PEF microscopy is tedious, however, so here we evaluate the use of multi-exposure speckle imaging (MESI). MESI uses the degree of blurring of a laser speckle pattern, caused by moving red blood cells, across various camera exposure times to quantify fractional CBF changes. We used MESI to measure CBF changes in mouse models of AD (APP/PS1, 12-18 months) after treatment with anti-Ly6G (4 mg/kg, injected IP) or isotype control antibodies in isoflurane anesthetized mice. We averaged the MESI signal across the full 3 x 3-mm imaging window, which included measurements from multiple surface arterioles and venules as well as the capillary bed. We found that CBF gradually increased in AD mice to ~140% of the baseline value over 1 hr after injection of anti-Ly6G (see Figure), but remained closer to baseline in animals receiving isotype control antibodies. The measured increase in CBF after anti-Ly6G administration was comparable to vessel-by-vessel measurements made using 2PEF. By 72 hrs. after anti-Ly6G administration flow had decreased to near baseline levels, consistent with the time scale for neutrophil replacement. Our work shows that MESI is a viable method for assessing CBF changes in AD mice, while providing higher time resolution and much reduced experimental and data analysis effort. We plan to use this method to test whether drugs that have already passed safety trials in humans and that target the leukocyte adhesion pathway lead to improved cortical blood flow in AD mice, with the goal of identifying potential therapies for improving brain blood flow in AD patients.

**Abstract:** There is a strong correlation between neurodegenerative diseases, e.g. Alzheimer's disease (AD), brain microvascular dysfunction, and reduced brain blood flow. Therefore, a functional understanding of the changes in structure and function of vascular network in the brain with age and AD is essential. Imaging methods such as multiphoton microscopy can generate 3D images of the cortical vascular network with micrometer resolution in vivo from animal models. However, the quantitative analysis of these complex structures requires imaging segmentation and is hampered by features of live animal imaging such as motion and poor contrast. The segmentation of vessels is a primary bottleneck that has prevented the systematic comparison of 3D vascular architecture across experimental populations. We explored the use of convolutional neural networks to segment fluorescently-labeled vessels in volumetric multiphoton microscopy images of the mouse cortex. We evaluated different artificial neural network architectures and machine learning techniques in the context of this segmentation problem. We show that our optimized convolutional neural network architecture, which we call DeepVess (Fig. A), yielded a segmentation accuracy that was better than both the current state-of-the-art and a trained human annotator (Fig. B), while also being orders of magnitude faster. Additionally, we implemented a centerline extraction algorithm as a post-processing step to enable comparisons of topological properties of the vascular networks (vessels in red, blue

indicates amyloid plaques, Fig. C). To explore the effects of aging and AD on capillary structure, we applied DeepVess to 3D images of cortical blood vessels in young and old mouse models of AD and wild type littermates. We found little difference in the distribution of capillary diameter or tortuosity between these groups, but did note a decrease in the number of longer capillary segments (>75 μm) in aged animals as compared to young, in both wild type and Alzheimer's disease mouse models.

**Abstract:** Innate immunity contributes to the pathogenesis of Alzheimer's disease (AD). It has recently been reported that the subpopulation of microglia transit from a homeostatic state to a disease-associated state in AD transgenic mouse brains. Specifically, various gene markers are induced in the disease-associated microglia. Among them, *secreted phosphoprotein 1* (*SPP1*) encodes a pro-inflammatory immune protein, osteopontin (OPN), which is secreted by immune cells including macrophages and dendritic cells. While OPN regulates the secretion of various cytokines to mediate inflammation, its precise physiological and pathological functions in microglia are unclear. Understanding the regulation of *SPP1* in microglia may elucidate the molecular control underlying the transition of microglia upon AD progression. Here, we show that *SPP1* is aberrantly upregulated in the cortex of aged APP/PS1 mice (an AD mouse model) and restrictively expressed in disease-associated microglia. Immunofluorescence analysis showed that in aged wild-type mice, OPN was mainly expressed in neurons and weakly expressed in a few glial cells. Remarkably, OPN expression was significantly induced in microglia associated with amyloid plaques in aged APP/PS1 mice. Furthermore, we found that epigenetic modification of *SPP1* was correlated with its gene regulation in the microglia of APP/PS1 mice. These findings suggest that the epigenetic modulation may regulate the induction of marker genes in disease-associated microglia upon AD progression. Thus, understanding the regulation of the epigenetics and gene expression of *SPP1* may enhance our understanding of the change of microglial state in AD.

**Abstract:** Alzheimer’s disease (AD), the most common form of dementia, has no effective treatment. Emerging evidence suggests that microglia, the major myeloid cell type in the brain, may contribute to AD pathogenesis. During AD progression, the microglia transit from their homeostatic state to a disease-associated state. However, it is unclear how this state transition is regulated and how the disease-associated microglia (DAM) are involved in AD pathology. We previously demonstrated that interleukin 33 (IL-33) administration rescues impaired cognitive functions and pathology in an AD transgenic mouse model, in part through enhancing amyloid phagocytosis by microglia. Here, we report that IL-33 administration regulates the gene signature of microglia in AD transgenic mice using single-cell RNA sequencing. While IL-33 administration did not significantly affect the proportion of homeostatic microglia in APP/PS1 mice, it modulates the transcriptome signature of DAM. Furthermore, immunofluorescence staining showed that there are more microglia co-localized with amyloid plaques after IL-33 treatment. Thus, our results collectively suggest that transition of microglial state may play a role in mediating the beneficial effects of IL-33 in AD.

**Abstract:** Alzheimer’s disease (AD) is pathologically defined by deposition of amyloid-β (Aβ) peptides as senile plaques, neurodegeneration, and neuroinflammation. Recent evidence suggests that failure in Aβ clearance, rather than overproduction, is etiologically linked to sporadic AD.

Our group previously demonstrated that genetic deletion of the anti-inflammatory cytokine, interleukin10 (IL-10), ameliorates AD-like pathology in APP/PS1 transgenic mice and increases mononuclear phagocytic Aβ clearance. We hypothesize that mononuclear phagocytes are the major responders to IL-10 via STAT3 signaling. To test this, we conditionally and inducibly deleted STAT3 in monocytes by tamoxifen-treating Csf1r-Cre $Stat3^{f/f}$ APP/PS1 mice and wildtype littermates after onset of AD-like pathology (at 6 months of age), and analyzed mice at 12 months. Ablation of STAT3 signaling in mononuclear phagocytes did not affect overall spatial learning and memory in APP/PS1 mice. However, pathological assessment of gliosis (GFAP and CD68) and plaque load (ThioS and 6E10) strikingly revealed greater severity in Csf1r-Cre $Stat3^{f/f}$ APP/PS1 females than in males. Furthermore, biochemical analysis revealed increased Aβ40 and Aβ42 abundance in brain homogenates from $APP/PS1^{+}Csf1r\text{-}Cre^{+}Stat3^{fl/fl}$ vs. $APP/PS1^{+}Csf1r\text{-}Cre^{-}Stat3^{fl/fl}$ mice. Interestingly, these differences were exquisitely sex-specific; stratification by sex revealed that Aβ40 and Aβ42 levels in guanidine- and detergent-soluble brain compartments, as well as Aβ oligomers, were increased in female STAT3 monocyte-deleted mice, but no effect was observed in males. Importantly we show that the most potent female sex-hormone, estradiol, interacts with the STAT3 pathway. Continuation of this work is expected to help elucidate how innate immunity is differentially affected by sex in the context of AD.

**Abstract:** Failed Aβ clearance is emerging as a key etiological factor in late-onset Alzheimer's disease (AD), and the role of the innate immune system in this process has recently taken center stage after multiple top hits in genome-wide association studies. The anti-inflammatory innate immune cytokine, interleukin-10 (IL-10), is genetically linked to increased risk of late-onset AD. Data from our lab confirms that IL-10 signaling is pathologically elevated in AD brains and in the APP/PS1 mouse model of cerebral amyloidosis. Furthermore, genetic deletion of IL-10 activates Aβ clearance. Others have shown that IL-10 treatment inhibits the mTOR complex master energy sensor, and pharmacological inhibition of this complex promotes immunological tolerance. *We hypothesize that IL-10 inhibits the mTOR pathway to promote Aβ immune tolerance in macrophages*. IL-10 induces macrophage Aβ tolerance, earmarked by reduced Aβ phagocytosis, decreased cytokine expression, and failure to activate NF-κβ. Aβ tolerized macrophages show increased phosphorylation of AMPK (an mTOR complex suppressor), and exhibit decreased isocitrate dehydrogenase and increased lipoprotein lipase (Lpl) expression. This phenotype suggests a deviation from TCA to lipid metabolism. Intriguingly, IL-10 treatment does not induce mitochondrial polarization; instead, it decreases mitochondrial activity similar to Aβ or bacterial lipopolysaccharide treatment. IL-10 treated macrophages have enhanced lipid storage in the form of lipid droplets, which suggests anabolism rather than catabolism of lipids. Increased expression of glycolytic genes and inhibition of the tricarboxylic acid cycle in brain macrophages from the $APP_{swe}/PS1_{\Delta E9}$ mouse model of cerebral amyloidosis provides *in vivo* validation for these findings. Further, APP/PS1 brains have increased lipid droplets inside brain macrophages and altered expression of lipid metabolism genes including *Lpl*. Moreover, transcriptomics analysis demonstrates that the mTOR signaling pathway is decreased in $APP_{swe}/PS1_{\Delta E9}$ brains. IL-10 deletion restores brain mTOR signaling, which correlates with increased Aβ phagocytosis. This study reveals how IL-10 impacts innate immune tolerance to Aβ by altering lipid metabolism and AMPK-mTOR signaling.

Engin., Yale Univ., New Haven, CT; [6]Physiol. & Biophysics, Zilkha Neurogenetic Inst., Los Angeles, CA

**Abstract:** Transforming growth factor-beta (TGF-beta), a prominent immunosuppressive cytokine regulator, increases in abundance in the brains of Alzheimer disease (AD) patients as well as in rodent models of the disease. Our group has shown that genetic ablation of TGF-beta-Smad 2/3 signaling in peripheral mononuclear phagocytes (macrophages) causes brain recruitment and resolution of cerebral amyloidosis, combined with associated cognitive disturbance in AD-like mouse models. We bridged this genetic approach into the pharmacological domain by utilizing next-generation nanoparticle technology to block TGF-beta signaling in peripheral macrophages. The concept is to 're-balance' innate immunity and neuroinflammation in the pre-clinical TgF344-AD rat model, which manifests the full spectrum of age-dependent AD pathologies and cognitive impairment. To specifically target peripheral macrophages, we developed PEG-PLGA nanoparticles encapsulating a small molecule TGF-beta-Smad 2/3 inhibitor and the non-toxic fluorescent tracker, Coumarin-6 (designated nano-C6/SB). We conducted two long-term peripheral treatment studies with nano-C6/SB-one beginning prior to plaque accumulation and the other starting after established disease. We cognitively/behaviorally tested aged TgF344-AD rats and controls, and subsequently analyzed their brains for evidence of peripheral macrophage infiltration and AD-like pathology. We show that peripheral nano-C6/SB treatment: 1) promotes brain infiltration of C6 and Trem2 double-positive peripheral mononuclear phagocytes that localize to amyloid plaques; 2) attenuates cerebral amyloidosis and tauopathy; and 3) partially remediates cognitive deficits. Nano-C6/SB directly targets peripheral macrophages, effectively inhibiting TGF-beta signaling and increasing Abeta phagocytosis. These cells are almost exclusively Trem2 positive, as opposed to Trem2 negative brain-resident microglia. We conclude that PEG-PLGA nanoparticles encapsulating small molecule TGF-beta-Smad 2/3 inhibitors hold pre-clinical promise to directly target Trem$2^+$ peripheral macrophages for cerebral Abeta clearance.

**Abstract:** Mitochondria, central to basic life functions due to their generation of cellular energy, also serve as the place for cellular decisions leading to apoptosis. A key protein in mitochondria-mediated apoptosis is the voltage dependent anion channel (VDAC), which also mediates the exchange of metabolites and energy between the cytosol and the mitochondria. We hypothesized that Glia maturation factor (GMF) a pro-inflammatory molecule changes the mitochondrial permeability and induces apoptosis through overexpression of VDAC1 in amyloid beta (Aβ 1-42) peptide treated SH-SY5Y human neuronal cell line in an in vitro model of AD. Our results showed that GMF- treated SH-SY5Ycells showed higher expression of VDAC1, increased release of cytochrome c and apoptosis compared with control group. We also checked the co-localization of GMF with VDAC1, Aβ and phosphorylated-tau (p-tau) expression in post-mortem human AD brains. Results showed higher co-localization of GMF with VDAC1, Aβ and phosphorylated-tau (p-tau) in AD brains compared with age matched control brains. We propose that enhanced level of GMF in AD brain leads to the overexpression of VDAC1 and release of cytochrome c and subsequently apoptosis. Our data suggest that overexpression of VDAC1amplifies and regulates the significant function of GMF in the pathogenesis of AD.

**Abstract:** Studies with animal models of Alzheimer's disease (AD) have shown that in addition to neuroinflammation, systemic immune challenge/inflammation can influence AD pathology and AD-like cognitive changes in complex ways. Such effects are most likely mediated by peripherally activated innate immune cells (i.e., monocytes and other myeloid cells) and/or their products that signal though compromised blood brain barrier. One of the key pathways that signals innate immune cell activation and hence, their expression of multiple mediators is p38a MAP kinase. In this study, we tested the effect of Cre-loxP mediated myeloid cell specific knockout of the kinase (mp38cko) on AD pathology in the APP-PS1 Tg mice. Contrary to expectation, mp38cko resulted in increased (over 2-fold) rather than decreased levels of beta-amyloid accumulation in the brain (-as determined by ELISA) and plaque load relative to wt p38/APP-PS1 Tg mice. This was accompanied by an increased neuroinflammatory response i.e., increased expression of IL-1b, TNFa and iNOS. Interestingly, an analysis of intestinal microbiota indicated significant changes in certain species in the mp38cko mice relative to controls in particular, a down-regulation of Bifidobacterium choerinumand Bacteroides acidifaciens that are known to produce beneficial and anti-inflammatory factors i.e., small chain fatty acids such as butyrate. In line with these microbial changes observed, mp38cko mice displayed increased susceptibility to high fat diet/low-dose streptozotocin-induced type-2 diabetes. These findings point to the potential role of gut microbiota in homeostatic counterbalancing of host immune response and hence, their influence/impact on systemically administered anti-inflammatory approaches to treat AD and other neurodegenerative and neuroinflammatory diseases.

**Abstract:** Microvesicles (MVs) and exosomes comprise the overall larger group of cell-secreted extracellular vesicles (EVs). These cargo-holding vesicles mediate cell-to-cell communication and have recently been implicated in neurodegenerative diseases such as Alzheimer's disease (AD). While the bulk of the literature focuses on the smaller exosomes (10-100 nm diameter), several reports have also tied the larger MVs (100 nm-1 μm) to AD. This evidence points to an increase in MVs in AD and suggests that MVs may be linked with amyloid-β (Aβ), the primary protein component of the neuritic plaques in the AD brain. Since microglial cells play such an important role in AD-linked neuroinflammation, we sought to characterize MVs shed from microglial cells, better understand MV interactions with Aβ, and determine whether internalized Aβ may be incorporated into secreted MVs. Multiple strategies were used to characterize MVs shed from microglia after ATP stimulation. Confocal images of isolated MVs bound to fluorescently-labeled annexin-V via externalized phosphatidylserine revealed a polydisperse population of small spherical structures. Dynamic light scattering measurements yielded MV diameters ranging from 150-600 nm (mean of 350 nm). Electron microscopy of resin-embedded MVs cut into thin slices showed well-defined uranyl acetate-stained ring-like structures with diameters ranging from 50-300 nm. The use of a fluorescently-labeled membrane insertion probe, NBD C6-HPC, combined with an Aβ ELISA effectively showed a strong interaction between MVs and Aβ protofibrils, but not Aβ monomers. Despite the lesser monomer interaction, MVs had an inhibitory effect on monomer aggregation. Microglia rapidly internalized Aβ protofibrils, and subsequent stimulation of the microglia with ATP resulted in the release of MVs containing the Aβ protofibrils. The role of MVs in neurodegeneration and inflammation is an emerging area and further knowledge of MV interaction with Aβ may shed light on extracellular spread and influence on neurotoxicity and neuroinflammation.

**Abstract:** OBJECTIVES; Here we show that the human amylin peptide of type 2 diabetes, like amyloidogenic amyloid-beta (Abeta) protein of Alzheimer's disease (AD), is an antimicrobial peptide (AMP). As with Abeta, amylin's AMP activity is mediated by oligomerization and fibrillization triggered by binding of microbial cell surface carbohydrate moieties. Antimicrobial activity involves agglutination and entrapment pathways that parallel the AMP actions of Abeta. Previous studies report amylin/Abeta co-localization in post-mortem human brain tissues. We characterized amylin and Aβ for cooperative synergistic antimicrobial activities in a 3D blood brain barrier (BBB) cell culture model
METHODS; Minimal inhibitory concentration of amylin's was assayed by spot tests and plating. Binding, fibrillization and bacterial membrane disruption were confirmed by electron microscopy. In-house developed competitive inhibition ELISA's were used to characterize specificity of amylin for microbial surface binding. A 3D ReN cell based BBB model was used to test infection induced Abeta/amylin mediated antimicrobial activity.
RESULTS; Data shows amylin-mediated disruption of bacterial membranes is consistent with established pathways mediating antimicrobial activities of classical AMPs. Competitive inhibition ELISA data shows surface carbohydrate binding mediates amylin's AMP activities. 3D cell culture data are consistent with synchronous and synergistic AMP action of Abeta and amylin against bacterial pathogens.
CONCLUSION; Findings from this study suggest amylin plays a protective immune role in pancreas, entrapping pathogens in amyloid deposits. Pancreatic plaques that accumulate in diabetes may be generated as an innate immune response to genuine, or incorrectly perceived, infection. Data from 3D BBB cell culture system suggest possible synchronous antimicrobial actions of amylin and Abeta may also generate the amylin/Abeta deposits reported for human brain.

**Abstract:** INTRODUCTION; Late-Onset Alzheimer's disease (LOAD) is a complex disease involving interacting genetic and environmental etiologies. There is growing evidence that neuropathic pathogens, such as Herpes simplex virus type 1 (HSV-1), are associated with AD pathology and may contribute to initiating the disease. Our lab has reported that Amyloid-Beta 42 protein (Aβ42) is an antimicrobial peptide (AMP) with protective properties against bacterial and fungal infections in transgenic mice, *C. elegans*, and Drosophila. HSV-1, a neurotropic virus that has near ubiquitous infection in the elderly population, is capable of upregulating Aβ42 production and causing abnormal tau phosphorylation *in* vitro. These properties make it a strong candidate for impacting AD pathology. Our research found that Aβ42's antimicrobial properties extend to protection against multiple families of neurotropic virus infection in both animals and cultured cells. Our model involves Abeta-mediated agglutination of viral particles via surface glycolproteins, preventing membrane fusion and infection. METHODS; Anti-viral properties were assayed by cell culture infectivity, electron microscopy, and *in vitro* binding assays. Mouse mortality, brain tissue analysis, and 3-D cell culture model of the brain characterized physiological Abeta antimicrobial activity. RESULTS; Abeta *in vitro* assays show significant infection protection from HSV1 through binding of amyloid to viral envelope surface glycoproteins. The 5XFAD AD mouse challenged with HSV1 demonstrates increased survival against HSV1 intracranial challenge, reduced viral titers, and advanced development of amyloid

plaques. These properties are also replicated in our 3-D cell culture model and with other neurotropic viruses, developing viral entrapping amyloid plaques in under 3 days. CONCLUSION; Aβ42's antimicrobial properties are expanded to include anti-viral protection against the neurotropic viruses including HSV1. Our model of anti-viral activity is consistent with our previous findings against bacterial and fungal infections, and further solidifies Abeta's roll as an AMP in the immunoprivileged brain. These findings are not only significant for understanding AD, but provide novel pathogen driven amyloidosis model systems for further study.

**Title:** Sex-and genotype differences in astrocyte reactivity in humanized apoe mice

**Authors: *A. EID**[1], I. MHATRE[2], Y. HAN[1], J. R. RICHARDSON[1]
[1]Dept. of Envrn. Health, Roger Stempel Sch. of Publ. Hlth. and So, Florida Intl. Univ., Miami, FL; [2]Kent State Univ., Kent, OH

**Abstract:** Alzheimer's disease (AD) is a progressive neurodegenerative disorder, and is characterized by the presence of pathological hallmarks including amyloid beta (Aβ) plaques, and neurofibrillary tangles. Patients diagnosed with AD also experience neuronal loss in the hippocampus and regions of the cerebral cortex, specifically the frontal cortex. This loss is thought to be facilitated by the pathological products themselves, as well as chronic neuroinflammation. It has been classically accepted that microglia are involved in mediating this neuroinflammatory response, but recent evidence has also shown that astrocytes play a prominent role, particularly as it pertains to generation of nitric oxide. Aging, family history, sex, particularly female, and APOEe4 genotype have been shown to play prominent roles in increasing AD risk. The prominent expression of APOE in astrocytes suggests a potential link between APOE genotype and neuroinflammation. However, it is not currently known whether there are intrinsic sex and genotype differences in astrocytes that may influence the inflammatory response. To address this question, we isolated mixed and sex-specific primary

microglia and astrocytes from postnatal day (PND) 0-3 humanized APOE3 and APOE4 and measured their response to either LPS (microglia) or a mix of pro-inflammatory cytokines (astrocytes). In the mixed and sex-specific microglial cultures, we observed few differences in pro-inflammatory cytokine mRNA levels. However, APOE4 primary astrocytes generated higher levels of media nitrite, an indicator of nitric oxide production compared to APOE3 astrocytes. We also found increased expression of the pro-inflammatory cytokines TNFα, IL-6, iNOS and IL-1B mRNA in APOE4 astrocytes. In our sex-specific studies in primary astrocytes, we observed higher expression of TNFα, iNOS, and IL-6 following cytokine treatment in female APOE4 astrocytes compared to male APOE4 astrocytes. Taken together, these data demonstrate significant differences in response of astrocytes to inflammatory stimulus based on sex and APOE genotype, which may provide insight sex and APOE genotype differences in AD.

**Title:** Regulation of metabolic genes in microglia in a murine model of Alzheimer’s disease

**Authors: *J. F. CODOCEDO**, G. E. LANDRETH
Dept. of Anat. and Cell Biol., Indiana Univ. Sch. of Med., Indianapolis, IN

**Abstract:** Microglia, the resident macrophages of the CNS, act in a homeostatic capacity to maintain the brain microenvironment. In the murine models of AD it has been demonstrated that plaque-associated microglia exhibit a distinct gene expression profile that include the up-regulation of several genes associated with lipid metabolism. Analogous changes are observed in other degenerative diseases and are reflective of microglial metabolic reprograming. Recent discoveries on the role of metabolic pathways in immune cell function has supported the idea that metabolic reprograming may govern the phenotype of immune cells by controlling transcriptional and posttranscriptional events that are central to their phenotypic activation. However, the microglial metabolic changes that occurs during AD progression, and their impact in their activation, remain largely unknown. We evaluated the expression of genes related to glucose and lipid metabolism during the development of the disease in the cortex and hippocampus of 5XFAD mice model. In agreement with previous reports, we observed a time dependent increase in expression of genes related to lipid metabolism, LPL and FABP5. In addition, we observed an increase in the levels of glucose transporter 5 (GLUT5) and hexokinase 2 (HK2) which are critical for the uptake and metabolism of glucose. Interestingly, the increase in HK2 seem to be dependent on the disease progression whereas the increase in Glut5 is only

dependent on the disease status. We determined that the increase in HK2 is expressed selectively within activated microglia associated with amyloid plaques by immunohistochemical analyses. This could explain the regional increase in HK2 which at 4 month is only detected in hippocampal microglia and at later stages is also observed in the upper layers of the cortex, following the spread of Aβ plaques. These data suggest a unique metabolic signature in AD that can be important in the development of biomarkers for early diagnostics and also could allow the establishment of metabolic intervention strategies to rescue microglial function.

**Title:** Aβ peptide binds, agglutinates and neutralizes endotoxins released during infection

**Authors: *T. I. MITCHELL**[1], D. VIJAYA KUMAR[2], W. A. EIMER[2], N. NAVALPUR[3], R. E. TANZI[3], R. D. MOIR[3]
[2]Genet. and Aging Res. Unit, [1]Massachusetts Gen. Hosp., Charlestown, MA; [3]Genet. and Aging Res. Unit, Massachussetts Gen. Hosp., Charlestown, MA

**Abstract:** OBJECTIVES; We previously showed amyloid-beta (Aβ) protein of Alzheimer's disease (AD) is an antimicrobial peptide (AMP), and demonstrated this in cell culture, worms and animal models. Here we demonstrate that the broad-spectrum activity of Aβ also encompasses binding and neutralization of bacterial endotoxins (LPS). Like many classical AMPs that also neutralize microbial virulence factors, Aβ possesses this property that might enable it to thwart microbial toxins that gain access into the brain. Endotoxin and other virulence factor neutralization are particularly important for the immune privileged brain that primarily combats infection through local innate immune pathways. In this study we demonstrate bacterial endotoxin neutralization activities of Aβ.
METHODS; Experiments tested binding and neutralization actions of Aβ against bacterial lipopolysaccharide (LPS), an archetypal microbial endotoxin. Aβ-mediated anti-LPS activities were tested in in vitro assays such as the LAL test, and cultured human neuroglioma, microglia and mouse macrophage cells.
RESULTS; Data is consistent with binding and potent inhibition of LPS activities by Aβ, including suppression of various proinflammatory cytokines key to mediate harmful neuroinflammation in infection. Monomeric and oligomeric forms of Aβ first target specific

carbohydrate domains on LPS. Aβ binding leads to agglutination and protective sequestration of soluble LPS.
CONCLUSION; Findings from this study suggest Aβ may play a protective role by neutralization of virulence factors like endotoxins in brain. Also endotoxin neutralization is mediated by Aβ binding, oligomerization and fibrillization and parallels LPS-agglutination activities of classical AMP. Our findings are consistent with the emerging Aβ-mediated antimicrobial protection hypothesis in AD.

**Abstract:** Chronic inflammation plays a central role in Alzheimer’s disease (AD) and in accelerating AD pathology. Multiple mechanisms link neuroinflammation to AD. Our studies focus on a particular pathway of neuroinflammation, the cyclooxygenase (COX) pathway, which is relevant to AD. COX-2 is highly induced in AD and negatively impacts neuronal function. The COX pathway is key to the conversion of arachidonic acid to bioactive prostaglandins (PGs), which are lipid compounds with hormone-like effects. Prostaglandins are implicated as playing vital roles in AD. Our goal is to characterize factors of the prostaglandin D2 (PGD2) signaling pathway that have biomarker potential. Our hypothesis is that these biomarkers of neuroinflammation can be used to diagnose early stages of AD. We focus on the PGD2 pathway in conjunction with the microglial activation known to occur in AD. PGD2 is the most abundant prostaglandin in the brain, and the one that increases the most under pathological conditions. DP2 receptor activation by PGD2 leads to a decrease in cAMP and an increase in calcium, and promotes neuronal loss. In this study we analyzed the levels of the DP2 receptor and microglia

activation in wild type (WT) and TgF344-AD (Tg-AD). Tg-AD rats express mutant human "Swedish" amyloid precursor protein (APPsw) and Δ exon 9 presenilin-1 (PS1ΔE9) driven by the prion promoter. Tg-AD rats present the full array of AD pathology including cerebral amyloidosis, tauopathy, gliosis, neuronal loss in the cerebral cortex and hippocampus, and cognitive impairment at 16 months of age. Changes in DP2 levels and microglia activation were assessed in the rat brains at pre-pathology (4 months of age) and when signs of neuroinflammation are significant (11 months of age) by immunohistochemistry. Our results demonstrate an age-dependent increase in DP2 receptor levels in three areas of the hippocampus: CA1, CA3 and dentate gyrus (DG). Microglia activation was prevalent in CA1 and DG but not in CA3 areas of the hippocampus in 11 month TG-AD rats. Our results support a microglia-PGD2-DP2 receptor crosstalk as a contributor to hippocampal neurodegeneration in Tg-AD rats. These results provide new information for developing potential new diagnostic biomarkers and therapeutic strategies for asymptomatic early stages of AD.

**Abstract:** In brain Apolipoprotein E (APOE) is secreted mainly by astrocytes, and is the major lipid carrier. Only properly lipidated APOE can efficiently function in brain but the differential role of APOE isoforms in the context of their different lipid composition is poorly understood. APOE affects Aβ clearance and deposition in isoform-dependent manner, and *in vitro*, it was

demonstrated that APOE affects Aβ aggregation and its phagocytosis by microglia. We hypothesize that, based on their different lipidation, APOE3 and APOE4 native lipoproteins impact microglial response in isoform-dependent manner. We used Cx3cr1 mice infused bi-laterally into cortex with Hilyte™-labeled Aβ42 pre-incubated with native APOE3 (Aβ+APOE3) or APOE4 (Aβ+APOE4) particles. We used *in vivo* time-lapse two-photon microscopy to investigate the microglia barrier around Aβ infusion site. In separate experiments, the injected mice were perfused at different time points, microglia sorted by FACS and used for RNA-seq. Flow cytometry was used to determine the proportion of the microglia cells that have or have not engulfed Aβ. The two-photon images acquired during the first 2 hours, demonstrated that microglia cells extended their processes faster towards the Aβ+APOE3 infusion site than towards the Aβ+APOE4. Flow cytometry determined that Aβ uptake by microglia was higher in mice injected with APOE3 than in those injected with APOE4 native lipoproteins. Using RNA-seq approach we compared the transcriptome of two microglia populations, namely microglia that have engulfed Aβ (double positive) and microglia without Aβ (single positive) separately for the mice injected with APOE3+Aβ or APOE4+Aβ. In the dual positive microglia from both APOE3 and APOE4 groups, the genes that were significantly upregulated were recently identified as disease associated microglial genes. In contrast, genes important for the normal microglia function, the homeostatic microglia genes, were upregulated in single positive cells. Interestingly, we also identified a significant number of genes and Gene Ontology categories uniquely up-regulated in mice injected either with APOE3+Aβ or APOE4+Aβ. Altogether, two-photon imaging results demonstrate that infusion of Aβ together with native APOE3 induces a more rapid response by microglia than with native APOE4 thus isolating the infused Aβ and suggesting a protective mechanism for diminishing the spread of Aβ. In regard to the transcriptome, we postulate that native APOE3 and APOE4 infused with Aβ affect the transcription of common as well as unique microglial genes and pathways. The study highlights isoform-specific effect of APOE on microglia response to Aβ.

**Abstract:** Alzheimer's disease (AD) is the most common form of dementia with no cure and only palliative therapeutics. The rare familial form of AD (FAD) is caused by autosomal dominant mutations that increase the peptide amyloid-β (Aβ), which aggregates to form both amyloid plaques and soluble oligomers (oAβ), the latter considered a proximal neurotoxin. *APOE4* is the greatest genetic risk factor for AD, compared to the common *APOE3* and the rare but protective *APOE2*. The mechanism underlying *APOE* modulation of AD risk remains unclear. Even less understood is the critical link between female sex and *APOE4*-induced AD risk. A common and early symptom of AD pathology is Aβ-induced neuroinflammation enhanced by *APOE4*. Importantly, oAβ-induced neuroinflammation is mediated by the Toll-like receptor-4 (TLR4), a key component in the innate immune response. Thus, our hypothesis is that blocking the TLR4 pathway will reduce AD pathology, particularly in female *APOE4* carriers. To test this hypothesis, we used the EFAD-Tg mice, which overexpress specifically Aβ42 and express human *APOE4* (E4FAD) or human *APOE3* (E3FAD). Both male and female E4FAD mice and female E3FAD mice were treated with IAXO101 (TLR4 antagonist) using prevention (4-6 month/M) and reversal (6-7M) paradigms. Efficacy of the drug was assessed in behavioral tests. ELISAs were run to determine Aβ levels in TBS, TBSX and FA sequential protein extraction fractions, and IL-1β levels in TBS fraction. Immunohistochemical measures include total Aβ deposition and astrogliosis. Amyloid deposition was measured by area covered in plaques via Thio-S staining. In the reversal paradigm, IAXO induced a significant increase in learning and memory, and a decrease in soluble Aβ in the female E4FAD mice. In the male E4FAD mice, amyloid deposition and astrogliosis were reduced, effects less pronounced in the female E3FAD mice. There were no significant effects with the prevention paradigm. Thus, inhibition of the TLR4 pathway by IAXO101 affected selective readouts for both neuroinflammation and Aβ solubility/deposition, two components of AD-related pathology. Further investigation is needed to understand the mechanism of the sex difference and the role of age and level of pathology for the use of TLR4 inhibitors as a therapeutic for AD.

**Abstract:** Alzheimer's Disease (AD) is a progressive age-related neurodegenerative disorder characterized by the accumulation of extracellular amyloid beta (A*β*) as well as CNS and systemic inflammation. Innate immune cells like CNS resident microglia and circulating monocytes use microRNAs to rapidly respond to inflammatory signals, such as A*β* exposure. MicroRNA (miRNA) profiles are altered in tissue, circulating monocytes, and serum of AD cases. MiR-155 is a miRNA that modulates the phasic inflammatory responses of immune cells, driving pro-inflammatory responses. However, the role of miR-155 in modulating neuroinflammation in AD remains unknown. *We hypothesize that miR-155 participates in AD pathophysiology by modulating inflammatory cell function, gene expression and Aβ equilibrium*. We generated trigenic mouse models of AD to investigate the role of miR-155 in microglia alone or in microglia and monocytes during disease progression. $APP^{swe}/PS1^{\Delta E9}$ mice were crossed with mice containing homozygous floxed miR-155 alleles and expressing Cre recombinase from the CX3CR1 locus. For *in vivo* acute and microglia-specific deletion of miR-155, mice express a tamoxifen inducible Cre recombinase directing miR-155 deletion to microglia, while a constitutively active Cre is expressed in the microglia and monocyte deletion model. Microglia specific deletion of miR-155 was achieved by a one-time tamoxifen treatment via oral gavage at 8 weeks of age. At 6 and 9 months of age microglia were isolated by *ex vivo* FACS and miR-155 deletion was assessed by endpoint PCR. We observed deletion of floxed miR-155 alleles, substantially reduced miR-155 expression and changes in inflammatory gene expression in microglia by qPCR. Targets of miR-155 including cMAF, CSF1R, SOCS1, and SHIP1 were upregulated at both time points. We observed that acute miR-155 deletion in microglia increases mortality ($p=0.0009$) in the $APP^{swe}/PS1^{\Delta E9}$ line, compared to vehicle animals that maintained miR-155 expression. We observed cohorts over 72 hours using the Noldus Phenotyper System and determined that increased mortality in this model may involve seizures. Concentrations of soluble and insoluble A*β* in cortical, striatal and hippocampal lysates were assessed using Luminex. *In vivo* continuous miR-155 deletion in microglia and monocytes also altered survival, and changes in soluble and insoluble A*β* were detected. Our results support the hypothesis that miR-155 deletion alters survival, innate immune gene expression and *Aβ* equilibrium in an AD model further elucidating the molecular pathways regulating neuroinflammation in AD and supporting a critical role for inflammatory cells in AD pathogenesis.

**Title:** Platelet derived growth factors disrupt the blood-brain barrier and elevate amyloid pathology in 5xfad mice

**Authors: *Q.-V. A. DUONG**[1], A. KADDOUMI[2]
[1]Auburn, AL; [2]Drug Discovery and Develop., Auburn Univ., Auburn, AL

**Abstract:** Alzheimer’s disease (AD) is the most common neurodegenerative disorder affecting 5.4 million people in the United States. Currently only symptomatic medicines are available but the search for novel therapeutic treatments continues. Previous evidence has shown the beneficial effects of growth factors in the treatment of AD pathology. Based on reported positive results obtained with the product Endoret®, the aim of this study was to in vitro and in vivo investigate the beneficial effects of platelet-derived growth factors (PDGFs) against AD pathology with a focus on the blood-brain barrier (BBB) function. For the in vitro studies, a cell-based BBB model was used to evaluate the effect of PDGFs on the monolayer intactness and amyloid-β (Aβ) transport. For the in vivo studies, 5xFAD mice were divided into 3 groups (n=7/group, 4 months old, males). Mice received intranasal PDGFs at 10% (group 1) and 100% (group 2) and normal saline (group 3 as control) every other day for 4 weeks. At the end of treatment, mice were sacrificed and brains were collected. Our results from in vitro studies showed that 24-hour treatment of PDGFs enhanced the monolayer tightness and increased Aβ transport across the monolayer in a concentration dependent manner. Findings from the in vivo studies, however, demonstrated 10 and 100% PDGFs exacerbated the amyloid pathology in 5xFAD brains. PDGFs at both doses disrupted the BBB integrity and functionality, increased brain amyloid deposit as confirmed by ELISA and immunostaining, which was associated with increased caspase-3, and neuroinflammatory markers such as IL-1β and TNF-α. In conclusion, the adverse effects observed in this study suggest PDGFs may not provide beneficial effect against AD, and the consideration to utilize growths factors derived from platelets should be further investigated.

**Abstract:** Alzheimer’s disease (AD), characterized by progressive memory loss and dementia, brain atrophy and death, is associated with rampant neurodegeneration due to extracellular deposition of neurotoxic amyloid (Aβ) plaques and hyperphosphorylation of tau, resulting in intraneuronal neurofibrillary tangles (NFTs). Extracellular Aβ deposition stimulates microglial and astrocytic localization and process extension toward plaques. This is associated with a shift to an inflammatory or reactive state, characterized by upregulation of cytokine/chemokine expression and heightened surface expression of Iba1 in microglia and GFAP in astrocytes. Recent research suggests that pro-inflammatory microglia may drive neurotoxic astroglial responses, indicating that microglial-astrocyte interactions can shape neurodegenerative pathology. Although astrocytes also play a direct role in neuronal homeostasis and synapse function, relatively little is known about their roles in modulating pathology and neurodegeneration/regeneration in AD. Historically, GFAP has been used to identify astrocyte populations in the CNS, however, many astrocyte populations, including those in the cortex of C57BL/6 mice, do not typically express GFAP. In this study, we use the pan-astrocytic marker S100B in conjunction with GFAP to define the heterogeneity of the astrocyte population within the CNS, and analyze how these populations shift towards a reactive phenotype in response to the neuroinflammatory environment of Aβ plaques in AD. In the 5XFAD mouse model of AD, cortical astrocytes near plaques typically transition from a homeostatic S100B+/GFAP- state to a reactive S100B+/GFAP+ state. Between 4 and 6 months in 5XFAD cortex, the percentage of GFAP+ astrocytes increases with plaque pathology. However, using immunohistochemistry and confocal imaging, we have identified a previously uncharacterized, small population of astrocytes in close proximity to plaques that retain their homeostatic, S100B+/GFAP- phenotype. These findings highlight the phenotypic heterogeneity of the plaque-associated astrocyte response in the cortex of 5XFAD mice through disease progression and suggest that distinct

signaling mechanisms may be necessary to skew astrocytes towards reactive vs. homeostatic phenotypes. Our data also provides further evidence that GFAP should not be used as a pan-astrocytic activation marker in AD research. Understanding the heterogeneity of the astrocyte population will help better understand how the interactions between distinct subpopulations of plaque-associated astrocytes and microglia drive AD-associated pathology and/or neuronal health.

**Abstract:** Alzheimer’s disease (AD) is the most common neurodegenerative disorder and the most prevalent type of dementia. Its enigmatic pathogenesis currently hampers the attempts to identify diagnostic biomarkers that would contribute to early detection along with a therapeutic approach that would halt the disease progression. Alongside the most widely accepted hypothesis that implicates the accumulation of senile plaques and neurofibrillary tangles, a growing body of evidence entangles immunological mechanisms in AD pathogenesis. However, the exact function of the neuroinflammatory response in the disease mechanism remains elusive, as it appears in both beneficial and detrimental guises. These opposing effects appear to be largely dependent on the phasic progression of the disease. With the present study, we aim at portraying the role of the neuroinflammatory process involved in different stages of AD. To that aim, we examined post-mortem formalin-fixed paraffin-embedded (FFPE) human brain tissue of early and advanced AD patients in comparison to age-matched controls. We performed gene expression profiling using the nCounter® neuroinflammation panel of NanoString technology, which enables the comprehensive multiplex gene expression analysis of 770 genes and the identification of 23 neuroinflammatory pathways. RT-PCR and immunohistochemistry were subsequently utilized for the validation of our findings. Considering the pivotal position of neuroinflammation in AD, our study endeavors to provide further insight not only into the underlying mechanisms of the disease pathogenesis, but also into strategies for the modulation of AD progression.

**Abstract:** Alzheimer’s disease (AD) is a neurodegenerative disorder that affects more than 5 million people in the United States. There is currently no known cure available. Mouse models of AD are used to study behavioral degradation as well as the plaque and tangle pathology that develops. Many models, however, only focus on amyloid or tau. A new mouse containing mutations in human amyloid precursor protein (hAPP) and microtubule-associated protein tau (MAP tau) has been developed in our lab (Lippi et al., 2017 SfN poster). This mouse has undergone behavioral characterization and the brains of these mice have been probed for plaque and tangle pathology. One area of particular interest is that of inflammation, since the AD brain is seen to be in a state of chronic inflammation. Inflammatory proteins, such as tumor necrosis factor alpha (TNFα) are common markers of microglial activation and play key roles in the inflammatory response pathway. Preliminary data show transgenic (Tg) mice have higher levels of TNFα, on average, than those with no AD mutations. In addition, increased levels of TNFα were seen to significantly correlate with the nesting score, which is indicative of deterioration activities of daily living (ADL) (Deacon, 2012). It is possible that glycogen synthase kinase 3 (GSK3) may be affecting inflammation increases in the Tg mice (Hooper, 2008) and future work will probe for GSK3 protein levels in this new model. An improved understanding of the inflammatory activation process and how this is perturbed in a mouse model containing both amyloid and tau pathology may lead to new therapies for AD.

**Abstract:** Alzheimer's disease (AD) is a progressive neurodegenerative condition that is characterized by the presence of amyloid plaques and tau tangles in the brain. Mouse models of AD aim to recapitulate not only behavioral deficits of AD but also plaque and tangle pathology; however, many models only focus on amyloid or tau. In the present study, a new hAPP/Tau mouse was developed from a cross of the J20 (hAPP) and rTg4510 (Tau P301L) mice, and the impact of Zinc (Zn) supplementation was explored. The hAPP/Tau mice were compared to mice with TauP301L, with a CaMKIIa promoter to drive tau expression, CaMKIIa promoter only mice, and mice with no mutations present. The brains were assessed for plaque and tangle pathology, free Zn levels, and inflammatory and tau protein levels. Only hAPP/Tau mice displayed insoluble plaques as detected by Congo Red staining. In addition, an increased amount of tangle pathology in the infralimbic region (IL) and hippocampus (HP) was noted through Thioflavin-S staining. Zinc water exacerbated tangle pathology in the HP and IL of hAPP/Tau mice. There was no significant difference between hAPP/Tau mice and single tau mice for the phosphorylated tau epitope, AT8, or total tau. Zinpyr-1 staining showed that hAPP/Tau mice had significantly lower free Zn in the dentate gyrus and CA3 regions of the HP, possibly due to Zn binding to AD-protein species in the region. hAPP/Tau mice displayed significantly higher GFAP levels than CaMKIIa promoter mice and had higher levels on average than mice with no mutations present. This increase in GFAP inflammation correlated with several behavioral measures. Mice with lower nesting scores (Smith et al., 2017 SfN Poster), had higher levels of GFAP and mice that spent less time in the target quadrant of the Barnes maze had higher levels of GFAP. Brain pathology seen in this novel hAPP/Tau mouse mimics that seen in the brains of AD patients. This hAPP/Tau mouse should be considered as a potential model to test future therapeutics or to analyze brain pathology's influence on behavior.

**Abstract:** Undoubtedly, neuroinflammation is a major contributor to disease progression in Alzheimer´s disease (AD). Neuroinflammation is characterized by the activity of brain resident glial cells, in particular microglia, but also by peripheral immune cells, which infiltrate the brain at certain stages of disease progression. The specific role of microglia in shaping AD pathology is still controversially discussed. Moreover, a possible role of microglia in the interaction and recruitment of peripheral immune cells has so far been completely ignored. Here, we ablated microglia cells in 12 months old WT and AD transgenic mice (APP-PS1) for 4 weeks using the Colony stimulating factor 1 receptor (CSF1R) inhibitor PLX5622 (Plexxikon, Inc.) and analysed its consequences to AD pathology and in particular to peripheral immune cell infiltration. First, PLX5622 treatment successfully reduced microglia numbers. This was, however, compensated by the appearance of a treatment resistant infiltrating macrophage population ($Iba1^+/TMEM119^-$) highly expressing the phagocytosis marker CD68 and the lymphocyte activation, homing, and adhesion molecule CD44, specifically at sites of amyloid-beta plaques in the brains of APP-PS1 mice. In consequence, ablation of microglia significantly raised the number of $CD3^+/CD8^+$ T-cells and reduced the expression of anti-inflammatory genes specifically in the brains of APP-PS1 mice. We conclude that in neurodegenerative conditions chronically activated microglia might limit T-cell recruitment to the brain and that macrophages connect innate with adaptive immune responses. Investigating the role of peripheral immune cells, their interaction with microglia and understanding the link between innate and adaptive immune responses in the brain might be a future directive in treating AD pathology.

**Abstract:** Influenza viruses until today are a leading cause of worldwide severe pandemics and represent a major threat to human and animal health. Although the primary target of influenza viruses in mammals is the lung, infection can cause neurological disorders, including delirium and encephalopathy. We could show previously that a peripheral influenza A virus infection caused by a non-neurotropic virus variant leads to long-term neuroinflammation and synapse loss together with impaired memory formation in young adult mice (Hosseini et al. 2018, JNS). Processes of neuroinflammation have indeed been associated with neurodegenerative diseases such as Alzheimer’s disease (AD) and prolonged or excessive innate immune responses are considered a risk factor for AD. Therefore, in order to investigate the role of influenza infection for the development and progression of AD two months old APP/PS1 mice were infected intranasally with non-neurotropic H3N2 (maHK68) influenza A virus. Whereas the infection had no effect on neuronal cell number in the CA1 region analysis of spine density revealed a reduction 120 days post infection in comparison to WT and also to non-infected APP/PS1 mice. A detailed analysis of microglia density and morphology revealed neuroinflammation in the hippocampus already of uninfected APP/PS1 mice but microglia activation was even more pronounced in APP/PS1 mice upon H3N2 infection. Taken together these results demonstrate that influenza infection as a peripheral immune stimulation may exacerbate AD possibly by triggering microglia hyperactivation.

**Title:** Modeling glycosylation in Alzheimer's disease using patient-derived stem cells

**Authors: *K. ROSENBALM**, D. NIX, M. TIEMEYER
UGA/CCRC, Athens, GA

**Abstract:** The pathology of Alzheimer's disease (AD) is complex and involves incompletely understood inflammatory responses. The contributions of inflammatory cells, either resident in the brain (microglia) or recruited from peripheral sources (monocytes/macrophages), are an emerging interest with regard to the initiation and progression of AD. Glycoprotein and glycolipid glycans regulate inflammatory cell differentiation, activation, trafficking, and survival. For each of these glycan-mediated activities, immune cells express glycan binding proteins, such as Siglecs, that recognize glycans within the cell's environment triggering subsequent responses, which can be pro- or anti-inflammatory depending on the glycan structure, receptor specificity, and cell type involved. To investigate whether glycomic changes accompany and/or contribute to the pathology of AD, we characterized the glycome of AD patient-derived induced pluripotent stem cells (iPSCs) and differentiated neural cultures, including glycosphingolipids as well as N-linked and O-linked glycoprotein glycans. We observed alterations in the abundance of sialylated and sulfated O-glycan structures in differentiated neural cultures. In addition, given CD33/Siglec-3's involvement as a risk factor for AD, we also analyzed the expression of anti-inflammatory glycan ligands for Siglec receptors in these tissues. In both our mouse and human iPSC AD models, we have observed an upregulation of Siglec-F ligands as well as a concomitant reduction of Siglec-9 ligand in AD iPSCs. The glycome of AD iPSCs was largely unchanged in comparison to normal control iPSCs, indicating the specificity of glycosylation alterations for these Siglec ligands. Using 5xFAD mouse brain immunohistochemistry, we observed that the increased expression of Siglec-F ligands occurs in a cell type specific manner at the brain's immune barrier, the choroid plexus epithelium. Naïve derived 3-D choroid plexus tissue ("chorganoids") have demonstrated a comparable amount of Siglec ligand expression between normal control and AD tissues, where we have observed increased expression of Siglec ligands after challenging chorganoids with Toll-like receptor ligands. Future combinatorial co-culture experiments will provide a novel opportunity to assess cell-specific glycomic and functional responses in AD.

**Abstract:** More than 5 million Americans are currently living with Alzheimer's dementia (AD). Studies have identified chronic inflammation as a key feature of AD. Whether inflammation is a cause or byproduct of AD is not known. However, chronic inflammation appears to be important to the pathophysiology of AD. As there is no cure for AD, research to explore modifiable risk factors that could potentially reduce inflammation and the likelihood of developing AD is vital. One such factor is diet. Using the dietary inflammatory index (DII), we can map an individual's diet on a continuum from -1, being highly anti-inflammatory, to 1, being highly pro-inflammatory. Our current research aims to investigate the inflammatory index of the diets of individuals with AD, Mild Cognitive Impairment (MCI), and healthy controls. Mild cognitive impairment is a significant risk factor in the development of dementia, as Alzheimer's disease may already be pathologically present. Although individuals with MCI experience decline in memory and cognitive ability, they have preserved daily living activities. Participants with AD, MCI, and healthy controls completed food frequency questionnaires assessing consumption of various foods over the past month. Preliminary analysis revealed, in agreement with other work, that healthy controls consumed significantly greater amounts of omega-3 rich foods, a potent anti-inflammatory, than did participants with AD ($p<0.001$). Additionally, we found that although participants with MCI did not significantly different from control participants, participants with MCI trended towards significance in consuming greater amounts of omega-3 rich foods than participants with AD ($p=0.06$). Next, we are analyzing the pro- and anti-inflammatory effects of foods assessed in the food frequency questionnaire. We hypothesize that individuals with AD will have diets with a DII score closer to 1, meaning they are highly pro-inflammatory; whereas, control individuals will have a DII score closer to -1, meaning they are highly anti-inflammatory. Additionally, we hypothesize that individuals with MCI will consume diets with a DII more similar to those with AD than controls due to the antecedent presence AD pathology and subsequent inflammation. Further research is needed to understand the interplay

between diet and AD/MCI, specifically in terms of how anti-inflammatory and pro-inflammatory components of foods consumed influence the course of neurodegeneration and dementia.

Univ. of California Irvine, Irvine, CA

**Abstract:** Abnormal buildup of amyloid-beta (Aβ) species is a prominent pathological hallmark for Alzheimer’s disease (AD), but its underlying mechanisms by which toxic Aβ species accumulates in the brain remain to be elucidated. Recent evidence from in vivo and in vitro studies suggests that the buildup of toxic metabolites in the brain is primarily mediated by impaired clearance mechanisms, rather than overproduction. Low density lipoprotein receptor-related protein 1 (LRP1) in the endothelial cells mediates Aβ clearance from the brain parenchyma. Aging as well as certain environmental factors have shown to decrease its expression in endothelial cells, and genetic ablation of endothelial LRP1 in mice significantly accumulated soluble Aβ in the brain. We have previously demonstrated that blocking IL-1 signaling ameliorated Aβ and tau buildup in the brain and rescued cognition in the mouse model. Recent studies also show that IL-1β, together with IL-6 and TNFα, plays a critical role in age-related inflammation and cellular responses. Therefore, we hypothesize that sustained IL-1β promotes the loss of LRP1 in endothelial cells. We first examined the exposure to IL-1β (1 ng/ml) for 24 hrs significantly downregulated LRP1 in the human primary microvascular endothelial cells (MVECs), and its effect was long-lasting after removal of IL-1β from the media. The IL-1β-induced reduction of LRP1 was not mediated by the proteasome- or lysosome-dependent degradation mechanisms. Instead, we found that IL-1β significantly upregulated microRNA-205-5p, -200b-3p, and -200c-3p in MVECs. These microRNAs were predicted to bind LRP1 mRNA to halt its translation. The application of synthetic microRNA-205-5p, -200b-3p, or -200c-3p mimic effectively downregulated LRP1, and pre-treatment with antagomirs

against these microRNAs restored LRP1 in IL-1β-exposed MVECs. These results strongly suggest that miRNA-205-5p, -200b-3p, and -200c-3p are directly involved in the LRP1 regulation in MVECs. The expression of these microRNAs appeared to be controlled by NF-kB as NF-kB inhibitor, BMS-345541, inhibited the IL-1β-mediated increased expression of these three microRNAs and rescued LRP1. Our study provides novel mechanisms addressing that inflammation is a key triggering event for AD pathogenesis. These three candidate miRNAs involved in the regulation of LRP1 might lead to therapeutic applications of miRNA inhibitor and NF-kB inhibitor to treat AD in the future.

**Title:** Modulation of the inflammatory response by RNA-binding protein TIA1 in the P301S mouse model of tauopathy

**Authors: *C. LEBLANG**[1], B. WOLOZIN[2], J. LUEBKE[1]
[1]Anat. and Neurobio., [2]Pharmacol. and Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA

**Abstract:** Tauopathies such as Alzheimer’s Disease and Frontotemporal Dementia are characterized by aggregation of hyperphosphorylated tau protein, widespread neuro-inflammation and neuronal death. We have recently shown that the RNA-binding protein TIA1 regulates tau pathophysiology and toxicity in part through sequestering phospho-tau oligomers in pathological stress granules (Vanderweyde et al., 2016; Apicco et al., 2017). Haplo-insufficiency of TIA1 in the P301S mouse model of tauopathy reduced the accumulation of tau oligomers, as well as the development of downstream cognitive deficits, cortical thinning, and synapse loss. In the healthy brain TIA1 acts as a regulator of the innate immune response and of cell death by sequestering TNFα and COX2 mRNA transcripts in normal stress granules (Ash et al., 2014; Lopez de Silanes et al., 2005). The putative role of TIA1 in the immune response led us to hypothesize that full TIA1 knockout would increase the immune response in the P301S mutant mouse model. Here, we characterized the inflammatory response in P301S vs. WT mice that were TIA1+/+, TIA1+/- or TIA1 -/-. Immunohistochemistry and 3D cell counting techniques were used to assess microglial morphology and MHCII antigen presentation in the CA1 and

Dentate Gyrus regions of the dorsal hippocampus. Microglial activation was significantly greater in all P301S groups compared to WT, confirming that tauopathy induces neuro-inflammation in this model. There was a significantly higher number of activated microglia in the P301S TIA1 -/- compared to P301S TIA+/+ and P301S TIA+/-, which did not differ. The inflammatory response was not observed in the WT TIA1 -/- group, indicating that the inflammatory phenotype seen in the P301S TIA-/- group requires the presence of tau and/or downstream neuropathological insults. Gross atrophy of the hippocampus was observed in P301S TIA1 -/- mice, but not in the other genotypic groups, perhaps reflecting the severe inflammation selectively present in P301S TIA1-/- mice. Immuno-electron microscopy was used to assess microglial ultrastructure and neuronal interactions, to quantify synapse loss, and to characterize colocalization of tau with TIA1. These studies suggest that TIA1 plays an important role inhibiting inflammation in the context of tauopathy, but that this role is only apparent with full TIA1 deletion. Ongoing studies are quantifying levels of inflammatory cytokines and phagocytic markers to determine the mechanisms by which TIA1 regulates neuro-inflammation.

**Abstract:** Alzheimer’s disease (AD) is a progressive neurodegenerative disorder with a significantly increased risk for carriers of E4 allele. Aging is the strongest risk factor for AD and tightly associated with impaired brain homeostasis. Microglia play a crucial role in maintaining brain homeostasis and microglial dysfunction is linked to neurodegeration. However, APOE

isoform specific effects and its association with age- and AD-related changes in the microglial transcriptome still remain poorly understood. To get further insight in the specific effects of APOE isoform in response to aging, we performed RNA-seq using isolated microglia from WT and APP/PS1 mice expressing human APOE3 and APOE4 (WT/E3, WT/E4, APP/E3, APP/E4). The transcription profiles of younger (3.5 month), young (7.5 month) and older mice (13.5 month) were further analyzed to identify microglia specific genes affected by aging or APOE isoform. We found commonly affected genes associated with aging in both APP transgenic and WT mice regardless of APOE isoform including disease-associated microglial genes (DAM). Surprisingly, our data show that microglia from APOE3 expressing mice showed higher number of differentially expressed genes with aging compared to APOE4 expressing mice, but differential expression was stronger in APP transgenic mice. We also identified a number of commonly affected genes by aging in APOE3 or APOE4 expressing mice regardless of amyloid phenotype. The conclusions from this study are: a) aging is the strongest factor that affects brain transcriptome; b) APOE isoform-specific effect on brain transcriptome correlates to amyloid phenotype and is less pronounced in WT mice; c) the microglia transcriptome is affected by amyloid pathology, aging and APOE isoform.

**Abstract:** Alzheimer’s disease (AD) primarily affects older adults. Amyloid-beta (Aβ) accumulation is associated with the pathological progression of AD. Emerging evidence shows that innate immune system dysfunction plays a key role in Aβ accumulation. Improving the function of innate immune system to enhance Aβ clearance has been proposed to be an important strategy for restricting the development of AD. This study aimed to determine the effects of two hematopoietic growth factors, stem cell factors (SCF) and granulocyte colony-stimulating factor

(G-CSF) in improving innate immune function and enhancing Aβ clearance in aged APP/PS1 mice. SCF and G-CSF was subcutaneously injected for 12 days in 25-month-old male APP/PS1 mice. Five weeks after treatment, mice were sacrificed for pathological examinations using immunohistochemistry in brain sections. We observed that SCF in combined with G-CSF (SCF+G-CSF) treatment significantly reduced the area, number, and size of Aβ plaques in both the cortex and hippocampus as compared to the vehicle control APP/PS1 mice. In addition, both the $Iba1^+$microglia and $CD45^+$microglia/macrophages were significantly increased by SCF+G-CSF treatment. The association of $Iba1^+$microglial cells with Aβ plaques was also significantly increased by SCF+G-CSF. Increased uptake of Aβ by$CD45^+$microglia/macrophages was seen in SCF+G-CSF-treatedAPP/PS1 mice. Moreover, SCF+G-CSF treatment led to increased IL-4 expressing cells and decreased nitric oxide synthase 2-positive cells. These findings suggest that SCF+G-CSF treatment in oldmice with cerebral amyloidosis enhances Aβ clearance, increases the recruitment of microglia/macrophages, and modulates innate immune activation. This study reveals potential therapeutic benefits of SCF+G-CSF treatment for restricting AD pathology in older adults.

**Title:** Altered inflammatory signalling in cerebrospinal fluid of mild cognitive impairment versus Alzheimer’s disease: Analysis of cytokines/chemokines, amyloid-beta and tau

**Authors: *M. BIANCHI**, J. A. PRENDERVILLE, T. BURKE, C. W. MCDONNELL
Transpharmation Ireland Limited, Dublin, Ireland

**Abstract:** Mild cognitive impairment (MCI) is a syndrome wherein a person experiences greater cognitive decline than is normal for their age and often progresses to dementias, including Alzheimer’s disease (AD). Inflammation has been proposed as a pathogenic factor for both MCI and AD, but available data on cytokine/chemokine expression in cerebrospinal fluid (CSF) in MCI or AD are inconsistent. Here, we analysed a panel of cytokines/chemokines as inflammatory markers (IL-1β, IL-6, TNF-α, IFN-γ, IL-10, IL-12p70, IL-13, IL-2, IL-8, and IL-4) in CSF from MCI, AD and healthy control donors. Validated biomarkers of disease progression, namely Amyloid-Beta ($Aβ_{1-42}$) and TAU were also analysed to validate our diseased population. CSF from donors diagnosed with MCI, AD and aged matched controls (n=15 per group) were obtained from a biobank. Expression of cytokines/chemokines, amyloid-beta ($Aβ_{1-42}$), Total-TAU (T-TAU) and Phospho-TAU at Thr181 (P-TAU) were assessed using MesoScale

Diagnostics assays. Donors also supplied a complete history and completed the mini-mental state examination (MMSE) and Alzheimer's disease assessment scale (ADAS).
A significant deficit in MMSE performance was observed in the MCI and AD groups compared to healthy controls and ADAS score was significantly higher in the AD group compared to MCI. CSF $A\beta_{1-42}$ concentration was significantly lower in both MCI and AD compared to control, while T-TAU was significantly increased with a significantly higher concentration in AD. P-TAU was increased in AD only. TNF-α concentration was significantly higher in both MCI and AD compared to healthy controls while IL-6 was increased in the AD group. IL-8 and IL-10 were significantly elevated in the AD group compared to MCI and healthy controls.
This is one of few studies directly comparing MCI and AD individuals using optimised multiplex assays to assess cytokine, $A\beta_{1-42}$ and TAU concentration in CSF. In line with the literature, T-TAU and $A\beta_{1-42}$ were increased and decreased in MCI and AD, respectively. TNF-α has been previously reported to be upregulated in CSF of AD patients. We report a significant TNF-α increase in MCI and AD which may indicate a role for TNF-α in MCI to AD progression. Moreover, an increase in IL-8 and IL-10 specifically in AD suggests a disease-specific CSF cytokine/chemokine profile. These results demonstrate that neurodegenerative changes in MCI and AD are associated with alterations in cytokine signalling and immune system function. Thus, inflammatory signalling could represent an innovative therapeutic target in MCI/AD as well as a potential biomarker to indicate disease progression.

**Abstract:** The presence of decreased brain blood flow in both human patients and animal models (APP/PS1) of Alzheimer's disease has been long known but no physiological explanation of this phenomenon has emerged. Using high-resolution *in vivo*imaging of blood flow in mouse models of Alzheimer's disease, we have identified transiently stalled capillary segments as the major cellular mechanism causing this blood flow decrease. In AD mice, about 2% of capillaries have stalled blood flow due to a leukocyte stuck in the lumen, while wild type (wt) mice have ~4 times fewer stalled capillaries (Fig. 1a and b). We determined that the majority of the capillary stalls are caused by neutrophils firmly adhered to the interior of the vessel wall. Administration of antibodies against Ly6G, a neutrophil-specific receptor, led to a ~60% reduction in the number of stalled capillaries and a ~30% increase in blood flow in cortical penetrating arterioles (Fig 1c and d). Administration of isotype control antibodies produced no changes in the number of stalls or blood flow. A single treatment with anti-Ly6G in AD mice led to significantly improved cognitive performance within 3-6 hr in tests of short-term and working memory. This acute improvement in cognitive performance was evident in mice with relatively advanced AD pathology (17 month old APP/PS1 mice, which show first cognitive impacts at 8 months) (Fig 1e and f). In summary, we have shown that neutrophils plug blood flow in a small fraction of brain capillaries in AD mouse models and that blocking this adhesion substantially increases brain blood flow and rapidly improves cognition. These data suggest that brain hypoperfusion likely contributes to cognitive deficits in mouse models of AD.

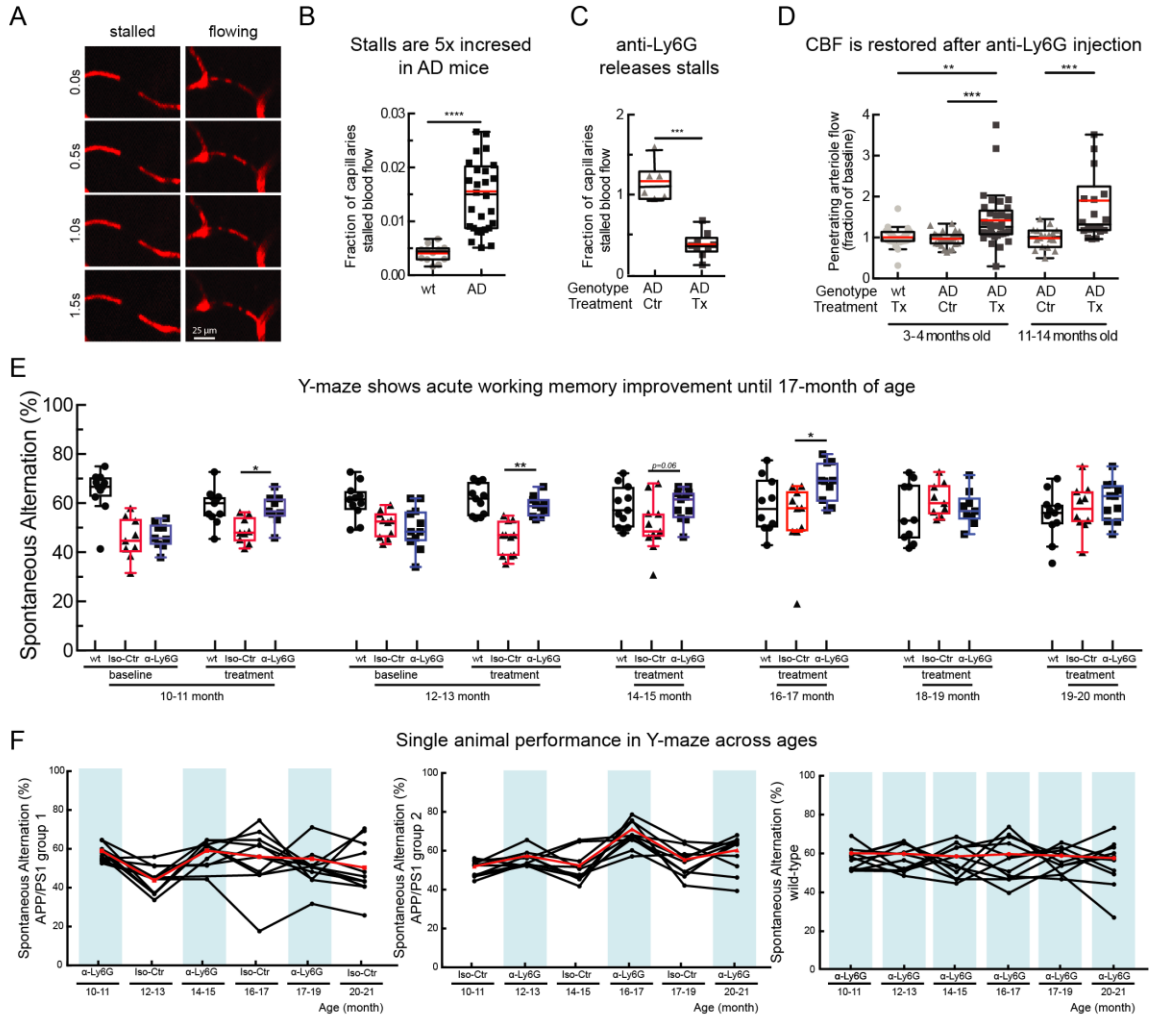

Figure 1: Stalling is a novel mechanism that leads to reduced blood flow and impaired cognitive function in AD. (A) Representative images showing a stalled vessel (stalled on left and flowing on right) red: Blood plasma. (B) Capillary stalls are 5x elevated in AD mice (C) anti-Ly6G treatment reduced the number of stalls by about 90%. (D) Blood flow is restored after single anti-Ly6G treatment. (E) Spontaneous alternation in the Y-maze task, bi-monthly measured staring at 10-11 month old APP/PS1 and wt mice at baseline and at 3-6 hr after a single administration of α-Ly6G or Iso-Ctr antibodies, (F) Single animals across age; left: group1, middle: group2 and right wt animals. Red line shows the median of each group.

**Title:** Microglial ABCA7 contributes to the regulation of brain immune system

**Authors: *T. AIKAWA**[1], Y. REN[2], Y. YAMAZAKI[1], Y. A. MARTENS[1], M.-L. HOLM[1], C. T. ANDERSON[1], Y. W. ASMANN[2], G. BU[1], T. KANEKIYO[1]
[1]Neurosci., [2]Hlth. Sci. Res., Mayo Clin., Jacksonville, FL

**Abstract:** The *ABCA7* gene encoding ATP-binding cassette transporter A7 is ranked as one of the top susceptibility loci for late-onset Alzheimer's disease (AD). Importantly, loss-of-function variants in *ABCA7* have been shown to increase the risk for AD. ABCA7 belongs to the ABC transporter family and likely regulates the distribution of phospholipids and cholesterol which associates with the phagocytic pathway. Although the accumulation and deposition of amyloid-β (Aβ) peptides in the brain are central events in AD, increasing evidence indicates that the brains immune system plays a critical role in disease development and progression. While we found that lipopolysaccharide (LPS)-induced mRNA expressions of pro-inflammatory cytokines were suppressed in the primary microglia and brains from heterozygous *Abca7* deficient (*Abca7*$^{+/-}$) mice compared to control wild-type mice, contributions of ABCA7 to the brains immune system are not fully understood. Thus, to identify the molecular pathway, we performed RNA-seq in the cortex from control and *Abca7*$^{+/-}$ mice with or without LPS administration. When network analysis was performed in the top-ranked module, identified through weighted gene co-expression network analysis (WGCNA), *Cd14* was identified an intramodular hub-gene inducing the differences in transcript profiles. We also confirmed that ABCA7 deficiency diminished the LPS-induced upregulation of CD14 in isolated microglia from those mice. These results indicate that CD14-mediated pathway in microglial ABCA7 could be involved in regulating the brain immune system. ABCA7 loss-of-function possibly compromises normal immune responses in the brain, which may contribute to AD pathogenesis.

**Title:** Fractalkine signaling drives distinct TREM2-dependant and TREM2-independant microglial responses to early amyloid pathology

**Authors: *S. PUNTAMBEKAR**[1], A. OBLAK[2], G. E. LANDRETH[3], B. T. LAMB[4]
[1]Indiana University-Purdue University, Indianapolis, Indianapolis, IN; [2]Stark Neurosci. Res. Inst., [3]Stark Neurosci. Res. Institute, NB214C, Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Stark Neurosciences Res. Inst., Indianapolis, IN

**Abstract:** The phagocytic and immune activity of CNS microglia in the homeostatic brain is restricted by inhibitory check-points such as the CX3CL1-CX3CR1/Fractalkine signaling pathway. While these negative signaling mechanisms are critical to limit by-stander damage within the immune-privileged brain, they prove to be detrimental under neurodegenerative conditions. In Alzheimer's disease (AD), characterized by accumulation of extracellular Aβ plaques and intra-neuronal NFTs due to hyperphosphorylation of tau, down-regulation of CX3CR1 has been implicated in shifting microglia towards a protective, disease associated (DAM) phenotype with a heightened phagocytic capacity. This protective phenotype is associated with increased expression of Triggering Receptor Expressed on Myeloid Cells-2 (TREM2). Consistent with these single-cell transcriptomics data, our studies using mouse models of AD have shown a reduction in fibrillar (ThioS$^{bright}$) Aβ plaque abundance in the CNS of APPPS1 CX3CR1$^{-/-}$ mice in early stages of pathology. Increased phagocytosis of injected Aβ by microglia in C57Bl/6 CX3CR1$^{-/-}$ mice suggests that the loss of CX3CR1 in the APPPS1 mouse model drives microglia towards a neuroprotective phenotype. By contrast, we see an increased proportion of ThioS$^{dim}$ plaques with a filamentous morphology in the APPPS1 CX3CR1$^{-/-}$ mice. These highly neurotoxic, filamentous plaques are associated with larger foci of dystrophic neurites in the cortex and hippocampus. Interestingly, this defect in plaque compaction is accompanied by reduced TREM2$^{+}$ microglia/macrophages around diffuse but not compact plaques. Furthermore, Iba1$^{+}$ cells surrounding diffuse plaques fail to polarize TREM2 to their plaque-interacting processes. To assess whether attenuated TREM2 responses and increased neurotoxicty correlate to defects in the microglial capacity to phagocytose/clear extracellular debris, we performed ex-vivo phagocytosis assays. Microglia from APPPS1 CX3CR1$^{-/-}$ mice show a significantly increased capacity to phagocytose and process internalized particles.

Consistent with our ex-vivo data, we see an increased proportion of plaque-associated Iba1$^{+}$ cells that internalize dystrophic neurites. Increased microglial phagocytosis is accompanied by region-specific changes in expression of phagocytic receptors (MerTK, Axl, TLR4) and pro-inflammatory mediators (iNos, TNF etc) in the cortex vs. hippocampus. Our data suggests that the loss of CX3CR1 during early pathology drives microglial activation that is primed to phagocytose/clear pathological structures (TREM2-independent) but is unable efficiently compact Aβ plaques (TREM2-dependant).

**Title:** Neuroprotective effects of digoxin on Alzheimer’s dementia model in rats

**Authors: *M. A. ERDOGAN**[1], G. YIGITTURK[2], O. ERBAS[3]
[1]Physiol., Izmir Katip Celebi Univ. Fac. of Med., Izmir, Turkey; [2]Histology, Ege Univ. Fac. of Med., Izmir, Turkey; [3]Physiol., Istanbul Bilim Univ. Fac. of Med., Istanbul, Turkey

**Abstract: Aims:** Alzheimer’s disease (AD) is the most common age-related neurodegenerative disorder, which causes progressive development of cognitive deficits with severe learning and memory loss, behavioral changes and eventually to morbidity and death. A complex mechanism for pathogenesis of AD has been recently proposed that involves an increase in inflammation. TNF-α is the major cytokine synthesized by activated microglia and neurons and initiating the inflammatory cascade. Examinations of postmortem AD brains has revealed that increased TNF-α co-localizes with Aβ plaques. IL-17 and TNF-α are also known to interplay and drive common molecular pathways. Although IL-17 can induce pro-inflammatory cytokines by itself, its effects are vastly increased when cooperating with TNF-α. Because Digoxin has some anti-inflammatory features due to inhibitory effects on IL-17/TNF-α in previous animal studies, we investigated the effects of Digoxin in an intracerebroventricular (ICV)-streptozotocin (STZ) animal model of sporadic-AD. **Methods:** A total of 18 Sprague-Dawley adult rats were divided into 3 groups of control (n=6), ICV-STZ+saline (n=6) and ICV-STZ+Digoxin (n=6). Twelve rats with AD, induced by STZ injection (3 mg/kg) into both lateral ventricles using a stereotaxic frame, were divided into 2 groups 5 days after the STZ injection: one treated with Digoxin (0.1 mg/kg/day, i.p.) and the other with 0.9% NaCl (1 ml/kg/day, i.p.) for 3 weeks. No surgery/treatment was given to the controls. After treatment, a passive avoidance learning (PAL) test was used followed by removal of the brain tissue in all animals. Brain TNF-α and ChAT

levels were determined, and neurons in the hippocampal CA1 and CA3 regions were counted by Cresyl violet staining. **Results:** ICV-STZ was found to significantly shorten the latency time on the PAL, increase brain TNF-α level, decrease brain ChAT activity and neuron counts in the hippocampus. On the other hand, Digoxin significantly attenuated all these detrimental effects induced by STZ. **Conclusions:** Digoxin significantly prevented the ICV-STZ-induced memory deficit by attenuating the hippocampal neuronal loss, neuroinflammation and cholinergic deficit in rats. These findings suggest that Digoxin may be beneficial for treating AD.

**Abstract:** Alzheimer's disease (AD) is the most common form of neurodegenerative disease with cognitive impairment in the elderly people. The classic neuropathological hallmarks are the formation and accumulation of extracellular amyloid plaques (APs) and intracellular hyperphosphorylated tau containing neurofibrillary tangles (NFTs). In addition, neuroinflammation plays an important role in the pathogenesis of AD. We have previously demonstrated the increased expression of glia maturation factor (GMF), a brain predominant neuroinflammatory protein in AD specific brain regions. Triggering receptor expressed in myeloid cells 2 (TREM2) is implicated in AD pathogenesis. Here, we studied the expression of TREM2 and GMF and their association with APs and NFTs in the temporal cortex of AD brains. Immunohistochmemical analysis revealed an increased expression of GMF and TREM2 in AD brains as compared to age matched non-AD brains. Furthermore, we used double immunohistochemical and immunofluorescence labeling to analyze the co-localization of TREM2 and GMF with APs as well as NFTs in AD brains. TREM2 is upregulated and associated with GMF within the vicinity of APs in AD brains. Expression of TREM2 was also increased at the vicinity of NFTs in AD brains. Additionally, an increased TREM2 immunoreactivity was found to correlate with strong immunolabeling of ionized calcium-binding adopter molecule-1 (Iba-1), an activated microglial marker, as well as 6E10 labeled APs and phosphorylated tau stained NFTs. Brain regions with increased APs were associated with TREM2-immunoreactive microglia as well as GMF immunoreactivity in AD brains. These findings suggest that expression of GMF and TREM2 exacerbates neuroinflammation, neurodegeneration and other pathological changes associated with AD.

**Title:** Trem2 regulatory region activity in human cell lines

**Authors: *L. BEKRIS**[1,2], R. AKHTER[3], E. DYNE[2], M. KHRESTIAN[1], Y. SHAO[1]
[1]Cleveland Clin. Genomic Med. Inst., Cleveland, OH; [2]Kent State Univ., Kent, OH; [3]Cleveland Clin. Lerner Res. Inst., Cleveland, OH

**Abstract:** Triggering receptor expressed on myeloid cells 2 (TREM2) genetic variation is associated with Alzheimer's disease (AD) risk and neuroinflammation. ADAM10 cleavage produces a soluble form of TREM2 (sTREM2) which is increased in MCI and AD. Since ADAM10 is not elevated in AD it is still unclear how sTREM2 levels increase in AD. In the human brain, TREM2 mRNA is expressed in regions known to be affected in AD. However, given that TREM2 plays a role in neuroinflammation in AD mouse models, it is important to understand the underlying mechanisms driving changes in TREM2 expression for potential neuroinflammation and therapeutic intervention strategies. In this investigation, it was hypothesized that trans-acting factors present in certain cell types, such as glial cells, modulate TREM2 regulatory element activity. The aims of this study were to: 1) Demonstrate that the activity of the TREM2 promoter is cell type specific. 2) Demonstrate that genetic variation in the specific regions of the promoter alter activity according to cell type. 3) Demonstrate that the 3'UTR influences promoter activity according to cell type. Information from this study will reveal which cell lines have TREM2 active trans-acting factors that influence the TREM2 gene regulation. The TREM2 promoter region was PCR amplified from human genomic DNA and cloned into a pGL4.10 luciferase reporter vector. Genomic DNA was genotyped for selected promoter SNPs. Three variant combinations (TREM2 promoter haplotypes) were identified and cloned into a pGL4.10 luciferase reporter vector alone and with the TREM2 3'UTR. This produced six TREM2 regulatory region haplotype constructs that were transiently transfected into eight human cell lines, including neuronal, glial and a hepatocyte cell line. The results show that TREM2 regulatory element luciferase reporter constructs have different activity level that depends on cell type and promoter haplotype. These results suggest that TREM2 expression is specific to certain cell types and implicates the presence of critical cell type specific trans-acting factors that act upon the TREM2 specific regions of the promoter. Understanding TREM2 regulation provides insight into potential targets for activation or inhibition of TREM2. Further research is warranted to characterize the trans-acting factors that contribute to TREM2 gene regulation.

**Title:** Soluble TREM2 and inflammatory biomarkers in Alzheimer's disease

**Authors: *J. B. LEVERENZ**[1], M. KHRESTIAN[2], Y. SHAO[2], L. BEKRIS[2]
[1]Neurolog. Insitute, [2]Genomic Med. Inst., Cleveland Clin., Cleveland, OH

**Abstract:** Alzheimer's disease (AD) has been genetically and pathologically associated with neuroinflammation. Triggering receptor expressed on myeloid cells 2 (TREM2) is a microglial receptor involved in neuroinflammation that is genetically linked to AD risk. However, little is known about the relationship between soluble TREM2 (sTREM2) levels and other inflammatory biomarkers in both central and peripheral compartments in AD.Given that sTREM2 levels have been described as elevated in AD, it was hypothesized that we would also observe an elevation of sTREM2 levels in CSF in our AD cohort. Secondarily, and that there is a relationship between sTREM2 levels and blood brain barrier (BBB) integrity and other measures of central and peripheral inflammation. Cognitively normal controls, mild cognitive impairment (MCI) and AD donated cerebrospinal fluid (CSF) and plasma to the Cleveland Clinic Lou Ruvo Center for Brain Health Biobank. Inflammatory and BBB biomarkers were measured using a Luminex, Millipore system and clinical core services. We confirmed previous findings of elevated sTREM2 in the CSF of MCI and AD. Peripheral inflammatory markers were, for the most part, not associated with CSF or plasma sTREM2 levels. Interestingy, there were significantly positive correlations between CSF sTREM2 and plasma sTREM2 and between CSF sTREM2 and a marker for blood brain barrier integrity. A consistent association of peripheral or central markers of inflammation and CSF sTREM2 levels was not found, suggesting a limited impact of general inflammation on sTREM2 levels. An association between peripheral sTREM2 levels and CSF sTREM2, as well as an association between CSF sTREM2 and a marker of blood brain barrier integrity, was observed in AD, suggesting a potential role of peripheral TREM2 in central TREM2 biology.

**Abstract:** Mutations in the triggering receptor expressed on myeloid cells 2 (TREM2) gene have been associated with a significantly increased risk of Alzheimer's disease (AD). We have been characterizing a TREM2-agonizing antibody called A-002a, developed by Alector, Inc. This antibody activates the TREM2 receptor and induces DAP12 signaling in vitro. We hypothesized that agonizing TREM2 would ameliorate amyloid pathology via the engagement of microglia. To assess this, we performed intracranial and systemic administration of the A-002a antibody to 5XFAD mice. We examined brain tissue 3 days following a single intracranial injection and following 16 weekly intraperitoneal injections. In both instances we found that beta-amyloid deposition was decreased and cognition was improved in the systemic administration study. To assess the microglial response to A-002a we examined Iba1 immunohistochemically stained tissue sections that were counterstained with Congo red to localize the compact amyloid plaques. We determined that both intracranial and systemic administration of A-002a significantly increased the staining density for Iba1. In the intracranial study, we found a 100% increase in the Iba1 immunoreactivity in the hippocampus and frontal cortex. In the systemic administration study we found an 80% increase in the Iba1 immunoreactivity in the frontal cortex and a 200% increase in the hippocampus. We developed an analysis workflow that allowed us to count the number of Iba1-positive microglial cell bodies in a fixed area immediately surrounding the Congophilic amyloid plaques. We found that the numbers of microglia associated with amyloid plaques following intracranial administration of A-002a was increased from 3 microglial cells per plaque to an average of 8 microglial cells per plaque in both the frontal cortex and hippocampus. Also, a similar increase was seen following systemic administration of A-002a, where we found that there was a significant increase from an average of 2 microglial cells per plaque to an average of over 5 microglial cells per plaque. The size of the plaques was controlled for, where only plaques of a given size were selected for analysis. In conclusion, an anti-TREM2 antibody, A-002a, that has been shown to agonize TREM2 activates microglia and increases the numbers of microglial cells associated with amyloid plaques, while significantly reducing amyloid deposition in the 5XFAD mouse model.

**Abstract:** Beta amyloid (Aβ) peptide is shown to be toxic to the mitochondria and implicates these organelles in the progression and pathogenesis of Alzheimer's disease (AD). Glia maturation factor (GMF), a neuroinflammatory protein isolated and cloned in our laboratory plays an important role in the pathogenesis of AD. Mitochondria are constantly altering their size and shape while traversing through neurons; from the cell bodies to nerve terminals and synapses of neurons, the sites of high-energy demand. Mitochondrial fission and fusion proteins are equally balanced in healthy neuronal cells. Mitochondrial fragmentation is generally observed in the effected brain regions in (AD). We hypothesized that Glia maturation factor (GMF) a brain-localized inflammatory protein perturbs mitochondrial dynamics by altering fission and fusion protein levels and through oxidative stress- induced apoptosis as evident in Aβ (1-42) treated human neuroblastoma (SH-SY5Y) cell lines in an *in vitro* model of AD. We, report that cells incubated with GMF and Aβ (1-42) promotes mitochondrial fragmentation, disturbs mitochondrial dynamics by shift in the mitochondrial fission and fusion protein balance. This in turn leads to increased oxidative stress, oxidative DNA damage and shifts the Bax/Bcl2 expression resulting in release of cytochrome-c, and increased activation of effector caspases expression and eventual apoptosis. We report that GMF significantly upregulates fission protein Drp1 and Fis1 but downregulates fusion proteins OPA1, Mfn1 and Mfn2 levels. This study shows that GMF, an important neuroinflammatory mediator alters mitochondrial dynamics through oxidative stress mediated apoptosis. We conclude that upregulated GMF could be a risk factor for AD and suppression of GMF should represent a new and promising therapeutic strategy for combating AD

**Title:** Locus coeruleus noradrenergic system and beta-adrenergic receptor modulation of neuroinflammation in mouse models of Alzheimer’s disease

**Authors: *A. K. EVANS**, B. YI, J. ERNEST, M. SHAMLOO
Stanford Sch. of Med., Palo Alto, CA

**Abstract:** Locus Coeruleus (LC) noradrenergic (NA) neurons degenerate early in Alzheimer’s disease (AD). Loss of NA tone likely contributes to AD pathophysiology and its progression. We have previously demonstrated that beta-adrenergic activation leads to modulation of chronic neuroinflammation in mouse models of AD. The current study was designed to examine mechanisms of adrenergic modulation of neuroinflammation in mouse models of AD using selective deletion of beta-adrenergic receptor (adrb1 and adrb2) subtypes on myeloid-lineage cells (e.g. microglia and macrophages). Transgenic mice over-expressing human amyloid precursor protein (APP) were crossed with adrb1- or adrb2-floxed mice expressing cx3cr1-creER to generate a myeloid-specific tamoxifen-inducible deletion of adrb1 or adrb2. Adrenergic modulation of inflammation was also examined in adrb1- or adrb2-flox/cx3cr1-creER mice in a model of LPS-induced neuroinflammation. Specificity of adrenergic effects on inflammation following LPS were also examined with selective beta-adrenergic pharmacology. At termination of each study, mice were anesthetized, blood was collected for plasma by cardiac puncture, and mice were transcardially perfused with cold phosphate buffered saline. Brain was removed and one hemisphere was fixed and the other flash frozen. Plasma was frozen on dry ice. All tissues were stored at -80 C. Amyloid beta and plasma cytokine concentrations were quantified by ELISA. RNA was isolated from brain homogenate and cytokine gene expression was quantified by real-time polymerase chain reaction. We report modulation of cytokine gene expression following knockout of adrb1- or adrb2- in myeloid-lineage cells. Deletion of beta-adrenergic receptors exacerbated the inflammatory response to LPS. Effects of LPS on cytokine responses were inhibited by beta-adrenergic agonism. These data support the hypothesis that beta-

adrenergic receptors modulate systemic and central inflammation with implications for modulation of disease progression in AD.

**Title:** A meta-analysis of complement proteins in Alzheimer's disease

**Authors: *S. KRANCE**[1], H. MAO[1], Y. ZOU[1], X. HE[1], M. PAKOSH[2], W. SWARDFAGER[1]
[1]Dept. of Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada; [2]Library and Information Services, Univ. Hlth. Network, Toronto, ON, Canada

**Abstract:** Purpose: Genome-wide association studies implicate complement pathway activity as a cause of Alzheimer’s disease (AD), and the hallmark AD biomarker amyloid-β has been shown to activate the complement cascade; however reports of complement proteins measured in peripheral blood and cerebrospinal fluid (CSF) have conflicted. This meta-analysis seeks to quantitatively combine data from clinical studies of complement pathway data, in peripheral blood and CSF studies. Methods: Literature was searched using Medline, PubMed, Embase, PsycInfo, Cochrane Controlled Trials Register, and Cochrane Database of Systematic Reviews. Original peer-reviewed studies measuring complement and complement regulator protein concentrations in AD and healthy elderly control (NC) subjects were included. Mean (± standard deviation) concentrations for AD and NC were extracted and combined in random effects models. Results: From 3596 records, 73 studies measuring relevant CSF or peripheral blood protein concentrations have been included thus far. Preliminary results show increased CSF concentrations of complement component 1q (C1q; $N_{AD}/N_{NC}$=151/117, Z=2.46, p=0.01; $I^2$=54%) in AD compared to NC. Concerning complement pathway regulators, clusterin concentrations were increased in both CSF ($N_{AD}/N_{NC}$=371/437, Z=4.18, p<0.0001; $I^2$=31%) and plasma ($N_{AD}/N_{NC}$=1269/1651, Z=2.06, p=0.04; $I^2$=97%) in AD compared to NC, and amyloid P (AP) concentrations were increased ($N_{AD}/N_{NC}$=283/109, Z=2.94, p=0.003; $I^2$=0%) in CSF. Conclusions and Implications: The CSF results support involvement of the complement pathway in AD; elevated C1q and AP levels might promote activity earlier in the classical complement cascade, while elevated clusterin could inhibit formation of the membrane attack complex (MAC) in the final stages of the cascade. These changes would be consistent with increased

opsonization and inflammatory activity, while limiting MAC-induced cell lysis. Increased peripheral blood clusterin concentrations in AD might imply communication/coordination of immunoregulatory activities between the brain and periphery.

**Abstract:** The pathognomonic protein deposits in AD elicit an activation of microglia, but role of this innate immune activation in the course of AD is controversial, in part because mouse models of AD pathology do not fully capture the complex human disease condition. To tackle this problem, we undertook a comprehensive analysis of microglia in different stages in human AD brains to lay the groundwork for mapping the innate immune response towards extracellular and intracellular pathologies in human neurodegenerative disease. Morphologic characterization of microglia in different stages of AD using immunohistochemical (IHC) markers revealed increased microglial activation with advancement of AD neuropathological changes and an increase in dystrophic microglia in late disease stages. Our immunohistochemical findings were corroborated with cell type and pathway specific gene expression profiling using the human Neuropathology gene expression panel on the Nanonstring nCounter system, which demonstrated an increase in microglial activation with progression of AD neuropathological changes. This analysis also revealed distinct differences in gene expression profiles derived from patient samples carrying an AD associated risk variant of the microglia receptor Trem2. We further homed in on these differences by using the nCounter human Neuroinflammation panel to elucidate differentially regulated pathways in AD patients carrying Trem2 risk variants in comparison to disease stage matched patients with a normal variant of Trem2.
Our studies demonstrate that combining morphologic characterization of microglia cells with

novel cell type and pathway specific gene expression analysis in human post mortem brain specimens allows for interrogation of the innate immune system in the complex environment of a coexisting multitude of different protein pathologies in AD and provides novel insight into the role of the immune system in AD pathogenesis and progression.

**Title:** Associations between inflammatory profiles and human neuropathology are altered based on apolipoprotein E4 genotype

**Authors: N. AYTAN**[1], J. FRIEDBERG[2], J. D. CHERRY[3], W. XIA[4], *T. D. STEIN[5]
[1]Neurol., [2]Boston Univ. Med. Sch., Boston, MA; [3]Neurol., Boston Unviersity, Allston, MA; [4]Dept. of Pharmacol. & Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA; [5]Boston VA Med. Ctr., Boston, MA

**Abstract:** Alzheimer disease (AD) is a chronic neurodegenerative disease with a multitude of contributing genetic factors, many of which are related to inflammation. The *apolipoprotein E (APOE) allele E4* is the most common genetic risk factor for AD; *APOE E4* is related to a pro-inflammatory state independent of beta-amyloid deposition in mice, but its association with inflammatory profiles and the development of AD pathology in human brain tissue is largely unknown. To test the hypothesis that microglia and AD-implicated cytokines were differentially associated with AD pathology based on the presence of E4, we examined post-mortem brain tissue from participants with and without the *APOE E4* allele within a community based aging cohort ($n$ = 211). Cellular density of Iba1, a marker of microglia, was positively associated with tau pathology density as measured by AT8 immunostaining in E4 positive participants ($p$ = 0.045), but not in E4 negative participants. Analysis of cytokines implicated in AD, i.e. IL-10, IL-13, IL-4, IL-1α, revealed a significant negative association with AT8, independent of beta-amyloid$_{1-42}$ levels, in E4 negative, but not E4 positive participants. Overall, the association of mostly anti-inflammatory cytokines with less tau pathology suggests a protective effect in E4

negative participants. These associations are largely absent in the presence of E4 where tau pathology is significantly associated with increased microglial cell density. Taken together, these results suggest that *APOE E4* mediates an altered inflammatory response and increased tau pathology independent of beta-amyloid pathology.

**Title:** Effects of colonic inflammation induced by dextran sulfate sodium on the brain pathology of an Alzheimer's disease mouse model

**Authors: *M. SOHRABI**, J. WIESER, C. K. COMBS
Dept. of Biomed. Sci., Sch. of Med. and Hlth. Sciences, Univ. of North Dakota, Grand Forks, ND

**Abstract:** Alzheimer’s disease (AD) is a progressive age-related neurodegenerative disorder and the most common form of dementia. The disease is characterized by the accumulation of extracellular Aβ plaque deposition, intracellular neurofibrillary tangles, and neuro-inflammation. These pathophysiological features spread throughout brain regions as the disease progresses and result in neuronal death, synaptic loss, and learning and memory decline. Aging is also associated with inflammaging which leads to increased permeability of the gut epithelial monolayer and blood-brain barrier. Besides AD, inflammatory bowel disease (IBD) is another chronic inflammatory condition with increased incidence among elderly. In spite of the fact that it is known that the brain communicates with the gastrointestinal tract via the well-established gut-brain axis, the influence exerted by chronic intestinal inflammation on the brain phenotype in AD is not fully understood. We hypothesized that increased gut inflammation would alter the brain pathology of a mouse model of AD. To test this idea, 2% dextran sulfate sodium (DSS) dissolved in the drinking water and fed *ad libitum* to male C57BL/6 wild type and $APP^{NL-G-F}$ mice (AD mouse model) at 6-10 months of age for two cycles of three days each. DSS is a negatively charged sulfated polysaccharide which results in bloody diarrhea and weight loss, pathology similar to human IBD. Both wild type and $APP^{NL-G-F}$ mice developed an IBD-like condition with an attenuated disease activity index in the AD mice. Brain histologic and biochemical assessments demonstrated increased insoluble/soluble $A\beta_{1-42}$ and soluble $A\beta_{1-40}$

levels along with the increased microglial immunoreactiviy in DSS treated $APP^{NL-G-F}$ mice compared to wild type and vehicle treated $APP^{NL-G-F}$ mice. These data demonstrate that gut inflammation is capable of altering plaque deposition and immune cell behavior in the brain. This study increases our knowledge of the impact of peripheral inflammation on Aβ deposition and neuroinflammatory aspects of AD via an IBD-like model system.

**Title:** Il-6 correlates with spatial navigation dysfunction in amnestic mild cognitive impairment

**Authors: *N. ROGERS**[1], C. SANMARTIN[2], D. PONCE[3], J. VALDES[1], M. BEHRENS[1]
[1]Dept. de Neurociencias, Univ. de Chile, Santiago, Chile; [2]Univ. Mayor, Santiago, Chile; [3]Ctr. de Invetigación Clínica Avanzada (CICA), Santiago, Chile

**Abstract:** The hippocampus plays an essential role in the consolidation of declarative and spatial memory; early dysfunction characterized by disturbances in evocation of recently acquired memories and spatial navigation can be seen in Amnestic Mild Cognitive Impairment (aMCI), widely recognized as a prodromal stage of Alzheimer's disease (AD). This structure is also particularly vulnerable to systemic inflammation, which in turn has been associated with pathological aging, consistent with the hypothesis that inflammatory and immune mechanisms are involved in the pathogenesis of AD. Epidemiological studies have shown an association of elevated plasma levels of IL1-B and IL-6 in AD. IL-1B plays a role in innate immunity as a mediator of the inflammatory response; it also mediates the secretion of other inflammatory interleukins such as IL-6. We aimed to determine if spatial navigation impairment in these patients, assessed by a virtual Morris Water Maze (vMWM), correlates with IL-1B and IL-6 plasma levels and gene expression in peripheral blood mononuclear cells (PBMC). We recruited 38 patients (20 healthy controls and 18 aMCI patients (Alberts et al 2011). Montreal Cognitive Assessment (MoCA) and Clinical Dementia Rating (CDR) were used as tools for diagnosis. No significant epidemiological differences were found between groups (age, sex, comorbidities, educational level). Spatial navigation was tested through a three-staged version of Virtual Morris Water Maze (vMWM) of increasing difficulty. IL-1B and IL-6 plasma levels and mRNA were measured in plasma and PBMC from aMCI patients and controls, by ultra-sensitive ELISA and qPCR respectively. aMCI patients showed a higher expression of IL-6 compared to controls

(1.28 versus 0.24 fold-changes, $p<0.05$, Mann-Whitney's U-test). Then Spearman correlations between interleukins measures and vMWM variables were conducted and we observed: positive correlation between IL-6 expression and success ratio ($r = - 0.35$, $p = 0.04$); negative correlations with the amount quadrant crossings ($r = 0.52$, $p = 0.047$), and latency to target ($r = 0.58$, $p = 0.025$) in the aMCI group; and a positive correlation between plasma IL-6 levels and distance ratio ($r = 0.57$, $p = 0.005$), a measure of path efficiency. No significant results were observed for IL-1B and behavioral variables. As a conclusion, aMCI patients's performance in the vMWM correlated proportionally to higher expression of IL-6 in PBMC. These results suggest an association between a pro-inflammatory systemic milieu and markers of hippocampal dysfunction that should be explored in future research.

**Title:** Mir-146a regulates neutrophil extracellular trap formation that precedes Alzheimer's diseases with oligomeric Aβ deposits

**Authors: *S. KIM**
Bundang Hosp. of Seoul Natl. Univ., SEONGNAM CITY, Korea, Republic of

**Abstract:** Alzheimer's disease (AD) is a complex brain disease and the most common form of neurodegenerative dementia. Several genetic, environmental, and physiological factors, including inflammations and metabolic influences, are involved in the pathogenesis of AD. Inflammations are composed of complicated networks of many chemokines and cytokines with diverse cells. Inflammatory molecules are needed for the protection against pathogens, and maintaining their balances is important for normal physiological function. Recently, our studies found that miR-146a, a negative regulator of inflammation, precedes netosis in AD-Tg mice with oligomeric Aβ (oAβ) deposits. The relationship between neutrophil extracellular traps and AD has not been understood yet. Thus, our aim was to determine the role of neutrophil extracellular trap compounds as prognostic biomarkers of oAβ in AD and to study whether miR-146a affects Netosis.
In this work, we investigated the molecular role of miR-146a in the pathogenesis of oAβ in AD Tg mice using Confocal microscope and CLARITY technique. The microRNAs are mainly in

immune cells, which are one of the main protagonists of Netosis. Thus, the infiltration of activated monocyte/neutrophils in brain mediates an overactivation of the immune system. In addition, findings show that neutrophils shed neutrophil extracellular traps (NETs), which consist of cell-free DNA (cfDNA), histones, NE (neutrophil elastase), and cathepsin G that trigger the coagulation and inflammation underlying vascular complications. NE activity can provide new NET prognostic information in AD-Tg mice. These findings provide evidence of a crucial role of miR-146a in neutrophil extracellular trap generation and Acknowledgments: This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number: HI17C1260) high risk in pathogenesis of AD.

**Abstract:** Cytosolic Phospholipase A2 (cPLA2) are enzymes catalyzing the sn-2 position of membrane phospholipids to release fatty acids (eg. arachidonic acid) and lysophospholipids (eg. lysophosphatidylcholine). In the central nervous system, cPLA2 activation is implicated in the pathogenesis of various neurodegenerative diseases that involves neuroinflammation, thus making it an important pharmacological target. We present a new class of arachidonic acid analogues (33 compounds), together with curcumin, and their ability to inhibit cPLA2. Several compounds inhibit cPLA2 more strongly than arachidonyl trifluoromethyl ketone (AACOCF3;

IC50 16.5+- 3.0uM), an inhibitor that is commonly used in the study of cPLA2-related neurodegenerative diseases. One of the inhibitors (2i) with IC50 2.9+-0.2uM was found to be cPLA2-selective, non-toxic, cell and brain penetrant and capable of reducing reactive oxygen species (ROS) and nitric oxide (NO) production in stimulated microglial cells. Computational studies shed insights on how 2i interacts with cPLA2. We also showed curcumin directly inhibits cPLA2, reduces ROS and NO production in stimulated microglial cells.

**Title:** The role of immune cells in Alzheimer’s disease analyzed by crossing 5xFAD mice with $CX3CR1^{+/GFP}$ and $CCR2^{+/RFP}$ mice

**Authors: *H. CYNIS**, Y. YOLUC, V. NYKIEL, S. GEISSLER, S. BARENDRECHT
Fraunhofer IZI-MWT, Halle, Germany

**Abstract:** Alzheimer’s disease (AD) is a neurodegenerative disorder, characterized by an abnormally fast cognitive decline. In recent years, the role of CNS resident microglia in AD came into focus. Microglia cells normally ensure the immune surveillance of the brain. In addition, it became evident, that also peripheral monocytes might enter the brain under certain disease conditions and thereby could contribute to pathology. The aim of our project is to determine the contribution of both microglia and infiltrating peripheral macrophages to AD-like pathology in mice. Therefore, we have crossed the well-characterized 5xFAD mouse model of AD with two different reporter mice: $CX3CR1^{+/GFP}$ and $CCR2^{+/RFP}$ knock-in mice. These mice express green, respectively red, fluorescent protein instead of one allele of these receptors. These allow us to easily distinguish between resident CNS immune cells (microglia - green) and infiltrating cells (monocytes/macrophages - red) based on the fluorescent color. In addition, the function of the different immune cells is also expected to be altered by a 50% reduction of gene expression of the targeted receptors. We performed immunohistochemistry, as well as biochemical analysis of the brains to compare regular 5xFAD mice with 5xFAD mice combined with $CX3CR1^{+/GFP}$ and $CCR2^{+/RFP}$, respectively. Here, we will present data on the analysis of brains from 6 months, as well as 12 months old mice, from both sexes. We expect that a partial knock-out of each receptor results in an aggravation of pathology. The next step in our project is to investigate the behavioral consequences of the partial knock-out, as well as the complete

knock-out ($CX3CR1^{GFP/GFP}$ or $CCR2^{RFP/RFP}$), of these receptors on the neuropathology of 5xFAD mice using a battery of phenotyping tests. Subsequently, the brains of these mice will also be investigated using immunohistochemistry and biochemical methods, again at the ages of 6 and 12 months, and in both sexes. This project will help to elicit the role of different immune cells in the pathology of AD, increasing the understanding of this disease, and in future possibly leading to new targets for the development of therapies.

**Title:** An emerging role for Hsp27 in vascular cognitive impairment and dementia

**Authors: *B. R. PRICE**[1], T. L. SUDDUTH[2], C. A. DICKEY[3], D. M. WILCOCK[2]
[1]Physiol., [2]Sanders Brown Ctr. on Aging, Univ. of Kentucky, Lexington, KY; [3]Mol. Med./Byrd Inst., Univ. of South Florida, Tampa, FL

**Abstract: Background:**
Hyperhomocysteinemia (HHcy) is a risk factor for vascular cognitive impairment and dementia (VCID), as well as Alzheimer's disease. The mechanism by which HHcy promotes VCID or AD remains unknown. Using the HHcy mouse model of VCID, we found the earliest detectable event in the brain is a robust neuroinflammatory response. This is followed by neurovascular astrocyte disruptions, cerebral hypoperfusion, microhemorrhages, white matter degeneration, and cognitive impairment.
To gain mechanistic insights into the signaling pathways by which HHcy induces this sequelae of events, we focused on heat shock protein 27 (Hsp27). Hsp27 binds protein-folding intermediates and prevents their aggregation without directly refolding them itself. Aberrant phosphorylation of Hsp27 has been reported in a variety of cancers and neurodegenerative diseases. Given that Hsp27 is shown to be involved in cerebrovascular dysfunction in stroke models, and is known to signal through the p38 MAPK signaling pathway, a critical driver of the proinflammatory response, we hypothesized Hsp27 is an early mediator of HHcy-induced neuroinflammation, and therefore, the downstream events that occur as a result.
**Methods:**
Wildtype and $Hsp27^{-/-}$ mice were subject to a HHcy-inducing diet for 14 weeks. Tissue from the

left hemisphere was histologically examined for microglial activation, the astrocytic end-foot integrity, and microhemorrhages. Tissue from the right hemisphere was used to evaluate the neuroinflammatory state using qRT-PCR. Western blot and MSD were used to confirm some of the identified proteins.

**Results:**

Our wildtype-HHcy model displayed significant pro-inflammatory responses and astrocytic end-foot disruptions, as well as significant microhemorrhage induction. Significantly, we found that there was no induction of the pro-inflammatory phenotype in the $Hsp27^{-/-}$ mice subjected to the HHcy-inducing diet for 14 weeks. We also found a reduction in the microhemorrhage incidence in the $Hsp27^{-/-}$ mice, as well as improved survival of the mice, indicating that they were resistant to the HHcy diet.

**Conclusions:**

Hsp27 appears to be an early essential mediator of HHcy-induced pathology. Deletion of Hsp27 provides protection from diet-induced attrition, neuroinflammation, and cerebrovascular events. This suggests that Hsp27 may be an attractive therapeutic target for the treatment of VCID.

**Abstract:** Alzheimer’s disease (AD) is a neurodegenerative disorder characterized by extensive amyloid plaque deposits, inflammation, and cognitive decline. Microglia act primarily to provide important immune defense and homeostasis, but these functions are frequently perturbed in neurodegenerative diseases. Since microglial dysfunction has been implicated in the pathogenesis of AD, pharmacological interventions that restore microglia function and ameliorate pathology are of clinical interest. Microglia are reliant upon colony-stimulating factor

receptor-1 (CSF1-R) activation for survival. Accordingly, small-molecule therapeutics that inhibit CSF1-R signaling resulted in microglia death in the brain, reduced microglial activation, and enhanced neuronal survival in AD mouse models. However, depletion of microglia in a disease state may elicit deleterious side effects and potentially limit the clinical appeal for long-term CSF1-R inhibitor use. Although withdrawal of inhibitor leads to rapid repopulation and restoration of normal function of microglia, it is unknown how a disease context would influence the functions of repopulated microglia. In the 5xFAD mouse model of AD, we show that treatment with the highly selective CSF1-R inhibitor PLX5662 effectively ablates microglia from the brain, curtails inflammation, and reduces plaque burden in the brain. Following withdrawal of PLX5662, microglia repopulated to similar levels as control-treated animals. Interestingly, we observed regional differences in repopulated microglia's ability to alter plaque burden. This suggests that newly repopulated microglia in certain brain regions may be endowed with enhanced disease-modifying effects which could inform future studies with CSF1-R inhibitors.

**Abstract:** Microglia activation and neuroinflammation plays key roles in neurodegenerative diseases. We present evident here that the sphinster homolog 2 (Spns2), a S1P transporter, regulates microglia states in vitro and in vivo. Spns2 deficiency in primarily cultured microglial cells significantly reduced the production of inflammatory cytokines, while increased anti-inflammatory cytokines, induced by lipopolysaccharide (LPS) and amyloid beta peptide1-42 (Aβ42) oligomers. This regulation is accompanied by altered Toll-like receptor 4/nuclear factor kappa B (TLR-4/NFκB) signaling, shown by reduced levels of phosphorylated P65 (pP65). To study the in vivo effect of Spns2KO on microglia activation, we stereotactically administered Aβ42 oligomers into mouse brains. After 6 weeks, Spns2 deficient brains showed significantly reduced microglia activation labeled by IBA1. More interestingly, Spns2 deficiency ameliorated working memory deficit that was caused by Aβ42. These results show that Spns2/S1P signaling mediates the polarization states of microglia during neuroinflammation, and plays a potentially

crucial role in AD pathology. (Supported by a Scientist Development Grant from American Heart Association National Center and a Biomedical Research Grant from American Lung Association to GW and NIH R01 5R01AG034389 to EB).

**Title:** 27-Hydroxycholesterol as a molecular link between hypercholesterolemia and synapsis dysfunction

**Authors: *P. MERINO-SERRAIS**[1], R. LOERA-VALENCIA[1], P. RODRIGUEZ-RODRIGUEZ[1], C. PARRADO-FERNANDEZ[1], M. ISMAIL[1], S. MAIOLI[1], E. JIMENEZ-MATEOS[3], I. BJORKHEM[2], J. DEFELIPE[4], A. CEDAZO-MINGUEZ[1]
[1]NVS, [2]Dept. of Lab. Med., Karolinska Institutet, Stockholm, Sweden; [3]Royal Col. of Surgeons in Ireland, Dublin, Ireland; [4]Inst. Cajal (CSIC), Madrid, Spain

**Abstract: Background:** Hypercholesterolemia in middle age is considered a risk factor for the development of Alzheimer’s disease (AD) and dementia (Kivipelto et al., 2001). Given the fact that cholesterol itself does not pass the blood-brain barrier (BBB), is still unclear how high levels of cholesterol in the circulation could have an impact on cognition. Accumulating evidence shows that high levels of the BBB permeable cholesterol metabolite, 27-OH, are able to induce neurodegenerative processes leading to cognitive decline (Liu et al., 2016). Moreover, higher levels of 27-OH were found in brains and cerebrospinal fluid (CSF) from AD patients (Heverin et al., 2004). In the present study, we explored the possibility that high levels of 27-OH could impact neuronal morphology and PSD95 synthesis. **Materials and Methods:** Hippocampal rat primary neurons; Cyp27Tg: transgenic mice overexpressing Cyp27A1 (sterol 27-hydroxylase enzyme, converts cholesterol to 27-OH). **Results:** *In vivo*, we analysed the dendritic spine

density in Cyp27Tg. A 3D morphological analysis of CA1 LY-injected neurons showed a significant reduction in dendritic spine density. Using a series of molecular biology tests we found decreased PSD95 levels and a dysregulation of the REST-miR124a-PTBP1-PSD95 axis in Cyp27Tg. *In vitro*, we entirely reconstructed the dendritic arbour from 70 hippocampal primary neurons using the somatodendritic marker MAP2. A 3D analysis showed in neurons treated with 27-OH a significant reduction in the complexity of the dendritic tree. We found in neurons treated with 27-OH an extreme lack of dendritic spines and PSD95 levels. Moreover, after 27-OH treatment, the neurons showed a dysregulation in the REST-miR124a-PTBP1-PSD95 axis. **Discussion**: These data further suggest that high levels of 27-OH impair dendritic spine density, complexity of the dendritic tree and the REST-miR124a-PTBP1-PSD95 axis. Our results reveal a possible molecular link between hypercholesterolemia and neurodegenerative diseases. **Conclusions**: We propose reduction of 27-OH levels as a useful strategy for preventing memory and cognitive decline in these disorders.

**Title:** Soluble Amyloid beta42 act as allosteric activator of the core cholinergic enzyme, choline acetyltransferase

**Authors: *A. KUMAR**[1,2], E. LANA[2], R. KUMAR[2], C. LITHNER[2], T. DARREH-SHORI[2]
[1]Karolinska Institutet, Huddinge, Sweden; [2]Karolinska Institutet, Stockholm, Sweden

**Abstract:** Cholinergic neurons, defined by the expression of enzyme choline acetyltransferase (ChAT), mainly responsible for the synthesis of the neurotransmitter acetylcholine (ACh), are the primary target in Alzheimer’s disease (AD). Another hallmark of AD pathology is the

presence of aggregated amyloid-β (Aβ) proteins, believed to play a crucial role in AD-associated cholinergic dysfunction and neurodegeneration. Despite the high vulnerability of cholinergic neurons to Aβ, the exact underlying mechanism how Aβ interacts with cholinergic neurons in the AD is still lacking. To shed light on the pathophysiological role of Aβ in early cholinergic dysfunction, we previously showed that Aβ acts as an allosteric modulator of the cholinergic signaling by forming soluble ultra-reactive ACh-degrading complexes termed BAβACs, together with apolipoprotein-E and butyrylcholinesterase (Kumar et al., *Brain, 2016*). **Aim:** In this study, we further investigated whether Aβ peptides interact with ChAT protein and whether such interaction alters the activity of this core-cholinergic enzyme. **Method:** We performed both *in silico* and *in vitro* analyses to study the direct interaction effect of Aβ peptides on recombinant ChAT activity and catalytic efficiency using a newly designed High-Throughput fluorometric assay and *in silico* molecular docking studies. **Result:** Detailed *in vitro* enzyme kinetic analysis indicated that both soluble Aβ40 and Aβ42 increase ChAT activity by ~ 21% and 26%, respectively. Interestingly, Aβ42 was more efficient in activating ChAT and showed a ~ 10 fold less $EC_{50}$ value as compared to Aβ40. Most importantly, the significant increase in ChAT activity was observed at the Aβ40:Aβ42 concentrations of 1.28:0.12 ng/ml, corresponding to Aβ peptides physiological concentration ranges in CSF. Advanced *in silico* molecular docking analysis confirmed the above findings, and further provided the possible binding sites for Aβ peptides on ChAT protein. **Conclusions:** We report for the first time that Aβ42 peptides act as allosteric enhancer of ACh-biosynthesizing enzyme, ChAT. Together with two previous observations, this point at a complex molecular cross-talk between Aβ and the enzymatic machinery involved in maintaining cellular, synaptic and extra-synaptic ACh homeostasis, warranting further investigation.

**Title:** The effect of glycemic changes on brain metabolism and sleep/wake *in vivo* using biosensor technology

**Authors: *C. M. CARROLL**[1], M. STANLEY[3], M. PAIT[4], C. HOLLINGSWORTH[4], D. M. HOLTZMAN[5], S. L. MACAULEY[2]
[1]Neurosci., Wake Forest Sch. of Med., Winston-Salem, NC; [2]Gerontology, Wake Forest Sch. of Med., Winston Salem, NC; [3]Univ. of British Columbia, Vancouver, BC, Canada; [4]Wake Forest Univ., Winston Salem, NC; [5]Dept Neurol., Washington Univ., Saint Louis, MO

**Abstract:** Type 2 diabetes increases the risk for developing Alzheimer's disease by 2-4-fold; however, it remains unclear how alterations in peripheral and brain metabolism affect normal brain functioning. The goal of this study, therefore, was to elucidate how the brain regulates metabolism in euglycemic conditions, as well as when challenged with hyper- and hypoglycemic conditions. ISF lactate, glutamate, and glucose all have well-established patterns across the sleep/wake cycle. To replicate these metabolic patterns, we implanted biosensors bilaterally into the mouse hippocampus and paired cortical EEG and EMG recordings to measure arousal state. ISF glucose was used as a reference to contrast changes in ISF glutamate and ISF lactate across manipulations to glycemic state as a function of arousal. During euglycemia, ISF lactate increased progressively in both waking and REM sleep and decreased across NREM sleep. ISF glutamate increased across waking bouts, while ISF glucose showed an initial dip followed by an increase. ISF glucose also increased across NREM sleep, but decreased across REM sleep. We then wanted to explore the effect of hyper- and hypo-glycemia on the brain's metabolic profile as a function of sleep/wake state. The mice were challenged with a 2mg/kg IP injection of glucose resulting in a hyperglycemic challenge, as well as a hypoglycemic challenge with 1mg/kg injection of glibenclamide, a KATP antagonist. As expected, ISF glucose increased following glucose injection and decreased following glibenclamide injection. ISF lactate increased in response to both injections, indicating a decoupling of the typical glucose and lactate relationship as a function of these glycemic challenges. When we compared these metabolic changes to alterations in arousal state, we found that waking increased in response to both injections, while NREM sleep decreased after both injections. These data led us to conclude that not only do spontaneous changes in arousal state affect levels of ISF lactate, glucose, and glutamate, but acute changes in glycemic condition can lead to changes in both arousal state and metabolic profile. Metabolic and sleep dysfunction are known markers of Alzheimer's Disease, so understanding the interactions between these factors may help to clarify the mechanism behind the increased AD risk seen in Type 2 Diabetes.

**Title:** Maintained LTP and memory are lost by amyloid-$\beta_{1-42}$-induced $Zn^{2+}$ influx into dentate granule cells

**Authors: *Y. SATO**, T. MURAKAMI, H. FUJII, H. TAMANO, A. TAKEDA
Univ. of Shizuoka, Shizuoka, Japan

**Abstract:** Amyloid-β (Aβ) accumulation, the hallmark pathology of Alzheimer's disease (AD), is believed to play an upstream role in AD pathogenesis. Through mechanisms that are uncertain, Aβ oligomers can induce synapse dysfunction that contributes to cognitive decline in the pre-dementia stage of AD. The soluble forms of $A\beta_{1-42}$ are the most toxic species that cause neuronal damage in the brains. On the other hand, $Zn^{2+}$ has been implicated in AD pathogenesis by inducing Aβ oligomerization. We have reported that $A\beta_{1-42}$ takes $Zn^{2+}$ as a cargo into the dentate granule cells in the normal brain and transiently affects memory acquisition via impairment of LTP induction in the normal brain; the formation of Zn-$A\beta_{1-42}$ in the extracellular compartment rapidly increases both intracellular $Zn^{2+}$ and $A\beta_{1-42}$ in dentate granule cells of normal young rats, followed by $A\beta_{1-42}$-induced cognitive decline that is due to increase in intracellular $Zn^{2+}$ released from $A\beta_{1-42}$. On the other hand, the mechanism of memory retention is poorly understood and memory is lost by not only neuronal death but also abolishment of plastic synapse changes. Involvement of Aβ-induced abolishment of plastic synapse changes in memory loss remains to be clarified. Here we tested whether $A\beta_{1-42}$-induced $Zn^{2+}$ influx affects memory via impairment of maintained LTP in the normal brain of freely moving rats. Both three-day-maintained LTP at perforant path-dentate granule cell synapses and 3-day-old space memory were impaired by local injection of 250 μM $ZnCl_2$ (2 μl) into the dentate gyrus. Three-day-maintained LTP was also impaired by local injection of either $A\beta_{1-40}$ or $A\beta_{1-42}$ (25 μM, 2 μl) into the dentate gyrus. $A\beta_{1-40}$-induced impairment of maintained LTP was rescued by co-injection of CaEDTA, an extracellular $Zn^{2+}$ chelator, but not by co-injection of ZnAF-2DA, an intracellular $Zn^{2+}$ chelator. In contrast, $A\beta_{1-42}$-induced impairments of maintained LTP and space memory were rescued by co-injection of either CaEDTA or ZnAF-2DA. Intracellular $Zn^{2+}$ in dentate granule cells was locally increased by $A\beta_{1-42}$ injection into the dentate gyrus, but not by $A\beta_{1-40}$ injection into the dentate gyrus. The present study indicates that maintained LTP and memory are lost by $A\beta_{1-42}$-induced $Zn^{2+}$ influx into dentate granule cells, which more readily occurs than free $Zn^{2+}$-induced $Zn^{2+}$ influx. In contrast, it is likely that maintained LTP is lost by $A\beta_{1-40}$ via a different mechanism that may involve extracellular $Zn^{2+}$.

**Abstract:** Besides amyloid and tau pathologies, Alzheimer's disease (AD) is characterized by synaptic loss and a reduction in brain synaptic proteins. However, it remains elusive to what extent the decrease of a synaptic protein is translated into phenotypically and clinically significant effects. Shank3, a postsynaptic protein located in postsynaptic densities (PSD), may be an exception. The loss of a single allele of the SHANK3 gene is sufficient to cause profound cognitive symptoms, indicating that its expression in the brain must be tightly regulated. It is also the main candidate gene for 22q13.3 deletion syndrome, which is characterized by severe cognitive defects. These facts led us to hypothesize that a Shank3 deficiency could contribute to the apparition or aggravation of cognitive symptoms and neuropathology in AD. We first confirmed a 30-50% *postmortem* loss of Shank3 in brains of AD patients (Braak stage 4-5) and a significant correlation between Shank3 concentrations and *antemortem* cognitive scores in these individuals. A more marked decrease was also found in AD synaptosomes. To further probe the role of Shank3 in AD, we developed a new model by crossing mice with or without Shank3 deficiency with the 3xTg-AD model of AD neuropathology. We validated our new model using *in situ* hybridization on sections and Western Blot on PSD extracts from parietotemporal cortex. The results confirmed that Shank3 protein and mRNA expression were significantly reduced by 30-50% in Shank3-deficient mice compared to non-deficient animals, which is similar to our finding in the brains of AD patients. The novel object recognition behavioral test (NOR) showed that a synergy occurred between Shank3 disruption and APP/tau transgenes at 9 months as only 3xTg-AD-Shank3 mice failed the NOR test at this age. All groups with Shank3 defects failed the NOR at 12 months. Anxiety and locomotion parameters have also been evaluated by dark-light

emergence and openfield tests. No difference has been found between groups. Levels of other synaptic proteins, such as PSD-95, Cortactin and Septin3 were analysed using Western blot on PSD extracts from the parietotemporal cortex but not significant variation was found between groups or ages. Further investigations of the effect of Shank3-deficiency on the neuropathological markers of AD (amyloid-β and tau protein) by ELISA and Western Blot analysis are ongoing. Taken together, these results suggest that Shank3 deficiency could play a role in the apparition of cognitive impairment in AD, but the exact mechanism remains to be unveiled.

**Abstract:** Neuroimaging and other biomarker assays suggest that the pathological processes of Alzheimer’s disease (AD) initiate years prior to clinical dementia onset. However some 30%-50% of older individuals that harbor AD pathology do not become symptomatic in their lifetime. It is hypothesized that such individuals exhibit cognitive resilience that protects against AD dementia. We hypothesized that in cases with AD pathology structural changes in dendritic spines would distinguish individuals that had or did not have clinical dementia. We compared dendritic spines within layers II and III pyramidal neuron dendrites in Brodmann Area 46 dorsolateral prefrontal cortex using the Golgi-Cox technique in 12 age-matched pathology-free controls, 8 controls with AD pathology (CAD), and 21 AD cases. We used highly optimized methods to trace impregnated dendrites from brightfield microscopy images which enabled accurate three-dimensional digital reconstruction of dendritic structure for morphologic analyses. Spine density was similar among control and CAD cases but reduced significantly in AD. Thin

and mushroom spines were reduced significantly in AD compared to CAD brains, whereas stubby spine density was decreased significantly in CAD and AD compared to controls. Increased spine extent distinguished CAD cases from controls and AD. Linear regression analysis of all cases indicated that spine density was not associated with neuritic plaque score but did display negative correlation with Braak staging. These observations provide cellular evidence to support the hypothesis that dendritic spine plasticity is a mechanism of cognitive resilience that protects older individuals with AD pathology from developing dementia.

**Title:** Beta-amyloid increases neuronal $Ca^{2+}$activity in hippocampal neurons via reduction of nicotinic acetylcholine receptor-mediated inhibitory inputs

**Authors: *J. SUN**, S. KIM
Colorado State Univ., Fort Collins, CO

**Abstract:** Beta-amyloid (Aβ) peptide accumulation has long been implicated in the pathogenesis of Alzheimer’s disease (AD). However, a well-defined mechanism that is generally agreed upon about how Aβ causes AD pathogenesis has not yet been established. Imaging intracellular $Ca^{2+}$ dynamics using a genetically encoded $Ca^{2+}$ indicator, GCaMP, shows that acute 250nM Aβ42 treatment is sufficient to increase calcium activity in cultured mouse hippocampal excitatory neurons. Furthermore, this Aβ42-induced calcium increase is dependent on glutamate NMDA receptors as indicated by a decrease in activity when the receptor antagonist (50μM DL-APV) is applied. Importantly, Aβ42 inhibits nicotinic acetylcholine receptor (nAChR) function, causing neuronal dysfunction. Notably, applying Aβ42 coupled with inhibition of nAChRs via 20μM curare further increases $Ca^{2+}$ activity. As nAChRs are highly expressed in hippocampal GABAergic interneurons, we hypothesized that Aβ42 reduces GABAergic neuronal activity via blocking nAChRs, leading to an increase in hippocampal excitatory neuron activity. Indeed, Aβ42-induced $Ca^{2+}$ hyperactivity is significantly reduced when Aβ42 is applied with 25nM muscimol, a $GABA_A$ agonist. Taken together, Aβ42 blocks nAChRs in GABAergic neurons, reducing inhibitory activity ultimately making excitatory neurons more excitable. Given that neuronal hyperexcitability in the pre-symptomatic stages of AD may play an important role in the disease progression, knowledge of Aβ42’s interaction with GABAergic inhibitory neurons via nAChRs may yield potential receptor targets for therapeutics for patients with AD.

**Abstract:** Alzheimer's disease (AD) is characterized by the aggregation of amyloid beta peptide (Aβ) that is derived from the amyloid precursor protein (APP), which can undergo two mutually exclusive pathways. The amyloidogenic pathway involves BACE and γ-secretase activities and leads to Aβ formation. In contrast, the non-amyloidogenic pathway involves ADAM10, a disintegrin and metalloproteinase 10, which cleaves APP in the domain corresponding to Aβ, thus precluding Aβ production. Recently, we have identified a new binding affinity between the cytoplasmic tail of ADAM10 and AP2. This interaction leads to the clathrin mediated endocytosis of ADAM10, and therefore its activity towards its substrates at the cellular surface is affected. Interestingly, ADAM10/AP2 interaction was observed to be significantly increased in AD patients' brain compared to healthy control subjects, suggesting a role of ADAM10/AP2 in AD pathogenesis. In this framework, we have recently developed a cell permeable peptide (CPP) capable of interfering with ADAM10/AP2 association and, thereby, with ADAM10 endocytosis. The intraperitoneal (IP) administration of this CPP to wild-type mice for two weeks is safe and effective for both impairing ADAM10 endocytosis and increasing ADAM10 synaptic localization. As a result, the relative activity of ADAM10 towards APP is increased, leading to greater levels of sAPPα. The 14-days IP administration of the CPP to a mouse model of AD;

APP/PS1 mice at a full-blown pathology stage (9 months old), suggests that the treatment reverts both the decrease in ADAM10 synaptic localization and the reduction in the synaptic levels of the GluN2A subunit of NMDA that was observed in APP/PS1 mice. A significant decrease of sAβ levels was also observed in the cortex of those treated APPPS1 mice suggesting an effect on the amyloid cascade. Furthermore, results obtained in a Y-maze test suggest a rescue of the cognitive impairment in APP/PS1 mice at early stages of Aβ induced pathology (6 months old) after CPP administration. These positive results point to ADAM10 internalization as a potential target mechanism for the development of an effective AD therapy acting on the neuronal activity. In order to investigate the functional impact of this approach, ongoing electrophysiology assays are being performed to provide insight on molecular changes observed at the synapses and their effect on synaptic transmission.

**Abstract:** We have recently identified the RING Finger Protein 10 (RNF10) as a novel synapse-to-nucleus protein messenger, enriched at the excitatory synapses and associated with the GluN2A subunit of NMDA receptors. RNF10 translocates from synapses to the nucleus, upon the activation of synaptic GluN2A-containing NMDA receptors, inducing the expression of specific target genes that have a role in Alzheimer's disease (AD) pathogenesis or that are

associated with the regulation of dendritic spine morphology.Our objective is to characterize RNF10 in Aβ signalling, by using RNF10 knockout (KO) mice and by studying RNF10 trafficking in neuronal cultures. RNF10 expression is reduced in AD patients' hippocampi at the earlier stages of the disease and Aβ oligomers trigger RNF10 translocation from the synapse to the nucleus. RNF10 KO mice present reduced body weight with an increase in food intake. In behavioural characterization at 6 months, in novel object recognition test, these animals do not present any difference when compared with wild-type animals, but at older ages, in the Y-Maze test, homozygous RNF10 KO animals spend more time in the novel arm. The molecular characterization shows downregulation of the amyloid cascade players in the hippocampus, and a consequent decrease in amyloid levels. Concerning spine morphology, RNF10 KO animals show a significant decrease in mushroom-type spines, without changes in the length or in the width. Overall, these data suggest an involvement of RNF10 in AD pathogenesis, pointing towards a possible protective role for RNF10 in cognitive dysfunction along aging.

**Title:** Excitation:inhibition imbalance associates with increased pathology in Alzheimer's disease

**Authors: *S. GOURMAUD**, K. SANSALONE, D. J. IRWIN, D. M. TALOS, F. E. JENSEN
Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Epileptic seizures occur in at least 20% of Alzheimer’s disease (AD) patients. In parallel, patients with chronic epilepsy may exhibit AD-like neuropathology, such as amyloid-β42 ($A\beta_{42}$) and tau pathology. These data suggest an interaction between epilepsy and AD. Network hyperexcitability and epileptogenesis have been associated with a number of molecular abnormalities leading to an excitation: inhibition (E:I) imbalance, including the downregulation of the GABAergic signaling via decreased expression of $GABA_A$ receptors ($GABA_AR$) and dysregulation of calcium ($Cl^-$) co-transporters NKCC1 and KCC2. We hypothesize that similar epilepsy-associated alterations will be observed in brain tissue from AD patients, and to a greater extent in tissue from AD patients with seizure history. We further hypothesize that seizures in AD patients may promote neurodegeneration.Postmortem temporal cortex tissue from AD cases

(n=18), with (AD+Sz) or without (AD-Sz) known seizure history, and control samples (n=7) were used for Western blot and ELISA analysis. Tissue samples were obtained from the Center for Neurodegenerative Disease Research (CNDR) of the University of Pennsylvania (Philadelphia, PA) with the local IRB approval.We found that the expression of NKCC1 was significantly upregulated in AD (159% of controls, $p<0.05$), with no change in KCC2. However, we found a significant decrease in KCC2 levels in AD+Sz compared to AD-Sz (56.5% of AD-Sz, $p<0.05$), suggesting an increase in depolarizing $GABA_AR$s in the AD cohort with seizure history. Similarly, levels of α1 subunit of $GABA_AR$ were significantly decreased in AD+Sz compared to AD-Sz (65% of AD-Sz, $p<0.05$), although there was no difference when comparing all AD cases with controls. We also found a significant increase of phosphorylated tau Thr212/Ser214 in all AD compared to controls (2828% of controls, $p<0.0001$), and a further significant increase in the AD+Sz group compared to the AD-Sz cohort (164% of AD-Sz, $p<0.05$). In addition, we found a significant increase in the duration of cognitive impairment prior to death in the AD+Sz group compared to AD-Sz (+8 years, $p<0.001$), suggesting that seizures may induce cognitive impairment earlier in AD patients.These results demonstrate that the hyperexcitability phenotype in AD is associated with markers consistent with impaired GABAergic inhibition and suggest that seizures may worsen AD pathology, exacerbating tau hyperphosphorylation and cognitive impairment. These findings indicate a bidirectional relationship between epileptogenic changes and AD related neuropathologic changes in human brain tissue.

**Title:** Impaired LTP-like synaptic plasticity in amnestic mild cognitive impairment

**Authors: *S. BUSS**[1], K. M. MCDONALD[1], V. M. CHEN, 02215[1], J. MACONE[1], D. PRESS[2], P. J. FRIED[3], A. PASCUAL-LEONE[1]
[2]Dept Neurol., [3]Neurol., [1]Beth Israel Deaconess Med. Ctr., Boston, MA

**Abstract: Background.** Mild cognitive impairment (MCI) can represent a transition state between healthy cognitive aging and dementia. Amnestic MCI (aMCI) is the earliest and most common clinical manifestation of Alzheimer's disease (AD). Models of AD implicate beta-amyloid in declines of long-term potentiation (LTP) plasticity. Transcranial magnetic stimulation (TMS) offers the potential to directly assess the efficacy of neuroplastic mechanisms in humans. While TMS measures of LTP-like plasticity are impaired in patients with dementia due to AD, it is not yet known if aMCI shows a similar pattern.
**Objective.** To compare measures of LTP-like plasticity in patients with aMCI and demographically similar controls.
**Methods.** In 17 aMCI (Mean ± SD, age: 69 ± 9 years, gender: 41 percent female) and 24 controls (Mean ± SD, age: 66 ± 8 years, gender: 58 percent female), motor evoked potentials (MEPs) were elicited by single-pulse TMS to the motor cortex before and after intermittent theta burst stimulation (iTBS). LTP-like plasticity was assessed in terms of the change in MEP amplitude 5, 10, 20, and 30-min post-iTBS.
**Results.** There were no significant differences in age, gender, or baseline MEP amplitude between the two groups. Compared to controls, aMCI participants showed almost no facilitation in MEP amplitude after iTBS. The difference was significant between groups at 5-min post-iTBS (p=.017).
**Conclusion.** The mechanisms of LTP-like plasticity are impaired in aMCI compared to controls. TMS plasticity measures may be a valuable tool for measuring the efficacy of the mechanisms of neural plasticity in early AD pathogenesis, and is a promising tool to investigate targets for future therapies in AD.

**Abstract:** Alzheimer's disease (AD) is the most common neurodegenerative disease in the elderly. Although hippocampal synaptic dysfunction has been found in early stage of AD, the mechanism involved in the synaptic dysfunction is still unknown. In the present study, field potential recording and biochemical experiments showed that long-term potentiation (LTP) declined with intraneuronal Aβ accumulation in hippocampal CA1 of 5XFAD mice at 2-3 months old. Further, we used whole-cell patch-clamp to determine the action potential (AP) of hippocampal CA1 pyramidal neuron by current-clamp configuration in acute brain slices of 5XFAD mice at 2.5 months old. We found that the frequency of spontaneous APs of CA1 pyramidal neuron in 5XFAD mice increased dramatically, while the amplitude of APs, the resting membrane potential and the frequency of spontaneous burst firing did not change compared to WT mice. Moreover, the initial frequency of APs, the input resistance, as well as rheobase of CA1 pyramidal neuron in response to evoked protocols were not changed in 5XFAD mice compared to their littermates. These findings indicated that the intrinsic excitability of CA1 pyramidal neuron was not altered by the transgenic background in early stage of AD-like pathology. Next, in the voltage-clamp, we found that the amplitude of miniature inhibitory postsynaptic current (mIPSC) of CA1 pyramidal neuron decreased and the frequency of mIPSC increased in 5XFAD mice, while the miniature excitatory postsynaptic current (mEPSC) did not change. Concurrently, there was no difference in dendritic spine density of CA1 neurons in 5XFAD mice compared to WT mice. Furthermore, the firing rate of CA1 pyramidal neurons in WT mice was successfully suppressed by γ-aminobutyric acid A ($GABA_A$) receptor agonist, Gaboxadol (GBX), but the CA1 pyramidal neuron in 5XFAD mouse exhibited lower sensitivity to GBX, indicating a desensitization of $GABA_A$ receptor on postsynaptic membrane. We also detected synaptic subcellular distribution of $GABA_A$ receptor alpha1 subunit ($GABA_A$ Rα1) in hippocampus from 2.5-month-old 5XFAD mouse, we found the expression of $GABA_A$ Rα1 in synaptosome decreased obviously while the total amount of $GABA_A$ Rα1 was not altered compared to WT mouse. In conclusion, in early stage of AD-like pathophysiological process, the inhibitory input efficiency decline due to $GABA_A$ receptor desensitization on postsynaptic membrane of CA1 neuron in hippocampus may contribute to the hippocampal network aberrance.

**Authors: *M. ALWESMI**[1,2], M. KARABOVA[1], M. BROADSTOCK[1], C. BALLARD[1], P. T. FRANCIS[1]
[1]King's Col. London, London, United Kingdom; [2]Princess Nourah bint Abdulrahman Univ., Riyadh, Saudi Arabia

**Abstract: Introduction:** Down's syndrome (DS), or trisomy21, is the most common genetic condition that results in intellectual disabilities. The incidence of DS is around 1 in 800 live births; it is almost caused by inheritance of a whole extra copy of chromosome 21 (chr21). People with DS have a high risk of developing Alzheimer's disease (AD) pathology at an earlier age in contrast to the typical population, around the age of 40. Synaptic dysfunction is one of the ultimate neuropathological alterations preceding neuronal death in the brain of subjects with AD, however, it is poorly understood. Intersectin-1 (ITSN1) and synaptojanin1 (SYNJ1) are presynaptic proteins with genes located on chr21 that are involved in synaptic vesicles recycling. The triplication of these genes may cause synapse disruption and contribute to symptoms and to AD pathological mechanism in the brains of DS. In this study we investigate the interaction of disomic and trisomic synaptic proteins with AD pathology. **Methods:** Post-mortem tissue was available from 15 DS, 10 AD and 12 control subjects. Concentrations of 5 synaptic proteins, ITSN1, SYNJ1, β-tubulin, synaptophysin (SYN38) and PSD95 were assessed in the frontal and temporal cortices by semi-quantitative western blotting. AD pathological hallmarks, amyloid beta $(A\beta)_{1\text{-}40\ \&\ 1\text{-}42}$, total tau (tTau) and phosphorylated tau (pTau), have been detected using MILLIPLEX® MAP assay and semi-quantitative immunohistochemistry (IHC) where possible. **Results:** SYNJ1 levels were significantly lower in AD compared to DS and control in the frontal and temporal cortices. There was a significant decrease in the levels of SYN38 in the temporal region of DS compared to control. The levels of insoluble $A\beta_{1\text{-}40}$, $A\beta_{1\text{-}42}$ and pTau/tTau were significantly higher in DS and AD than control in the frontal cortex and only in DS in comparison to controls in the temporal cortex (Kruskal-Wallis test and Dunn's pairwise tests with Bonferroni correction $p<0.005$). There was a significant inverse correlation between SYN38 and insoluble pTau/tTau ratio in the temporal cortex ($rs=-.503$, $n=36$, $p=0.002$). IHC did not show interaction between AD pathology and synaptic proteins. **Conclusions:** These studies

revealed that the extra copy of the genes encoding two of the 5 synaptic proteins studied in DS results in different trends in their levels against diagnostic category. Further investigation is required to understand how SYNJ1, where levels were similar to control despite the presence of severe AD pathology, may take part in disease pathogenesis.

**Title:** Repositioning of udenafil, a PDE5 inhibitor approved for male erecetile dysfunction, as an Ab and phospho-tau clearing drug in Alzheimers disease

**Authors: *H. KIM**[1], Y. YOON[2], J.-Y. KOH[3]
[1]Asan Inst. for Life Sci., Seoul, Korea, Republic of; [2]Dept. of Ophthalmology, Asan Med. Ctr., Univ. of Ulsan Col. of Med., Seoul, Korea, Republic of; [3]Univ. Ulsan Col. Med., Seoul 138-040, Korea, Republic of

**Abstract:** Alzheimer’s disease (AD) is the most common cause of dementia. AD is characterized by brain atrophy, extracellular deposition of beta-amyloid (Ab) peptide, intra-neuronal accumulation of phosphorylated tau, neuronal and synaptic loss, and inflammation. Recent studies suggest that lysosomal dysfunction may contribute to the accumulation of pathogenic proteins in AD as well as in other neurodegenerative diseases. While precise mechanisms leading to lysosomal dysfunction in these conditions are yet to be determined, some studies have demonstrated that cAMP may have a beneficial effect on lysosomal function by correcting its pH. Consistently, we have previously showed that PDE inhibitors such as cilostazol are able to normalize lysosomal function by increasing cAMP levels. Udenafil (Zydena; Dong-A ST Co, Seoul, South Korea) is a clinically approved PDE5 inhibitor, which has been used to treat male erectile dysfunction. While it is supposed to act selectively on PDE5, our screening assay revealed that it also inhibited PDE1, and substantially increased cAMP levels in cultured cortical neurons and astrocytes. We tested this in a cell model of arrested autophagy. Astrocytes were exposed to chloroquine (CQ), which inhibited acidification of lysosomes and fusion between

cargoes and lysosomes. Addition of Udenafil (1 uM) re-acidified lysosomes in CQ-treated astrocytes, and promoted the fusion between cargoes and lysosomes. As a result, Udenafil treatment restored autophagy flux in CQ-treated astrocytes. In synthetic Ab1-40 exposed astrocytes, Udenafil also reduced the intracellular accumulation of Ab. Indicating that these effects were mediated by cAMP, dibutryl cAMP (db-cAMP) mimicked, and protein kinase A inhibitor blocked the effects of Udenafil. Since Undenafil has been safely used in human patients, provided its efficacy is proven in future studies, drug repositioning of Udenafil, or other PDE inhibitors, seems a highly cost-effective route to developing new drugs targeting lysosomal dysfunction in AD.

**Title:** Sigma-1 receptor interactions with lipid rafts

**Authors: V. ZHEMKOV**[1,2], M. KIM[1,2], *I. BEZPROZVANNY[1,2]
[1]Dept Physiol, UT Southwestern Med. Ctr. Dallas, Dallas, TX; [2]Lab. of Mol. Neurodegeneration, Peter the Great St. Petersburg State Polytechnic Univ., St Petersburg, Russian Federation

**Abstract:** Sigma-1 Receptor (S1R) is a single-transmembrane intracellular receptor, primarily residing in the endoplasmic reticulum (ER) membrane. Pharmacological activation of the receptor has been shown to be neuroprotective in a number of brain disorders including Alzheimer’s, Huntington’s diseases, Amyotrophic lateral sclerosis. It has been proposed that S1R functions as an auxiliary regulatory subunit for various ion channels and receptors, modulating their activity and gating properties. However, the molecular mechanism underlying S1R function in the cell remains unknown. In our study we explored S1R-lipid interactions using a combination of biophysical and biochemical approaches. First, we confirmed that S1R localizes at the specific ER compartment - mitochondria-associated membranes (MAM). Then, we showed that wild-type S1R binds to major raft components such as cholesterol and sphingomyelins. We identified protein motifs responsible for S1R-cholesterol interactions. Intact cholesterol-binding sequence was essential for proper S1R targeting to the MAM regions.

Finally, we purified and then reconstructed recombinant S1R in artificial lipid bilayers (supported lipid bilayers and giant unilamellar vesicles). Bilayers of different lipid composition were used to study S1R protein-lipid interactions. We propose that on the molecular level S1R may function as a lipid raft-stabilizing protein of the ER.

**Title:** A novel mechanism of neurotoxicity in Alzheimer's disease: Astrocyte-derived extracellular vesicles

**Authors: *C. J. NOGUERAS-ORTIZ**[1], E. J. GOETZL[2], V. MACHAIRAKI[3], D. KAPOGIANNIS[4]
[1]Natl. Inst. on Aging, Baltimore, MD; [2]Geriatric Res. Ctr., San Francisco, CA; [3]Dept. of Neurol., John Hopkins Sch. of Med., Baltimore, MD; [4]Natl. Inst. on Aging (NIA/NIH), Baltimore, MD

**Abstract:** Background: Alzheimer’s disease (AD) is the most common neurodegenerative disease and is neuropathologically characterized by deposition of amyloid-β (Aβ) peptides extracellularly and hyperphosphorylated tau intracellularly. A plethora of molecular mechanisms have been shown to mediate progressive synaptic loss and neurodegeneration in AD, with recent research documenting the transneuronal propagation and seeding of pathogenic Aβ and tau. However, the mechanisms underlying the propagation of neurodegeneration in AD remain largely elusive.
Extracellular vesicles (EVs), nanovesicles secreted from all cells including neurons and astrocytes, may be important vehicles for the spread of Aβ, tau and other pathogenic molecules in AD. In our Lab, we have pioneered a technique for isolating neuronal- and astrocyte-derived EVs (NDEVs and ADEVs, respectively) from plasma and have found that, in AD patients, these EVs contain high levels of pathogenic Aβ and tau as well as potentially toxic complement. Based on these observations we hypothesized that ADEVs and/or NDEVs from plasma of AD patients are neurotoxic.
Methods/Results: We isolated plasma ADEVs and NDEVs from 4 patients with sporadic AD and 4 age-matched controls and used them to incubate cultures of rat cortical neurons and human iPSC-derived neurons. Neurons incubated with ADEVs from AD patients exhibited significantly

decreased neurite density by Tuj-1 immunoreactivity, decreased cell viability by MTT assay, and increased necrotic cell death by EthD-1 assay, compared to neurons treated with patient NDEVs or control ADEVs or NDEVs.
Conclusions: This is the first demonstration that blood-borne ADEVs from AD patients are neurotoxic, as hypothesized based on their cargo, which points to a novel mechanism in AD.
Future experiments: Results obtained with plasma-derived EVs will be validated using brain- and CSF-derived EVs from AD patients as well as ADEVs and NDEVs from AD-hIPSC-derived cultures. Additionally, we will seek to clarify the mechanisms of ADEV-mediated neurotoxicity and evaluate whether it is dependent on EV internalization by neurons and Aβ, tau and complement transmission.

**Title:** The Alzheimer’s disease risk gene BIN1 regulates network hyperexcitability

**Authors: *Y. VOSKOBIYNYK**, J. COCHRAN, T. RUSH, J. ROTH, M. WAQAS, E. D. ROBERSON
Univ. of Alabama at Birmingham, Birmingham, AL

**Abstract:** Alzheimer’s Disease (AD) affects about five million Americans, who receive only a very modest benefit from current treatment options. Multiple treatment trials have failed in the past, raising interest in identifying new targets to treat AD. GWAS have identified bridging integrator 1 (*BIN1*) as one of the leading genetic risk factors in AD. Neurons express unique BIN1 isoforms, and a growing body of evidence indicates loss of neuronal BIN1 in AD. However, the function of neuronal BIN1 remains unclear and its contribution to AD is critical to investigate. We generated brain-specific BIN1 knockout (KO) mice and discovered that the loss of BIN1 in the brain leads to network hyperexcitability, with increased seizure susceptibility. Network hyperexcitability is observed in AD: patients with mild cognitive impairment or dementia due to AD have epileptiform activity. Such aberrant activity is recapitulated in multiple rodent models of AD. Multiple lines of evidence suggest that increased network hyperexcitability results from inhibitory neuron dysfunction in AD patients. Network synchrony

is tightly regulated by the activity of inhibitory GABAergic interneurons that coordinate synchronous excitatory neuron firing required for proper brain oscillatory activity. Therefore, interneuron impairment may play an important role in AD pathogenesis. To investigate the mechanisms by which brain-specific BIN1 loss induces network hyperexcitability, we generated mice lacking BIN1 in inhibitory or excitatory neurons. Assessing pharmacologically-induced seizures, behavior, and acute slice electrophysiology, we investigated the mechanisms by which BIN1 loss in inhibitory or excitatory neurons regulates network hyperexcitability. We found that loss of BIN1 in inhibitory neurons increased seizure susceptibility, phenocopying BIN1 loss in the whole brain, while BIN1 loss in excitatory neurons decreased seizure susceptibility. Mice lacking BIN1 in inhibitory neurons had age-dependent behavioral deficits and decreased survival. In addition, initial electrophysiological studies provide evidence that loss of neuronal BIN1 decreases neuronal activity. These data generate fundamental insights about the mechanistic role BIN1 plays in AD to provide promising therapeutic strategies for targeting inhibitory neuron dysfunction and network hyperexcitability in AD.

**Abstract:** Alzheimer's disease (AD) is characterized by accumulation of amyloid-β peptide (Aβ) in the brain regions that subserve memory and cognition. We have previously demonstrated that effects of soluble oligomeric $A\beta_{1-42}$ and human amylin on hippocampal long-term potentiation (LTP) are mediated by the amylin receptor, comprised of dimers of calcitonin receptor (CTR) and receptor activity membrane proteins. In this study, we first examined $A\beta_{1-42}$ and human

amylin-evoked depression of LTP at Schaeffer collateral-CA1 hippocampal synapses in heterozygous CTR (hetCTR) mice, that demonstrate half the complement of amylin receptors as their wild-type (WT) littermates. In mouse hippocampal brain slices, field excitatory postsynaptic potentials (fEPSPs) were recorded from the stratum radiatum layer of the CA1 area in response to electrical stimulation of Schaeffer collateral afferents. In WT mice, $A\beta_{1-42}$ (50 nM) and human amylin (50 nM) depressed LTP evoked using 3-theta burst stimulation (TBS) protocols. HetCTR mice did not demonstrate abnormalities in basal synaptic transmission or LTP. However, in hetCTR mice, Aβ- and human amylin-induced reduction of LTP was approximately half that observed in WT mice. We also investigated effects of HetCTR depletion on hippocampal LTP in TgCRND8 AD mice at 8-12 months of age. Basal synaptic transmission as measured by the average slope of input/output (I/O) curves was significantly impaired in TgCRND8 mice compared to age-matched WT and HetCTR mice. HetCTR+TgCRND8 mice demonstrated improved LTP compared to TgCRND8 mice, which show low basal levels of LTP. Application of AC253 (250 nM), an amylin receptor antagonist, further improved LTP in HetCTR+TgCRND mice to levels comparable to those observed in age-matched WT littermates. These results show 1) that the degree of hippocampal LTP reduction evoked by Aβ and human amylin in hetCTR mice is blunted in proportion to the CTR (and hence amylin receptor) knockdown 2) genetic depletion of amylin receptors in TgCRND8 AD mice results in an improvement in LTP. These studies provide further evidence for consideration of the amylin receptor as a therapeutic target in AD.

**Title:** Linking actin-dependent dendritic spine remodelling and ADAM10 activity in AD: The role of CAP2

**Authors: *L. L. VANDERMEULEN**[1], S. C. PELUCCHI[1], M. B. RUST[2], S. FRYKMAN[3], M. DI LUCA[1], E. MARCELLO[1]
[1]Dept. of Pharmacol. and Biomolecular Sci., Univ. of Milan, Milano, Italy; [2]Inst. of Physiological Chem., Univ. of Marburg, Marburg, Germany; [3]Ctr. for Alzheimers Disease, Dept. of Neurobio., Karolinska Inst., Stockholm, Sweden

**Abstract:** Alzheimer’s disease (AD) is pathologically characterized by amyloid beta (Aβ) depositions and by hyperphosphorylated tau. A disintegrin and metalloproteinase 10 (ADAM10), is responsible for the α-secretase cleavage of Amyloid Precursor Protein (APP), that prevents Aβ generation. The synaptic localization and its activity towards APP are modulated by protein partners, that interact with the cytoplasmic tail of ADAM10. Considering the importance of the ADAM10 cytoplasmic domain in the regulation of ADAM10 activity, we performed a two-hybrid screening that has recently identified cyclase-associated protein 2 (CAP2) as a novel protein binding partner of ADAM10. CAP2 is an actin-binding protein implicated in actin cytoskeleton remodelling and vesicle trafficking of non-neuronal cells.
The aim of the project is the evaluation of the role of the ADAM10/CAP2/actin complex in the amyloid cascade and in AD-related synaptic dysfunction, in order to rescue early synaptic defects in AD. Preliminary data show that CAP2 is self-aggregating and interacts with both actin and ADAM10. Remarkably, in the hippocampus of CAP2 knockout mice the postsynaptic levels of ADAM10 and the NMDA receptor subunit 2A (GluN2A) are significantly reduced, suggesting that the lack of CAP2 affects their localization. In particular, the binding of CAP2 to actin is essential for ADAM10 synaptic localization. In CAP2 knockout mice brain sections, we also measured an altered spine morphology and density in hippocampal neurons. These data indicate the relevance of CAP2 in synaptic function, and in particular, in structural plasticity. With regards to AD, a significant reduction in CAP2 protein levels and in its postsynaptic localization is detected in the hippocampi of AD patients when compared to age-matched healthy control subjects. Where, in AD patient hippocampi an increased association of CAP2 to actin is observed. In addition, we found that in primary hippocampal cultured neurons treated with Aβ oligomers, the postsynaptic levels of CAP2 are reduced, suggesting that CAP2 localization is a target of Aβ oligomers. Moreover, a decreased interaction between CAP2 and ADAM10 upon Aβ oligomer treatment is found. Overall these data indicate a potential role of CAP2 in AD pathogenesis.

**Title:** Subunit-specific effects on AMPA-type glutamate receptors caused by amyloid beta oligomers during hippocampal long-term potentiation

**Authors: *H. TANAKA**, D. SAKAGUCHI, T. HIRANO
Dept. of Biophysics, Grad. Sch. of Science, Kyoto Univ., Kyoto, Japan

**Abstract:** Alzheimer's disease (AD) is the most common cause of dementia. Recent studies have suggested that amyloid beta (Aβ) oligomers are toxic entities especially at an early stage of AD, and that they impair the ability of learning and memory by blocking induction of synaptic plasticity such as long-term potentiation (LTP) in the hippocampus. However, the pathological effects at synapses remain to be clarified at a molecular level. To address this issue, we have tried to visualize effects of Aβ oligomers on changes of AMPA-type glutamate receptors (AMPA receptors) during hippocampal LTP. First, we coated cover glass with a presynaptic adhesion molecule Neurexin, and cultured rat hippocampal neurons on it. The coated Neurexin bound to a postsynaptic adhesion molecule Neuroligin and induced the formation of postsynaptic-like membrane (PSLM) on the glass surface. Then, we performed live-cell imaging of AMPA receptor subunit GluA1 or GluA2 labeled with super-ecliptic pHluorin (SEP), a pH-sensitive form of GFP, using total internal reflection fluorescence microscopy. This method enables us to observe GluA1- or GluA2-SEP signals around PSLM with a high signal-to-noise ratio by reducing the background fluorescence. LTP-inducing stimulation increased the GluA1- and GluA2-SEP signals in both PSLM and non-PSLM. We also recorded individual exocytosis of GluA1- and GluA2-SEP, whose frequencies increased after LTP induction by electrical field stimulation. The increase of GluA1-SEP signals and the frequency of GluA1-SEP exocytosis were suppressed by Aβ oligomers, whereas the effects on GluA2-SEP were limited. These results suggest that Aβ oligomers primarily inhibit the increase in number of GluA1 containing AMPA receptors and suppress the hippocampal LTP expression.

**Authors: *E. C. TURNER**, A. CACCAMO, C. BRANCA, E. FERREIRA, S. ODDO
The Biodesign Inst., ASU-Banner Neurodegenerative Res. Ctr., Tempe, AZ

**Abstract:** Alzheimer's disease (AD) is characterized by severe neuronal loss, and exposing the mechanisms underlying this loss in AD is critical to the development of new therapeutic approaches. Previously, we have shown that necroptosis, a programmed form of necrosis, is activated in AD. Necroptosis is activated by formation of a necrosome, a multiprotein complex which consists of protein kinases RIPK1 and RIPK3 and pseudokinase MLKL. Here, we analyzed the absolute levels of RIPK1, RIPK3, and MLKL by immunofluorescence and western blot in multiple human brain regions and across all Braak stages. In addition, we assessed necrosome formation, which is an indirect indication of necroptosis activation. Consistent with our previous findings, we show that there is a correlation between necroptosis markers and Braak stage. The changes we report in MLKL levels are the most notable, as the phosphorylation and translocation of MLKL represents the final step before membrane rupture and cell death. Altogether, these data provide strong evidence for targeting necroptosis as a valid therapeutic approach for AD.

**Authors: *R. VARTAK**[1], C. BRANCA[1], I. S. PIRAS[2], A. CACCAMO[1], S. ODDO[1]
[1]Arizona State Univ., Tempe, AZ; [2]Translational Genomics Res. Inst., Phoenix, AZ

**Abstract:** Recently, we have shown that necroptosis is activated in and contributes to neuronal loss in Alzheimer's disease (AD). Necroptosis is a caspase-independent cell death pathway activated by the formation of the necrosome, which consists of kinases RIPK1 and RIPK3 and the pseudokinase MLKL. Tau plays a crucial role in the neuronal loss in AD and other tauopathies; however, the mechanisms underlying Tau-induced neuronal loss remain elusive.

Our data in human AD brains suggest a possible interaction between tau and necroptosis activation. To this end, we found that Braak stage strongly correlates with necroptosis activation as indicated by levels of necroptosis markers RIPK1 and MLKL. We also show that phosphorylated Tau co-localizes with the necrosome. We provide biochemical and molecular evidence to show that necroptosis contributes to tau induced neuronal loss in AD and other tauopathies.

**Authors: *S. KNOWLES**[1], R. VELAZQUEZ[3], A. CACCAMO[3], S. ODDO[3,2]
[2]Sch. of Life Sci., [1]Arizona State Univ., Tempe, AZ; [3]Arizona State University-Banner Neurodegenerative Dis. Res. Ctr. at the Biodesign Inst., Tempe, AZ

**Abstract:** Accumulation of amyloid-β (Aβ) and neurofibrillary tangles are the prominent neuropathologies in patients with Alzheimer's disease (AD). Strong evidence indicates that an imbalance between production and degradation of key proteins contributes to the pathogenesis of AD. The mammalian target of rapamycin (mTOR) plays a key role in maintaining protein homeostasis as it regulates both protein synthesis and degradation. A key regulator of mTOR activity is the proline-rich AKT substrate 40 kDa (PRAS40), which directly binds to mTOR and reduces its activity. Notably, AD patients have elevated levels of phosphorylated PRAS40 (pPRAS40), which correlate with Aβ and tau levels as well as cognitive deficits. Physiologically, pPRAS40 is regulated by Pim1, a protein kinases of the protoconcogene family. We have identified a Pim1 inhibitor (Pim1i) that crosses the blood brain barrier and reduces pPRAS40. Here, we tested the effects of a selective Pim1i, on spatial reference and working memory and AD-like pathology in 3xTg-AD mice. Pim1i-treated 3xTg-AD mice performed significantly better than their vehicle treated counterparts and as well as non-transgenic mice in a spatial reference memory task after 4 weeks on treatment. Additionally, 3xTg-AD Pim1i-treated mice showed a reduction in soluble and insoluble Aβ40 and Aβ42 levels, as well as a 45.2% reduction

in Aβ42 plaques within the hippocampus. Furthermore, phosphorylated tau immunoreactivity was reduced in the hippocampus of Pim1i-treated 3xTg-AD mice by 38%. Mechanistically, these changes were linked to a significant increase in proteasome activity. These data strongly suggest that Pim1i might be a valid therapeutic target for AD. Notably, there were peripheral side effects with the Pim1i, evident by splenomegaly at autopsy. In light of these side effects, we next proposed a series of experiments in order to reduce peripheral side effects and extend our findings. We are currently developing a strategy to increase the amount of Pim1i absorbed by the brain while reducing the concentration in the periphery. Additionally, we plan to examine the Pim1i effects on neuronal cell loss in the 5xFAD mouse model of AD. Completion of the proposed work may springboard the use of the Pim1i for AD to clinical trials.

**Abstract:** Aging is the most prominent risk factor for Alzheimer’s disease (AD), The ribosomal protein S6 kinase 1 (S6K1), a ubiquitously expressed enzyme, plays a key role in aging and it regulates protein translation and cell homeostatic systems. For example, deletion of the S6K1 gene in mice increases lifespan and decrease the incidence of age-dependent motor deficits, insulin resistance, and obesity. The goal of this study was to assess the role of S6K1 in AD pathogenesis**.**
We used postmortem human AD brains to probe for a link between S6K1 and AD pathogenesis. We also bred 3xTg-AD mice with S6K1 knockout mice to reduce the expression of S6K1. Using a multidisciplinary approach, we have collected data from aged NonTg, 3xTg-AD, and 3xTg-AD/S6K1$^{+/-}$ mice brains. Our findings show that higher S6K1 activity correlates with increased Aβ levels and decreased Mini Mental State Examination (MMSE) scores in AD patients. We found that reducing S6K1 levels also reduces Aβ and Tau pathology in 3xTg-AD/S6K1$^{+/-}$ mice, improves spatial learning and memory deficits as well as rescues synaptic deficits. Moreover, our

preliminary data show that cognitive improvements in 3xTg-AD/S6K1$^{+/-}$ mice are linked to a decreased phosphorylation of his downstream targets, rpS6 and eEF2K proteins. Our results are extremely exciting as implicate S6K1 dysregulation as a previously unidentified molecular mechanism underlying synaptic and cognitive deficits in AD.

**Title:** Genetic reduction of Nrf2 exacerbates cognitive deficits in a mouse model of Alzheimer's disease

**Authors: *A. RODIN**, C. BRANCA, E. FERREIRA, A. CACCAMO, S. ODDO
Arizona State Univ., Tempe, AZ

**Abstract:** Aging is the major risk factor for several neurodegenerative diseases, including Alzheimer's disease (AD). However, the mechanisms by which aging contributes to neurodegeneration remain elusive. The nuclear factor (erythroid-derived 2)-like 2 (Nrf2) is a transcription factor that regulates expression of a vast number of genes by binding to the antioxidant response element. Nrf2 levels decrease as a function of age, and reduced Nrf2 levels have been reported in postmortem human brains and animal models of AD. Nevertheless, it is still unknown whether Nrf2 plays a role in the cognitive deficits associated with AD. To address this question, we used a genetic approach to remove the Nrf2 gene from APP/PS1 mice, a widely used animal model of AD. We found that the lack of Nrf2 significantly exacerbates cognitive deficits in APP/PS1, without altering gross motor function. Specifically, we found an exacerbation of deficits in spatial learning and memory, as well as in working and associative memory. Different brain regions control these behavioral tests, indicating that the lack of Nrf2 has a global effect on brain function. The changes in cognition were linked to an increase in Aβ and interferon-gamma (IFNγ) levels, and microgliosis. The changes in IFNγ levels are noteworthy as previously published evidence indicates that IFNγ can increase microglia activation and induce Aβ production. Our data suggest a clear link between Nrf2 and AD-mediated cognitive decline and further strengthen the connection between Nrf2 and AD.

**Abstract:** Severe neuronal loss is a key characteristic of the Alzheimer's disease (AD) brain, and is a focal point for AD research. Necroptosis is a programmed form of necrosis, which involves the formation of the necrosome, a multiprotein complex containing receptor-interactive protein kinases (RIPK) 1 and 3, which activates the mixed lineage kinase domain-like (MLKL) protein. We found that necroptosis is activated in human AD brains. Specifically, we found that RIPK1 and MLKL positively correlated with Braak stages, and inversely correlated with cognitive scores. Furthermore, we generated a causal gene regulatory network modeling RIPK1 interaction in AD-relevant tissues. The network was inferred from DNA and transcriptomic data generated from post-mortem samples across two brain regions, which were used to build RIPK1 networks in the anterior prefrontal cortex and the entorhinal cortex. Across both regions, we identified 819 genes whose expression covariate with *RIPK1* expression. These genes significantly overlapped with multiple, independent AD gene expression profiles, comprising non-demented AD (which are characterized by moderate neuropathology, without cognitive impairment) and clinical AD. There was uniform consistency between the signed relationship linking *RIPK1* expression with its downstream neighbors, and the direction of differential expression in the clinical AD profiles; specifically, genes negatively regulated by *RIPK1* overlapped with genes down regulated in AD. This large, concordant overlap between genes regulated by *RIPK1* and genes differentially expressed across multiple AD severity and regional contexts suggests that RIPK1 activity could explain a significant portion of transcriptomic changes in AD.

**Abstract:** Alzheimer’s disease (AD) is an age-related neurodegenerative disorder of the central nervous system, which causes the most common form of dementia in the elderly. More than 95% AD cases were found in people aged over 65 years, termed as late onset AD (LOAD). In recent years, many AD risk variants have been identified through next generation sequencing (NGS), in which apolipoprotein E ε4 (ApoE ε4) is believed to be the major and most well-known genetic risk factor for LOAD. To identify novel genetic factors other than ApoE ε4 that contribute to LOAD development, we conducted a whole-exome analysis of 246 ApoE ε4-negative LOAD cases and 172 matched controls in Hong Kong Chinese population. We identified a rare stop-gain variant (p.Q48X) in **m**ixed **l**ineage **k**inase domain **l**ike pseudokinase (*MLKL*) gene. The rare variant (*MLKL: p.Q48X*) introduces a premature termination codon (PTC) TAA at the 48th codon of MLKL mRNA. As the PTC occurs close to the beginning of *MLKL* transcription, nonsense-mediated mRNA decay would probably be induced. The qRT-PCR showed that the *MLKL* mRNA level of *MLKL: p.Q48X* carrier is significantly lower than subjects with wild-type (WT) *MLKL*. In addition, Sanger sequencing analysis of *MLKL* cDNA indicated that the variant carrier lost the heterozygosity of *MLKL* at the cDNA level. These results demonstrated that *MLKL* mRNA decay was induced by the *MLKL:p.Q48X* variant. To verify the impact of this variant on AD pathogenesis, *MLKL* was knock down (KD) in HEK293 cells expressing human *APP695* with Swedish mutation. Aβ42 and Aβ40 were detected using ELISA. The results demonstrated that the Aβ42/Aβ40 ratio was significantly elevated at the absence of *MLKL*. We then detected the expression of APP, α-, β-, and γ-secretase after *MLKL* KD through qRT-PCR and western blot. The data showed no significant changes of these target genes at both mRNA

and protein levels, suggesting that *MLKL* modulate Aβ generation through regulating γ-secretase activity. To evaluate γ-secretase activity, *MLKL* was knock down in N2a cell expressing NotchΔE or APP695 Swedish mutant. The production of NICD and AICD (the γ-cleavage product of Notch and APP) was significantly elevated in *MLKL* KD cells through western blot analysis. The γ-secretase fluorogenic substrate assay further confirmed that γ-secretase activity was enhanced at the absence of *MLKL*. Taken together, our study identified a rare *MLKL* loss-of-function variant in a Hong Kong Chinese ApoE ε4-negative LOAD cohort. This variant confers susceptibility to AD through enhancing γ-secretase activity.

**Title:** Specific miRNAs enriched in neural stem cell-derived exosomes reduce vulnerability of hippocampal synapses to the dysfunctional impact of amyloid beta and tau oligomers

**Authors: *M.-A. MICCI**[1], O. ZOLOCHEVSKA[2], B. KRISHNAN[3], R. KAYED[3], W.-R. ZHANG[3], E. BISHOP[1], C. ANACKER[4], G. TAGLIALATELA[3]

**Abstract:** Alzheimer’s disease (AD) is the most common and severe age-associated neurodegenerative dementia. While aging is the most significant risk factor for AD, disruption of synapses by oligomers of both amyloid beta (Aβ) and tau, via converging synergistic mechanisms, is one of the earliest events leading to memory dysfunctions. Interesting, AD pathology can occur years before symptoms become manifest, suggesting that aging renders synapses more vulnerable to the detrimental action of oligomers. Although there is ample consensus that an effective treatment should target the synaptic damaging impact of oligomers of both Aβ and tau, a strategy to achieve this goal remains unresolved. We previously found that exosomes specifically secreted by hippocampal neural stem cells (NSC-exo) render synapses resistant to the dysfunctional impact of amyloid oligomers. We have further shown that doses of

oligomers of Aβ and tau (alone or in combination) that are ineffective in reducing long-term potentiation (LTP) in the hippocampus of young wild type mice (2 months), significantly reduces LTP in the hippocampus of old mice (18 months), suggesting an age-dependent synapse vulnerability. Here we set up to determine whether increasing NSC in the hippocampus of aged mice can reduce synaptic sensitivity to amyloid toxicity in an exosomes-dependent fashion. We further set to determine whether specific miRNA cargos in NSC-exo could mediate their protective effect on the synapses.
We found that age-dependent synaptic vulnerability was rescued by delivering NSC-exo in the intracerebroventricular space (icv) into aged (18 months old) mice. We further found that increasing the number of NSC in the aged hippocampus (using 18 months old transgenic iBax$^{nes}$ mice induced with tamoxifen) significantly reduced synaptic vulnerability to low doses of oligomers. Using Deep sequencing, we found that NSC-exo possess a unique set of miRNAs (miR-485, miR-322,miR-17), as compared to exosomes secreted from mature neurons, and showed that icv injection of their mimics (alone or in combination) into male and female wild type mice significantly reduced synaptic binding of amyloid oligomers and prevented Aβ and tau oligomer-driven reduction of LTP in hippocampal slices. These results further points to NSC-exo as modulators of synaptic susceptibility to the dysfunctional impact of both Aβ and tau oligomers and unmask a novel therapeutic target for AD based on the delivery of NSC-exo or their bioactive cargoes.

**Title:** Epigenetic modulation of synaptic resilience to amyloid beta oligomers in Alzheimer’s disease

**Authors: *O. ZOLOCHEVSKA**, G. TAGLIALATELA
Neurol., Univ. of Texas Med. Br., Galveston, TX

**Abstract:** Alzheimer’s Disease (AD), the sixth leading cause of death in the US and the most common form of age associated dementia, is accompanied by synaptic loss, at early stages, and

neuronal death, at late stages of the disease. Amyloid beta (Aβ) and tau oligomeric aggregates, the most toxic species of the two hallmark proteins in AD, are capable of targeting and disrupting synapses thus driving cognitive decay. Certain individuals (here referred to as Non-Demented with Alzheimer's Neuropathology – NDAN) are capable of withstanding Aβ and tau toxicity, and thus remain cognitively intact despite the presence of AD neuropathology. Understanding the involved mechanism(s) would therefore lead to the development of novel and effective therapeutic strategies aimed at promoting synaptic resilience to amyloid toxicity. Proteomic studies of postsynaptic density fractions of hippocampi prepared from post-mortem brains of AD, NDAN and healthy control individuals revealed 31 unique proteins that are significantly different in AD vs. NDAN. Potential drivers of these changes, microRNA-485, -4723 and -149, were predicted by Ingenuity Pathway Analysis and experimentally confirmed to be differentially expressed in AD vs. control and NDAN brains. We hypothesized that changes in these microRNAs (miRNAs) levels play an important role in either promoting synaptic resistance or sensitization to Aβ oligomers binding. To test our hypothesis, we used an *in vivo* model to determine if modulation of these miRNAs can affect the ability of Aβ oligomers to associate with synaptic elements. Synaptosomes were prepared from hippocampi of wild-type mice (male and females) 24 hours after intracerebroventricular injection of mimics or inhibitors of the identified miRNAs, and Aβ binding was evaluated using flow cytometry. We found that *in vivo* modulation of microRNA-4723, -485 and -149 levels significantly decreased Aβ binding to the synapses in both male and female mice. Taken together, our findings suggest that miRNA regulation and homeostasis are crucial for Aβ interaction with synaptic terminals, and strongly suggests that, in NDAN individuals, a unique epigenetic profile could be driving synaptic resistance to Aβ toxicity, thus contributing to preserved cognitive abilities.

**Abstract:** Memory dysfunction in the early stages of Alzheimer's Disease (AD) has been attributed to deficits in hippocampal-entorhinal circuit. To understand whether hippocampal neuronal deficits substantially precede the overt appearance of clinical AD including the formation of extracellular amyloid plaques, we carried out dendritic spine analysis of hippocampal CA1 pyramidal neurons at 1 month of age in $APP_{Swe}$/PS1ΔE9 (APP/PS1) mouse model of AD. We noticed a selective reduction of mushroom spines as against the percent contributions of thin and stubby spine density in the tertiary apical dendrites of CA1 pyramidal neurons. However, dendritic spine density was unaltered in secondary apical dendrites. We further hypothesized that the molecular basis of decrease in spine density in the hippocampus could have its roots in impaired activity dependent protein translation, which is critical for synaptic plasticity. We observed that in 1m old APP/PS1 mouse hippocampus, all the signaling proteins involved in the Akt-mTOR cascade, such as Akt, mTOR, GSK, p70-s6k, 4E-BP and S6 regulating the activity dependent protein translation were repressed. Since the number of dendritic spines, spine plasticity, and morphology are basic to memory consolidation and storage, we further investigated memory impairment in 2 month old APP/PS1 mouse using explicit and implicit memory tests. Explicit memory was assessed with episodic- like memory tasks and implicit memory with contextual Fear conditioning and Morris Water Maze (MWM) task. 2m old APP/PS1 mice showed specific impairment in 'where/which'-episodic-like - memory tasks. However, the "what" component of the episodic-like-memory was intact. In contextual fear conditioning, the mice exhibited a significant long-term fear memory deficit compared to wild-type littermates, while in MWM learning, 2m old APP/PS1 mice showed normal spatial learning capabilities. Therefore, we conclude that there are early signs of molecular and structural deficits in the hippocampus that culminates in selective learning impairments during the prodromal stage of AD in APP/PS1 mice.

**Abstract:** Synaptic dysfunction, considered to occur early in AD is often seen as loss of dendritic spines. Fibrillar actin (F-actin) is highly enriched in dendritic spines and defines spine structure. We recently reported that synaptosomal F-actin levels were significantly decreased in APPswe/PS1ΔE9 (APP/PS1) mice as early as one month of age. APP/PS1 mice showed recall deficit upon contextual fear conditioning (cFC) at two months, which was reversed by F-actin stabilizing agent, jasplakinolide. Reactive oxygen species (ROS) generated by β-amyloid (Aβ) has been implicated in Alzheimer's disease (AD) pathogenesis. However, it is unclear whether ROS contributes to F-actin loss in synaptosomes, in vivo, in mice. Therefore, we investigated whether altered redox signaling could contribute to F-actin loss and behavioral deficits seen early in AD. We used age matched WT and APP/PS1 mice for our experiments. Highly enriched F-Actin and G-Actin fractions were isolated from synaptosomes prepared from cortices of WT and APP/PS1 mice. We also used AMS-derivatization approach to determine reduced form of F-actin. AAV-glutaredoxin1 viral particles were delivered into hippocampus of mouse brain using stereotaxic injections. Reduced form of F-actin was significantly decreased while reduced form of G-actin was unaffected in synaptosomes of APP/PS1 mice as early as one month and this loss was sustained until nine months, when overt symptoms are observed. S-glutathionylation of synaptosomal actin, which is known to hinder F-actin stabilization was significantly increased in one month APP/PS1 mice in comparison to WT mice. Further, to determine the role of Aβ mediated endogenous ROS levels on F-actin loss and behavioural deficits in APP/PS1 mice AAV-glutaredoxin1 viral particles were transduced into the hippocampus of the mouse brain. Remarkably, we found that cFC behavioral deficits seen in APP/PS1 mice and loss of synaptosomal F-actin levels were restored by over expression of glutaredoxin1 in AD mice. We conclude that Aβ induced ROS-mediated glutathionylation of actin as one of the mechanisms hindering F-actin stabilization in synaptic compartments leading to behavioral deficits in APP/PS1 mice, which can be reversed by over expression of glutaredoxin1. Our novel findings provide evidence that F-actin loss through oxidative modification at the synapse plays a critical role in synaptic dysfunction in AD pathogenesis.

**Abstract:** Vascular Dementia may begin as mild cognitive changes due to blockade of blood vessels that worsen gradually as a result of multiple minor strokes, leading to cumulative damage. Patients with multiple micro infarcts as well as repeated occurrence of micro infarcts have high risk of developing dementia. Therapies to delay progression of cognitive impairments are required to minimize deficits associated with dementia. Most common animal model used to study vascular dementia is cerebral artery occlusion, which produces clear major infarct in brain depending on side of occlusion. Since we wanted to create micro infarcts rather than a severe insult we opted for bilateral intracerebroventricular injection of endothelin-1 (ET-1), which is a vasoconstrictor peptide into 4$^{th}$ventricle. We observed decreased CD31 expression which is a marker for endothelial cells in ET-1 injected animals probably due to constriction in micro vessels after 3 days of endothelin treatment. Further, there was transient associative memory deficit and down regulation of Akt-mTOR pathways in hippocampal tissue of mice injected with endothelin at 7 days indicating the effect of blockade in blood flow. The reduction in Akt1-mTOR signaling resulted in consequent decrease in GSK α/β signaling in hippocampus after 7 days of endothelin injection implying that activity dependent protein translation could potentially be affected. However, there was recovery in learning and memory deficits and Akt-mTOR signaling after 30 days of endothelin treatment. Micro infarcts caused by ET-1 injection leading to impairment of Akt1-mTOR signaling indicate a possible molecular mechanism impacting synaptic plasticity during vasoconstriction. The present study provides insights in understanding vascular pathology leading to behavior dysfunction during multiple small insults in the large disease spectrum of vascular dementia.

**Abstract:** Despite an intuitive understanding of biochemical pathways leading to differential proteolysis of Amyloid Precursor Protein, there is a little understanding of how these molecules are distributed at the synapses. The alteration in number and lateral organization of these transmembrane molecules in synapse is considered as a crucial factor in health and diseases like Alzheimer's Disease (AD). Despite several years of AD research there is indeed a limited knowledge on the factors that control the expression and activity of these molecules at the synaptic membrane. Here we try to combine high density single particle tracking and super resolution imaging techniques like Photo Activation Localization Microscopy (sptPALM), Direct Stochastic Optical Reconstruction Microscopy (dSTORM) and Stimulated Emission Depletion Microscopy (STED) to understand the localization of APP and different secretases (BACE and Presenilin) involved in the processing of APP. Additionally, we illustrate trafficking of wild type APP (APPwt) through diffusional behaviour from thousands of spatially discrete single molecule trajectories from live neuronal cells. We incorporate the experimentally observed spatio-temporal details of APP and BACE in a computational model. We simulate reaction-diffusion dynamics of these molecules on synaptic membranes and endocytic vesicles. These *Insilico* experiments reveal multiple alterations on subsynaptic organization of APP and secretases which alters the proteolytic processing of APP by amyloidogenic pathway. A combination of state of the art microscopy and biophysically realistic model allows us to appreciate finer organization and recycling of APP and secretase molecules at an excitatory synapse.

**Abstract:** Cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) are second messengers regulating signal transduction that cooperate to ensure memory acquisition and consolidation. Increasing their levels by phosphodiesterase inhibitors (PDE-Is) has been demonstrated to enhance cognitive functions and rescue memory loss in animal models of aging and Alzheimer's disease (AD). However, their increase in non-targeted areas and side effects due to the high doses used, have limited their application to the treatment of erectile dysfunction, pulmonary hypertension and chronic obstructive pulmonary disease. Recently, we have demonstrated that a combination of sub-efficacious doses of cAMP- and cGMP-specific PDE-Is exerted an additive effect to improve synaptic plasticity and memory in physiological conditions. Based on these findings, here we aimed to study whether this treatment was effective to rescue the AD phenotype in the APPswe mouse model. We found that a 3-week chronic treatment with a combination of sub-efficacious doses (not affecting memory per se) of the cAMP-specific PDE4-I roflumilast (0.01 mg/kg) and the cGMP-specific PDE5-I vardenafil (0.1 mg/kg) improved recognition, spatial and contextual fear memory. Interestingly, the cognitive enhancement persisted for 2 months beyond therapy suspension. Conversely, acute administration of PDE-Is did not affect memory in APPswe mice. In conclusion, we have shown that combining sub-efficacious doses of roflumilast and vardenafil, drugs already approved for other clinical applications in the elderly, reverse the AD phenotype. This treatment might have several advantages compared to single PDE-Is administration at high doses, such as a possible long-standing human use and a perspective of a better compliance due to the possibility to minimize side effects. More importantly, the persistence of the effect beyond the administration suggests a potential as disease-modifying therapy.

**Abstract:** Impairment of adult hippocampal neurogenesis is an early critical event in animal models of Alzheimer’s disease (AD), contributing to progressive memory loss and cognitive decline. Compelling evidence suggests that dysregulation of the balance between neural stem cell (NSC) proliferation and differentiation may contribute to AD phenotype, although the underlying molecular mechanisms are still unclear. Recently, the nuclear pore complex protein, nucleoporin Nup153, in addition to its role in nucleus-cytoplasm transport, has been described as a key regulator of adult NSC plasticity through the interaction with the transcription factor Sox2. Here we investigated the role of Nup153 in NSC dysregulation in a mouse model of AD. Our results revealed that NSCs residing in the hippocampal dentate gyrus of 2-month-old 3×Tg AD mice display reduced levels of Nup153 compared to wild-type (WT) mice. A similar decrease of Nup153 expression, at both mRNA (-36%±3) and protein levels, was also found in cultured hippocampal NSCs obtained from newborn 3×Tg mice (AD-NSCs). Moreover, Co-IP experiments revealed that Nup153 association with Sox2 was significantly reduced in AD-NSCs compared to WT-NSCs. Vector-mediated Nup153 overexpression was used to assess its role in AD-NSC function in comparison to empty-vector expressing control cells. Of note, overexpression of Nup153 increased AD-NSC proliferation, assessed by BrdU incorporation (%: AD-NSCs 33.8±1.1; AD-NSC-Nup153 69±4.5), neurosphere assay (n° of neurosferes: AD-NSCs 43.6±4.2; AD-NSC-Nup153 82.2±0.5) and phosphorylation of serine 10 on histone H3 (2-fold increase). Scratch assay revealed that Nup153 overexpression was sufficient to recover AD-NSC migration to WT-NSC level (% of remaining gap: WT-NSCs 38.3±3.1; AD-NSCs 58±3.8; AD-NSC-Nup153 31±2.2). Interestingly, this effect was paralleled by increased expression of PSA-NCAM. Inhibition of nitric oxide synthase by LNAME (5mM), antioxidant treatment (ascorbic acid, 1mM) or gamma-secretase inhibition (1μM) all increased Nup153 levels in AD-NSCs (2-fold increase), whereas treatment of WT-NSCs with amyloid-β oligomers (200 nM) led to Nup153 down-regulation (1.7 fold decrease). Collectively, these findings suggest that increased nitro/oxidative stress, which characterizes many neurodegenerative diseases including AD, may

induce Nup153 downregulation through the accumulation of Aβ42. In conclusion, our data uncover a novel role for Nup153 in AD and a potential new target to ameliorate AD-NSC function.

**Abstract:** Incidence of Alzheimer's disease (AD) is higher in women as compared to men. Although neuroprotective effect of estrogen is well recognized, the underlying pathogenic mechanisms explaining the higher burden of AD in women are unclear, taking into account the longer lifespan in women. Several studies have demonstrated that synaptic dysfunction is considered to occur prior to the appearance of the pathophysiological and behavioural symptoms of AD. Fibrillar actin (F-actin) is one of the major cytoskeleton proteins present in dendrites and is very important for defining dendritic spine structure. Here, we measured F-actin and G-actin levels, in synaptosomes derived from the cortices of WT and APP/PS1 mice at different ages from both male and female mice. We found significant decrease in synaptosomal F-actin levels in male, but not in female, APP/PS1 mice at 4 months of age. Intriguingly, synaptosomal F-actin levels started decreasing in female APP/PS1 mice at the age of 8 months and this was sustained until 1 year of age. Furthermore, male APP/PS1 mice, but not female mice showed deficient recall upon contextual fear conditioning at the age of 4 months. However, female APP/PS1 mice started showing deficient recall upon contextual fear conditioning at the age of 8 months and cognitive deficits were sustained until 1 year as examined in both male and female mice. The

appearance of cognitive deficits and loss of synaptosomal F-actin occurred in females only as they aged, specifically as they entered menopause. These findings indicate that the neuroprotective effects of estrogen may play an important role in protecting from β-amyloid induced toxicity at the synapse and estrogen plays a critical protective role in preventing synaptic dysfunction during early stages of AD progression.

**Abstract:** The increase of oligomeric amyloid-beta (oAβ) has been related to synaptic dysfunction, thought to be the earliest event in Alzheimer’s disease (AD) pathophysiology. However, low physiological concentrations of Aβ have neurotrophic and neuroprotective properties and exert a positive modulatory function on synaptic plasticity and memory. Moreover, Aβ deletion in the healthy brain results in a dramatic impairment of synaptic plasticity and memory, suggesting that the peptide is needed to ensure these functions. Here, we have investigated whether different species, aggregation forms and concentrations of Aβ might differently influence synaptic function. In particular, we have tested the individual contribution

of monomeric or oligomeric Aβ40 and Aβ42 at 200 nM and 200 pM concentrations on hippocampal CA3-CA1 long-term potentiation (LTP) and spatial memory. When at 200 nM, oAβ40, oAβ42 and monomeric Aβ42 impaired LTP and memory, whereas only 200 pM oAβ42 exerted a positive effect at the synapse. Remarkably, 200 pM oAβ42 was able to rescue the detrimental effect due to depletion of endogenous Aβ. Quantification of monomer-like and oligomer-like species carried out by transmission electron microscopy revealed an increase of the monomer/oligomer ratio in the oAβ42 200 pM versus 200 nM preparation, suggesting that the content of monomers and oligomers depends upon the final concentration of the solution. Taken together, these findings suggest that the Aβ biphasic effect is influenced by different isoforms or aggregation status of the peptide. Moreover, our data suggest that, when at high concentrations, both monomers and oligomers exert a neurotoxic action. Conversely, when at low concentration, the presence of oligomers is needed for LTP and memory. Such observations should be taken into consideration when studying the role of the peptide in physiological or pathological conditions, and when developing Aβ-tailored therapies especially aimed at clearing oligomers but sparing monomers.

**Abstract:** Alzheimer’s disease (AD) is a debilitating, progressive neurodegenerative disease that is characterized by cognitive deficit. Existing therapies for AD provide symptomatic relief but treatments that can modify the progression of neurodegeneration are not available. While cognitive deficits in AD are manifested only late in life, early detection of AD is essential for developing treatment strategies that can alter the course of AD. This study aimed to explore the global changes in gene expression at early pre-symptomatic stages in APPswe/PS1ΔE9

(APP/PS1) transgenic mice in entorhinal cortex (EC) and hippocampus (HP). Thereafter, global gene expression changes in AD transgenic mouse model were compared to transcriptome data from human autopsy tissue.
Total RNA isolated from EC and HP from 4 male APP/PS1 transgenic (Tg) and wild type (WT) control mice each at 1 month and 3 months of age was processed for depletion of ribosomal RNA, cDNA library preparation followed by Illumina paired end sequencing. The raw reads were quality controlled and aligned to mouse genome and read counts were generated and normalized using DESeq2. Further, pathway analysis was performed on the significantly differentially expressed genes. Reads aligned to human reference genome were downloaded from AMP-AD Knowledge Portal. Read counts were generated from aligned reads which were normalized using DESeq2 for differential gene expression analysis. The group that corresponded to human controls had 201 samples, MCI had 159 samples and AD had 221 samples each.
App and Prnp were found to be upregulated in both EC and HP at 1 month and 3 months of age in APP/PS1 mice, which served as a positive control for the integrity of the data. In summary, expression of 309 genes was significantly altered at 1 month; and 208 genes at 3 months in EC. However, only 17 genes were significantly altered at 1 month; and 79 at 3 months in HP. Analysis of the data obtained from the AMP-AD RNA-seq study revealed that 2971 genes were significantly altered in the AD group compared to controls. However, only 117 genes were significantly altered in AD compared to MCI.
This study shows extensive gene expression perturbations as early as one month of age in APP/PS1 transgenic mice and also in human AD autopsy tissue. Greater changes in differential gene expression were observed in EC than HP at both time points. Moreover, genes involved in chemical synaptic transmission were perturbed in both 1-month EC from Tg mice and in human AD. Our data presents an interesting comparison of gene expression changes across two ages and two brain regions in APP/PS1 mice and between human MCI and AD.

**Abstract:** The deposition of β-amyloid(Aβ) plaques in the specific brain regions is one of the key pathological hallmark of Alzheimer's disease(AD). Imaging and following of AD pathology is important to understand and manage the disease. Among many approaches to detect Aβ plaques, two-photon microscopy(TPM) is an attractive tool for observing biological system. Several TP probes based on dipolar structure have been developed so far, which show a substantial level of fluorescence by nature and an enhanced level of signal via intercalating into Aβ plaques. It is critical issue to remove residual signals to get much clearer and specific image data. To overcome this problem, here we propose a new folding/unfolding based TP excitable probe. A new probe has a structure of two aromatic fluorophores which prefer to exist in folded, self-quenched, form. In contrast, upon insertion into β-sheet structure of Aβ aggregates, folded structure become stretch out accompanying significant fluorescence signals. The probe enables ex vivo and in vivo tissue imaging of Aβ plaques in disease-model mouse, with a remarkably suppressed background noise. These results demonstrate that new dye will be useful in bioimaging and biomedical application with less background signal.

**Abstract:** Alzheimer's disease(AD) is the most common type of dementia. Pathologies of Alzheimer's disease are represented by amyloid plaque, neuro-fibrillary tangle(NFT) and gliosis. NFT, majorly consist of Tau protein, is highly correlated with cognitive impairment in AD. Recently, sleep deprivation and circadian rhythm disruption show high correlation with AD

pathology. Previously, molecular mechanism of circadian rhythm disruption by amyloid beta(Aβ) was revealed. Focus of this study is molecular mechanism of circadian rhythm disruption in AD especially with tauopathy. AD pathology model mice($ADLP^{Tau}$) were used in this study. $ADLP^{Tau}$ has hTau P301L and showing tauopathy, not amyloid pathology. $ADLP^{Tau}$ shows tauopathy and circadian rhythm disruption. Specifically, phase delay and body temperature of $ADLP^{Tau}$ mice was altered from wildtype. In mRNA level, several clock gene oscillation was disrupted. In protein level, Per2 core clock protein was decreased in entire time point. From this results, degradation of Per2 induced by tauopathy was investigated and we suggest this for major underlying mechanism of circadian rhythm disruption in AD and tauopathy.

**Abstract:** Synergistic effect between Amyloid-β (Aβ) and hyper-phosphorylated tau is a predominant event in Alzheimer’s Disease (AD) pathogenesis. However, identifying a molecular mediator between Aβ and Tau is still on progress. Here, we report the novel role of Plexin, the plasma membrane protein which serves as an axon guidance and repulsion signaling molecule as a receptor for Aβ and accelerates tau hyper-phosphorylation.
Aβ oligomer treatment altered the surface expression pattern of Plexin and induced tau hyper-phosphorylation. Plexin increased the total tau level in a dose dependent manner and likewise, knockdown of the Plexin in hippocampal neuron reduced the total amount and hyper-phosphorylation of tau even in the presence of Aβ.
In the AD mouse model which manifest both Aβ and tau pathology, Plexin is colocalized with

Aβ plaque and knockdown of the Plexin in hippocampus alleviated Aβ-induced tau pathology and rescued cognitive impairment.
In conclusion, these observations indicate that Plexin can functions as a receptor for Aβ which triggers toxic tau hyper-phosphorylation in AD pathogenesis. Our finding strengthens the Aβ - tau axis hypothesis and may provide a new therapeutic target against AD.

**Abstract:** The mammalian target of rapamycin (mTOR) plays a fundamental role in cell proliferation, survival and autophagy. In particular, mTOR complex 1 (mTORC1) has a key role in the regulation of protein synthesis activated by stimuli such as amino acids, insulin and growth factors. Both insulin signaling and protein synthesis are impaired in Alzheimer's disease (AD), the most common cause of elderly dementia. Because of this, the mTORC1 signaling pathway has received much attention in recent AD research. However, results from such studies remain controversial. While most groups have shown an upregulation of the mTORC1 pathway in experimental models of AD, others have reported an opposite effect. We are currently studying the mTORC1 pathway in two different models of AD: wild-type Swiss mice receiving intracerebroventricular (icv) infusions of amyloid-β oligomers (AβO), toxins that build up in the

AD brain and are thought to cause synapse failure and memory loss, and transgenic APPswe/PS1ΔE9 mice. Our results show that mTORC1 signaling is significantly reduced in the mouse hippocampus 7 days after icv infusion of AβOs. Surprisingly, we do not find any changes in mTORC1 signaling in the hippocampi of APPswe/PS1ΔE9 mice, a transgenic model engineered to overproduce the amyloid-β peptide, at either 4 or 8 months of age, when AD-related neuropathology and memory impairment are detected. Results may point to potentially critical differences between acute and chronic models of AD, and to disease stage-dependent regulation of mTORC1 signaling. Further, results may be connected to recently reported differences in mTORC1 subcellular localization (plasma membrane versus lysosomes), a possibility we are currently exploring. Resolving these apparently conflicting results may be an important step towards proper understanding of mTORC1 signaling in AD, and to the development of therapies focused on reestablishing proteostasis.

**Title:** Abeta accelerates tau propagation in the neuronal cell line

**Authors: *K. SUH**, D. KIM, I. MOOK-JUNG
Seoul Natl. Univ., Seoul, Korea, Republic of

**Abstract:** Presence of amyloid plaques and neurofibrillary tangles are major characteristics of Alzheimer's disease (AD). Both pathological proteins, amyloid beta (Aβ) and tau, are known to have highly conserved spatial pattern in accumulation among the patients that it can be the criteria for the degree of pathology. Especially, tau propagates in prion-like manner along the neuronal circuit, and as this propagation occurs in prior to cognitive decline, the spreading phenomena would play an important role for inducing the clinical symptoms of AD. In addition, accumulation of Aβ always precedes the formation and propagation of tau, which implies the effect of pre-existing Aβ in the progression of tauopathy, although the clear relationship between Aβ and tau propagation is poorly understood. First, we constructed a novel mouse model for AD, $ADLP^{APT}$ mice, which expresses both Aβ and human tau. We observed the accelerated tauopathy affected by Aβ in $ADLP^{APT}$ mice. However, Aβ pathology is not affected by the presence of tau, indicating that Aβ can work as an accelerant for the propagation of tau but not vice versa. Then, to demonstrate the process of the phenomena observed *in vivo,* we first examined whether

neurons uptake extracellular tau with the help of Aβ. Using neuronal cell line, we found that neuronal uptake of tau is accelerated in Aβ dependent manner. Taken together, we show that Aβ facilitates the propagation of tau by increasing neuronal uptake of extracellular tau, and the internalized tau induces formation of neurofibrillary tangles and cytotoxicity in receptor neurons, thereby promoting neuronal cell death.

**Title:** Effects of broad-spectrum antibiotics induced gut microbiota manipulation on tau pathology in Alzheimer's disease model mouse

**Authors: *H. CHOI**, Y. KIM, D. LEE, I. MOOK-JUNG
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

**Abstract:** The gut-brain axis (GBA) is the bidirectional communication between the gastrointestinal tract and the brain. The gut microbiota has recognized as a key regulator of this axis and there is increasing evidences that changes in the gut microbial diversity and composition can influence various neurological disease and neurodegenerative disease. The most prevalent neurodegenerative disease, Alzheimer’s disease (AD) is characterized by accumulation of amyloid beta (Aβ) peptides and neurofibrillary tangles (NFTs) comprised of hyper-phosphorylated tau proteins in the brain, resulting in the cognitive impairment. In this study, using $ADLP^{APT}$ transgenic AD mouse model, we determined whether the pathological features of AD are affected by the alterations in brain signaling from the AD-associated gut microbiota in the early stage of the disease. So we examined Aβ plaque load and NFTs formation after the altered gut microbiota in AD model mouse through its manipulation by broad-spectrum antibiotics (ABX) treatment. We found that levels of aggregated tau and hyper-phosphorylated tau significantly decreased in the ABX-treated $ADLP^{APT}$ mouse compared to the DW-treated $ADLP^{APT}$ mouse, but did not observed the reduction of Aβ plaques. These findings suggested that the altered gut microbiota might contributed to the interactions between the gut and brain that impact tau-related pathology in the early stage of AD.

**Abstract:** AIM: Human mesenchymal stem cells (hMSCs) possess potent immunosuppressive capacity that mainly depends on paracrine mechanisms. With the aim to develop a cell-free system to target inflammatory processes in AD, we are investigating the immunomodulatory potential of preconditioned MSC-derived extracellular vesicles (pMSC EVs) on microglia polarization in 3xTg AD model.
METHODS
Cytokine preconditioning with IFNγ and TNFα was selected as leading ex vivo strategy to prompt hMSC immunosuppressive phenotype. pMSC EVs were isolated from MSC culture medium by ultracentrifugation and tested *in vitro* on primary microglia - extracted from cortices and hippocampi of postnatal 1-2 day old mice - 2 h after inflammatory challenge. EV immunoregulatory effects were assessed after 48 h by evaluating the modulation of cytokine release (ELISA) and M1 and M2 marker expression (Western Blot). 7-month-old 3xTg mice, used in *in vivo* experiments, were intranasally injected with 15 $x10^9$ EVs and sacrificed after 3 weeks for the analysis of cortical and hippocampal microglial phenotype. Golgi Cox was used for the staining of neuronal dendritic branching.
RESULTS
hMSCs, underwent to inflammatory preconditioning, showed an increased expression of immunomodulatory markers (COX2, IDO) and preserved the expression of stemness markers (CD90, CD73) as well as the ability to differentiate into mesodermic lineage. pMSC-EVs foster microglia M2 phenotype, as evidenced by the significant reduction in the release of pro-inflammatory cytokine IL-6 and the increase of the anti-inflammatory cytokine IL-10. EVs

significantly reduced microglial density and IBA1/CD68 co-localization in the hippocampal CA1 region of EV-treated 3xTg mice compared to the controls. In the same area, EV-treated mice showed an increase of dendritic spine density compared to control animals.
CONCLUSION
Cytokine preconditioning represents a feasible method for improving MSC immunoregulatory potential without altering cell stemness properties. Preconditioned-MSC EVs might represent a therapeutic tool able to improve synaptic plasticity. This positive effect may be attributable to the ability of EVs to dampen neuroinflammation by influencing microglia behaviour.

**Abstract:** The entorhinal cortex (EC) is one of the most vulnerable brain region that is attacked during the early stage of Alzheimer’s disease. Accumulation of abnormally hyperphosphorylated tau in the EC is the earliest pathological hallmarks in AD patients and neurofibrillary tangles are known to spread in a hierarchical pattern during disease progression. However, the neuronal function of tau is still unknown despite its probable influence on specific neural circuits in the early Alzheimer’s disease. In the present study, we found that accumulation of pathological tau begins in the lateral entorhinal cortex (LEC), followed by the hippocampal CA1 region of 2- to 3-month-old tau mice. In these ages, spontaneous excitatory and inhibitory postsynaptic currents (sEPSC) are changed in hippocampal CA1. Taken together, our findings suggest the possibility that tau alters specific neural circuits by modulating synaptic transmission in the early tauopathy.

**Abstract:** Cerebral β-amyloid (cAβ) deposition and cholinergic dysfunction have been considered as major pathological and functional hallmarks of Alzheimer’s disease (AD). Acetylcholinesterase (AChE) is the one of the major cholinergic enzymes and there is no report to show the relationship between cAβ accumulation and peripheral AChE alteration in early stage of AD pathogenesis. Recent studies demonstrate that cAβ starts to deposit 15 to 20 years ahead of symptomatic appearance and this preclinical AD is important for early diagnosis of disease. In this study, we investigated the link between cAβ deposition and the peripheral AChE in cognitively normal (CN) individuals. A total of 407 individuals underwent Pittsburgh compound B (PiB)-positron emission tomography were participated in our study. Lower levels of plasma AChE and its enzymatic activity were detected in CN individuals with cAβ deposition than in those without cAβ. Plasma AChE levels and enzymatic activity were negatively correlated with the degree of cAβ deposition. Our results suggest that blood AChE can be used as a potential blood biomarker for the prediction of cAβ deposition in CN individuals.

**Abstract:** Mitochondria play essential roles in maintaining the high levels of brain energy demands required to maintain physiological ion gradients across membranes critical for the generation of action potentials and to sustain transport systems at endothelial barriers. About 90% of the energy requirement is produced through glucose oxidation, a tightly controlled mitochondrial process leading to ATP production. As the major consumers of oxygen, mitochondria are also the most important generators of reactive oxygen species (ROS) as by-products of the electron transport chain. Thus, it is not surprising that mitochondrial dysfunction is emerging as a major contributor to the pathobiology of age-associated neurodegenerative disorders and is being considered a crucial player in the pathophysiology of AD. Indeed mitochondrial alterations, oxidative stress, reduced ATP production, low levels of central components of the oxidative phosphorylation path, and overall glucose hypometabolism coexisting with synaptic alterations have been reported in AD and recapitulated in different transgenic models. In spite of numerous studies, the mechanistic links among ROS homeostasis, cellular metabolic alterations, and changes in cell bioenergetics, particularly at the level of synapsis and in relation to oligomeric forms of amyloid-β (oligAβ), still remain elusive. Through a combination of classic biochemical and immunocytochemical approaches together with the evaluation of real-time changes in global energy metabolism, our studies provide insights into the detrimental role of oligAβ in neuronal cells. Our findings demonstrate that oligAβ induces detrimental changes in mitochondrial function with loss of mitochondrial membrane potential, release of cytochrome C, and enhanced ROS generation. Assessment of global energy metabolism in the Seahorse metabolic analyzer after sequential addition of different inhibitors of the mitochondrial metabolic pathways, demonstrate an oligAβ-mediated reduction in oxygen consumption affecting basal and maximal respiration capacity and causing decreased ATP production. Pharmacologic targeting of Aβ-challenged neurons with compounds of known

antioxidant activity such as melatonin and the vitamin E-analog trolox, restored mitochondrial integrity/function, rescuing metabolic and bioenergetic changes induced by oligAβ. Overall, our studies provide insights into the complex molecular mechanisms triggered by oligAβ which profoundly affect mitochondrial performance and highlight the potential of antioxidant pharmacologic targeting to ameliorate metabolic/bioenergetics alterations.

**Abstract:** Alzheimer’s disease (AD) is an incurable dementia disorder that affects 10% of the population over the age of 65. The key to prevention of AD lies in understanding the early changes that occur in the brain prior to behavioral symptoms. Presenilin mutant mice show enhanced LTP and NMDA receptor (NMDAR) activity prior to showing deficits. The present study was designed to determine whether a more complex mouse model (5XFAD), which expresses 2 presenillin and 3 amyloid precursor protein (APP) mutations and develops plaques, also shows early transient hyperexcitability.
Heterozygous 5XFAD and wildtype littermates of both sexes (combined data) were raised to 1, 2, 3, or 4 months of age and euthanized by exposure to isoflurane. Hippocampal slices were prepared in low-$Ca^{++}$ (0 added) artificial cerebrospinal fluid (aCSF; all in mM: 124 NaCl, 2 KCl, 1.25 $KH_2PO_4$, 26 $NaHCO_3$, 10 glucose, 2 $MgSO_4$) and Schaffer collateral to CA1 synapses were studied with a Med64 multielectrode array. Slice recovery and early long-term potentiation (LTP; single 100Hz tetanus) was performed in 2mM calcium aCSF. For drug studies, input/output curves were obtained for total field excitatory post-synaptic potentials (fEPSP), slices were then changed to .5mM Mg aCSF, 30µM DNQX & 10µM picrotoxin solution, followed by adding 4µM Ro-25-6981 (GluN2B antagonist), and 50µM AP5 (NMDAR antagonist). Drug studies were inadvertently done in low-$Ca^{++}$ aCSF. Input/output curves

analyzed using a stimulus-response variable 4-parameter fit. Experimenters and analyzers were blinded to genotype information. Sample sizes were 3-6.
There was no effect of genotype on the total fEPSP on curve fit at any age (p = .7-.97). There were significant differences in curve fits for the NMDAR and NMDAR GluN2B subunit at 1 month of age, with greater amplitude fEPSPs per stimulus level in the heterozygotes. Non-GluN2B NMDAR responses were increased at 2 months of age. By 4 months of age, the 5XFAD heterozygotes showed significantly decreased amplitude responses for NMDAR, and GluN2B and non-GluN2B NMDARs than wildtype. There was no significant effect of genotype or age on early LTP, measured 45-50 minutes following a single tetanic stimulation.
These results suggest that there was a transient period of enhanced NMDAR responses at 1-2 months of age in 5XFAD mice that became hyporesponsive by 4 months of age. The enhanced NMDAR responses, involving the GluN2B subunit, were at 1 month of age, prior to reported appearances of amyloid plaques. This early NMDAR hyperactivity in the 5XFAD model did not appear to alter LTP, induced by high-frequency stimulation, but could lead to NMDAR excitotoxicity prior to the onset of AD symptoms.

**Abstract:** People who suffer from Alzheimer’s disease (AD) exhibit memory loss and other mental dysfunctions, which are believed to be due to hippocampal synapse dysfunctions. Soluble

oligomeric amyloid-beta (Aβ) peptides are suggested to be an important factor in mediating these hippocampal synaptic deficits. We previously reported that Aβ triggers aberrant activation of EphA4 and that blockade of EphA4 activity alleviates the hippocampal synaptic plasticity deficits in AD (APP/PS1) transgenic mice. While Aβ causes aberrant accumulation of extracellular glutamate due to ineffective clearance by astrocytes, EphA4/ephrinA3 signaling regulates glutamate transporter expression in astrocytes, which is responsible for glutamate clearance. In this study, we investigated the molecular basis underlying the EphA4-dependent synaptic deficits in AD. Repetitive stimulation of postsynaptic cornu ammonis 1 (CA1) neurons in the hippocampus of normal mice reduced synaptic response, as evidenced by decreased field excitatory postsynaptic potential (fEPSP) slope, which is termed “synaptic fatigue” and impacts neurotransmission efficacy. We found that synaptic fatigue is enhanced in the hippocampus of APP/PS1 mice, which can be rescued by the inhibition of EphA4 signaling. Collectively, our findings raise the intriguing possibility that EphA4 signaling mediates synaptic fatigue in AD.

**Abstract:** Hippocampal synaptic function and plasticity deteriorate with age, often resulting in learning and memory deficits. As microRNAs (miRNAs) are important regulators of neuronal protein expression, we examined whether miRNAs may contribute to this age-associated decline in hippocampal function. We found that age-upregulated miR-204 contributes to a decline in cognitive functions by repressing EphB2, a key synaptic regulator in hippocampus in part through regulation of the surface expression of the NMDA receptor NR1 subunit. As EphB2 is known to be targeted and degraded by amyloid beta in some patients of Alzheimer’s disease, we tested whether down-regulation of miR-204 could rescue deficits in synaptic plasticity and cognitive function in Alzheimer model mice. Adeno-associated virus (AAV) mediated, down-regulation of miR-204 through stereotaxic injection into dentate gyrus of hippocampus increased

surface expression of NR1 subunit of NMDA receptor, allowing improved NMDA signaling pathway. In turn, this synaptic change led to induced long term potentiation in hippocampus and enhanced spatial memory and recognition abilities in 5X FAD Alzheimer model mice. More importantly, this AAV mediated down-regulation of miR-204 significantly reduced amyloid beta plaque formation in the mice compared to control group that received AAV control, providing a novel therapeutic potential for recovery of cognitive functions in Alzheimer patients.

**Title:** A<β>$_{1-42}$ impairs mGluR5-mediated enhancement of depolarization-induced suppression of inhibition and eCB mobilizations in the hippocampus

**Authors: *J. LEE**, J. KWAG
Dept. of Brain and Cognitive Engin., Korea Univ., Seoul, Korea, Republic of

**Abstract:** Accumulation of amyloid beta (Aβ) in the hippocampus impairs endocannabinoid (eCB) signaling, leading to synaptic dysfunction in Alzheimer's disease (AD). In hippocampal CA1 pyramidal cells (PCs), postsynaptic depolarization mobilizes eCB and causes short-term depression of inhibitory postsynaptic current (IPSC), called depolarization-induced suppression of inhibition (DSI). Especially, eCB mobilization and DSI are known to be synergistically enhanced by the activation of metabotropic glutamate receptor 5 (mGluR5) but how $A\beta_{1-42}$ impairs the mGluR5-mediated enhancement of DSI and eCB mobilization is not clear. Hippocampal slices were treated either with 200 nM $A\beta_{1-42}$ or 0.02% DMSO (vehicle). We performed whole-cell voltage-clamp recordings on hippocampal CA1 PCs *in vitro* and stimulating electrode was placed at the Schaffer collateral to evoke IPSC (eIPSC). Postsynaptic depolarization was induced by giving voltage steps to 40 mV 200 times at 1 Hz to mimic postsynaptic spikes and DSI was measured by taking the mean amplitude of 10 consecutive eIPSC following the postsynaptic spikes. mGluR5 was activated by applying group I mGluR

agonist (DHPG, 50 μM) and mGluR1a antagonist (LY367385, 100 μM) and 3 μM AM251 was used to block cannabinoid receptor type 1. 20 μM CNQX and 50 μM D-AP5 were used to block AMPA and NMDA currents in all experiments. All data were statistically analyzed with unpaired Student's *t*-test. In the vehicle-treated hippocampal slices, postsynaptic spikes alone had no effect on eIPSC amplitude thus no DSI was induced while mGluR5 activation alone induced eIPSC suppression (postsynaptic spike alone: 120 ± 10%; n = 4, mGluR5 alone: 76 ± 11%; n = 6, $p < 0.05$). However, mGluR5 activation during postsynaptic spikes induced DSI and the eIPSC suppression was greater than that with mGluR5 activation alone (postsynaptic spike + mGluR5: 45 ± 7%; n = 5, mGluR5 alone: 76 ± 11%; n = 6, $p < 0.05$), indicating that *in vivo*-like postsynaptic spikes with the concomitant activation of mGluR5 is required to induce DSI. Application of AM251 completely blocked the DSI (postsynaptic spike + mGluR5 with AM251: 118 ± 20%; n = 4, postsynaptic spike + mGluR5: 45 ± 7%; n = 5, $p < 0.01$), indicating that our DSI depends on eCB mobilization. Interestingly, in the $A\beta_{1\text{-}42}$-treated slices, activation of mGluR5 during postsynaptic spikes failed to induce DSI induced by postsynaptic spikes and mGluR5 (Aβ: 71 ± 5%; n = 8, vehicle: 45 ± 7%; n = 5, $p < 0.05$), suggesting that $A\beta_{1\text{-}42}$ may have blocked DSI by interrupting the eCB mobilization. Together, our results suggest that the modulation of eCB mobilization could have a potential as a therapeutic target for recovering synaptic function in AD.

**Title:** Optogenetic activation of hippocampal SST-positive interneurons recovers impaired theta oscillation in Alzheimer's disease model *in vivo*

**Authors: *H. CHUNG**[1], J. KWAG[2]
[1]Korea Univer, Seoul, Korea, Republic of; [2]Dept. of Brain and Cognitive Engin., Korea Univ., Seoul, Korea, Republic of

**Abstract:** Excessive accumulation of amyloid β oligomers (Aβo) in the hippocampus disrupts hippocampal theta (3-12 Hz) and gamma (30-90 Hz) oscillation leading to learning and memory impairment in Alzheimer's disease (AD). Hippocampal somatostatin-positive ($SST^+$) interneurons are known to be involved in the generation of hippocampal oscillation and they have been reported to structurally disintegrate in AD. Thus, modulation of $SST^+$ interneurons may have a potential for recovering impaired hippocampal oscillation in AD. To directly investigate such hypothesis, we recorded spontaneous local field potential (LFP) at hippocampal CA1 region of anesthetized mice *in vivo* and $SST^+$ interneurons were selectively activated with optogenetic technique. To optically modulate $SST^+$ interneurons, light-sensitive channel (channelrhodopsin-2) virus was injected into the hippocampus of SST-Cre mice. AD mice model was created by intrahippocampal injection of 10 μM Aβo and was incubated for 3 weeks. Hippocampal oscillation was quantified by analyzing the power spectrum density (PSD) of LFP before and after light stimulation from which peak frequency and power of theta and gamma oscillation were calculated. Single unit activity was detected and sorted to analyze inter-spike interval distribution (ISId) of $SST^+$ interneurons.
We found no difference in peak frequency of theta and gamma oscillation in control mice and AD mice model. However, peak power of theta and gamma oscillation both decreased in AD mice model, similar to other studies in AD. When $SST^+$ interneurons were selectively activated with light in the AD mice model, surprisingly, the decreased peak power of theta oscillation was recovered to the level similar to that of control mice while peak power of gamma oscillation was unaffected by light stimulation. These results suggest that impaired theta oscillation can be recovered by selective activation of $SST^+$ interneurons. To further investigate how $SST^+$ interneuron spike activity was affected in AD, we analyzed ISId of $SST^+$ interneurons. ISId of $SST^+$ interneurons of AD mice model was exponentially decayed from peak at 4 ms, however, light stimulation recovered ISId similar to that of control mice, showing bell curve with peak at 50 ms, indicating that temporal spiking pattern of $SST^+$ interneurons affected by Aβo can also be recovered by light stimulation of $SST^+$ interneurons. Our results demonstrate that theta oscillation impairment in AD mice model could arise from altered spiking activity of $SST^+$ interneurons, suggesting that modulating $SST^+$ interneuron activity could have a potential for therapeutic target for recovering hippocampal oscillation in AD.

**Title:** P2X2R overexpression induced by chronic SOAβ treatment, produces changes in the subcellular distribution of fe65 and potentiates the amyloidogenic processing of APP

**Authors: D. MENNICKENT**[1], T. SILVA-GRECCHI[1], P. A. GODOY[1], O. RAMIREZ-MOLINA[1], A. CASTRO[2], J. GAVILAN[1], J. PANES-FERNANDEZ[1], G. MORAGA-CID[1], *J. FUENTEALBA[3]
[1]Physiol., [2]Biochem., [3]Univ. de Concepcion, Concepcion, Chile

**Abstract:** Soluble oligomers of amyloid beta peptide (SOAβ) have been considered as central factors in Alzheimer's disease (AD). Aβ peptide is generated through the sequential cleavage of the amyloid precursor protein (APP), a process that requires the previous endocytosis of APP and that can be modulated by the multidomain adaptor protein Fe65. This protein is able to regulate the transcription of key genes directly related to AD pathogenesis, encoding proteins like APP and BACE 1. On the other hand, we have described that chronic SOAβ treatment induces an increase in the expression of the P2X2 purinergic receptor in PC12 cells and rat hippocampal neurons. Additionally, it has been described that the P2X2a isoform has an intracellular domain that can interact with Fe65, a segment which is absent on the P2X2b isoform. Using mice hippocampal neurons chronically treated with SOAβ (0.5 μM), and patch clamp experiments (voltage clamp), we found that SOAβ treated cells displayed an increase in evoked ATP currents (C: 100 ± 50%; SOAβ: 231 ± 70%; n=9). Additionally, immunocytochemistry (ICC) experiments demonstrated that these cells exhibited an increase in their P2X2R immunoreactivity (C: 100 ± 1 %; SOAβ: 149 ± 15%; n=5). Moreover, cells treated chronically with SOAβ showed a reduction in the Fe65 nuclear-cytoplasmic (N-C) ratio (C: 100 ± 6%; SOAβ: 80 ± 4%; n=5). A similar behavior was observed in PC12 cells transfected to express the P2X2a isoform, but not in those transfected with P2X2b (C: 100 ± 5%; P2X2a: 70 ± 6%; P2X2b: 95 ± 6%; n=3). Colocalization analyses demonstrated that SOAβ decreased the colocalization of Fe65 with APP (C: 100 ± 17%; SOAβ: 47 ± 12%; n=5); results that correlate with the increase observed in the colocalization of APP with clathrin (C: 100 ± 8%; SOAβ: 127 ± 8%; n=4) and Rab5 (C: 100 ± 6%; SOAβ: 132 ± 16%; n=5). In conclusion, these results suggest that chronic SOAβ treatment promotes the endocytosis of APP, potentiating its amyloidogenic processing. Additionally, we propose that P2X2R overexpression promotes Aβ generation by inducing changes in the interaction between Fe65 and APP, resulting in the potentiation of SOAβ chronic toxic effects.

**Abstract:** Alzheimer’s disease (AD) is a progressive neurodegenerative disorder that is caused by the accumulation of amyloid plaques. Formation of amyloid plaques depends on beta-amyloid (Aβ) production and clearance; impaired Aβ clearance has been implicated in late-onset AD. However, underlying mechanisms are not fully understood. Here, we found that Aβ deposition was increased in 5xFAD mice lacking low-density lipoprotein receptor-related protein 4 (Lrp4), a member of the LDL receptor family. Neuronal inflammation, synaptic dysfunction, and cognitive deficits in 5XFAD mice were exacerbated by Lrp4 deficiency. However, Lrp4 mutation did not affect Aβ production or blood-brain barrier (BBB) integrity. Lrp4 was mainly expressed in astrocytes in the brain and could interact with Aβ and ApoE. Lrp4 mutant astrocytes were impaired in Aβ uptake and degradation. Together, our findings reveal a critical role for astrocytic Lrp4 in Aβ metabolism and a potential pathological mechanism of AD development.

**Title:** Organotypic hippocampal slice cultures as tools to investigate mechanisms of presynaptic disruption in sporadic and familial Alzheimer's disease models

**Authors: *C. DURRANT**, O. SHEPPARD, M. P. COLEMAN
Clin. Neurosciences, Univ. of Cambridge, Cambridge, United Kingdom

**Abstract:** Loss of presynaptic proteins in the hippocampus is an early and clinically-relevant alteration in the brains of patients with Alzheimer's disease (AD). Long term organotypic hippocampal slice cultures (OHSCs) from neonatal amyloid mice provide an excellent platform to examine mechanisms of synaptic disruption, largely retaining the cellular composition and neuronal architecture of the *in vivo* hippocampus, but with *in vitro* advantages of accessibility to live imaging, sampling and intervention.
OHSCs were made from P6-P9 wild-type, TgCRND8 or APP NL-G-F knockin mice and maintained in culture for up to 2 months. Transgenic cultures were monitored for spontaneous pathology development and the mechanisms behind presynaptic disruption were probed via pharmacological manipulation of Aβ production and genetic knockdown of tau. Wild-type cultures were treated with a battery of environmental factors associated with risk of sporadic AD, such as pro-inflammatory compounds, and assessed for AD-related pathological changes.
In both TgCRND8 and APP-knockin OHSCs there is a progressive accumulation of intra-axonal Aβ. In TgCRND8 cultures, this correlates with a decline in presynaptic proteins and alterations in mRNA levels for synaptic proteins. Beta-secretase inhibitor abolished accumulation of $A\beta_{1\text{-}42}$ but surprisingly did not rescue synaptophysin levels. This raises the question of whether BACE1-independent APP products, or APP overexpression as in Down syndrome and APP duplication patients, underlie some synaptic defects. Elucidation of any synaptic changes in the APP-knockin model is ongoing, providing an effective experimental system to test this hypothesis. LPS or IL1β treatment of wild-type slices resulted in a significant loss of synaptophysin protein, similar to that seen in the TgCRND8 model.
OHSCs represent an important new system for understanding mechanisms of presynaptic disruption in AD. Comparison between genetic and sporadic models of AD may help identify common pathways to target for therapeutic intervention. Future work will examine mechanisms resulting in synaptophysin depletion, particularly in relation to the involvement of tau, relative contribution of APP overexpression and mutations, as well as alternative APP processing products.

**Abstract:** It is widely known that the toxic effects of the beta-amyloid soluble oligomers (SO-Aβ) are central on the pathogenesis of the Alzheimer Disease (AD). In our group, it has been demonstrated that SO-Aβ have the capability to form pores in the cell membranes, allowing the flux of cations (such as calcium) and big molecules, for example ATP. We have shown that the formation of the amyloid pore causes a leakage of ATP on rat hippocampal neurons and cell lines. ATP is able to activate a family of receptors known as the P2X receptors (P2XR). We have demonstrated that after chronic treatment with SO-Aβ, the P2X2 receptor increases its functional expression. On the other hand, Calmoduline/Kinase II α (CAMKIIα) is a serine/threonine kinase, which, upon activation, phosphorylates itself on the T286 residue, granting it with autonomous activity that allows it to participate in the synthesis and liberation of neurotransmitters, microtubule assembly dynamics, ionic channels modulation, synaptic plasticity, amongst others. In neurodegenerative processes such as AD, there is a decrease in the active form of CAMKIIα (pCAMKIIα), and also a redistribution from the synaptic zone to the perinuclear area, which accompanies the impairment of the neuronal network. The aim of this work is to evaluate the impact of the calcium dyshomeostasis/overload induced by P2X2R overexpression on the activation and localization of CAMKIIα, in the context of AD. Using molecular biology techniques, we observed that after chronic SO-Aβ treatments, mice hippocampal neurons showed an increase on the levels of P2X2R compared to the control cells (C: 100.0 ± 6.4%; SOAβ: 130.1

± 10.7%, n=5). This was correlated with increased $Ca^{2+}$ signal evoked by ATP (C: 100.0 ± 12%, SOAβ: 194 ± 24%, n=4). Immunocytochemistry approaches on mice hippocampal neurons, showed that the overexpression of P2X2R induced changes on the immunorreactivity pattern of pCAMKIIα (in soma and neurites), which induced alterations on the cells morphology, and electrophysiological recordings assessed by Sholl Analysis and Patch Clamp, respectively. These results suggest that P2X2R overexpression can potentiate the toxicity of SO-Aβ, due to the chronic $Ca^{2+}$ overload and inactivation of CAMKIIα, and thus, altering the mechanisms of neuronal plasticity, the basis of the pathophysiological mechanism of AD.

**Title:** Beta-Amyloid effects on synaptic and oscillatory activity in the CA3-CA1 circuit of the hippocampus

**Authors: *C. E. GAUTHIER**[1], M. O. NAVA[2,3,6], J. M. MUÑOZ[4], M. A. VALEDERRAMA[6], F. A. MÚNERA[5]
[2]Med., [1]Univ. Del Rosario, Bogotá D.C., Colombia; [3]Medecine, [4]Biol., [5]Med., Univ. Nacional, Bogotá D.C., Colombia; [6]Biomed. Engin., Univ. de los Andes, Bogotá D.C., Colombia

**Abstract:** Recent evidence suggests that, in early stages of Alzheimer´s Disease (AD), soluble Aβ induces an imbalance between glutamatergic and GABAergic neurotransmission systems resulting in the functional impairment of neural networks. Such alterations are particularly important in the hippocampus where learning and memory processes take place depending on accurate oscillatory activity tuned via the fimbria/fornix complex.
**Aim**: to evaluate the effects of soluble Aβ variants (25-35 and 1-40) on excitability, synaptic plasticity and oscillatory activity in the hippocampal CA3-CA1 synapse.
**Method**: the acute effects of Aβ were studied in anesthetized rats after intrahipocampal injection. A microelectrode with injection cannula was placed for field excitatory postsynaptic potentials (fEPSP) recording in CA1. A stimulating electrode was placed in CA3. Once stablished the input-output (I/O) relationship of the preparation, stimulus intensity necessary for evoking ~50%

(I50) of the maximal response was selected for evaluating short- and long-term plasticity.
**Results**: it was found excitability reduction after Aβ injection compared with controls (inverse Aβ 35-25). After HFS (100-μs, I50 intensity, 100-Hz, 600 pulses) LTP impairment was found in Aβ-injected subjects. Spectral variations (theta and gamma band) during the processing of synaptic stimuli were characterized, finding that the observed phase modulation reversal after LTP induction was reduced after Aβ administration.
**Conclusion**: Aβ-induced synaptic plasticity and excitability impairment in the hippocampus is associated with lack of phase modulation reversal triggered by HFS. Therefore, we confirm that soluble Aβ impairs neural network activity. This new analysis approach is a useful model for understanding the physiopathology of early AD.

**Title:** Region- and circuit-specific changes in somatostatin and parvalbumin interneuron networks in novel Alzheimer’s disease mouse models: Insights into seizure-induced circuit remodeling

**Authors: *J. J. LAWRENCE**[1,2], R. WANG[1], B. HOANG[1,3,4]
[1]Dept. Pharmacol. and Neurosci., [2]Ctr. for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [3]Dept. Chem. and Biochem., [4]Honors Col., Texas Tech. Univ., Lubbock, TX

**Abstract:** Dysfunction of GABAergic inhibitory interneuron circuits is implicated in early stages of Alzheimer’s Disease (AD) pathogenesis. Two major classes of inhibitory interneuron classes, parvalbumin (PV)-positive and somatostatin (SOM)-positive classes, exhibit differences in function and connectivity, yet their contributions to hippocampal-dependent memory impairment in AD are poorly understood. In addition, both PV and SOM subtypes contribute to the maintenance of excitation-inhibition balance, yet it is not clear how impairment of PV and SOM circuits in AD disrupts excitation-inhibition balance and contributes to seizure susceptibility. Knowledge of which specific hippocampal PV and SOM interneuron subtypes are

most vulnerable to during AD remains poorly understood. In this study, we investigated the differential contributions of specific PV and SOM circuits to the etiology of AD using the J20 mouse transgenic model that overexpresses a mutant form of human amyloid precursor protein (hAPP). To enable PV or SOM circuits to be visualized during AD pathogenesis, we created homozygous PV-CRE;tdTomato and SOM-CRE;tdTomato mouse lines in which the red fluorescent protein tdTomato is driven by the PV or SOM promoter, and subsequently crossed them into heterozygous J20 AD mice. We then investigated alterations in the number, laminar distribution, and axonal connectivity of distinct PV- or SOM- interneuron subtypes in heterozygous J20 mice by comparing quantitative changes in tdTomato intensity to their age-matched wild-type (WT) sibling littermates. In preliminary experiments, we found a 2-5 fold reduction in PV-CRE/;tdTomato expression in all layers of the hippocampus of 7-month-old J20 AD mice. However, this reduction was both region- and layer-specific; the loss of tdTomato fluorescence was more profound in CA3 stratum radiatum and CA1 stratum pyramidale layers, specifically implicating dysfunction of dendritically targeting PV subtypes in CA3 and PV basket cells in CA1. In contrast, tdTomato intensity was generally increased in the hippocampus of SOM-CRE;tdTomato;J20 mice. The most striking difference was a 22-fold increase of tdTomato intensity concentrated in the inner molecular layer of the dentate gyrus (DG). This observation is consistent with compensatory SOM/NPY circuit remodeling accompanying the epileptic phenotype of the J20 mouse. Our study provides novel insights into differential alterations of PV and SOM circuitry during AD pathogenesis. This work will advance knowledge that will lead to new treatment strategies for GABAergic subtype-specific vulnerabilities in AD.

**Title:** Is synaptic plasticity in the ventral dentate gyrus more sensitive to Alzheimer's pathology than in the dorsal?

**Authors: *A. SCHREURS**, D. BALSCHUN
Brain & Cognition, KU Leuven, Leuven, Belgium

**Abstract:** Alzheimer's disease (AD) is the most common neurodegenerative disorder, but a cure is still lacking. Since many clinical trials that targeted late pathological phases have failed and a preventive strategy would be of most therapeutic interest, the field is increasingly focusing on early AD stages. These preclinical phases are linked with synaptic deficits and can be modelled in transgenic mice expressing Alzheimer-associated mutated human genes. An integral part of synaptic function and fundamental process underlying learning and memory formation, is synaptic plasticity. It is commonly studied using sensitive electrophysiological readouts, such as long-term potentiation (LTP) induced by high-frequency stimulation. Here, we examined LTP in hippocampal slices from bigenic APP(V717I) x Tau(P301L) mice that mimic both amyloid and tau pathology, the main hallmarks of AD. This model displays a rather late onset pathology, with amyloid plaques abundantly present from 10 months and tau tangles from 13 months of age in AD-relevant brain regions (Terwel et al., 2008). We have previously found LTP deficits in the medial prefrontal cortex and dorsal hippocampal CA1 region of APPxTau mice at 3-5 months of age, well before the appearance of plaques and tangles, and likely caused by oligomeric forms of amyloid-beta and/or tau. In contrast, no deficits were observed in the dorsal dentate gyrus (DG) at this age. However, the DG is important for various types of learning and memory and also affected in AD patients. In the current study, we therefore hypothesized that DG-LTP would get impaired in APPxTau mice at more advanced ages. To investigate this, we used male mice at two age groups: 6-8 months (i.e. before onset of plaques and tangles) and 14-16 months (at the final stage of full-blown pathology). Furthermore, we compared LTP from dorsal versus ventral DG slices, since we have previously reported that the ventral DG expresses much higher levels of LTP than its dorsal or intermediate counterparts, but that this dorsoventral gradient was less pronounced in aged mice (Schreurs et al., 2017). In line with this apparently higher sensitivity of the ventral DG to age-related processes, we found in the current study that LTP was impaired in the ventral, but not dorsal DG of 6-8 months old APPxTau mice. Yet surprisingly, the ventral DG-LTP deficit seemed to be completely restored again in the oldest age group (14-16 months). Our findings add a new facet to the increasing evidence for dorsal-ventral differences in hippocampal function, but the complex mechanisms underlying the region- and age-dependent differences in DG-LTP remain to be elucidated.

**Title:** Amyloid-beta oligomers inhibit the expression and function of acid-sensing ion channel 1a

**Authors: *T. LENG**, R. ZHOU, Z.-G. XIONG
Neurosci. Inst., Morehouse Sch. of Med., Atlanta, GA

**Abstract:** Alzheimer's disease (AD) is a common neurodegenerative disease characterized clinically by progressive impairments in learning/memory and neuronal loss. Although the exact mechanism underlying the generation of AD remains to be determined, accumulation of the amyloid-β (Aβ) peptide 1-42 and the formation of extensive plaques have been suggested to be the primary event leading to the progress of the disease. Lines of evidence also suggest that the memory deficit can be caused by diffusible oligomeric assemblies of Aβ1-42. However, how exactly diffusible Aβ1-42 causes synaptic dysfunction and memory loss remains elusive. Acid sensing ion channels (ASICs) are proton-gated cation channels, which are abundantly distributed throughout the nervous system. There has been experimental evidence suggesting that activation of ASIC1a contributes to the synaptic plasticity and learning and memory. Thus, a reduced function of these channels may contribute to the impairment of leaning/memory of AD patients. In this regard, we tested the effect of Aβ1-42 on ASIC1a expression and acid-activated current in primary cultured mouse cortical neurons. Our results show that incubation with 100 nM Aβ1-42 oligomers for 3 to 7 days significantly decreased ASIC1 protein expression. In addition, the density of ASIC current was decreased dramatically. Ongoing studies will determine whether the decreased function of ASIC1a by Aβ1-42 oligomers contributes to impaired learning and memory at the early stage of AD.

**Title:** Two protein prenylation pathways differentially affect synaptic plasticity and cognitive function

**Authors: *D. A. HOTTMAN**[1], W. QU[2], W. LIU[1], L. YUAN[3], L. LI[1]
[1]Exptl. and Clin. Pharmacol., [2]Neurosci., Univ. of Minnesota, Minneapolis, MN; [3]Des Moines Univ., Des Moines, IA

**Abstract:** Prenylation is a post-translational modification that adds hydrophobic prenyl molecules to proteins and facilitates trafficking of proteins to membranes. Protein prenylation includes two processes, farnesylation and geranylgeranylation, catalyzed by farnesyltransferase (FT) and geranylgeranyltransferase-1 (GGT) or GGT-2, respectively. Prenylated proteins are involved in regulating synaptic morphology and neuronal functions. Previously we have shown that genetic manipulation of FT and GGT differently affects the pathogenesis of Alzheimer's disease (AD). Heterozygous deletion of FT ameliorated amyloid-β (Aβ) pathology, neuroinflammation, and cognitive impairment in a mouse model of AD, whereas heterozygous deletion of GGT reduced Aβ and neuroinflammation but failed to rescue cognitive deficits. Recently, we have shown that systemic GGT haplodeficient mice and forebrain neuron-specific GGT knockout out mice exhibit severe impairment in hippocampal long-term potentiation (LTP), loss of synaptic spines, and deficit in memory function. In contrast, our preliminary studies demonstrated that FT haplodeficient mice showed a similar magnitude of LTP in acute hippocampal slices comparing to their wild-type (WT) littermates. Consistent with the electrophysiology data, haplodeficient FT mice showed similar learning and memory capability and comparable anxiety levels as WT mice. These findings indicate that the two prenylation pathways mediated by GGT and FT differentially affect synaptic plasticity and cognitive function. To further assess the cellular mechanisms underlying the differences, analyses are underway for the prenylation level of FT/GGT downstream targets and the cell-type specific FT/GGT functions employing the Cre-loxP system. Results from this study will shed lights on the roles of prenylation pathways in shaping neuronal functions and provide novel insights into the pathogenesis of AD.

**Title:** Increased PSD-95 may explain why old memories are protected against Alzheimer's disease

**Authors: *K. B. DORE**, R. MALINOW
Neurosciences, UCSD, La Jolla, CA

**Abstract:** Accumulation of the amyloid-beta (Aβ) peptide has been strongly implicated in Alzheimer's (AD) but the molecular mechanisms by which it destroys synapses are poorly understood. Interestingly, the effects of Aβ on synapses can be prevented by NMDA receptor

(NMDAR) blockade. PSD-95, a major scaffolding protein at the synapse, binds directly to NMDARs and studies have shown it is significantly depleted in brain tissue of AD patients as well as in neural tissue exposed to Aβ. Given these properties of PSD-95 and the fact that its overexpression potentiates synapses, we reasoned that increased amounts of this protein might interfere with the synaptic depression produced by Aβ. Using paired patch recordings in organotypic hippocampal slices; we show that PSD-95 overexpression can potentiate synapses even in the presence of Aβ. Interestingly, in tissue from GluA1 knockout animals, PSD-95 overexpression produced no significant potentiation but still blocked Aβ induced depression. Therefore, PSD-95 overexpression prevents Aβ-induced depression independently of its ability to potentiate synaptic transmission. Because of its direct interaction with the NMDA receptor c-terminal domain (NMDAR CTD), PSD-95 could block the signaling mediated by conformational movements in the NMDAR CTD, which are required for synaptic depression (Aow, Dore and Malinow, PNAS, 2015). To test this, we measured the effect of Aβ with or without PSD-95 overexpression on the NMDAR CTD conformation with FRET-FLIM. We observed that Aβ significantly reduced the FRET efficiency between GluN1-GFP and GluN1-mCherry, indicating that the NMDAR CTD adopted a conformation that was similar to the one measured during LTD induction. PSD-95 overexpression blocked this effect suggesting that interactions between PSD-95 and the NMDAR CTD block Aβ-induced conformational movement of the NMDAR CTD, and thereby block the signaling associated with such movement that produces synaptic depression. Importantly, we find that large spines, containing increased amounts of endogenous PSD-95 are not affected by Aβ. Big spines have a similar NMDAR CTD conformation as spines not exposed to Aβ. Moreover, PSD-95 content was specifically reduced in small spines exposed to Aβ; larger spines being unaffected. In neurons from the thalamus, which is less affected in AD, we observed that PSD-95 content was not affected by Aβ. Overall, our data suggests that increased amounts of PSD-95 are protective against AD. If older memories are encoded by synapses with more PSD-95, our results may explain why such memories are protected in AD.

**Title:** Cyp46A1 overexpression induces sex-specific changes in synaptic functions in aged mice

**Authors: *S. MAIOLI**[1], P. RODRIGUEZ-RODRIGUEZ[2], M. LATORRE LEAL[1], L. FRANCHINI[3], I. BJÖRKHEM[1], P. MERINO SERRAIS[1], A. CEDAZO MINGUEZ[1]
[2]NVS, [1]Karolinska Institutet, Stockholm, Sweden; [3]Univ. of Milan, Milan, Italy

**Abstract:** Emerging evidence have shown that up-regulation of Cyp46A1 reduces levels of amyloid beta plaques, rescues cognitive decline and promotes neuroprotection in several mouse models of neurodegenerative diseases, such as Alzheimer's disease (AD). In our lab we have performed extensive studies in vivo showing a key role of 24 (S)-hydroxycholesterol (24OHC) and 27 hydroxycholesterol (27OHC) in cognitive functions.
We have analyzed the behavior of males and females Cyp46A1 overexpressing (Cyp46 Tg) mice, with high levels of 24OHC in brain and plasma. Cyp46 Tg old females showed cognitive enhancement and increased levels of synaptic proteins in hippocampus, when compared to control mice (Maioli S, 2013). Noteworthy, these results were not found in old males, where Cyp46A1 overexpression led to impairment of spatial memory and increase of anxiety like-behavior. These results were further confirmed by sex-specific differences in the morphology of dendritic spines in CA1 neurons: while Cyp46 Tg females show a significant increase in area and length of the dendritic spines, Cyp46 Tg males show significant reduction of dendritic spine density when compared to control animals.
Studies in vitro suggest that 24OHC is able to activate neurosteroid signaling and biosynthesis in neurons: these novel mechanisms proposed for 24OHC may underlie the sex-specific changes observed in vivo.
In summary, we show sex-specific effects of overexpression of Cyp46A1 in synaptic functions in vivo, where the neuroprotective effects promoted by upregulation of Cyp46A1 seems to be activated only in female mice. These findings can have great clinical impact and help to define new targets for treatment of AD and new preventive interventions specifically addressed to women.

**Title:** Elucidating an Alzheimer's disease role for SORLA-mediated neuroprotection through synaptic enhancement

**Authors: *J. STUPACK**, H. XU, T. HUANG
Degenerative Dis., Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

**Abstract:** Cognitive impairment is invariably associated with Alzheimer's Disease (AD) onset, and with the lack of effective therapies currently available, understanding mechanisms underlying AD-associated synaptic dysfunction is essential. SORLA is a genetic AD risk factor that plays a role attenuating Aβ generation through trafficking of Amyloid Precursor Protein (APP). It is currently unknown whether SORLA may have additional roles in conferring neuroprotective effects in addition to limiting amyloidogenic APP processing. Interestingly, transgenic SORLA overexpression in mice results in resistance to Aβ-dependent LTP impairment, indicating a further role for SORLA in enhancing synaptic function. This suggests that SORLA has additional roles in promoting neuronal protection. Evidence from freshwater hydrozoa (*Hydra* spp.) indicates that SORLA promotes head and limb regeneration after injury; whether SORLA confer similar effects in enhancing regeneration and outgrowth in neuronal dendrites is not known. Our results indicate that SORLA overexpression can promote neurite outgrowth and regeneration with injury in cultured neurons. Further, SORLA overexpression can enhance dendritic arbor and complexity in the hippocampus in transgenic SORLA animals. These results implicate a new role for SORLA in neuronal morphogenesis and repair. We are currently working to determine mechanisms underlying SORLA-dependent neurite outgrowth, repair, and synaptic enhancement. Given that SORLA is an AD risk factor, we will determine whether SORLA-dependent enhancement mechanisms can confer resistance to synaptic dystrophy and cognitive impairment with Aβ proteotoxicity. As SORLA likely has effects in both attenuating Aβ accumulation and mediating neuroprotective effects in neurite regeneration and synaptic function, enhancing SORLA-associated mechanisms may prove to have good efficacy in future therapeutic strategies in AD.

**Abstract:** The normal microvasculature of the brain preserves its integrity; in Alzheimer's disease (AD), Notch's cut, which is dependent on presenilin, is diminished, which prevents angiogenesis, thus affecting the normal function of the vasculature and the integrity of the brain. In this regard, it has been suggested that this pathological angiogenesis leads to the aggregation of plaques and the secretion of a neurotoxic peptide that kills cortical neurons. Angiogenesis in AD can be seen as neurovascularization, increase in capillary density, formation of vascular loops and glomeruloid structures as well as the expression of angiogenic factors. The triple transgenic murine model (3xTg-AD) develops aggregates of both Aβ and Tau, a characteristic described in the development of AD in humans. This allowed us to evaluate the effect of mutations in APP (amyloid precursor protein), Tau and presenilin (PSEN1 and PSEN2) as well as the effects of Aβ and tau accumulation in the microvasculature of these mice. Murine models for AD with mutations in APP have already described differences in microvessels such as aggregates of Aβ, hindered microcirculation, etc. In fact, some studies have used the 3xTg-AD model in which they describe a decrease in cerebrovascular volume and an increase in collagen I and IV.In this study we aimed to determine if there were changes in the microvessels at different stages of AD progression (9 and 13 months) in a triple transgenic murine model (3xTg-AD) by means of western blot analysis. We analysed the protein components of the tight junctions in the vascular system of the brain and observed the structure of the microvessels by means of photonic microscopy. We found differences between 3xTg-AD and controls in the protein composition of the microvessels as well as a decreased amount of Zo1 and occludin proteins from the tight junctions. Morphological differences were also observed in the microvessels of the animals 3xTg-AD in comparison with the WT and between the animals of 9 and 13 months, with morphological damage being more evident in the older animals.

**Title:** V-ATPase dysfunctions contribute to lysosome-autophagosome mediated proteinopathy and synaptic pathophysiology in early stages of Alzheimer's disease pathogenesis

**Authors: *S. H. MUSTALY**, N. KAPECKI, K. D. BEAMAN, A. GILMAN-SACHS, J. MCDAID, S. SCHRANK, R. A. MARR, G. E. STUTZTMANN
Rosalind Franklin Univ., North Chicago, IL

**Abstract:** Alzheimer's disease (AD) is a neurodegenerative disorder characterized by abnormal protein aggregates and synaptic deficits. The organelles that regulate these processes, such as lysosomes for protein handling, and synaptic vesicles for neurotransmission, require highly acidic microenvironments in order to function. This is maintained by a vacuolar H+-ATPase (V-ATPase) which pumps in $H^+$ ions against a concentration gradient. In lysosomes, this process is essential for autophagy, a catabolic pathway to degrade abnormal proteins; in synaptic vesicles the acidic environment is necessary for neurotransmitter uptake and synthesis. In AD, V-ATPase disruption can lead to abnormal β-amyloid and tau accumulation, and deficient synaptic vesicle stores. A concurrent mechanism with V-ATPase defects is intracellular $Ca^{2+}$ dyshomeostasis, which alters ion exchange and thus pH within these organelles. We hypothesize that altered $Ca^{2+}$ signaling disrupts V-ATPase ion exchange and instigates AD pathology. We used immunoassays and live cell imagin in model cells, induced human neurons (iN) transformed from AD patient, and AD mouse models to explore this hypothesis. Immunohistochemistry in fixed hippocampal slices from 3-month old 3xTg-AD mice revealed diminished expression of V-ATPase subunits (V1B2, V0a1), lysosomes (Lamp1), pre-synaptic vesicles (synaptophysin), and increased expression of mature autophagosomes (LC3B) relative to non-transgenic (NTg) controls. These phenotypes in 3xTg-AD were restored to NTg levels with a 30-day Ryanodex treatment (NAM of ryanodine receptor (RyR); 10mg/kg). The decreased V-ATPase expression and increased autophagosomes in 3xTg-AD mice reflects impaired lysosomal and synaptic vesicle functionality, which is mediated through upstream RyR-$Ca^{2+}$ dyshomeostasis. Live cell imaging of iN and RyR-overexpressing HEK293 cells using a lysosomal-pH indicator (LysosensorDND-160) revealed lysosomal alkalization with RyR stimulation (caffeine 10mM), suggesting that aberrant RyR-$Ca^{2+}$ signaling disrupts autophagosome-lysosome mediated protein degradation. Protein aggregates, such as β-amyloid and hyperphosphorylated tau, were increased in iN treated with 500nM bafilomycin (V-ATPase inhibitor). Expression of these protein aggregates was resolved with Ryanodex treatment. Therefore, increased RyR-mediated $Ca^{2+}$ release alkalizes lysosome pH resulting in abnormal protein aggregation. Prior to overt histopathology or cognitive deficits, abnormal $Ca^{2+}$ signaling in AD disrupts intracellular organelle function leading to altered autophagic-mediated protein clearance and synaptic pathophysiology.

**Abstract: Introduction:** It is necessary to have indicators to assess the stage of disease in order to develop disease-modifying therapy for Alzheimer’s disease (AD). In this study, to develop a system for risk assessment or early diagnosis of AD, the classification among data of normal control (NL) subjects, mild cognitive impairment (MCI) patients, and AD patients was conducted by applying machine learning methods to the Japanese Alzheimer’s Disease Neuroimaging Initiative (J-ADNI) database (accession no.: JGAS00000000051). **Method:** Machine learning methods using deep neural networks (i.e., deep learning) and support vector machines (SVMs) have been applied to the classification of clinical data with the features extracted from the J-ADNI database (number of included subjects: NL 149, MCI 231, and AD 149). Alzheimer's disease assessment scale-cognitive subscale: ADAS-cog, the clinical dementia rating: CDR, mini-mental state examination: MMSE, the global deterioration scale: GDS, and the analytical parameters from the structural MRI were used as features for the machine learning methods. The classification performance was assessed by a 10-fold cross validation. **Results:** Classification among NL subjects, MCI, and AD patients, and classification between NL and AD, were successfully classified at 93.6 ± 4.0% (n = 529, SVM) and 98.7 ± 1.7% (n = 290, deep learning) accuracy, respectively, by using four kinds of clinical and psychological tests. The NL-AD classification task was conducted at 84.2 ± 4.1% (n = 290, SVM) accuracy using only FreeSurfer analysis data from structural MRI data. **Discussion:** Almost all of the features were included in the analysis for the structural MRI data. If only the relevant features could be selected, the classification accuracy would be improved. In the future, a convolutional neural network (CNN) will be applied and an MCI conversion prediction will be investigated. **Conclusion:** Machine learning methods were successfully applied to the J-ADNI database and performance could be improved when relevant features were selected in the analysis.

**Abstract:** The deposition of the amyloid β-protein (Aβ) in senile plaques is one of the histopathological hallmarks of Alzheimer's disease (AD). Aβ-plaques arise first in neocortical areas and, then, expand into further brain regions in a process described by 5 phases. Since it is possible to identify amyloid pathology with radioactive-labelled tracers by positron emission tomography (PET) the question arises whether it is possible to distinguish these Aβ phases with amyloid PET imaging. To address this question we reassessed the end-of-life study cohort of the phase 3 [$^{18}$F]flutemetamol trial (93 autopsy cases covering all neuropathological phases of Aβ deposition) by combining the standardized uptake value ratios (SUVRs) with pons as reference region for neocortical and caudate nucleus-related [$^{18}$F]flutemetamol-retention and tested them for their prediction of the neuropathological pattern found at autopsy. By defining threshold levels for neocortical and caudate nucleus SUVRs we were able to distinguish four different levels of [$^{18}$F]flutemetamol uptake termed PET-Aβ phase estimates. When comparing these PET-

Aβ phase estimates with the Aβ phases as determined neuropathologically we found that PET-Aβ phase estimate 0 corresponded with Aβ phases 0-1(2), 1 with Aβ phases (2)-3, 2 with Aβ phase 4 and 3 with Aβ phase 5. Thus, we provide a novel method to convert SUVR levels into PET-Aβ phase estimates that correspond to the neuropathological phases of Aβ deposition. This method opens a unique chance to study amyloid pathology in living individuals with direct conclusions about the pathological correlatives and its progression and is more sensitive than visual assessment strategies. (ClinicalTrials.gov identifier NCT01165554)

**Title:** Local to remote cortical functional connectivity in Alzheimer's disease

**Authors: *H. LI**[1], Y. ZHANG[2]
[1]Inst. of Psychology, Chinese Acad. of Scienc, Beijing City, China; [2]Shanghai Mental Hlth. Ctr., Shanghai, China

**Abstract:** Previous studies reported alterations in both local and remote functional connectivity in Alzheimer’s disease (AD) patients, however, few studies investigated the local and remote

alterations in the same group of patients. In the present study, we aimed to explore whether AD patients would show abnormal local-to-remote functional connectivity in functional homogeneity. Fourteen AD patients (age: 72.21 ± 7.79, 5 males) and 23 healthy older adults (age: 74.47 ± 4.52, 11 males) were included in the current study. The data were obtained from the Alzheimer's disease Neuroimaging Initiative database (http://adni.loni.usc.edu). All of them completed structural and resting-state fMRI scanning and a standardized clinical interview and comprehensive neuropsychological assessments, which were used to provide standard measurement of participants' cognitive ability. We employed resting-state functional magnetic resonance imaging (rfMRI) connectome index, regional functional homogeneity on the 2-dimensional cortical surface, to detect full-cortex vertex-wise changes of the local rfMRI connectivity. When the changes of local functional connectivity were found, the regions were taken as seed regions to explore the remote functional connectivity in AD patients. We further investigated the correlations between alterations in local and remote connectivity and neuropsychological scores in AD patients. We found that AD patients presented decreased left posterior cingulate cortex in comparison with healthy controls. The results revealed significantly decreased remote functional connectivity between left posterior cingulate cortex and right middle cingulate cortex in AD patients. Both the local and remote functional connectivity in AD patients were negatively correlated with immediate Auditory Verbal Learning Test and immediate Wechsler Memory Scale Logical Memory score.
The remote functional connectivity in AD patients was also negatively correlated with delayed Auditory Verbal Learning Test score. The current study suggested that AD patients showed decreased local and remote functional connectivity with the surface-based regional functional homogeneity method. Both alterations in local and remote connectivity in AD patients fell in default mode network. The distance-related connectivity profiles show that the dysfunctional pattern of the decreased cortical connectivity may be a potential biomarker of patients with neurodegenerative disease.

**Title:** Brain pathology and cognitive reserve are associated with executive functioning performance, but not memory, in healthy older adults in an ADNI dataset

**Authors: *C. BAUER**, T. HAMMOND, C. BROWN, B. T. GOLD
Neurosci., Univ. of Kentucky, Lexington, KY

**Abstract: Background**: Alzheimer's Disease (AD) is a debilitating condition in which potential protective mechanisms are not well understood. Here, we sought to examine brain pathology and cognitive reserve and how they are associated with memory and executive function (EF) in both healthy aging and diseased states. More specifically, for AD pathology, we focused on structural connectivity of major brain networks, as well as biochemical analysis of the CSF, as an independent predictor. We hypothesized that AD pathology would be negatively correlated with memory and EF, particularly in impaired individuals, while the opposite effect would be observed with cognitive reserve. **Method:** Using the Alzheimer's Disease Neuroimaging Initiative (ADNI) database, we selected all 203 participants with available DTI scans at the time of this study. Participants were divided into healthy (no MCI or AD) and impaired (MCI or AD) groups. An AD pathology composite consisting of FA values of major white matter tracts, volumetric measures, and Tau over Abeta was calculated using backwards elimination of variables in SPSS to include only statistically relevant variables. Similarly, a cognitive reserve composite was calculated using this same approach, ultimately including both education and ANART scores. Dependent variables memory performance and EF were estimated from composites of neurocognitive outcome measures. The association between AD pathology/cognitive reserve and memory/EF performance was tested using the general linear model. **Results:** The AD pathology composite was negatively correlated with memory composite scores in impaired individuals ($p < 0.001$), but not in healthy older adults. AD pathology was negatively correlated with EF in both groups ($p < 0.001$, $p < 0.040$). Likewise, cognitive reserve was positively correlated with memory only in impaired individuals ($p < 0.032$), but not healthy older adults. Cognitive reserve was positively correlated with EF in both groups ($p< 0.013$, $p < 0.001$). **Conclusion:** We provide pilot data suggesting that both a brain pathology and cognitive reserve composite can separately predict memory and EF performance in impaired individuals, and EF performance in healthy older adults. These results imply that EF may be affected by clinically silent disease burden even before any diagnosis, and that cognitive reserve could be useful during this phase to reduce disease-related decline. Further work is necessary to see if cognitive reserve truly moderates this association. The preservation of networks in prodromal AD through prophylactic interventions remains critical.

**Abstract:** Alzheimer’s disease (AD) is a progressive neurodegenerative disease which symptom is a disturbance of memory and cognitive functions. Recently, many findings have been reported that both of EEG and fMRI could be useful to find differences between AD and elderly controls. In this study, resting - state EEGs were recorded for 6 patients with AD and 6 elderly controls, and BFCNs (brain functional connectivity networks) were constructed, where connectivity between any pair of electrodes was quantified by synchronization likelihood (SL). We constructed BFCN of AD patients with control SL value of 1, for six frequency bands (Fig.1). When AD average SL value of AD for each node pair, was lower than that of the control, the color of the edge was defined to be blue, while, if AD SL value is higher, red was assigned. The AD-BFCN connections, comparing with those of elderly controls, were strong on frontal (Fp1-Fp2) and parieto-occipital (P3-Pz-O1-O2) in lower α, upper α,β,θ and γfrequency bands. Thus, AD might be characterized by disconnection between frontal and parieto-occipital networks.

**Title:** Functional connectivity of the entorhinal cortex in young adults predicts spatial distribution of tau in cognitively normal older adults

**Authors: *J. N. ADAMS**[1], A. MAASS[1,2], T. M. HARRISON[1], W. J. JAGUST[1,3]
[1]UC Berkeley, Berkeley, CA; [2]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany; [3]Lawrence Berkeley Natl. Lab., Berkeley, CA

**Abstract: Background:** Because the entorhinal cortex (ERC) is the initial site of tau deposition in aging and Alzheimer's disease, its connectivity may drive the location of tau deposition. We therefore examined patterns of functional connectivity with the ERC in young adult (YA) subjects to predict the spatial distribution of tau deposition in cognitively normal older adults (OA).
**Methods:** fMRI was performed on 24 YA (27±4 yrs, 10 females) during both resting-state and an encoding task. Using an ROI of the ERC, seed-to-voxel correlations were performed separately for resting-state and encoding (correct trials) within each hemisphere. Regions of significant connectivity for each condition ($p$<0.001 uncorrected) were used to create masks for subsequent analyses. In 112 OA (76±6 yrs, 67 females), we quantified tau with [18F] AV-1451 PET and amyloid-β (Aβ) with [11C] PiB. Suprathreshold tau voxels (SUVR >1.31) were defined as 2 SDs above a group mean cortical value. OA subjects were divided into Aβ- ($n$=65) and Aβ+ ($n$=46) groups based on global PiB uptake.
**Results:** ERC functional connectivity patterns derived from YA were similar during resting-state and encoding (Fig 1A,B; Dice coefficient = 0.49), and included temporal, retrosplenial, and medial frontal regions. The proportion of suprathreshold tau voxels was significantly higher within versus outside the ERC connectivity masks for both Aβ- and Aβ+ OA (Fig 1C; $p$<0.001). Within the masks, mean YA functional connectivity strength in a voxel was positively associated with the mean difference in tau SUVR between the Aβ+ and Aβ- groups for resting-state ($r$=0.39) and encoding ($r$=0.25, $p$s<0.001; Fig 1D).
**Conclusions:** Within regions of significant functional connectivity with ERC in YA, tau SUVR values were more likely to be high in OA, with a stronger effect in Aβ+ OA. Connectivity strength also predicted the spatial pattern of differences in tau deposition between Aβ- and Aβ+ OA. These results indicate that ERC functional connectivity patterns in YA are associated with tau deposition in OA, and this relationship may further be related to the presence of Aβ.

**Title:** Vitamin D deficiency and temporal lobe morphology associated to visual memory in healthy young people

**Authors: *K. KUNITOKI**[1], H. TAKEUCHI[2], R. KAWASHIMA[3], Y. TAKI[4]
[1]Dept. of Nuclear Med. and Radiology, Tohoku Univ. IDAC, Sendai-Shi, Japan; [2]Tohoku Univ, IDAC, Sendai, Japan; [3]IDAC, Tohoku Univ., Sendai, Japan; [4]Tohoku Univ., Sendai, Japan

**Abstract:** - Introduction: Vitamin D deficiency is reported to increase the risk of Alzheimer's disease. Various effect of Vitamin D on central nervous system assumed (ex. immunomodulation calcium homeostasis and antioxidant). Though underlying mechanisms have been still unclear, previous studies showed cognitive decline and executive dysfunction in those who with vitamin D deficiency, and visual memory were reported to be lower among memory task. Therefore, this study aimed to reveal neural basis of the relationship between cognitive decline and lower vitamin D status. - Method: We used 3T brain MRI and blood data from 294 healthy Japanese participants aged 19 to 27. We obtained informed consent from all the subject, and obtained approval from our local ethical committee. Plasma vitamin D level was measured using ELISA method (25(OH)-Vitamin D direct day ELISA, Immundaignostik AG). 48 participants were in vitamin D sufficiency (more than 50 nmol/l) and 160 in deficiency(less than 30 nmol/l). Then, we picked these 208 participants and compared regional gray matter volume (left and right fusiform gyrus) of these two groups. There were no significant difference in age, sex, BMI and total brain volume between the two groups. T1-weighted MR images were analyzed using the Statistical Parametric Mapping 12 (SPM12), and voxel-based morphometry (VBM) analysis was conducted using the diffeomorphic anatomical registration through exponentiated lie algebra (DARTEL) procedures with 8-mm smoothing. MarsBar was used in ROI analysis with AAL brain atlas. - Results: There were no significant difference in the sufficient and the deficient group in whole brain analysis. In region-of-interest analysis, The right fusiform gyrus were significantly smaller in the deficient group than the sufficient group (corrected P=0.049). Left fusiform gyrus were not significantly different, however, there are tendency to smaller volume in the deficient group than the sufficient group (corrected P=0.081). - Conclusion: We revealed the smaller bilateral fusiform gyrus in the vitamin D deficiency group compared to the vitamin D sufficiency group. The fusiform gyrus is known as center of visual recognition. Therefore, lesser volume in this region may be a neural basis in lower visual memory in vitamin D deficient people. This result would be helpful to further analysis on the relationship between vitamin D and Alzheimer's disease.

**Authors: *P. G. UNSCHULD**[1], C. SCHROEDER[2], J. VAN BERGEN[2], S. J. SCHREINER[3], L. VIONNET[4], V. TREYER[5,2], A. BUCK[5], P. KAUFMANN[5], R. M. NITSCH[1,2], K. P. PRUESSMANN[4], C. HOCK[1,2]
[1]Psychiatrische Uniklinik Zürich, Zuerich, Switzerland; [2]Inst. for Regenerative Med., Univ. of Zurich, Zurich, Switzerland; [3]Univ. of Zürich, Zürich, Switzerland; [4]Inst. for Biomed. Engineering, Univ. of Zurich and ETH Zurich, Zurich, Switzerland; [5]Dept. of Nuclear Medicine, Univ. Hosp. Zurich, Zurich, Switzerland

**Abstract: Background:** Alzheimer's disease (AD) includes a decade long preclinical phase during which beta-amyloid (Aβ) progressively accumulates. This study investigated old-aged, non-demented adults for a relationship between hippocampal substructure-volumes, cortical Aβ burden and episodic-memory (EM) performance within the normal range. **Methods:** 61 nondemented old-aged adults (mean age: 70.23(SD 6.52) years) were administered a T1-weighted MP2RAGE sequence (TR/TE = 4.8 ms/2.1 ms, voxel size = 0.6mm$^3$) on a Philips 7-Tesla Achieva whole-body scanner (32-channel receive coil). 11C-PiB-PET and 18F-Flutemetamol-PET were used for dichotomization of the study population ("high-" versus "low-Aβ ") by standard SUVR positivity-cutoff. The Verbal Learning and Memory Test (VLMT), was used for dichotomization of the study group in high- versus low EM. FreeSurfer (V6.0) was used for assessing volumes of hippocampal subfields. Alpha was adjusted by FDR. **Results:** When performing a multiple Analysis of Variance (MANOVA), Mahalanobis distances indicated most distinguished effects on variation of hippocampal subfield volumes for coexistent criteria "high-Aβ" and "low EM" ($\lambda$=0.34, $p$=0.039). Secondary analysis indicated a significant interactive effect between Aβ and EM for the subiculum (F(1, 57) = 5.90, $p$=0.018). Volume of the subiculum was significantly lower in subjects with high- Aβ" and low EM compared to the rest of the study popualtion (F(1, 59) = 16.8, $p$=0.002). **Discussion:** Our findings are consistent with earlier reports that aging-related hippocampal pathology may manifest first by atrophy of the

subiculum. In addition, our data suggest that subicular volume might represent a surrogate marker for Aβ-burden related variation in episodic memory at high age.

**Abstract: Background:** A simple, accessible and inexpensive approach to identify amyloid positive subjects at or before the earliest stages of cognitive impairment could dramatically transform the design and execution of clinical trials evaluating new therapies for Alzheimer’s disease (AD) by greatly reducing cerebral PET amyloid imaging-related expenses, and could also be clinically useful for screening purposes. In this study, a non-invasive retina (an extension of the central nervous system) imaging approach with the Metabolic Hyperspectral Retinal Camera requiring no amyloid-labeling agent is evaluated as a mean to identify biomarkers correlating with the cerebral load of amyloid plaques determined with PET.**Methods:** The cohort (n=45) included probable AD cases (n=16) and age-matched controls (53 to 85 years) with no retinal diseases nor significant ocular media opacity. Hyperspectral retinal measurements were

obtained at 450-900 nm. Image texture analysis of the spatial/spectral dimensions in segmented retinal vascular areas allowed extraction of 16 different statistical measures. A classifier was trained using 112 datasets (1-3 per subject) to establish the predictive value of those texture features, based on the cerebral amyloid status determined from binary reads by a panel of 3 expert raters on $^{18}$F-Florbetaben PET studies. A leave-one-out approach determined the sensitivity and specificity values of the method. Other vascular metrics such as vessel tortuosity and diameter were also evaluated in the retinal images for possible correlation with the cerebral amyloid status.**Results:** Consistent with literature reports, 2/16 clinically probable AD cases were amyloid negative, while 5/29 cognitively normal subjects were amyloid positive. Excellent retinal scanning correspondence with PET amyloid status was achieved, independently of cognition, when texture features extracted from the principal retinal vessels were used, with sensitivity and specificity values of 84% and 86% respectively. The arteriolar diameter and the arteriovenous ratio were found to be statistically different between the amyloid negative and positive subjects, but not between AD and control cases. **Conclusions:** The developed machine learning approach, based on a non-invasive hyperspectral retinal imaging technique which does not require amyloid labeling, shows promise in predicting cerebral amyloid PET status and could serve as a screening tool to identify subjects in the early stages of the AD continuum, for instance in a drug development context. We are currently testing this approach and other retinal measures in additional subjects.

Radiology, Massachusetts Gen. Hosp., Charlestown, MA

**Abstract:** Cortical thinning in the temporal neocortex (TNC) has been linked to decreases in cognitive ability both in preclinical and clinical Alzheimer's disease (AD), and may be an early biomarker for cognitive vulnerability (1,4). While the TNC has a notoriously similar cytoarchitecture, few studies have evaluated the TNC histologically to establish more precise markers for neuroimaging tools. We aimed to establish the relative layer thickness histologically in Brodmann areas (BA) 36, 20, 21, and 22 in n=4 post mortem brain samples. The samples ranged in age from 45-82 years, 3 male/1 female and all were cognitive controls at death. Each TNC block was sectioned coronally at 50 μm and stained for Nissl. For each brain sample, data collection was based on three histological slices approximately 250 μm apart, which were then digitized using a Nikon microscope and Stereo Investigator software (MBF Bioscience). The stained and digitized TNC images were loaded into Freeview (Freesurfer) and the layers were labeled using the point set tool (pial surface to gray white matter boundary). The Laplace equation was applied using the line profile tool, and layer thickness measurements (mm) were computed (3). All BA measurements were restricted to the crown of each gyrus (no sulci were sampled) for consistency. The absolute measures were averaged, and all data are presented as a relative cortical thickness, as a percentage of the whole cortical thickness (2) to avoid tangential bias of each section. An ANOVA was performed using JMP (SAS Institute) with the relative thickness as the dependent variable and the case ID, BA and layer as the independent variables. The results showed that the thickness of the lamina differed significantly from one another but the thicknesses did not differ across BA 36, 20, 21, and 22 or among cases. The averages for the relative thickness for the layers were layer I (8%), layer II (8.4%), layer III (27%), layer IV (10%), layer V (24%) and layer VI (22%). Layer IV showed the least variability in cortical thickness and the pyramidal layer III was the thickest layer. The cytoarchitectural differences among these BAs were subtle: dark chromophilic neurons in layer II and closely apposed layers V and IV in area 36, chromophilic layer IIIb in area 20, layers II and IV appear band-like within area 21, and columnar organization dominates area 22. Using ground truth histology as the basis, these results about laminar differences within the TNC may ultimately create more specific measures for cortical thickness in neuroimaging tools to disambiguate the heterogeneity of AD.

**Title:** Brainstem structural integrity in the progression of Alzheimer's disease

**Authors: *S. DUTT**, Y. LI, D. A. NATION
Psychology, USC, Los Angeles, CA

**Abstract:** Prior research has established specific nuclei of the brainstem, namely the locus coeruleus and the dorsal raphe nucleus, as the earliest sites of tau pathology in Alzheimer's disease (AD). However, few studies have examined the utility of brainstem structural magnetic resonance imaging (MRI) in predicting dementia risk, nor have they related brainstem volumes to AD biomarkers or cognitive outcomes. The present study compared brainstem, midbrain, and pons volumes across the spectrum of neurocognitive decline and AD biomarker abnormality, examined neuropsychological profiles linked to these regional brainstem volumes, and investigated their predictive value for future dementia. Alzheimer's Disease Neuroimaging Initiative (ADNI) participants (N = 1677) classified as cognitively normal (CN), mild cognitive impairment (MCI), or AD underwent baseline MRI scanning, cerebrospinal fluid (CSF) lumbar puncture, and neuropsychological testing with clinical follow-up (6-120 months). T1-weighted structural images were segmented to obtain volumes of the whole brainstem, midbrain, and pons. Two neuropsychological tests from each of three domains of cognition (memory, attention/executive function, language) were examined. Levels of CSF $A\beta_{1-42}$ and phospho-tau classified individuals as biomarker-positive or biomarker-negative. One-way analyses of covariance, with age, sex, and education as covariates, tested group differences in neuropsychological and neuroimaging variables, and proportional hazards survival analyses via Cox regressions assessed risk for progression to dementia. We observed significantly smaller brainstem and midbrain volumes in AD and MCI patients relative to CN, with no difference in pons volumes. Among CN individuals, those who never progressed to dementia exhibited larger baseline brainstem and midbrain volumes, and larger baseline midbrain volume conveyed

decreased risk of progression to AD. CN older adults who were AD biomarker-positive also showed larger brainstem, midbrain, and pons volumes relative to those who were biomarker-negative. Among MCI patients, larger brainstem volumes correlated with better neuropsychological performance. Findings demonstrate reduced brainstem volume in MCI and AD compared to CN, and implicate whole brainstem and midbrain volume in risk for future dementia in preclinical populations. These volumetric differences early in the AD process are consistent with neuropathological findings of AD-related pathology first appearing in specific brainstem nuclei. Brainstem volumes may thus be an independent biomarker for identifying preclinical individuals at risk for dementia.

**Title:** Neural basis for preservation of musical memory and effects on functional intra network connectivity in early Alzheimer’s disease and mild cognitive impairment

**Authors: *M. H. THAUT**[1], T. A. SCHWEIZER[2], M. LEGGIERI[3], N. CHURCHILL[2], L. FORNAZZARI[2], C. FISCHER[2]
[1]Music and Hlth. Sci. Res. Collaboratory, Univ. iof Toronto, Toronto, ON, Canada; [2]Keenan Biomed. Res. Ctr. St. Michael's Hosp., Toronto, ON, Canada; [3]Inst. for Med. Sci., Univ. of Toronto, Toronto, ON, Canada

**Abstract:** OBJECTIVE AND RATIONALE. Recently emerging clinical behavioral research offers evidence that musical memories and associated autobiographical responses are preserved longer than other memories in Alzheimer’s Disease (AD). However, there is little research on the potential of music based interventions (MI) to therapeutically enhance cognitive functions in AD. There are also no studies examining the neural mechanisms underlying preserved musical memories or the potential impact of MI on brain function in AD. Therefore, the study aims were (A) to identify differences in musical memory networks (MMN) processing long-term familiar music (LTM, +20 years) vs . briefly familiar music (BFM, first listening 60 min before fMRI) for potential sparing mechanisms for MMN during the disease process, and (B) to examine if 3 weeks of structured daily listening can modify resting state functional connectivity with the MMN and cognitive measures.
METHODS. Twenty persons (10 musicians M+, 10 non-musicians M-, aged 65+) with early AD or MCI underwent brain scanning (fMRI) alternately listening to LTM vs. BFM. After a 3 week

daily listening protocol a post test scan was given to analyze functional intra network connectivity during resting state. Prior to first scan and second scan cognitive tests were administered (MOCA).
RESULTS. A MMN common for both conditions was found in left cerebellum, bilateral temporal lobes, left IFG, right basal ganglia, and bilateral superior marginal gyrus (voxel strength $p < .005$ during music listening for inclusion in MMN). LTM showed statistically significant additional bilateral and extensive activations including bilateral cerebellum, putamen, posterior cingulate, IFG, precentral gyrus, and SMA. The M+ group showed higher functional intra network connectivity at first scan, whereas the M- group showed greater average increases during resting state at post test. Cognitive measures improved but nonsignificantly.
CONCLUSION. LTM activates potential sparing mechanisms for MMNs and associated memory functions in an extensive bilateral network of prefrontal, emotional, motor, auditory as well as subcortical regions (cerebellum , putamen, limbic structures). The activation of extensive additional bilaterally distributed neural tissue, and engagement of subcortical regions may offer structural and functional cues why long-term MMNs may at least initially 'survive' biomarker development in AD and MCI. Furthermore, a short MI can alter functional brain connectivity in AD with a particular advantage for M- which may be relevant for therapeutic considerations of helping sustain or boost cognitive functions in AD and MCI.

**Abstract:** Cerebral microbleeds (CMB) are small foci of blood products, best seen using magnetic resonance imaging (MRI) techniques sensitive to iron deposits (*i.e.*, gradient-echo

(GRE) T2*-weighted and susceptibility-weighted imaging), frequently encountered in small vessel disease (SVD) and also in other central nervous system disorders including Alzheimer's disease (AD). Among available pulse sequences, T2*-weighted (GRE) MRI lacking the 180° refocusing pulse characteristic of spin-echo (SE) or fast-spin echo techniques is highly sensitive to the susceptibility effect. Notably, the areas of low intensity that appear on T2*-GRE images are larger than the corresponding hemosiderin deposits, representing the so-called "blooming" effect. It is important to note that because extent of blooming varies with MRI parameters, the size of the measured signal void will depend on factors beyond the size of the corresponding histopathological CMB. The MRI factors of greatest influence on CMB detection are pulse sequence, sequence parameters, spatial resolution, magnetic field strength and post-processing. The potential effect of these factors on microbleed conspicuity and detection is important to take into consideration. Here, we developed a high-resolution 3D-T2*-GRE sequence for both *in vivo* and *ex vivo* rodent brain imaging at 7 and 11.7T to detect microbleeds in mouse models of AD (*5xFAD*) and SVD ($Col4a1^{+/G498V}$). We also developed a user interface module allowing regional CMB quantification (*i.e.*, number and size per brain region). We first validated our software by cross-comparison MRI-histology (*i.e.*, Prussian Blue staining) in 1-month-old $Col4a1^{+/G498V}$ mice developing hundreds of microbleeds throughout the pons, thalamus, cerebellum and olfactory bulb. It is of note that we found an averaged 75% microbleed-size overestimation due to "blooming" effect. This proposed MATLAB gui works by thresholding 3D-MR datasets and creating a binary mask disguising voxels that are considered iron-containing voxels from those that are not. A breadth first search algorithm is then implemented on this binary mask, counting not only the number of microbleeding events, but also the size and shape of each bleed. Finally, we are currently optimizing our software by adding sublevels of quantification (including susceptibility-shape analysis) to distinguish between microbleeds and other superparamagnetic signals potentially coming from amyloid brain depositions, vessel calcifications and atherosclerotic plaques.

**Abstract:** In recent years significant research is directed to finding novel methods to detect subtle alterations among genetically at risk population for developing Alzheimer's Disease (AD), in presymptomatic stages. Understanding whether there are measurable alterations that can be used as early markers will open a time window for intervention and prevention. The current study aims to identify potential cognitive and neural alterations among healthy participants with near certainty to develop Alzheimer's disease. Here, we studied a group of participants with a unique duplication of the amyloid precursor protein (APP) gene, which causes familial Alzheimer's disease with autosomal dominant inheritance and early onset of disease with near certainty (98% penetrance). In this rare population, we sought to characterize the relation between genetic predisposition, cognitive performance as well as functional and structural brain organization which were estimated using MRI. Ten presymptomatic APP carriers and ten age-matched controls from the same family were recruited for this study. Participants underwent a 45-minute-long MRI scanning followed by an hour and a half of neurocognitive assessment, psychological screening and neurological examination. Preliminary behavioral results from a task assessing visual short-term memory for objects' identity and location (Oxford's `What Was Where` task), provide evidence for impaired performance in general item localization precision and in association generation between objects and their locations among carriers. Structural imaging data suggest a trend for reduced hippocampal volume. Functional connectivity analyses will take advantage of data-driven approaches such as the classical multidimensional scaling (MDS). This approach allows to explore different dimensions of the data and later quantify their effect on the variance using PCA, as was recently shown. Standard data-informed fMRI approaches will be used as well.
The combination of this unique cohort and the extensive data, collected across multiple levels per individual, may allow to more finely estimate the changes that occur in presymptomatic AD, and perhaps identify potential markers of the presymptomatic stage in non-familial forms of AD.

**Abstract: Background** Overlaps exist between the neural systems vulnerable to brain aging and Alzheimer's disease (AD). It is a matter of debate if ageing and AD progression are independent phenomenon.

**Objective**

We used the topological properties of the brain to predict age from brain functions. We then used the difference between the predicted age and the chronological age to tested if cognitively normal individuals in the preclinical phase of autosomal dominant Alzheimer's disease (ADAD) have premature ageing (DIAN cohort). We then tested if the amyloid status (positive (Aβ+) or negative (Aβ-)) contributed to the discrepancy between the estimated age from brain functions and the chronological age. We repeated these analyses in cognitively normal individuals at risk of sporadic AD while comparing *APOE4* carriers to non-carriers (PREVENT-AD cohort).

**Methods**

We used resting sate functional connectivity (rsfMRI) collected in 1,187 cognitively normal participants provided by the DIAN, the PREVENT-AD, the CAM-Can, the ADNI, and the ICBM to build the brain age predictive model. For each subject, BOLD activity time series from 238 regions were used to construct a 238x238 Pearson correlation matrix from which we extracted 26 graph metrics quantifying network topological properties. We used training data (n = 773) to generate a neural net model predicting age based on the graph metrics and assessed its accuracy using a validation set (n = 47) to assess potential bias and/or overfitting. The model was then tested in 367 left-out participants.

**Results**

The results show that age can be predicted from topological properties of graph constructed from rsfMRI in a large number of participants selected across multi-site cohorts. Our model explained above 60% of the variance between estimated age and chronological age in training, validation, and test sets. Importantly, our model estimated that DIAN mutation carriers (+) were older (mean = 42.36 years old; std = 14.10 y.o.) than their actual chronological age (mean = 34.27 years old; std = 9.56 y.o.) ($t_{(127)} = 5.17$; $p < 0.0001$). This discrepancy between the estimated and chronological age was greater in the mutation carrier compared to the non-carrier ($F_{(1,156)} = 7.69$; $p = 0.006$). The amyloid status however had no impact on discrepancy between the predicted and actual age ($F_{(1,126)} = 0.621$; $p = 0.54$). *APOE*4 carriers and amyloid status were not related to an over estimation of age in the PREVENT-AD individuals.

**Conclusions**

The preclinical phase of ADAD is characterized by accelerated functional brain aging. This phenomenon is independent from, and might therefore preceded, amyloid accumulation.

**Authors: *E. PARDILLA-DELGADO**[1], F. D'OLEIRE UQUILLAS[1], E. GUZMAN-VELEZ[1], J. T. FULLER[1], A. ARTOLA[1], A. BAENA[3], J. GATCHEL[1], L. RAMIRES-GOMEZ[2], Y. BOCANEGRA[3], F. LOPERA[3], Y. QUIROZ[1]
[1]Psychiatry, [2]Neurol., MGH/Harvard Med. Sch., Boston, MA; [3]Grupo de Neurociencias, Univ. de Antioquia, Medellin, Colombia

**Abstract:** Intro: Autosomal dominant Alzheimer’s disease (ADAD) provides an ideal model to study AD-related brain changes in the preclinical stages (i.e., before clinical symptoms occur), given that individuals are virtually certain to develop dementia in their 40s and do not have age-related comorbidities (e.g., cardiovascular disease). We previously showed that cognitively-unimpaired carriers of ADAD have abnormal hippocampal activation during associative memory

paradigms, several years before onset of clinical symptoms. Here, we examine whether task-related hippocampal activation is associated with amyloid-beta and tau accumulation in cognitively-unimpaired individuals who belong to the large Colombian kindred with ADAD due to E280A presenilin-1 (PSEN1) mutation. Method: 9 mutation carriers (age M=35, SD=5) and 17 age, sex, and education matched non-carrier family members (age M=37, SD=6) participated in the study. Participants completed cognitive testing, amyloid PiB PET, flortaucipir (FTP) tau PET, and a face-name associative memory task inside a 3.0T fMRI scanner. fMRI analysis focused on the hippocampal activation contrasting novel face-name pairs vs. repeated pairs. Regional FTP SUVRs were measured in entorhinal and inferior temporal cortices. PiB DVRs were measured in a neocortical aggregate region (FLR). Spearman's rank correlations were performed to characterize the associations among task-related hippocampal activation, cortical amyloid, regional tau, and cognition. Results: Compared to non-carriers, carriers had less activation in hippocampus (non-carriers: M=0.02, SD=0.26; carriers: M= -0.51, SD=0.37, Mann-Whitney U-test p=0.001). Among carriers, less hippocampal activity was associated with increased cortical PiB burden (r= -0.92, p=0.001), and higher entorhinal tau (r= -0.89, p=0.002), but not with inferior temporal (r= -0.50, p=0.17). Further, less hippocampal activation was associated with worse memory performance (r=0.70, p=0.03). Discussion: Our results confirm previous findings of abnormalities in hippocampal activation in preclinical stages of ADAD (approx. 9 years prior to symptom onset in our sample). Importantly, these abnormalities seem to be related to markers of AD pathology, providing further evidence for the use of memory-related functional activity as a possible biomarker of preclinical AD. This study is limited by its small sample size; therefore, these findings need to be validated with larger samples.

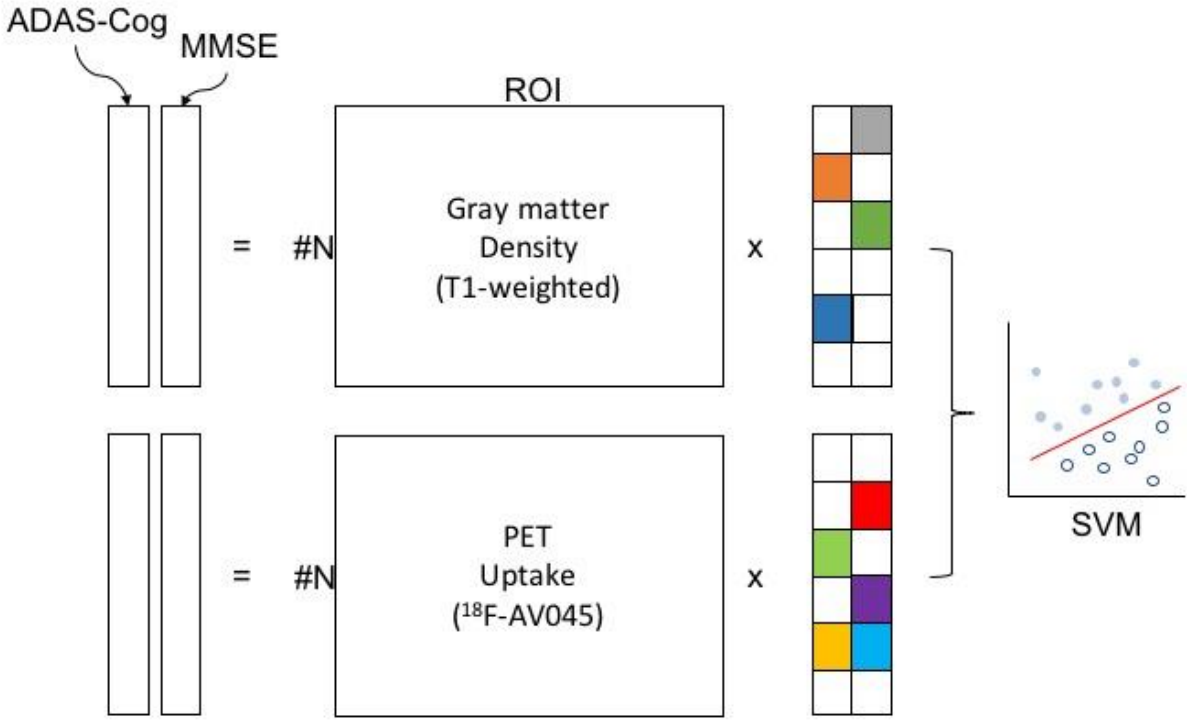
**Authors: *K. KWAK**[1], J.-M. LEE[2], A. C. EVANS[1]
[1]McGill Ctr. for Integrative Neurosci., Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [2]Dept. of Biomed. Engineering, Hanyang Univ., Seoul, Korea, Republic of

**Abstract:** Many neuroimaging biomarkers based on magnetic resonance imaging (MRI) and/or 18-fluorodeoxyglucose-positron emission tomography (FDG-PET) have been suggested for Alzheimer's Disease (AD)/mild cognitive impairment (MCI) detection, which can be roughly categorized into two types according to the brain structure or function. First, structural neuroimaging biomarker based on T1-weighted MRI include cortical thickness, tissue density and regional volume. Second, functional neuroimaging biomarkers based on FDG-PET include regional cerebral glucose metabolic rate changes. This study aims to investigate prediction model for Alzheimer's Disease and Mild Cognitive Impairment using a sparse model to jointly explain multiple variables from structural T1-weighted MRI and FDG-PET. Specifically, our method contains two subsequent steps: (1) clinical scores are determined by the same underlying abnormal regions from multi-modal images. (2) a support vector machine which predicts groups of subjects based on the measure of extracted region. The figure 1 demonstrates the proposed classification framework.



To validate our method, we performed 10-fold cross validation on the ADNI dataset with MRI and FDG-PET images from 71 AD subjects, 163 MCI subjects and 85 healthy control subjects (HCs). We extracted abnormal regions from multi-modal images and found this method to be discriminative and robust for AD and MCI prediction. Also, the extracting inter-related regions in T1 and FDG-PET is expected to promote prediction performance from the relationship between brain structural and functional information. The proposed classification framework has

excellent discriminatory power for AD and MCI compared to HCs. Furthermore, thanks to the availability of various imaging modalities, it would be beneficiary to combine their complementary biomarker for classification problem. But further studies are needed, as this may not apply in all situations, for example, distinguishing the AD from fronto-temporal dementia.

**Title:** Component diffusivities within default-mode network white matter that are associated with Alzheimer's disease pathology, but not age, predict longitudinal change in executive function in cognitively normal older adults

**Authors: *C. BROWN**, B. T. GOLD
Neurosci., Univ. of Kentucky, Lexington, KY

**Abstract: Introduction:** Alterations in microstructure of white matter (WM) pathways connecting the default mode network (DMN) mediate age- and Alzheimer’s disease (AD) pathology-related changes in DMN function, which in turn contribute to poorer executive function (EF). Previous work has focused on the summary measure of fractional anisotropy, but it is unclear whether alterations in specific component diffusivity measures are impacted by age and AD pathology. Further, it is unclear how these different component diffusivity measures may predict decline in EF over time. **Methods:** Thirty-two cognitively normal (CN) older adults with available diffusion tensor imaging (DTI), cerebrospinal fluid (CSF) levels of tau and β-amyloid (Aβ), and annual neuropsychological testing were included in the present study. DTI measures of DR and DA were measured within a previously developed template of DMN WM pathways. AD pathology was quantified using the CSF tau/Aβ ratio. An EF composite measure was created by averaging the standardized residuals of Trails-B and Digit Symbol tests after regressing out Trails-A as a measure of processing speed. Annual change in EF composite was calculated for each year and then averaged to calculate a single measure of average annual

change in EF over the three-year follow-up period. Bivariate correlations were performed to examine relationships between DTI metrics, AD pathology, and age. Further partial correlations were performed to examine the relationship between DTI metrics and average annual change in EF after controlling for baseline EF. **Results**: Bivariate correlations revealed that higher CSF tau/Aβ ratios were associated with increased DR ($r$ = 0.37, $p$ = .040) but not DA ($p$ = .369), while increasing age was associated with increased DA ($r$ = 0.37, $p$ = .040) but not DR ($p$ = .396). Three participants were identified as outliers in annual change in EF (>3 SD from mean) and were excluded from longitudinal analyses. Annual change in EF was associated with DR ($r$ = -0.48, $df$ = 26, $p$ = .009) but not with DA ($r$ = -0.26, $df$ = 26, $p$ = .188). **Conclusion:** These findings suggest different mechanisms underlying age- and AD pathology-related changes in WM microstructure. Further, it appears that longitudinal change in EF is associated with AD pathology-related changes in WM microstructure but not age-related changes in this CN cohort. These findings suggest that AD-related WM change plays an important role in future cognitive performance and may be an important target for studies aiming to slow or prevent cognitive decline.

**Title:** Anatomical and behavioral effects of high sucrose consumption on APOE animals

**Authors: *S. GRANT**
Northeastern Univ., Boston, MA

**Abstract:** Alzheimer’s disease is the most common form of age-related dementia. The estimated direct costs of Alzheimer’s disease and other related dementias on American society is $277 billion. Late-onset AD is correlated with a mutation on the apolipoprotein E (APOE) locus, and the APOEε4 allele is linked to substantial increases in AD risk. Alzheimer’s disease has been linked to the “Western diet”, which is characterized by high levels of refined sugars and saturated fats. In this study we characterized the anatomical and behavioral effects of a diet containing 68% sucrose (by energy) on female Sprague-Dawley rats with the APOEε4 allele. fMRI and diffusion weighted imaging (DWI) allowed for assessment of brain volumes, functional connectivity, and white matter architecture. Behavioral assays measured memory differences and cognitive impairment. Female APOEε4 rats on a high sucrose diet showed global decreases in functional connectivity, worsened behavioral memory and cognitive abilities, and

DWI differences in the hippocampus and frontal cortex. The data suggests that the presence of a "Western" high sugar diet is a detrimental environmental factor in the progression of Alzheimer's disease in at-risk patients.

**Abstract:** Episodic memory impairment is a predominant early symptom of Alzheimer's disease (AD). This is thought to be due to damage to areas within the hippocampus and medial temporal lobe cortical regions. Here we explore how episodic memory tests could be made more sensitive to early stage incipient AD. Behavioural data suggest that accelerated long-term forgetting (ALF) could be a very early sign of cognitive decline. Current neuropsychological protocols rarely test memory over longer than 30 minutes and therefore do not probe long term memory. We test the hypotheses that: 1) Hippocampal subfields subiculum and CA1 affected first in AD and are critical for long term memory performance. 2) ALF might be an early predictor of incipient AD. Our current dataset includes 22 healthy older controls, 21 individuals with subjective cognitive decline (SCD) and 9 mild cognitive impairment (MCI) patients who have undergone extensive cognitive testing, including 3 distinct tests of long term memory consolidation (story, word-list, complex figure). Immediate, 30-minute, and 4-week recall were tested. Furthermore, we explore the neuroanatomical structures that are critical for long term

memory using volumetric MRI and automated hippocampal subfield segmentation. We show here that healthy controls cannot be distinguished from individuals with SCD on the immediate or 30-minute recall timepoints of any test. However, after 4 weeks, those with SCD perform significantly worse than controls on the word-list, and indeed become statistically indistinguishable from the MCI patient group. Preliminary imaging data show a strong correlation of all hippocampal subfields with immediate recall on the word list, with a stepwise decrease in correlation strength as delay time increases. Only subiculum and CA1 subfields maintain statistically significant correlation with 4-week recall on the word-list. This preliminary analysis confirms previous literature suggesting that ALF may be a useful, pragmatic routine screening procedure for AD. Ongoing work will further examine the relationship between ALF and hippocampal subfield volumes in this cohort, as well as assessing the predictive power of ALF for future cognitive decline over subsequent years.

**Abstract:** Positron emission tomography (PET) imaging demonstrates high [C-11] Pittsburgh compound-B (PiB) retention in the default mode network (DMN), including precuneus cortex (PreC, BA7), which reflects accumulation of fibrillar amyloid-beta (Abeta) in Alzheimer’s disease (AD). N-truncated and pyroglutamate-modified Abeta forms [e.g., Abeta(pE3-42)], are particularly fibrillogenic. We hypothesized that Abeta(pE3-42) concentration corresponds to regional PiB retention in the PreC cortex. To test this hypothesis, we quantified [H-3]PiB binding and formic acid-extracted Abeta(pE3-42) and full-length Abeta1-42 concentrations in

PreC cortex, from cases with a premortem clinical diagnosis of no cognitive impairment (NCI, n=11), mild cognitive impairment (MCI, n=14), or mild AD (mAD, n=15). Analysis revealed that [H-3]PiB binding was significantly different across the clinical diagnostic groups, with greater levels in mAD compared to both NCI and MCI. Abeta(pE3-42) concentration was also higher in mAD cases compared to both NCI and MCI, while Abeta1-42 was higher in mAD relative to NCI but not MCI. Overall, higher PreC [H-3]PiB binding correlated strongly with greater Abeta(pE3-42) levels (r2=0.82) and greater Abeta1-42 (r2=0.81). Worse antemortem MMSE scores correlated with greater levels of both Abeta(pE3-42) and Abeta1-42 forms (r2=0.23 and r2=0.18, respectively). The strong associations of PreC PiB binding with Abeta(pE3-42) and Abeta1-42 suggests that increases in both Abeta forms contribute to PiB binding in this brain region. Weak associations of both Abeta forms with MMSE indicate that other pathological molecules (e.g., tau) are more relevant to global cognitive decline in AD. Characterization of pyroglutamate-modified and full-length Abeta forms in other DMN regions will further clarify their relation to pathogenesis and cognitive decline in AD, as well as to regional [C-11]PiB PET retention.

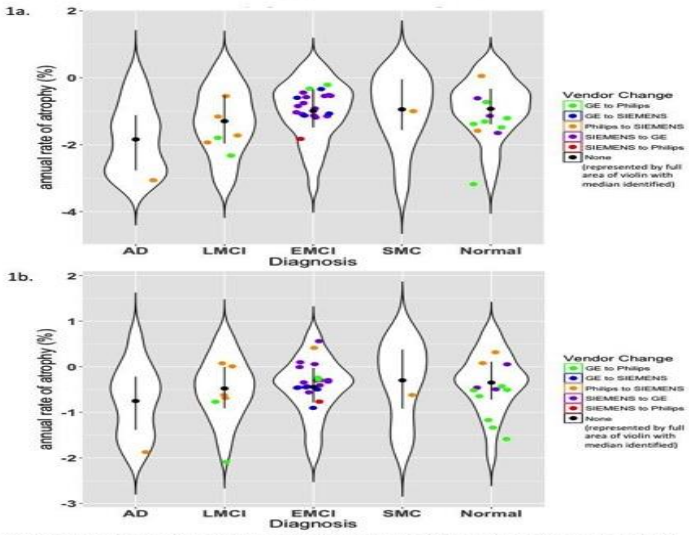
**Authors: *C. P. BOYLE**[1], C. R. CHING[2], S. I. THOMOPOULOS[2], A. ZAVALIANGOS-PETROPULU[2], A. MEZHER[4], P. M. THOMPSON[3]
[1]Imaging Genet. Ctr. @ Univ. of Southern C, Marina Del Rey, CA; [2]Imaging Genet. Ctr. @ Univ. of Southern California, Marina Del Rey, CA; [3]Imaging Genet. Ctr. @ Univ. of Southern California, Marina del Rey, CA; [4]Neurosci. Grad. Program, USC, Los Angeles, CA

**Abstract: Objective and Rationale:**
Reliable measurement of brain atrophy in longitudinal studies depends on stable MRI acquisition. In the Alzheimer's Disease Neuroimaging Initiative (ADNI) participating sites were encouraged to use the most current scanner technology, so some participants were scanned on different machines over time. Here we calculated the annual rate of brain tissue loss, expressed as a percentage, in different diagnostic (Dx) groups. We tested if the estimated mean rate of atrophy per Dx group differed between subgroups of subjects with and without a scanner vendor change.
**Methods:**
We used unbiased tensor-based morphometry (TBM) to analyze n = 2,358 scans, from 811 ADNI-GO/2 participants scanned with accelerated T1-weighted MRI at 3T.
The study cohort of 811 subjects included 183 healthy normal controls (age at screening visit: 73.1 ± 8.3 years, 94F/89M), 57 with significant memory complaint (SMC; age: 71.8 ± 5.4 years, 34F/23M), 292 with early mild cognitive impairment (EMCI; 71.3 ± 8.4 years, 130F/162M), 158 with late mild cognitive impairment (LMCI; 72.1 ± 7.8 years, 74F/84M), and 121 with Alzheimer's Disease (AD; 74.5 ± 8.1 years, 47F/74M) patients, scanned at 0, 3, 6, 12, 24 and 36 months. We identified subject visits involving a scanner change during serial scanning (n = 41 visits).
Numerical summaries were obtained from Jacobian (tissue loss rate) maps using two different region-of-interest (ROI) methods (Fig. 1). Numerical summaries were converted to atrophy or expansion rates, normalized for the interscan interval.
**Results and Conclusion:**
Plots were created (using R) showing atrophy rates using each ROI method (Fig. 1).
In the EMCI group - but not for other Dx groups - we found a significant difference between vendor change and no vendor change in the estimated atrophy rates (*p=.011;statistical ROI, p=.003;anatomical ROI; t-test)*. Continued analysis of later ADNI scans will offer more insight into effects of vendor change on atrophy rate estimates.

Figure 1: TBM-Derived Brain Atrophy and Vendor Change across ADNI-GO/2



Atrophy rates are defined as the numerical summary of the 3D Jacobian map within a statistically (Fig. 1a) or anatomically (Fig. 1b) defined ROI from the temporal lobes[1]. Violin plots show the probability density of the data at different values and include a marker for the median of the data. In each plot we visualize the data points with no vendor change with violins and scatter the relatively sparse data points with vendor change, for visual comparison. Visually, the data points with vendor change are consistent with the bulk of the data involving no change in vendor.

**Abstract:** Alzheimer's disease (AD) is one of the most neurodegenerative disorders that target the central nervous system. Brain biomarkers are one of the AD's tests that significantly help the

diagnosis. Our main aim is to use the carbon-11 labeled Pittsburgh compound B based positron emission tomography ($^{11}$C PiB-PET) scans to present a precise regional computer-aided diagnosis system to serve the personalized diagnosis of AD. A dataset of 103 $^{11}$C PiB-PET scans (19 normal control (NC), 65 mild cognitive impairment (MCI), and 19 AD) from Alzheimer's Disease Neuroimaging Initiative (ADNI) database is used to evaluate the system that in turn goes into five stages: (1) preprocessing to prepare the scans for the anatomical labeling and to de-noise them, (2) Labeling into 70 brain regions using Brodmann Areas (BAs) atlas, (3) Feature extraction, from each region, using Laplacian of Gaussian with automatic scale selection method, (4) Statistical analysis two-sample t-test, assisted by Bonferroni method to determine the significant BAs rather than working with the 70 region and to offer a precise diagnosis, and (5) Two diagnosis layers, regional then global diagnosis. The regional diagnosis, using probabilistic support vector machine (pSVM), shows the disease's severity in each significant region. The global diagnosis, using standard SVM, presents a final subject's diagnosis using the first layer's results. Due to the nature of the used methods, the statistical analysis and the diagnosis are done in two levels, level 1 between NC and abnormal groups (MCI+AD) and level 2 between MCI and AD groups separately. The found significant regions are 27 in level 1 and 33 regions in level 2 where these results are confirmed by the literature. For the classification performance, leave-one-subject-out method (LOSO) is applied for (1) the evlauation of different SVM kernels, the linear, radial basis function, and polynomial kernels, (2) the comparison with state-of-the-art classifiers and other related work that uses the same database. The linear pSVM/SVM shows better results than the other kernels with an overall accuracy of 98.05% and average accuracy, specificity, and sensitivity of 99.02%, 99.09%, and 96.48%, respectively. These results exceed the state-of-the-art classifiers' results of average accuracy, specificity, and sensitivity 94.72%, 72.62%, and 94.07% for the decision tree, ensemble classifier, and k-nearest neighbor, respectively. Also, our results exceed those of the related work that has a maximum overall accuracy of 87.50%. These results encourage evaluating the system on a larger dataset and analyzing other modalities in the future.

**Abstract:** Background
Alzheimer's Disease (AD) is the most common cause of dementia. Markers for early diagnosis and accurate progression are vital to manage the growing burden of AD. Transcranial magnetic stimulation (TMS) has shown AD is associated with cortical hyperexcitability, as reflected by a lower TMS-measured resting motor threshold (RMT) compared to cognitively intact healthy people. However, it is unknown how this hyperexcitability relates to the severity of cognitive dysfunction in AD.
Aim
The purpose of this study was to assess the relationship of RMT with cognitive dysfunction in AD.
Methods
A retrospective test-validation-evaluation analysis was conducted. First, the relationship was tested in a well-characterized test cohort, consisting of 20 AD subjects and 27 cognitively intact controls. Second, the relationship was validated in an independent cohort of 128 AD patients acquired from a multi-center clinical trial sponsored by Neuronix Ltd. (ClinicalTrials.gov Identifier: NCT01825330). RMT was defined as the intensity (as % of maximum stimulator output) required to elicit MEPs $\geq 50\mu V$ in at least 5 out of 10 trials. The Alzheimer's Disease Assessment Scale-Cognitive Subscale (ADAS-Cog) was used to capture the severity of dementia symptoms. Third, a meta-analysis of 7 published studies with total 152 AD subjects was conducted to evaluate the relationship between the inverse Mini-Mental Status Examination (MMSE) score and RMT. Across cohorts, clinical diagnosis of mild-to-moderate AD was determined by the study clinician based on DSM-IV/NINCDS-ADRDA.
Results
In the test cohort, simple linear regression (SLR) revealed a significant correlation between ADAS-Cog and RMT for the AD group ($n = 20$, $\beta = -0.62$, $p = 0.004$) but not for the control group ($n = 27$, $\beta = -0.13$, $p = 0.511$). Multiple regression and mediation-moderation analysis showed that scalp-to-cortex distance is a moderator, cortical thickness is an independent covariate, electric field intensity is the latent variable and excitation-inhibition balance is an RMT determinant. The validation cohort confirmed this result, with SLR showing a significant relationship between ADAS-Cog and RMT ($n = 128$, $\beta = -0.29$, $p = 0.001$). The meta-analysis found a medium effect with moderate heterogeneity by Hunter Schmidt estimation using a random-effects model ($r' = -0.23$, 95% CI: [-0.46, -0.09], $p = 0.049$ , $I^2 = 52.37\%$).
Conclusion
The present study found that in independent AD cohorts across assessments, RMT was related to

global cognition. As a reliable, inexpensive, noninvasive, and objective measure of cortical hyperexcitability, RMT may be a useful marker of disease progression in AD in future clinical trials.

**Authors: *Q. CHEN**[1], Z. ZHANG[2], T. BARAN[3], F. LIN[4]
[1]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY; [2]Dept. of Biostatistics & Computat. Biol., [3]Dept. of Biomed. Engin., [4]Sch. of Nursing, Univ. or Rochester, Rochester, NY

**Abstract:** Cognitive decline is common in normal aging and AD. Yet some older adults, known as Supernormals (SN), maintain cognitive superiority and resist to AD pathophysiology. Characterizing neural profile of SN may help identify therapeutic targets for cognitive decline and neurodegeneration. Our recent studies (Wang et al., *Cere Cortex*, 2017; Lin et al., *Cortex*, 2016) suggest that the function of a unique set of brain regions in SN is aging and AD-resistant. However, the white matter fiber pathways underlying the functional integrity, a critical aspect supporting information transport across brain regions, remain unexplored. Here we conducted a longitudinal study using a cutting-edge population-based structural connectome framework (Zhang et al., *Neuroimage*, 2018). We used the cohort from ADNI, including a group of SN identified by us (Lin et al., *JAD* 2017). We hypothesized that SN maintain a unique set of structural connectomes that are immune to AD pathophysiology, supporting longitudinal cognitive success.

**Title:** Insulin reduces amyloid-b production by regulating the processing of its precursor

**Authors: *O. KWON**, Y. CHO, S. CHUNG
Physiol., Sungkyunkwan Univ. Sch. of Med., Suwon-City, Korea, Republic of

**Abstract:** Alzheimer’s disease (AD) is caused by the accumulation of neurotoxic amyloid-β (Aβ) peptides. Aβ is derived from amyloid-β precursor protein (APP). In non-amyloidogenic pathway, APP is cleaved by α-secretase and γ-secretase at the plasma membrane excluding Aβ production. Alternatively, APP in the plasma membrane is internalized through clathrin-dependent endocytosis, and delivered to early endosomes and lysosomes, where it is cleaved by β-secretase and γ-secretase. Recently, some studies have shown that insulin in the periphery crosses the blood-brain barrier and plays important roles in brain. Furthermore, impaired insulin signaling has been linked to the progression of AD, and intranasal insulin administration improves memory impairments and cognition. However, the underlying molecular mechanisms of insulin treatment are remained largely unknown. To investigate the effects of insulin on APP processing, we tested the effects of insulin on neuroblastoma cell line (SH-SY5Y) overexpressing APP, and cultured rat cortical neurons. We found that insulin increased the level of cell surface APP, decreasing the endocytosis rate of APP. Insulin reduced Aβ generation through up-regulation of APP O-GlcNAcylation via Akt insulin signaling. Our present data suggest that insulin affects Aβ production by regulating APP processing through APP O-GlcNAcylation. These results provide a mechanistic insight into the beneficial effects of insulin and possible link between insulin deficient diabetes and cerebral amyloidosis in the pathogenesis of AD.

**Title:** The roles of PEN2 in maintaining the integrity of γ-secretase structure which is essential for intracellular autophagic clearance

**Authors: *H. HEO**[1], J. KANG[1], J. CHANG[1,2]
[1]Dept. of Biomed. Sci., Ajou Univ. Grad. Sch. of Med., Suwon, Korea, Republic of; [2]Dept. of Brain Sci., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

**Abstract:** Accumulation of various types of abnormal/unwanted intracellular substances has been thought to one of the main causes of the development of neurodegenerative diseases including Alzheimer's disease (AD). Autophagy-lysosome degradation system is responsible for the clearance of these materials. Thus, efforts have been made to identify the underlying cellular pathogenesis of AD by determination of the relationships between AD-related genetic alterations and autophagy. The series of these studies begins with the study on an important familial AD gene, *PSEN1*, which encodes a subunit of γ-secretase regulating the processing of beta-amyloid (Aβ) from amyloid precursor protein (APP). PSEN1 has been shown to be required for the maintenance of the acidic lysosome environment by regulating the lysosomal targeting of a V-ATPase subunit, V0a1. It has also been reported that genetic alterations in *PEN2/PSENEN* gene encoding PEN2, another subunit of γ-secretase, cause the onset of the familial AD. Therefore, to further investigate the pathogenesis of familial AD by γ-secretase abnormalities, we generated cell lines lacking PEN2 using a CRISPR/Cas9-mediated knockout (KO) system and analyzed the phenotypes associated with autophagy. We have found that the deficiency of PEN2 severely inhibits the assembly of the γ-secretase complex and simultaneously destabilizes PSEN1 and PSEN2 proteins. The autophagic activity of the PEN2-KO cell lines was weakened as compared with that of the normal cells as in the case of previously described PSEN1-KO cell lines. By further analysis of phenotypes induced by the re-expression of PEN2-D90N, a familial AD form of PEN2, we showed that PEN2 is a core component for maintaining the integrity of γ-secretase structure which is indispensable for proper autophagic process. From the above results, here we propose a novel cellular pathogenesis of AD associated with autophagy.

**Abstract:** One of the major hallmarks of Alzheimer´s Disease (AD) is the accumulation of soluble and aggregated amyloid β (Aβ) peptides in the brains of AD patients. Aβ peptides are generated from the amyloid precursor protein (APP). Most prominent, BACE 1 (β-site APP cleaving enzyme 1) cleaves APP at the β-secretase cleavage site and generates the N-terminus of Aβ. Second, the γ-secretase complex cleaves the remaining 99 amino acids long C-terminal fragment (CTF/C99) and releases the C-terminus of Aβ. As both secretases are not restricted to a single site, Aβ peptides vary in length. BACE 1 can only generate Aβ peptides starting in position p1 or p11 (Aβ1 x/11 x) whereas γ-secretase complex has several cleavage sites and can generate varying C-termini of Aβ. In the last years, it became evident that N-terminally truncated Aβ variants, such as Aβ2-42, are increased in AD brains. This is in line with results showing decreased levels of Aβ2-42 in CSF of AD patients. Since BACE-1 is not capable in directly generating this peptide, a suggested model for the emergence of N-terminal truncation is the existence of alternative enzymes. We have previously demonstrated that the metalloprotease meprin β cleaves APP as a β-secretase reminiscent of BACE 1, however, predominantly generating N-terminally truncated Aβ2-x variants. We observed that meprin β derived N-terminally truncated Aβ2-40/42 peptides display increased aggregation compared to non-truncated Aβ peptides and demonstrate increased staining of meprin β in brains of sporadic Alzheimer disease patients compared to non-demented control subjects. Surprisingly familiar AD mutations located at the N-terminal region of the Aβ-sequence dramatically influence the catalytic activity of meprin β. The APP Swedish (swe) mutation at position 672 results in reduced generation of N-terminally truncated Aβ. The recently described APP mutation A673T that has been shown to protect against AD and BACE 1 cleavage, also protects from meprin β derived N-terminally truncated Aβ2-40/42 peptides. This offers an interesting possibility, that

meprin β only generates Aβ peptides from APP in sporadic AD cases or AD cases harboring mutations close to the γ-secretase cleavage site. To address this possibility we crossed APP London mice with meprin β knock-out mice and analyzed histopathological hallmarks and behavioral phenotypes in these animals. In a reverse setup we used an overexpression system by injecting meprin β expressing AAV into the hippocampus of APP London mice and demonstrate its effect on APP processing in vivo. We propose that meprin β may be involved in the generation of N-terminally truncated Aβ2-x peptides of APP in vivo.

Massachusetts Gen. Hosp., Charlestown, MA

**Abstract:** Presenilin (PS)/γ-secretase is responsible for the generation of β-amyloid (Aβ) by cleaving the β-site processed APP (APP C99/CTFβ). Accumulation of Aβ, so called senile plaques, in the brains is a hallmark of Alzheimer's disease (AD). The successful development of specific antibodies and/or fluorescently or radioactively labeled compounds against Aβ allowed clear detection of the Aβ plaques not only in post-mortem AD brain but also in the brain of living patients. However, it has never been fully elucidated *when, which cells, and where within the cell* Aβ is generated. To tackle these crucial questions, we have successfully developed and validated a novel Förster resonance energy transfer (FRET) biosensor - C99 RFP-GFP (C99 R-G) probe to report the activity of endogenous PS/γ-secretase. C99 R-G is an ideal chimeric molecular probe that includes APP C99 (the precursor substrate of PS/γ-secretase) and two fluorescent proteins - EGFP (donor) and RFP (acceptor) in the 1:1 ratio. The cleavage of the APP C99 in the C99 R-G probe by endogenous PS/γ-secretase would result in the change of the proximity between EGFP and RFP, i.e., change in the FRET efficiency, and thus would simultaneously report the production of the Aβ peptides. Therefore, by monitoring changes in the FRET efficiency

between EGFP and RFP in the C99 R-G probe we would be able to “visualize” the APP C99 cleavage by PS/γ-secretase. The extensive validation of the probe in cultured primary neurons, CHO, MEF and HEK cell lines supports plausibility of using the C99 R-G probe to report PS/γ-secretase activity and “visualize” Aβ production on a cell-by-cell basis with high subcellular resolution. The probe can be easily modified to detect processing of other PS/γ-secretase, e.g. Notch1, suggesting that C99 R-G would be a prototype of assays to further investigate the roles of PS/γ-secretase in other diseases.

**Abstract:** How aging influences the processing of APP into Aβ is unknown. We propose an age-related accumulation of misfolded and aggregated long Aß peptides and APP-CTFs inside neurons that leads to either a) metabolic impairment and neuronal death or vice versa b) metabolic impairment of aging alters processing of APP causing aggregated long intracellular Aß peptides (iAβ). This is the opposite of the conventional amyloid hypothesis that Aß is first secreted from neurons as a soluble peptide, aggregates outside the cell to exert neurotoxicity. Our ability to culture neurons from any age animal allows investigation of age as a dependent variable, removed from an aging vasculature, hormones and immune system. We first demonstrated that gamma secretase inhibitors or modulators decreased intracellular accumulation of Aβ in neurons from the 3xTg-AD mouse, indicating that iAß contains Aβ processed by gamma secretase. Further, the kinetics of iAß decline was faster than inhibition of extracellular release. Punctate staining of Aβ aggregates with anti-Aß-aggregate or anti-C-terminal Aβ45 co-localized with the endosome marker rab7 as well as with mitochondria and

lysosomes. iAβ increased exponentially with age of neurons grown from young, middle age or old mice. The age-dependent increases in iAβ along with Alz-50 tau staining were exacerbated by glutamate. Inhibition of autophagy with bafilomycin lowered iAß as well as the NAD/NADH precursor nicotinamide, or either of two Nrf2-inducers for redox control. These results suggest that age-related metabolic impairment contributes to the generation of intracellular Aβ, possibly overwhelming clearance by autophagy unless neurons receive a metabolic boost.

**Authors: *Y. CHIU**, I. EBINUMA, Y. HORI, T. TOMITA
Lab. of Neuropathology and Neuroscience, Grad. Sch. of Pharmaceut., The Univ. of Tokyo, Tokyo, Japan

**Abstract:** Alzheimer disease (AD) is a progressive neurodegenerative disorder pathologically characterized by deposition of amyloid β peptide (Aβ) as senile plaques. Aβ is generated through the sequential cleavage of amyloid precursor protein (APP) by β- and γ-secretases. γ-Secretase is a 4-protein complex composed of Aph1, Nicastrin (Nct), Pen-2 and the catalytic subunit Presenilin 1 (PS1) or PS2. APP is cleaved by the γ-secretase at multiple positions, thereby causing the heterogeneity in the C-terminal length of Aβ, such as Aβ40 and Aβ42. Although Aβ42 consists 5-10% of total Aβ, Aβ42 is highly toxic and prone to aggregate. To date, various evidence indicates that the aberrant Aβ production is associated with the pathogenesis of AD.

However, the precise regulatory mechanism of Aβ generation remains unknown.
To identify the genetic regulators of Aβ production, we have established murine neuroblastoma Neuro2a cell pool whose genome was edited by CRISPR/Cas9 system with the genome-wide lentiviral gRNA library. Among this cell pool, we chose 3 monoclonal cell lines with altered levels of secreted Aβ. We isolated the gRNAs from these cell lines using next generation sequencer and analyzed the molecular functions of their targets in the Aβ production pathway. Through this study, we identified *Cib1* targeting gRNA from Neuro2a cells with increased Aβ production. CIB1 is a small myristoylated calcium-binding protein with 4 EF-hand domains. Notably, CIB1 was identified previously as PS2 binding protein by yeast 2-hybrid screening, while its role in Aβ production remained unclear. Disruption of *Cib1* increased the Aβ40 and Aβ42 production without affecting the expression level of APP, β- nor γ-secretase. In contrast, overexpression of mouse CIB1 in *Cib1* disrupted cell rescued the upregulated Aβ secretion, supporting our notion that CIB1 is a genetic regulator for Aβ production. Thus, our results suggest that *Cib1* is a suppressive factor in the AD pathogenesis by altering Aβ production. Further molecular and cellular studies would clarify the mechanistic role of CIB1 in APP processing and the etiology of AD.

**Title:** Cathepsin D regulates cerebral Aß42/40 ratios via markedly differential degradation of Aß42 versus Aß40

**Authors: *C. N. SUIRE**[1], S. LANE[2], M. A. LEISSRING[2]
[1]Neurobio. and Behavior, UC Irvine, Irvine, CA; [2]UCI MIND, Univ. of California, Irvine, Irvine, CA

**Abstract:** Mutations in presenilin/γ-secretase are known to cause early-onset Alzheimer's disease (AD) by increasing cerebral Aß42/40 ratios, but it is unknown whether this critical parameter is regulated by other factors that might be disturbed in sporadic AD. We report here that Aß42/40 ratios are regulated via markedly differential catabolism of Aß42 and Aß40 by cathepsin D (CatD), which we also show to be the principal Aß-degrading protease regulating lysosomal Aß levels *in vivo*. Genetic deletion of CatD results in several remarkable effects,

including: increases in insoluble Aß exceeding those present in mice lacking insulin-degrading enzyme, neprilysin or both; intralysosomal deposits of endogenous Aß42 by 3 weeks of age; and elevated cerebral Aß42/40 ratios comparable to those induced by *presenilin* mutations. Mechanistically, we show that the alteration in Aß42/40 ratios is driven by pronounced differences in the kinetics of Aß42 *versus* Aß40 degradation by CatD. Relative to Aß40, Aß42 exhibits a remarkably stronger, sub- to low-nanomolar affinity ($K_m$) for CatD and a nearly 200-fold slower turnover rate ($k_{cat}$), which together render Aß42 a highly potent competitive inhibitor of CatD. Notably, similar differences are observed for the processing of murine Aß42 and Aß40 by CatD, as well as the corresponding alpha-secretase-derived P3 fragments, reinforcing the conclusion that these effects are attributable to aggregation-independent factors. Collectively, our findings uncover a previously unrecognized interplay between Aß42 and CatD with strong relevance to AD pathogenesis.

**Title:** Traumatic brain injury induces amyloid precursor protein increase in adult mice

**Authors: *Y. XIE**[1], S. WANG[2], K. D. RYNEARSON[3], P. NGUYEN[3], B. P. HEAD[4], C. WU[3], S. L. WAGNER[3]
[1]Yunan Univ. of Traditional Chinese Med., Yunnan, China; [2]VA Healthcare System, UCSD, San Diego, CA; [3]Neurosciences, UCSD Sch. of Med., San Diego, CA; [4]Anesthesiol., VA Med. Ctr., San Diego, CA

**Abstract:** Traumatic brain injury (TBI) is considered a risk factor for the development of Alzheimer's disease (AD). Post-TBI consequences include increase expression of amyloid precursor protein (APP) and amyloid-β(Aβ) generation. Experimental studies of TBI-induced Aβ accumulation as a risk of AD pathology are usually performed using transgenic mouse models of amyloidosis. These transgenic mice continually over-express APP, producing supra-physiologic concentrations of APP and Aβ in the brain. Thus it is difficult to find out the direct relationship between TBI and AD under physiological conditions. To avoid confounds associated with transgene-driven APP overexpression, we would use wild type mouse to determine whether TBI causes acute increase in APP and amyloid β peptides ($Aβ_{40/42}$) in the brain and plasma. Male C57BL/6 mice of 6 months of age were divided into sham and TBI model groups. TBI were performed by controlled cortical impact (CCI) of the right parietal cortex. After one day

exposure to experimental TBI, Aβ levels in the ipsilateral, contralateral of the brain as well as in the plasma were quantified using a MSD-based sandwich enzyme-linked immunosorbent assay (ELISA).Protein levels of full-length APP in the mouse brain were measured by Western blotting.We found that TBI caused a significant increase in APP protein level in the injured hemisphere at Day 1 after TBI. This is consistent with other studies showing that TBI altered APP processing in transgenic mouse brains and in human brains.The increased processing of full-length APP caused increased production of $A\beta_{40}$ and $A\beta_{42}$ in mouse brain. We found that injury caused a increase in levels of $A\beta_{40}$ and $A\beta_{42}$ compared to sham both in the ipsilateral and contralateral brain at Day 1 postinjury. However, $A\beta_{40}$ and $A\beta_{42}$ in plasma were significantly decreased in injured animals compared with injured animals($P = 0.0022$ and $P = 0.0267$, respectively).Notably, TBI increased levels of full-length APP in ipsilateral brains. Similar to our Western blot data, levels of $A\beta_{40}$ and $A\beta_{42}$ in TBI mice brains increased too. Others have previously demonstrated that TBI increases levels of Aβ in the brain using human APP Tg mice. Here, we found that rapid generation of Aβ after injury also occurs in WT mice. Interestingly, in contrast to brain tissues, the levels of Aβ in mouse plasma was obviously decreased after TBI. Though there is a lot of evidence indicating that plasma levels of $A\beta_{40}$ and $A\beta_{42}$ robustly correlate to brain in AD patients and in APP Tg mouse, our results may indicate a faster clearance or a utilization for wound healing of Aβ in plasma.

**Title:** The amyloid-β precursor protein is a ubiquitous, permanent resident of a specialized tubular endoplasmic reticulum compartment

**Authors: *V. MURESAN**, Z. LADESCU MURESAN
Pharmacology, Physiol. and Neurosci., New Jersey Med. School, Rutgers Univ., Newark, NJ

**Abstract:** The function of the Amyloid-β Precursor Protein (APP), one of the most studied disease-relevant proteins, is poorly understood. APP is a type I transmembrane protein that undergoes extensive proteolytic cleavage into smaller polypeptides, which have been implicated in the neuronal pathology of Alzheimer's disease (AD). In neurons, the cleavage of APP generates N- and C-terminal fragments (NTFs and CTFs), and - subsequently - internal fragments. After cleavage by β-secretase, the NTFs, comprising the ectodomain of APP, distribute as soluble polypeptides in the lumen of intracellular membrane-bounded compartments, while the CTFs remain attached to the membrane via their transmembrane domain. Here we show that, in the brainstem derived neuronal cells, CAD, APP is cleaved to a large extent in a juxtanuclear compartment of the tubular endoplasmic reticulum (ER) that is associated with neurofilaments. While the CTFs exit the ER along the secretory route, and are transported into the neurites by TGN-derived vesicles, the NTFs - released in the ER lumen - never exit the ER, and are carried to the growth cones within specialized ER tubules that lack machineries for protein and lipid synthesis. Throughout the neuron, the NTFs colocalize with Reticulon 4B (Rtn4B), a structural protein of the tubular ER, but not with the longer isoform, Rtn4A (NogoA). The subcellular fractionation of rat brain homogenates reveals a fraction that contains Rtn4B and several forms of NTFs, but lacks the translocon-associated protein, TRAPα, Rtn4A, and full-length APP. The NTFs and Rtn4B redistribute identically under experimental conditions that disrupt the structural integrity of the compartments where they reside. The treatment of cells with Brefeldin A, an agent that blocks the anterograde vesicle transport along the traditional secretory route, does not affect the accumulation of NTFs and Rtn4 at the growth cone. Also, the induction of neurite retraction causes a coordinated retraction of the NTFs and Rtn4B, at a faster pace than the retraction of neurites. Thus, the NTFs and Rtn4B reside in the same compartment, both in the soma and in neurites; in neurites, this compartment represents a specialized, dynamic, biochemically distinct subcompartment of the tubular ER. The NTFs are trafficked in and out of neurites within the extending or retracting ER tubules. The ER localization of the NTFs is also detected in the neurites of cortical, hippocampal, and DRG neurons, and in advancing protrusions of HEK293 cells, and endothelial and epithelial cells (HUVEC, BAEC, MDCK). Together, these results indicate that the NTFs are ubiquitous residents of the tubular ER, with yet to be determined functions.

**Title:** N-terminal truncated Aâ4-x proteoforms and their relevance for Alzheimer pathophysiology

**Authors: *J. GHISO**, E. CABRERA, T. NEUBERT, A. ROSTAGNO
New York Univ. Langone Med. Ctr., New York, NY

**Abstract:** Impaired brain clearance and abnormal Aβ degradation are considered key events for the formation and progressive accumulation of soluble neurotoxic oligomers and the development of synaptic pathology, one of the strongest correlates to cognitive impairment in AD. Clearance studies, mostly centered in monomeric Aβ40, have provided a basic assessment of the participating mechanisms, but the complex molecular and structural heterogeneity of the brain Aβ peptidome -going far beyond the classic Aβ40/Aβ42 dichotomy- has been largely overlooked. The most common heterogeneity resides in the multiple N- and C-terminal truncated fragments that consistently populate the Aβ peptidome and of which little is known in regards to their homeostatic regulation and potential contribution to disease pathogenesis. Our studies indicate that while C-terminal truncations increase solubility and abrogate oligomerization/fibrillogenesis, features clearly associated with clearance mechanisms, N-terminal truncations, particularly abundant components of parenchymal deposits in AD, non-human primates, and multiple APP transgenic models drive enhanced pro-amyloidogenic properties. Notably, the poorly studied Aβ4-x fragments -truncated at position 4 but bearing an intact C-terminus, ending at Val40 or Ala42 as their respective full-length counterparts- provided further insights into the potential role of these truncated forms in AD pathogenesis. *In vivo* clearance experiments using oligomeric radiolabeled homologues validated their poor brain removal characteristics when compared with their monomeric counterparts or to the full-length oligomeric parent molecules. In addition, proteomic studies of tissue deposits in conjunction with the use of novel antibodies specific for the free N-terminus of Aβ4-x revealed their primarily topographic association with fibrillar plaque cores. Remarkably these antibodies, highly specific for the free N-terminus of Aβ4 and blind for any other Aβ derivatives including full-length Aβ40 and Aβ42, were able to abrogate oligomerization, fibrillization and neurotoxicity of the highly amyloidogenic Aβ4-42 *in vitro.* Overall, our findings highlight the potential contribution of N-terminal truncations for the disease pathogenesis and identify fragments truncated at Phe4 as novel, not previously recognized targets for therapeutic intervention.

**Authors: *Y. CHEN**, X. NIU, X. HOU, Y. GENG
IRCBC, SIOC, Chinese Acad. of Sci., Shanghai City, China

**Abstract:** Point mutations of Amyloid Precursor Protein (APP) could increase Abeta production and cause early onset Alzheimer’s disease. Whereas APP Iceland mutation reduces Abeta production and decrease AD risk. These evidence strongly support Abeta hypothesis for AD. However, some mutations on gamma secretase reduce Abeta production but still cause familial AD. There are also studies that suggest these AD causing Presenilin 1 mutations are loss of function mutations. Given the recent difficulties on the development of Abeta targeting therapies, doubts have been casted on the original hypothesis. One possibility is that Abeta is not the sole disease-causing production of APP. We studied metabolism of APP and identified a novel cleavage that is more dominant in disease-causing APP mutants. This suggests that product of this novel cleavage might contribute to the pathogenesis of familial APP mutations. Further studies have been done to identify the interacting proteases that might be responsible for this cleavage with a novel biochemical approach. This could provide new mechanism and drug target for AD.

**Title:** Enhanced cleavage of amyloid precursor protein (APP) by overexpression of beta-secretase (Bace1) alters the normal distribution of APP in neurons

**Authors: *T.-R. HUANG**[1], J. AOW[3,2], E. H. KOO[4,5]
[1]Grad. Sch. for Integrative Sci. and Engineering, Natl. Univ. of Singapore, [2]Natl. Univ. of Singapore, Singapore, Singapore; [3]Genome Inst. of Singapore, Agency for Science, Technol. and Res. (A*STAR), Singapore, Singapore; [4]Dept Neurosciences, UCSD, La Jolla, CA; [5]Yong Loo Lin Sch. of Medicine, Natl. Univ. of Singapore, Singapore, Singapore

**Abstract:** The amyloid-β-peptide (Aβ) is centrally implicated in the pathogenesis of Alzheimer's disease (AD). Cleavage of the amyloid precursor protein (APP) by β-secretase (Bace1) yields the secreted sAPPβ fragment and the β-CTF fragment that is then cleaved by γ-secretase to generate Aβ. Bace1 exhibits cleavage activity at the trans-Golgi-network (TGN), the endosomal network, and the plasma membrane. As APP processing by Bace1 represents the initial step in Aβ production, much research has focused on determining the intracellular location(s) and regulatory pathways of the APP/Bace1 interaction. Recent studies on APP and Bace1 trafficking in primary neurons or non-neural cell lines have relied on co-transfection of APP and Bace1 constructs tagged at the C-terminus with fluorescent proteins, followed by imaging assays that quantify colocalization or Förster resonance energy transfer (FRET) between the fluorescent proteins. We set out to examine a previously reported neuronal activity-dependent APP-GFP/Bace1-mCherry interaction. Unexpectedly, co-transfection of these tagged APP and Bace1 constructs in primary hippocampal neurons resulted in a loss of surface APP levels without corresponding reduction in signal from the C-terminal fluorescent protein tag, indicating a significant decrease in full-length APP (APP-FL) levels. The decrease was blocked by a Bace1 inhibitor, confirming the role of Bace1 mediated cleavage. In addition, dual labeling of APP N- and C-termini in permeabilized APP/Bace1 co-transfected neurons revealed an anterograde distance-dependent drop in the N-/C-termini signal ratio, suggesting that the increased APP cleavage occurs at the neuronal soma. Transfection with a Bace1-uncleavable APP mutant restored the loss in cell surface APP signal. Finally, biochemical experiments showed an increase in the β-CTF/APP-FL ratio in APP/Bace1 co-transfected cells, consistent with enhanced β-secretase cleavage of APP. Taken together, our results suggest that the majority of the fluorescent protein signal distal to the neuronal soma may not arise from tagged APP-FL, but rather from tagged β-CTF cleaved earlier in the secretory pathway. Thus, care is needed in interpretating results in situations where APP is detected only with a C-terminal tag in the presence of Bace1 overexpression. In this context, it is essential to monitor the presence of accelerated APP cleavage by BaceI. In light of these observations, previous findings may need to be reinterpreted if it is unclear whether APP is present as an intact molecule or as β-secretase cleaved CTF.

**Title:** The effect of APP mutations on its surface distribution and synaptic membrane cholesterol homeostasis

**Authors: *Q. ZHANG**[1,2]
[1]Pharmacol., Vanderbilt Univ., Nashville, TN; [2]Brain Inst. of Florida Atlantic Univ., Jupiter, FL

**Abstract:** Amyloid precursor protein (APP) is a type I transmembrane protein with a close tie to Alzheimer's disease (AD). Its proteolytic products, β-amyloid peptides (Aβs), are the major constituents of amyloid plaque, the hallmark of AD. Importantly, various point mutations of APP have been found in familial AD (FAD), and transgenic mice carrying those mutations exhibit some pathologies similar to AD. Most cell-based analyses FAD mutations had focused on the changes in Aβ production and aggregation, especially the more toxic Aβ42. However, more and more evidence has suggested that amyloid plaques or Aβ aggregation are not the cause of AD. So far, almost all therapeutic attempts targeting Aβ, β- or γ-secretases had failed, further questioning the amyloid cascade hypothesis. On the other hand, studies about APP's intrinsic function had led to a plethora of hypotheses. Importantly, those proposed functionalities often require APP to be in specific membrane sections such as cell surface or intracellular organelles. Moreover, α- or β-secretases and the associated nonamyloidogenic or amyloidogenic proteolysis are also sequestered in neuronal surface or intracellular membranes, testifying the significance of APP membrane distribution. Recently, we discovered an intriguing link between the plasma membrane cholesterol and APP distribution using live-cell fluorescence imaging and a dual-fluorescence APP reporter, which led us to test if and how different APP mutations affect its membrane trafficking and processing. We found that point mutations in the newly identified cholesterol-binding motif alters APP distribution in the manner similar to the reduction of surface membrane cholesterol. Furthermore, moderate decrease of surface membrane cholesterol was observed in neurons expressing such mutations. We have extended our investigation to major FAD mutations to test their impacts on the neuronal membrane cholesterol as well as APP trafficking. Together, our studies demonstrate the significance of APP transportation in addition to proteolytic processing and APP's association with the homeostatic regulation of neuronal membrane cholesterol, which can play an important role in AD etiology.

**Abstract:** The amyloid precursor protein (APP) plays a central role in the pathophysiology of Alzheimer's disease due to its sequential proteolytic cleavages that result in the generation of β-amyloid peptide (Aβ). Although APP is expressed widely in the central nervous system, its physiological function in the development and maintenance of the central nervous system remains elusive. From our previous work, we found that the APP homologue in zebrafish, Appb, is strongly expressed in the brain and spinal cord and the partial knockdown of Appb affected motor neuron guidance and Mauthner cell development. In this study, we characterized zebrafish with a homozygous *appb* mutation generated with CRISPR/Cas9 technology. We report that the mutation in *appb* displayed perturbed cell adhesion phenotypes at blastula stage, show smaller size at early stages but appear reasonably normal at later developmental stages. Furthermore, the larvae of zebrafish at 5 dpf showed behavioral deficits and adult mutants show anxiolytic behavior in novel tank diving test. While investigating the reason, we found the altered expression of other family members *appb* mutants. All together, these results indicate that the loss of appb results in early aberrations in the development, but phenotypes are likely compensated by the altered expression of other App family members.

**Title:** Role of the repressor element 1 silencing transcription factor in Alzheimer's disease

**Authors: *R. WANG**, B. MALONEY, D. LAHIRI
Indiana Univ., Indianapolis, IN

**Abstract:** Background:
Alzheimer's disease is one of leading world-wide causes of dementia. Its global prevalence constantly increases due to an aging population. Nevertheless, the underlying pathogenesis of AD is still poorly understood. Genetic, epigenetic, and environmental factors play important roles in AD etiology (Maloney and Lahiri, *Lancet Neurol*-2016). We hypothesize that AD results from misregulation of key biochemical pathways and their regulatory molecules, including transcription factors and non-coding RNAs. Misregulation of one such factor, Repressor Element Silencing Transcription Factor (REST) could lead to AD.
Methods:
Human neuroblastoma (SK-N-SH) and HeLa cell lines were transfected with siRNA against REST, as well as other siRNAs. Neuroblastoma differentiation was induced by all-*trans* retinoic acid (ATRA) treatment. Western blotting and qRT-PCR followed to determine protein, and mRNA expression levels respectively, of key gene products, REST, APP, BACE1, Neprilysin, and MAPT. In addition, RES levels were assessed in human tissue specimens from AD patients and non-AD-matched control subjects.
Results:
At least four REST bands were found by western blotting, 120kDa, 140kDa, 160kDa and above 250kDa. The latter two were positively correlated with AD progression. The specificity of REST bands were determined by REST siRNA transfection and at least two anti-REST antibodies recognizing different epitopes. The transfection of REST siRNA in differentiated neuroblastoma cell line altered brain derived neurotropic factor (BDNF) level.
Conclusion:
Our initial data indicates that REST have many post-translational modifications. Some isoforms of REST protein remains relatively stable even REST mRNA level drops significantly. While

there are two REST bands reduce with REST siRNA transfection, the knockdown of which leads to changes of BDNF precursor proteins. This might help to explain why REST level is correlated with AD progression.

**Title:** Amylin and pramlintide modulate γ-secretase activity and APP processing in lipid rafts by increasing gangliosides synthesis in TgSwDI mice

**Authors: *Y. MOUSA**[1], A. KADDOUMI[2]
[2]Drug Discovery and Develop., [1]Auburn Univ., Auburn, AL

**Abstract:** One of the major characteristics of Alzheimer's disease (AD) is the accumulation of misfolded amyloid beta (Aβ) protein. Several studies linked AD with diabetes mellitus through reported similarities between Aβ and human amylin. Accordingly, amylin and its analogue pramlintide were proposed as possible therapeutic molecules against AD; however, their effect on AD pathology is still controversial. The objectives of this study were to explore the effect of amylin and pramlintide on AD pathology and the predisposing molecular mechanisms behind the observed effects in TgSwDI mouse model. The CAA/AD mouse model TgSwDI (male, 4 months old) was used for these experiments. Mice were divided to 3 groups (n = 8/group), the control group received intraperitoneal injection of PBS as vehicle, and the amylin and pramlintide groups received 200 µg/kg/day each for 30 days. At end of treatments, behavioral studies were performed followed by brains collection. Brain homogenates and isolated lipid rafts were used to evaluate effect of treatments on Aβ-related biomarkers. Compared to control, amylin and pramlintide treatments did not improve cognitive function in TgSwDI. In addition, both peptides significantly increased soluble and insoluble Aβ in brain homogenates and reduced expression of post-synaptic marker PSD-95. Furthermore, in brain homogenates, amylin and pramlintide did not change the levels of APP, BACE1, presenilin-1, presenilin-2, and nicastrin, however, pramlintide significantly increased sAPP-β and both human peptides reduced sAPP-α levels. To explain these results, alteration in APP, BACE1, presenilin-1, presenilin-2 and nicastrin in lipid rafts was evaluated. Findings demonstrated that pramlintide and amylin significantly increased presenilin-2 and nicastrin levels, and only pramlinitide increased APP and

presenilin-1 levels in lipid rafts. Such effect was associated with increased expression of B4GALNT1, the enzyme responsible for gangliosides synthesis, and GM1. In conclusion, amylin and pramlintide increased Aβ brain levels by stimulating APP processing in the lipid rafts through activating gangliosides synthesis. Thus, these results suggest that amylin and pramlintide exacerbate AD pathology in TgSwDI mice.

**Title:** Increased miR-21 levels prevented beta-amyloid-induced tau toxicity in cultured hippocampal neurons

**Authors: *A. B. FERREIRA**, C. PARKER
Cell & Mol. Biol., Northwestern Univ., Chicago, IL

**Abstract:** MicroRNAs (miRNAs) are ~21-nucleotide-long, non-coding RNAs involved in the regulation of gene expression in a sequence-specific manner. An overall loss of miRNAs has been detected in aging brains. Furthermore, the levels of several miRNAs are significantly lower in brain samples obtained from Alzheimer's disease (AD) subjects when compared to age-matched controls. In the present study, we assessed the involvement of miR-21 in the regulation of genes associated with tau pathology in the context of AD. To analyze the effects of this miRNA on neuronal degeneration and tau-mediated toxicity induced by beta-amyloid (Aβ), we overexpressed miR-21 using a lentiviral vector in cultured hippocampal neurons obtained from embryonic day 18 (E18) pregnant rats. Neurons cultured for 3 weeks were transfected with GFP-miR-21 24 hours prior to their incubation with aggregated Aβ. Untreated cultures, GFP-miR-21 expressing neurons, and neurons cultured in the presence of Aβalone were used as controls. Neuronal survival was analyzed one day after the addition of the peptide. Post-translational tau modifications (i.e. phosphorylation and cleavage) known to induce neurodegeneration in the presence of Aβwere also analyzed. These experiments were performed by means of LIVE/DEAD Cell assays, quantitative Western blot analysis, and immunocytochemistry using specific tau antibodies in samples obtained from at least 5 independent culture preparations per experimental condition. Our results showed that increased levels of miR-21 prevented cell death in Aβ-treated cultured hippocampal neurons in a dose-dependent manner. This enhanced neuronal survival was accompanied by a significant decrease in calpain activation and, hence, in

the generation of the $tau_{45-230}$fragment. We have previously shown that this tau fragment has neurotoxic effects including neurite degeneration, synapse loss, and cell death in hippocampal neurons that develop in situ or in culture. Together, these results suggest that age-dependent downregulation of miR-21 could result in an increased susceptibility of hippocampal neurons to Aβ-induced neurodegeneration. In addition, they suggest that increased levels of miR-21 could attenuate Aβ-induced neuronal death, at least in part, by preventing calpain-mediated tau fragmentation into the $tau_{45-230}$neurotoxic fragment.

**Abstract:** Kainic acid, an analogue of the neurotransmitter glutamate, can trigger seizures and neuronal loss in the hippocampus/limbic structures in a manner that mirrors the neuropathology of human temporal lobe epilepsy (TLE). However, mechanisms behind this neurodegeneration remain unclear. Since amyloid-β (Aβ) peptides, which are critical to the development of Alzheimer's disease, can mediate toxicity by activating glutamatergic NMDA receptors, it is likely that enhanced glutamatergic transmission that renders hippocampal neurons vulnerable to kainic acid may involve Aβ peptides. Thus, we seek to establish what role Aβ plays in kainic acid-induced toxicity. Our results show that kainic acid injection leads to loss of hippocampal neurons accompanied by increased levels/processing of amyloid precursor protein (APP), resulting in the enhanced production of Aβ-related peptides. These changes were evident in activated astrocytes, implying a role for astrocytic Aβ in the degeneration of neurons. Accordingly, we showed that treating cultured astrocytes with kainic acid leads to increased Aβ production/secretion. Additionally, we revealed that kainic acid induces neuronal loss more in neuronal/astrocyte co-cultures than pure neuronal culture, and this is attenuated by precluding Aβ production. Collectively, these results suggest a role for APP/Aβ peptides derived from activated astrocytes in the degeneration of neurons associated with TLE.

**Title:** Novel role of death-associated protein kinase 1 in neuronal cell death and alzheimer's disease

**Authors: *N. KIM**[1,2], T. LEE[1,2]
[1]Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Harvard Med. Sch., Boston, MA

**Abstract: Background**
While the role of apoptosis in cellular and animal models of neurodegeneration has been largely documented, its occurrence and role in human Alzheimer’s disease (AD) brain is still controversial and not fully understood. Death-associated protein kinase 1 (DAPK1) is a Ser/Thr kinase and functions as a positive mediator of apoptosis and is genetically linked to AD. We previously showed that DAPK1 expression is markedly increased in 75% of human AD brains. Moreover, we showed that DAPK1 ablation in mice decreases tau phosphorylation at multiple AD-related sites. Furthermore, we demonstrated that the levels of insoluble Aβ are significantly reduced in APP-Tg/DAPK1-KO mice brain. However, little is known about the molecular mechanisms of DAPK1 involved in neuronal cell death and pathogenesis of AD because direct DAPK1 substrates have not been identified.
**Methods**
We conducted an unbiased peptide library screening and identified novel DAPK1 substrates that are involved in neuronal cell death and AD including N-myc downstream-regulated gene 2 (NDRG2). We investigated the role of DAPK1 in regulating NDRG2-mediated neuronal cell death in AD by Aβ treatment using comprehensive approaches including gene knockout, knockdown in cell culture models and mouse, and human patient tissues. The results are presented as means ± standard error of the three independent experiments. Statistical significances were calculated by one-way analysis of variance followed by Dunnett’s multiple comparison post-hoc test.
**Results**
We demonstrated that DAPK1 interacts with NDRG2 and directly phosphorylates the Ser350 residue. Moreover, DAPK1 overexpression increases neuronal cell death through NDRG2

phosphorylation after Aβ treatment. In contrast, inhibition of DAPK1 by overexpression of a DAPK1 kinase-deficient mutant and shRNA, or by treatment with a DAPK1 inhibitor significantly decreases neuronal cell death, and abolishes NDRG2 phosphorylation in cell culture and in primary neurons. Furthermore, NDRG2-mediated cell death by DAPK1 is required for a caspase-dependent PARP cleavage. In addition, DAPK1 ablation suppresses Aβ-induced cell death in mouse brain and neuronal cell death in APP overexpression mice. Finally, levels of phosphorylated NDRG2 Ser350 and DAPK1 are significantly increased in human AD brain samples.

**Conclusions**

Our results indicate that DAPK1 is a critical regulator of NDRG2 both in neuronal cell death and during the progression of AD. Our studies also suggest that DAPK1 represents a potential novel therapeutic approach for treating AD.

**Abstract:** An important worldwide health problem as the result of current lifestyle is metabolic syndrome (MS). It has been shown that MS induced by a high caloric diet (HCD) in rats, produces cognitive deterioration in the recognition of novel objects test (NORT) and decreases

synaptic connections and dendritic order in the hippocampus. However, it is unknown whether MS induced by an HCD participates in the cognitive process observed with the injection of $A\beta_{1-42}$ into hippocampus of rats as a model of Alzheimer disease (AD). The induction of MS in rats produces a deterioration in NORT, however, rats with MS injected with $A\beta_{1-42}$, show a major deterioration in the cognitive process. This event could be explained by the increment in the oxidative stress in both cases studied (MS and $A\beta_{1-42}$): in together, the hippocampus and temporal cortex produce an enhancer effect. In the same way, we observed an increment in interleukin 1B, TNFa and GFAP, indicative of an exacerbated inflammatory processes by the combination of MS and $A\beta_{1-42}$. We can conclude that MS might play a key role in the apparition and developed of cognitive disorders, including AD. We propose that metabolic theory is important to explain the apparition of cognitive diseases.

**Title:** Modulation of neurotoxic amyloid beta oligomers: A role for hsp60

**Authors: *C. MARINO**[1], F. CAPPELLO[2], G. TAGLIALATELA[1]
[1]Mitchell Ctr. for Neurodegenerative diseases, Dept. of Neurol., Univ. of Texas Med. Br., Galveston, TX; [2]BioNeC, Univ. of Palermo, Palermo, Italy

**Abstract:** Alzheimer’s disease (AD) is the most common form of dementia worldwide, affecting more than 40 million individuals. Being clinically and histologically well characterized, the design of disease-modifying therapies has been unsuccessful due to the number of factors leading to AD pathology. Among all the hypotheses suggesting possible mechanisms involved in AD pathology, the pro-amyloidogenic processing of amyloid precursor protein (APP), upstream of the amyloid beta peptide (Aβ) formation and subsequent neurotoxic oligomerization (Aβo), remains one of the most supported theories. Further, the impairment of the protein quality control machinery due to aging and aberrant accumulation of misfolded proteins during AD progression is another alteration characterizing the disease. Particularly, evidence suggests that the age-related impairments of chaperones, a class of modulatory proteins involved in the protein quality control of the cell, contributes to the neurotoxicity induced by Aβo, but the underlying mechanism remains unresolved. In the present work, we characterized the effect of the

mitochondrial chaperone Hsp60 in protecting against toxic Aβo conformations using both cell free, *in vitro and ex vivo* approaches. Specifically, the Chinese Hamster Ovary (CHO) cell line overexpressing human APP751 variant of APP (7PA2 cell line), a model of human Aβo production, was used along with immunocytochemistry, ELISA and western blotting techniques to investigate the effect of Hsp60 overexpression on Aβ production and release in the extracellular compartment. Further, we investigated changes in toxicity of toxic Aβo both *in vitro* by testing changes in cytotoxicity on neuroblastoma cell line and *ex vivo* by testing changes in long term potentiation on hippocampal brain slices. Finally, we used a cell free approach to characterize the effect on Hsp60 on toxic Aβ conformations by testing changes in the biophysical properties of treated oligomers using immunoprecipitation, proteinase K assay, western blotting and spectroscopy techniques. Our data suggest that Hsp60 has a direct effect on toxicity of Aβo resulting in a reduction of cytotoxicity and a rescue of synaptic plasticity, thus proposing Hsp60 as a potential candidate for future therapies targeting Aβo neurotoxicity.

**Title:** The gaseous anaesthetic xenon, a weak NMDA receptor antagonist, shows neuroprotective properties on ß-amyloid-mediated synaptotoxic effects

**Authors: *C. KNOLL**[1], K. HADIAN[2], K. SCHORPP[2], M. BÜRGE[3], G. RAMMES[4]
[1]Experimentelle Anästhesie, Muenchen, Germany; [2]Helmholtz Zentrum München, Munich, Germany; [3]Klinikum rechts der Isar der TU München, Munich, Germany; [4]Clin. Rechts der Isar, Munich, Germany

**Abstract:** Volatile and intravenous anaesthetics are routinely used for general anaesthesia in humans including patients suffering from Alzheimer's disease (AD). Several studies suggest that commonly used volatile anaesthetics such as isoflurane and sevoflurane may induce changes consistent with AD neuropathogenesis, e.g., increased amyloid beta protein (Aß) aggregation resulting in an increased synaptotoxicity. In contrast to that, the gaseous anaesthetic xenon has frequently been reported to be neuroprotective against cerebral damage. In our study, we investigated the interaction of equipotent concentrations of xenon, isoflurane and sevoflurane with different Aß-isoforms regarding Aß aggregation, synaptic activity and autophagy. Time-resolved fluorescence resonance energy transfer (TR-FRET) and silver staining revealed that

isoflurane and sevoflurane did not interfere with Aß aggregation whereas xenon even decreased the propensity for Aß to aggregate. Xenon partially restored $A\beta_{1-42}$-induced synaptotoxic effects measured by LTP. In the presence of $A\beta_{1-42}$ and $A\beta_{1-40}$, anaesthetic-induced reduction of neuronal activity propagation in the tri-synaptic hippocampal circuit, monitored by voltage-sensitive dye imaging (VSDI), completely recovered after xenon, but not isoflurane and sevoflurane removal. Autophagy, a catabolic process to maintain cellular homeostasis, which might be closely associated with the pathophysiology of AD, was not affected by either single drug or the combined application of anaesthetics with Aß. Our presented results show that commonly used anaesthetics may interfere with Aß-dependent pathophysiology of AD. Interestingly, in contrast to other volatile anaesthetics, xenon showed beneficial effects on Aß aggregation and on synaptic activity when experimental conditions resemble the clinical situation with patients suffering from AD and requiring anaesthesia for surgery. Our results point to neuroprotective properties of xenon, which might be a meaningful alternative for anaesthesia in AD patients.

**Abstract:** Alzheimer’s disease (AD) is the most common neurodegenerative disorder and cause of dementia. Pathologically, AD is characterized by the deposition of the amyloid beta (Aβ) peptide in extracellular senile plaques, and the microtubule-associated protein tau in intraneuronal neurofibrillary tangles. However, how these pathological hallmarks relate to the neuronal dysfunction and death underlying cognitive decline remains unclear. Aβ oligomers (Aβo) surrounding plaques, rather than amyloid plaques themselves, are thought to be the neurotoxic species of Aβ and to be upstream of tau aggregation. Among the downstream

neurotoxic effects of Aβo, calcium dyshomeostasis resulting in $Ca^{2+}$ overload in the cytosol of neurons and neurites, and mitochondrial dysfunction resulting in oxidative stress have been proposed as early pathogenic events according to the amyloid cascade hypothesis. Mitochondria buffer cytosolic $Ca^{2+}$ rises in physiological conditions, but whether there are alterations in mitochondrial $Ca^{2+}$ contributing to a more general cytosolic $Ca^{2+}$ dyshomeostasis in AD remains unknown. We hypothesized that soluble Aβ oligomers may lead to mitochondrial $Ca^{2+}$ overload in neurons.
To test this hypothesis, we developed and validated in vitro and in vivo a FRET-based ratiometric $Ca^{2+}$ indicator Yellow Cameleon 3.6 targeted to neuronal mitochondria (hsyn.2mtYC3.6). Using this tool and intravital multiphoton imaging, we measured $Ca^{2+}$ levels in neuronal mitochondria in the AD transgenic mouse model APP/PS1, which develops amyloid plaques similar to human AD as early as 4 month of age. Quantitative $Ca^{2+}$ imaging revealed an increase in the mitochondrial $Ca^{2+}$ concentration in APP/PS1 mice, compared to wild-type mice. Moreover, direct topical application of Aβo-enriched transgenic conditioned media (TgCM, obtained from 14 DIV neurons prepared from Tg2576 mouse embryos) to the brain of wild-type C57Bl/6 mice increased the $Ca^{2+}$ concentration in individual mitochondria, whereas conditioned media obtained from the wild-type littermates neurons (WtCM) or Aβo-depleted conditioned media had no effect on mitochondrial $Ca^{2+}$ levels. Taken together, these data support the idea that there is a mitochondrial $Ca^{2+}$ dyshomeostasis with $Ca^{2+}$overload in AD, and that it is, at least partially, due to soluble Aβo.

**Title:** Comparing salivary AB and oral microbiome in alzheimer's disease mouse models

**Authors: *A. M. FLODEN**, M. SOHRABI, S. NOOKALA, G. D. MANOCHA, C. K. COMBS
Biomed. Sci., Univ. of North Dakota, Grand Forks, ND

**Abstract:** Beta amyloid (Aβ) peptide containing plaque aggregations in the brain are a hallmark of Alzheimer’s Disease (AD). However, Aβ is produced by cell types outside of the brain

suggesting that the peptide may serve a broad physiologic purpose. It has been reported that elevated levels of Aβ can be found in the saliva of AD patients but the source and function of this salivary Aβ is not fully understood. Based upon our prior work documenting expression of amyloid precursor protein (APP) in intestinal epithelium we hypothesized that salivary epithelium might also express APP and be a source of Aβ. To begin testing this idea, we compared C57BL/6 wild type mice to two mouse models of AD, littermate control APP/PS1 mice and the APP (NL-G-F) mouse line. At 12-15 months of age, salivary secretion was stimulated from all three lines and compared to salivary gland, serum, and brain Aβ levels to determine whether a specific relationship existed between saliva, blood, and brain in either line. As expected, both APP/PS1 and APP (NL-G-F) lines demonstrated robust brain increases in Aβ 1-40/42 with lower levels of Aβ 1-40 in APP (NL-G-F). Both APP/PS1 and APP (NL-G-F) mice also showed an increase in Aβ 1-42 levels in serum with higher Aβ 1-40 levels in APP/PS1 compared to APP (NL-G-F) mice. On the other hand, significantly increased levels of Aβ 1-42 were quantified from saliva of only APP (NL-G-F) mice. No significant differences in total volume or flow rate were observed. To assess potential effects of salivary composition on oral microbiome, saliva was plated from all three strains compared to APP knockout mice. Total CFUs were not different between males across all strains although APP knockout male mice had increased numbers of tooth lesions. Female APP knockout mice had significantly lower CFUs compared to wild type female mice with no significant increase in tooth lesions, however. These data support the idea that a ratiometric relationship exists between saliva, blood, and brain Aβ levels and salivary composition may differ during disease state. In addition, APP expression or its metabolites may influence oral microbiome as well as tooth decay. AD mouse models may be useful for exploring the diagnostic potential of this relationship as well as the source and function of salivary Aβ.

**Abstract:** Amyloid-β (Aβ) oligomers are believed as the major component that contributes to synaptic deficits, cognitive impairment and initiates the cascade for the pathology of Alzheimer's disease (AD). Galectin-3 (Gal-3) is a member of the galectin protein family that promotes inflammatory responses. It also enhances cancer cell homotypic aggregation. Here we examined the role and mechanism of Gal-3 in Aβ oligomerization and amyloid plaque formation. Galectin-3 knockout (KO) mice, various genotypes of APP/PS1;Gal-3 mice and brain tissues from AD patients were used. Results show that Aβ oligomerization is reduced in Gal-3 KO mice injected with Aβ whereas overexpression of Gal-3 enhances Aβ oligomerization in the hippocampus of Aβ-injected mice. There is an age-dependent increase in Gal-3 expression that parallels with the amount of endogenous Aβ oligomerization in APP/PS1 mice. Moreover, Aβ oligomerization and amyloid plaque are reduced in APP/PS1;Gal-$3^{+/-}$ mice compared with APP/PS1;WT mice and the cognitive performance of APP/PS1;Gal-$3^{+/-}$ mice is also better. Galectin-3 is primarily expressed in microglia cells and Gal-3 is preferentially associated with Aβ monomers. Immunohistochemical result show that Gal-3 distribution overlaps with endogenous Aβ and amyloid plaque to some extent in APP/PS1 mice. Further, β-secretase activity is decreased but neprilysin expression is increased in Gal-3 KO mice. These explain why Aβ oligomerization is reduced in Gal-3 KO mice injected with Aβ. Consistent with the observation in mice, Gal-3 expression is increased in the frontal lobe of AD patients and it parallels with Aβ oligomerization. Because Gal-3 expression is dramatically increased as early as 3 months of age in APP/PS1 mice and anti-Aβ oligomerization is believed to protect against Aβ toxicity, Gal-3 could be considered as a novel therapeutic target against AD.

**Abstract:** Previous and current Alzheimer's disease research has a strong focus on the role of neurons and amyloid-beta peptides in the progression of Alzheimer's disease. Recent research has implicated a role for oligodendrocytes in the progression of the disease, demonstrated by focal demyelination at plaque sites and alterations to oligodendrocyte populations in animal models of early Alzheimer's disease. The main aim of this study is to understand the effect of amyloid-beta on oligodendrocyte development or health, which may have downstream effects on

myelin and contribute to the degeneration of neurons. To help us understand this, we have examined the effect of extracellular amyloid-beta on oligodendrocyte development *in-vitro.* Pure oligodendrocyte precursor cell (OPC) cultures were derived from mixed glial cultures from Sprague Dawley neonatal rats at postnatal day 1-3. OPCs were induced to mature into myelin-forming oligodendrocytes over 5 days *in-vitro* in the presence or absence of amyloid-beta. Tracing of oligodendrocyte morphology demonstrated significantly reduced branching, suggesting that oligodendrocytes exposed to 5uM amyloid-beta 1-40 and 1-42 are less mature when compared to controls. However, immunocytochemical and trace analysis demonstrated that 1uM amyloid-beta 1-40 as there was a statistically significant increase in the number of MBP-positive oligodendrocytes and branches (n=3 separate cultures per treatment, p<0.05). This suggests that low concentrations of amyloid-beta *in*-vitro plays a role in inducing OPC differentiation indicated by an increased number of mature oligodendrocytes. To complement *in-vitro* findings, we are currently investigating the effect of amyloid-beta on myelination during a learning task as well as the effect on OPC maturation in an animal model of Alzheimer's disease. By studying a model of induced myelination, we hope to correlate the amyloid-beta present in these animals and observe differences in their myelination profiles and oligodendrocyte populations to further support our hypothesis that oligodendrocytes have a key role in Alzheimer's disease progression.

**Abstract:** Results from both human and animal studies over the last decade have identified a clear increase in the rate of Alzheimer's disease (AD) in women. Sex differences in the

prevalence or severity of many diseases are well recognized. A common underlying feature of disorders more prevalent in females is an association with stress, such as in anxiety and depression. Stress increases glucocorticoids (GC) in the brain, and the link between GCs and AD has been confirmed by several studies. We previously found that acute stress rapidly increases levels of Aβ in the mouse brain (Kang et al., 2007). GCs function through a nuclear GC receptor (GR) that acts as a dimer to facilitate transactivation or as a monomer to repress transcription (transrepression). The sex-related differences in transactivation versus transrepression remain unclear and the influence of either pathway on AD pathology has not been defined. Using microdialysis, Aβ levels in the interstitial fluid (ISF) of the hippocampus were measured in male and female APP/PS1 mice (3-4 months old). Samples were collected every hour for a baseline period, 3-hour restraint stress, and 12-hour post stress period. To evaluate the effects of blocking the transactivation arm of GR signaling through GR dimerization, we crossed APP/PS1 mice with the glucocorticoid receptor dimerization deficient mouse model (GRdim), to create GRdim APP mice. We also studied the effects of pharmacologically blocking GR dimerization using Compound A, administered via reverse microdialysis before restraint stress. We observed a significant difference between male and female mice in the percent increase in ISF Aβ during acute stress, with female mice having a much greater and sustained increase in ISF Aβ compared to males. ISF Aβ levels in female GRdim APP mice did not rise dramatically during acute stress, and stayed near baseline during the post stress period. Compound A completely blocked the increase in ISF Aβ induced by restraint stress in female mice. These results suggest that females are more sensitive to stress-induced increases in Aβ, and that acute stress increases Aβ in female mice through a GR dimerization dependent mechanism.

**Abstract:** Alzheimer's disease (AD) is the most common form of dementia worldwide and the accumulation of amyloid-β (Aβ) peptide in the brain is considered the main hallmark of this disease. In AD, Brain-derived neurotrophic factor (BDNF) signalling is seriously impaired, compromising neuronal survival, differentiation and plasticity. Actually, in AD brain patients there are decreased levels of both BDNF and its receptor (TrkB-FL) and upregulated levels of TrkB truncated isoforms (negative modulators of BDNF signalling). Recently, we described that Aβ peptide accumulation leads to calpain overactivation and subsequent TrkB-FL cleavage, decreasing its levels and forming a membrane-bound truncated receptor (TrkB-T') and an intracellular fragment (TrkB-ICD).In this work we studied TrkB-ICD dynamics in neuronal cultures and we evaluated TrkB-FL cleavage in *post-mortem* human brain samples with varying degree of AD-related neurofibrillary pathology. The use of human brain samples for this study was approved by the Ethics Committee of Kuopio University Hospital, Finnish National Supervisory Authority, University of Eastern Finland and Finnish Ministry of Social Affairs and Health. Subjects' consent was obtained according to Declaration of Helsinki. Our data show that, in transfected primary neurons and in a neuroglioma cell line, TrkB-ICD I) is a stable fragment (half-life time: 8h), II) is translocated to nucleus overtime and III) promotes the phosphorylation of somal, axonal and nuclear proteins. In human brain samples, through proteomic analysis, we detected calpains activation, a decrease of TrkB-FL levels and an increase of TrkB-ICD levels in relation to increasing AD-related neurofibrillary pathology. Importantly, TrkB-FL transcript levels are not changed over AD progression, supporting the hypothesis that TrkB-FL decreased levels could be directly attributed to calpain activation. Taken together, these results shed light on the mechanism underlying the AD neuronal vulnerability due to impairment on the major endogenous neuroprotective pathway, BDNF/TrkB-FL system.

**Title:** Presenilin1 and Presenilin1 mutants alter the distribution and activity of BACE1 through acting on transport process

**Authors: N. LI**, Y. QIU, *H. QING
Beijing Inst. of Technol., Beijing City, China

**Abstract:** Alzheimer's disease (AD) is a progressive cognitive disorder and the mainly characterized by the degeneration of central nervous system. One of the hallmarks of AD is excessive production of Amyloid β-peptide (Aβ). Aβ is derived from the β-amyloid precursor protein (APP) through sequential cleavages by β-(BACE1) and γ-secretase. BACE1 is the key to the pathogenic process of AD. Presenilin1(PS1) is the active center of the γ-secretase, participating in the APP hydrolysis process. Previous studies show that PS1 can co-localize with the BACE1. The deficiency of the PS1 can not only inhibit the activity of the BACE1, but also decreases the expression of C-terminal products. To investigate how the PS1 affect the activity of BACE1, we studied the transport process of BACE1with PS1. We used sucrose density gradient centrifugation to separate organelles and tested the distribution of BACE1 in different organelles. We found that the transfection of PS1 results in an increased BACE1 level in endoplasmic reticulum (ER), which indicates that PS1 can affect the transportation of BACE 1. So, it proved that PS1 can change the distribution of BACE1 in subcellular structure through extension of the dwelling time in ER. Through immunofluorescene and Time-lapse results its was found that BACE1 distributed evenly in cytoplasm, co-localizing with ER, Golgi, and early endosome slightly without transfecting PS1. On the contrary, when transfecting PS1, BACE1 migrated to periphery of nucleus distinctly, co-localizing with Calnexin in high amount, indicating that PS1 can force BACE1 to migrate to ER. In the meantime, the transfection of PS1 increases co-localization of BACE1 with Syn-6 and EEA1, which shows PS1 improved the maturity of BACE1 in Golgi. Because BACE1 interacts with APP in early endosome, the transfection of PS1 promoted BACE1 binding with APP to perform the functions. The results above manifest that PS1 can extend the dwelling time of BACE1 in ER and improve the distribution of the BACE1 in ER and Golgi. We also tested the effect of PS1 mutations on BACE1 transportion. Results indicated that D257A mutant has no effect on BACE1 transportation; and S170F mutant facilitates the transfer and the maturity of BACE1 from ER to golgi as compared to PS1 wildtype. In conclusion, PS1 affects the distribution and activity of BACE1 through acting as the synthesis and maturity of BACE1 precursor.

**Abstract:** Aβ oligomers are the main components of senile plaques in the brain of Alzheimer's disease patients. Interestingly, a great body of evidence suggests that Aβ oligomer accumulation and not the amount or size of senile plaques, have a direct positive correlation with the onset of Alzheimer's disease. Moreover, it has been found that Aβ oligomers cause different deleterious effects over synaptic architecture, like loss of dendritic spines and decrease in CaMKII clusters. Overall, Aβ oligomers affect excitatory synapses causing failures in physiological synaptic plasticity (i.e., long-term potentiation), which is consistent with a malfunction in AMPA receptor dynamics. Using super resolution microscopy on living hippocampal neurons, we aimed to understand the dynamic of endogenous GluA2-containing AMPA receptors in response to $A\beta_{42}$ oligomers. We discovered that short-term (15-30 min) treatment with 1 μM $A\beta_{42}$ oligomers does not affect notably the dynamics of plasma membrane AMPA receptors. Higher concentration of 5 μM $A\beta_{42}$ oligomers, known to cause endocytosis of AMPA receptors, increase the fraction of immobile AMPA receptors at synaptic sites as fast as 15 min after treatment, without affecting those receptors localized in extrasynaptic sites. Finally, we wanted to test a low but longer application, using 0.5 μM $A\beta_{42}$ oligomers for a period of 2 hours. Interestingly, we observed an opposite effect, GluA2-containing AMPA receptors located at the plasma membrane became more mobile. Altogether, these data suggests a two-step process in which $A\beta_{42}$ oligomers trigger first, unbinding of AMPA receptors from synaptic sites followed by endocytosis of mobile receptors, thus overall decreasing the fraction of mobile receptors.

**Title:** Metallothionein induction prevents cognitive decline caused by $Zn^{2+}$ released from amyloid-$\beta_{1-42}$ in dentate granule cells

**Authors: *H. SUZUKI**, W. HASHIMOTO, S. KOBUCHI, T. MURAKAMI, M. TEMPAKU, Y. KOIKE, H. TAMANO, A. TAKEDA
Univ. of Shizuoka, Shizuoka, Japan

**Abstract:** The basal levels of extracellular $Zn^{2+}$ are in the range of low nanomolar concentrations (~10 nM) in the hippocampus and probably increased age-dependently. In the dentate gyrus, non-zincergic perforant pathway innervates dentate granule cells. Nonetheless, the rapid excess influx of extracellular $Zn^{2+}$ into dentate granule cells, which more readily occurs in aged rats, is a cause of aged-related cognitive decline. Amyloid-β (Aβ) is a causative candidate for the pathogenesis of Alzheimer's disease (AD). The formation of Zn-$A\beta_{1-42}$ in the extracellular compartment rapidly increases both intracellular $Zn^{2+}$ and $A\beta_{1-42}$ in dentate granule cells of normal young rats, followed by $A\beta_{1-42}$-induced cognitive decline that is due to increase in intracellular $Zn^{2+}$ released from $A\beta_{1-42}$. Metallothioneins (MTs) are small, cysteine-rich proteins and bind zinc and copper. They function as metal ion regulation and detoxification. The basal level of intracellular $Zn^{2+}$ is estimated to be ~0.1 nM in hippocampal neurons. MTs have $Zn^{2+}$-binding sites in hippocampal neurons and can capture $Zn^{2+}$ released from $A\beta_{1-42}$. MTs bind four $Zn^{2+}$ with high affinity (Kd, ~1 pM) and bind another two $Zn^{2+}$ with lower affinity. MTs bind the seventh $Zn^{2+}$ with nanomolar affinity (Kd, ~1 nM). Here we report that hippocampal MT induction defends cognitive decline, which was induced by $A\beta_{1-42}$-mediated excess $Zn^{2+}$ in dentate granule cells. Excess increase in intracellular $Zn^{2+}$, which was induced by local injection of $A\beta_{1-42}$ into the dentate granule cell layer, attenuated in vivo LTP at perforant pathway-dentate granule cell synapses, while the attenuation was rescued by preinjection of MT inducers, i.e., zinc, cadmium, and corticosterone, into the same region. Intraperitoneal injection of dexamethasone, which increased hippocampal MT proteins and blocked $A\beta_{1-42}$-mediated $Zn^{2+}$ uptake, but not $A\beta_{1-42}$ uptake, into dentate granule cells, also rescued $A\beta_{1-42}$-induced impairment of memory via attenuated LTP. The present study indicates that hippocampal MT induction blocks rapid excess increase in intracellular $Zn^{2+}$ in dentate granule cells, which originates in $Zn^{2+}$ released from $A\beta_{1-42}$, followed by rescuing $A\beta_{1-42}$-induced cognitive decline. Furthermore, LTP was vulnerable to $A\beta_{1-42}$ in the aged dentate gyrus, consistent with enhanced $A\beta_{1-42}$-mediated $Zn^{2+}$ uptake into aged dentate granule cells, suggesting that $A\beta_{1-42}$-induced cognitive decline, which is caused by excess intracellular $Zn^{2+}$, can more frequently occur along with

aging. Hippocampal MT induction is an attractive defense strategy against $A\beta_{1-42}$-induced cognitive decline.

**Title:** Rapid, real-time and sensitive measurement of *in vivo* amyloid-beta levels and half-life using novel micro-immunoelectrode technology

**Authors: *H. EDWARDS**, C. YUEDE, J. CIRRITO
Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

**Abstract:** Alzheimer’s disease (AD) is a neurodegenerative disease that is hallmarked by the accumulation of amyloid-beta (Aβ) peptide into oligomers and plaques. Soluble oligomers, particularly within the brain extracellular, or interstitial, fluid (ISF), are thought to be one of the highly toxic species of the peptide. We have developed a novel electrochemical technique to detect and measure these oligomers using a carbon fiber micro-immunoelectrode (MIE). The MIE uses amperometry to oxidize tyrosines within the protein of interest. Specificity for a protein target is provided by covalently attaching an antibody to the surface of the carbon fiber. The oxidation of tyrosine releases an electron which the carbon fiber detects as current; the amount of current detected is proportional to the amount of tyrosine present. The tip of the carbon fiber MIE is coated with an oligomer-selective antibody (A11), which provides specificity to oligomeric forms over monomeric Aβ. Additionally, we bathe the MIE in a 1% BSA solution to block all space not occupied by antibody. The electrodes are sensitive to detect Aβ oligomers (AβO) down to 0.2 fg/ml. We have validated the species of Aβ detected in vitro using size excluded human brain homogenates and can detect concentrations of AβO in human cerebral spinal fluid (CSF) samples. Additionally, we have used the MIE to monitor the minute to minute changes in oligomer kinetics in the brains of living mice. Using the AβO MIE in the APP/PS1 transgenic mouse model of AD, we measure rapid increases in AβO levels following injection of picrotoxin, a GABA-A receptor antagonist. The kinetics of AβO increases are distinct from Aβ40 monomer. Additionally, we detect decreased AβO levels following

administration of a γ-secretase inhibitor, which enables us to calculate the in vivo elimination half-life of AβO from the brain ISF in a living mouse.

**Title:** Amyloid β induces oxidative neuronal deaths in mouse cortical cultures in a concentration-dependent manner via NADPH oxidase- and/or mitochondria-dependent ROS production

**Authors: *J.-K. KIM**[1], S. HWANG[2]
[1]Chonnam Nat'l Univ. Med. Sch., Gwangju, Korea, Republic of; [2]Pharmacol., Chonnam Natl. Univ. Med. Sch., Gwangju, Korea, Republic of

**Abstract:** Amyloid β peptide (Aβ) is a main component of senile plaques in Alzheimer's disease and is known as a major pathogenic factor of the disease. Oxidative stress by the generation of reactive oxygen species (ROS) is known as one of the mechanisms of Aβ-induced neuronal death. Currently, NADPH oxidase (NOX) and mitochondria are considered as primary sources of ROS induced by Aβ. However the contribution of NOX and mitochondria to Aβ-induced ROS generation has not been well defined. Present study was performed to delineate the relative involvement of NOX and mitochondria to Aβ-induced oxidative neuronal death in mouse mixed cortical cultures. Intracellular and mitochondrial ROS were monitored employing dihydroethidium (DHE) and dihydrorhodamine 123 (DHR) respectively. Cell death was assessed by measuring lactate dehydrogenase efflux to bathing media 24 hr after exposure to $A\beta_{25\text{-}35}$, a fragment of Aβ with an equivalent neurotoxic effect. Treatment with 10-20 μM $A\beta_{25\text{-}35}$ induced significant DHE fluorescent signals but failed to induce any DHR fluorescent signals. Treatment with 20 μM $A\beta_{25\text{-}35}$ produced about 25% neuronal death. Furthermore, treatment with apocynin, a NOX inhibitor, markedly attenuated both the 20μM $A\beta_{25\text{-}35}$-induced DHE fluorescent signals and neuronal death, but mitotempo, a mitochondria-targeted antioxidant, did not affect both the DHE fluorescent signals and the neuronal death. While increasing the concentration of $A\beta_{25\text{-}35}$ to 40 μM induced significant fluorescent signals of both DHE and DHR, treatment with 40 μM $A\beta_{25\text{-}35}$ produced about 40% neuronal death. Treatment with mitotempo markedly attenuated both the DHR fluorescent signals and the neuronal death. The findings indicate that the concentration of $A\beta_{25\text{-}35}$ has an influence on the involvement of mitochondria for ROS production in Aβ neurotoxicity.

**Abstract:** Alzheimer’s Disease (AD) is characterized by progressive neuronal death, accumulation of neurotoxic and gliotoxic beta-amyloid peptides (Abeta), amyloid plaques, and neurofibrillary tau tangles. The exact mechanism of amyloid aggregation is still unclear. We have shown that astrocyte-derived exosomes contribute to AD progression by seeding amyloid plaques, although the exact mechanism of exosome-induced Abeta aggregation is unknown. We have also shown that these exosomes contain PAR-4, a protein sensitizing cells to ceramide-induced apoptosis. Proximity Ligation Assay showed that ceramide in the exosomal membrane forms a complex with Abeta. Treatment of neuronal cultures with Abeta42-associated exosomes (Abeta/Exos) showed increased neuronal structural damage and death as compared to Abeta42 oligomers or exosomes alone. Using immunocytochemistry, we detected intracellular labeling for ceramide and PAR-4 in neurons exposed to Abeta42/Exos suggesting transfer of pro-apoptotic ceramide and PAR-4 into neurons. To understand interaction of Abeta with ceramide and neuronal uptake of Abeta42/Exos we visualize binding to and uptake of these complexes using super-resolution fluorescence microscopy. Using an antibody developed in our laboratory, ceramides were labeled by immunocytochemistry to visualize their distribution on the plasma membrane of different cells with virtually molecular resolution by direct stochastic optical reconstruction microscopy (dSTORM). Super-resolution images showed that 50-60 % of all membrane ceramides are located in ceramide-rich platforms (CRPs) with a size of about 75 nm that contained at least 20 ceramide molecules. CRPs in exosomes are hypothesized to mediate binding to Abeta to initiate formation of Abeta/Exos and potentially, uptake into neurons. Exploiting super-resolution microscopy might give more insight into the precise molecular interaction between exosomes and Aβ and reveal the role of ceramide in Aβ aggregation and subsequently neuronal degeneration.

**Title:** Metabolic syndrome plus injection of amyloid-β 25-35 peptide into hippocampus not impairs spatial memory and decreased microgliosis in cholinergic regions

**Authors: *O. REYES**[1], A. PATRICIO-MARTÍNEZ[2,4], F. LUNA[5], I. D. LIMÓN[3]
[1]Lab. de Neurofarmacología, [2]Laborartorio de Neurofarmacología, [3]Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [4]Facultad de Ciencias Biológicas, Puebla, Mexico; [5]Laborartorio de Neuroendocrinología, Benemerita Univ. Autonoma De Puebla, Puebla, Mexico

**Abstract:** Metabolic syndrome (MetS) can lead neuroinflammation and cognitive impairment. The injection of Amyloid-$\beta_{25-35}$ peptide ($A\beta_{25-35}$) into cognitive regions induces oxidative stress, neuroinflammation, neuronal death and impairs spatial memory. Particularly, cholinergic nucleus in basal forebrain trigger a neuroinflammatory response in presence of $A\beta_{25-35}$, but we do not know how basal forebrain response in presence of MetS+$A\beta_{25-35}$ when $A\beta_{25-35}$ is injected in an innervated cholinergic region as hippocampus (Hp). The aim of our study was evaluated the spatial memory, microglia and astrocyte response in cholinergic nucleus of MetS plus $A\beta_{25-35}$ hippocampal injured rats. MetS group was obtained by consumption of 20% sucrose in drinking water meanwhile control group (C) received tap water. At eight weeks of treatment, MetS model was evaluated. After, all rats were yield to stereotaxic surgery to the injection of vehicle or $A\beta_{25-35}$ [100µM] into CA1 subfield of Hp, (coordinates; AP: -4.0, L: ±2.3, P: -2.6). The experimental groups were C+Vehicle, MetS+Vehicle, C+$A\beta_{25-35}$ and MetS+$A\beta_{25-35}$. At 15th day post-surgery, experimental groups were tested for spatial learning in the Morris water maze (MWM) and 5 days later, were memory tested. We obtained the brains to assess the immunoreactivity of glial fibrillar acid protein (GFAP) and the ionized calcium binding adaptor molecule 1 (Iba-1) in medial septal nucleus (MS), the vertical nucleus of diagonal band (VDB) and the horizontal limb of diagonal band (HDB). We found that MetS+$A\beta_{25-35}$ not modified spatial learning and memory in the MWM compared to the C+Vehicle. Regarding to microglia and astrocyte immunoreactivity, C+$A\beta_{25-35}$ exhibited increases of Iba-1 stained area in MS (16%), HDB (45%) and VDB (30%) meanwhile GFAP immunoreactivity did not modify in the same subfields

compared to the C+Vehicle. MetS+$A\beta_{25-35}$ reduced Iba-1 stained area in MS (20%), VDB (27%) and HDB (31%) and GFAP staned area did not modify in the same subfields compared to the C+$A\beta_{25-35}$. We found that the injection of $A\beta_{25-35}$ [100µM] into CA1subfield of Hp in MetS model, not impair spatial learning and memory tested in MWM, decrease the microglia reactivity in cholinergic nucleus and astrocyte reactivity differs in MetS model with or without neurotoxic lesion.

**Abstract:** Alzheimer’s disease (AD) primarily impairs the acquisition of hippocampal-dependent explicit memory (memory for facts and events) in association with chronic sleep loss. Recent studies have shown that accumulation of toxic soluble amyloid-beta oligomers (Aβo) give rise to cell death and memory deficits in early AD. However, one seminal question remains unanswered: How Aβo and sleep loss influence each other to induce neurodegeneration and cognitive impairments at the onset of AD? The main objective of this research project is to uncover the deleterious effect of soluble Aβo on memory acquisition and sleep hallmarks affected at the onset of AD. To achieve our goal, we took advantage of our AD animal model which mimics the synaptic and neuronal loss observed in early AD in the hippocampal CA1 region. Repeated hippocampal injections of soluble Aβo (once a day for 6 days; 0.2 µg/µL; 2 µL) induced gradual neuronal loss in the CA1area in Long-Evans rats. We observed by immunofluorescence a lower level of NMDA receptors in association with a higher level of the phosphatase STEP, which is implicated in the internalization of the glutamatergic NMDA and AMPA receptors. An increased level of reactive astrocyte marked with GFAP was also found

after Aβo injections. Aßo induced memory deficits in the spatial object recognition task, a hippocampal-dependent memory task, but not in the novel object recognition test, which rely mainly on the prefrontal cortex instead of the hippocampus. Aßo altered wakefulness and non rapid eye movement (NREM) duration during the dark period. Taken together, these results indicate that the neurotoxicity induced by Aßo in the hippocampal CA1 region decreased the acquisition of hippocampal-dependent memory and altered sleep architecture. The identification of the specific signature of Aβo on the different EEG features when Aβo begins to induce neurotoxicity in the CA1 area might serve as a non-invasive biomarker of early AD. A better understanding of the molecules affected by soluble Aβo when memory acquisition deficits start to appear will bring valuable information to develop new disease modifying targets efficient at the onset of the illness.

**Abstract:** Neurodegeneration in selective areas of brain underlies the pathology of Alzheimer's disease (AD). The p53 tumor suppressor protein functions as a key regulator of cell apoptosis and has been described to accumulate in affected brain areas from AD patients. However, the role of p53 in AD is controversial. Here, we evaluated the role of p53 on amyloid beta (Abeta)-induced neuronal apoptosis and the underlying mechanism. We found that whereas p53 mRNA levels remained unchanged, exposure of neurons to the amyloidogenic fragment 25-35 of the Abeta peptide (Abeta 25-35) promoted p53 phosphorylation and stabilization, which triggered mitochondrial dysfunction and neuronal apoptosis in vitro. Abeta activated the p53

phosphorylating kinase Cdk5 (cyclin dependent kinase 5) and treatment with the Cdk inhibitor, roscovitine, prevented p53 accumulation. Abeta-induced mitochondrial depolarization and neuronal apoptosis were prevented by both genetic and pharmacological inhibition of p53 (pifithrin-alpha, PFT-alpha) and Cdk5, (roscovitine). Furthermore, p53 accumulated in degenerating neurons upon Abeta exposure in vivo. Abeta-caused dendrite disruption and neurotoxicity were prevented by genetic deletion or inhibition (PFT-alpha) of p53 in vivo. Our results reveal that Abeta triggers Cdk5 activation, which induces p53 phosphorylation and stabilization, leading to neurodegeneration. Then, inhibition of the Cdk5-p53 pathway may provide a novel neuroprotective therapy against Abeta-induced neuronal loss. **Abstract:** The pro-inflammatory response mediated by astrocytes and microglia in response to peptide $A\beta_{25-35}$ induces the expression of inducible nitric oxide synthase (iNOS), an enzyme responsible for increasing levels of nitric oxide (NO). It has been observed that the increase in NO concentrations triggers biochemical pathways that contribute to neuronal death and cognitive damage. Cannabinoids have been shown to be neuroprotective agents because of their anti-inflammatory properties and to reduce excitotoxic processes. These properties have been proposed to cannabinoids as drugs for the treatment of various neurodegenerative diseases. The aim of this study was to evaluate the activation of the CB1 receptor plus $A\beta_{25-35}$ peptide

administration on the spatial memory, NO levels, iNOS expression and neurodegeneration into CA1 subfields of the hippocampus (Hp). Male Wistar rats were used. ACEA was used as a agonist for the CB1 receptor and AM-251 as a CB1 antagonist. Seven experimental groups were formed: 1) vehicle + PBS, 2) PBS + ACEA, 3) PBS + AM-251, 4) vehicle + $A\beta_{25-35}$, 5) ACEA + $A\beta_{25-35}$, 6) AM-251 + $A\beta_{25-35}$ y 7) AM-251 + ACEA + $A\beta_{25-35}$. Each treatments were administered bilaterally by stereotactic surgery into CA1 subfields of the Hp (AP: -3.8, L: ± 3.0, P: -2.0). The learning assessment was made in the eight-arm radial maze at 20 days after injection. The memory test was done eight days after the learning assessment. Twenty nine days post-lesion were euthanasia performed on animals to extract the brains. The results show that administration of the $A\beta_{25-35}$ peptide decreases the learning and spatial memory processes. However, the administration of ACEA + $A\beta_{25-35}$ improves the learning and memory processes respect to the $A\beta_{25-35}$ group. The PBS + ACEA and PBS + AM-251 groups did not modify the learning and memory process. On the other hand, we found that $A\beta_{25-35}$ group increase the NO levels in Hp compared to the vehicle + PBS group. In contrast, the ACEA + $A\beta_{25-35}$ treated group decreased the NO levels compared with the $A\beta_{25-35}$ group. Moreover, treatment with PBS + ACEA and PBS + AM-251 groups did not changes NO levels compared the vehicle group. Nevertheless, when evaluating iNOS expression in CA1 subfields of the Hp in each experimental group, the $A\beta_{25-35}$ group showed an increase in iNOS expression respect to the intact group. On the other hand, the ACEA + $A\beta_{25-35}$ decreases the iNOS expression respect to the group $A\beta_{25-35}$. Finally, we found that the group treated with ACEA + $A\beta_{25-35}$ decrease neuronal degeneration compared with the $A\beta_{25-35}$ group. These results suggest that activation of the CB1 receptor by ACEA decreases neurotoxicity induced by $A\beta_{25-35}$ peptide and improves memory process.

**Abstract:** Although β-amyloid plaques (derived from amyloid precursor protein, APP) and Tau-containing neurofibrillary tangles are the two most prominent features of Alzheimer's disease (AD), the disease is a multi-faceted disorder that likely involves many known and unknown genetic factors. Recent genome-wide association studies (GWAS) have uncovered >20 new susceptibility loci associated with sporadic, late onset AD (LOAD). Among which, the Ras and Rab interactor 3 (RIN3), a guanine exchange factor for Rab5 has been implicated in regulating endocytosis and intracellular trafficking of APP, hence production and clearance of Aβ. More recently, a missense mutation in the SH2 domain of $RIN3^{W63C}$ has been identified as a prominent risk factor for AD. Virtually nothing is known about the role(s) of RIN3 in AD pathogenesis. These findings warrant careful examination of RIN3 in AD pathogenesis at the cellular and molecular level.
Our hypothesis is that increased expression or activity of RIN3 activates and stabilizes Rab5 in its activated form to disrupt axonal function leading to neuronal degeneration. We focus on investigating the potential cellular mechanisms by which intraneuronal accumulation of APP/βCTF acts through RIN3 to impair axonal function, a likely mechanism that contributes to early AD pathogenesis. We found RIN3 was upregulated in APP/PS1 AD mouse model at as early as 3 month of age. This was accompanied with an increase in activated Rab5. Furthermore, both $RIN3^{WT}$ and $RIN3^{W63C}$ induced hyperactivation of Rab5 in vitro, and siRNA-mediated knockdown of RIN3 mitigated Rab5 activation. We are actively pursuing studies of knocking down expression of RIN3 in APP/PS1 AD mouse model. We would like to test if these measures rescue or prevent AD-related behavioral and neuropathological deficits. These studies will provide exciting opportunities in establishing RIN3 as a novel drug target for AD therapies.

**Abstract:** The interaction of senescent-related, genetic, and environmental factors significantly contributes to the etiology of late-onset, sporadic Alzheimer's disease (AD). We previously reported that serum levels of *p,p*'DDE, a long-lasting metabolite of the organochlorine pesticide DDT, was significantly higher in patients with AD and associated with risk of AD diagnosis. Further, brain levels of DDE were similar to levels found in blood in 10 matched samples (Richardson et al., 2014). Here we report that in 20 post-mortem AD brains, detectable levels of DDE were present in every brain (14.5 - 43.7 ng/g), and that levels in the temporal lobe were similar to those in the cerebellum, indicating that DDE levels are uniform throughout the brain. However, the mechanisms by which DDT may contribute to AD pathogenesis is unknown. Here, we demonstrate that DDT exposure significantly increased the mRNA levels of *APP*, *PSEN1* and *APOE* in differentiated SHSY5Y cells as well as *App* mRNA and protein levels in mouse primary hippocampal neurons. The increase in APP protein levels was accompanied by increased Aβ secretion in SHSY5Y cells exposed to DDT, and was abolished by the sodium channel antagonist tetrodotoxin. In male wild-type mice treated with 3 mg/kg DDT every 3 days for 30 days, significant increases in APP mRNA and protein levels (~25%), along with increases in mRNA expression of *Nep* (77%) and *ApoE* (150%) in the hippocampus, were observed. We also observed increased $A\beta_{42}$ levels in the hippocampus, and $A\beta_{40}$ and $A\beta_{42}$ in the cortex of female 3xTG mice at 12 months of age following exposure to 3 mg/kg DDT for 3 months. This was accompanied by enhanced plaque pathology in the female 3xTG mice exposed to DDT. Collectively, these data, combined with our previous epidemiological findings, identify a potential mechanism by which DDT exposure may contribute to increased risk of AD. Supported in part by NIH R01ES026057, R01ES026067-S2 and P30ES005022.

**Title:** Dysregulation of NSUN2 in Alzheimer's disease

**Authors: *Y. A. KIM**, I. SANTA-MARIA
Columbia Univ., New York, NY

**Abstract:** Accumulation of extracellular amyloid beta (Aβ) deposits, intracellular neuronal tangles composed of hyperphosphorylated tau and synaptic loss are the main hallmarks of Alzheimer's disease (AD), the most prevalent form of dementia. Currently, the molecular basis of AD is unclear. However, several studies support that altered microRNA (miRNA) expression and/or function plays an important role in AD pathogenesis. However, the mechanisms governing how miRNAs are regulated in the brain are poorly understood. RNA methylation is a prevalent posttranscriptional modification that regulates accuracy of translation initiation, RNA stability, biogenesis and processing of RNA. Historically, it has been shown that methylation occurs on transfer RNA, ribosomal RNA and messenger RNA. Recently, methylation of miRNAs has also been found. However, methyltransferases involved in this process are still under investigation. NSUN2 is one the few known brain-enriched methyltransferases in higher eukaryotes that is able to mediate methylation of miRNAs. Moreover, the loss of NSUN2 in *Drosophila* and mouse models causes memory and learning deficits, indicating a potential role of NSUN2 in cognitive function. Furthermore, in humans, mutations in the NSUN2 gene cause intellectual disability. Interestingly, the role of microRNA methylation in AD pathogenesis has not been reported. Here, our data supports dysregulation of NSUN2 in post-mortem brain tissue from AD patients when compared to healthy controls. In addition, we found that oligomeric Aβ induces both dysregulation of NSUN2 and changes in tau proteostasis in primary neuronal cultures. Furthermore, bioinformatic analysis shows predicted methylation sites in miRNAs that have been implicated in AD, supporting a possible link between NSUN2 dysfunction, microRNAs and AD pathogenesis.

**Title:** The role of ATF4 in neuronal death under Alzheimer's disease conditions

**Authors: *G. PETROFF**[1], S. P. CREGAN[2]
[1]Western Univ., London, ON, Canada; [2]Robarts Res. Inst., London, ON, Canada

**Abstract:** Alzheimer's Disease (AD), the most common cause of dementia, is pathologically characterized by amyloid plaques and neurofibrillary tangles. In addition to these pathological hallmarks, increased markers of neuronal stress have been reported. Amyloid β can aggregate into amyloid plaques, however it is thought that soluble oligomeric forms of the peptide are more toxic and induce greater neuronal stress. To try and mitigate stressors that they encounter, cells can enter into the Integrated Stress Response (ISR) pathway. Activation of the ISR leads to translational upregulation of activating transcription factor 4 (ATF4), which can then modulate its downstream target genes. Previously, it has been found that ISR members upstream from ATF4 are elevated in AD patients' brains. It is believed that acute activation of the ISR is pro-survival and that prolonged activation in response to chronic stressors can lead to the activation of pro-apoptotic pathways. This chronic activation can potentially result in the neurodegeneration seen in diseases such as Alzheimer's. Therefore, we aimed to determine if amyloid β-induced neuronal death occurs through ATF4-dependent upregulation of pro-apoptotic genes. Mouse CD1 primary cortical neurons, harvested on embryonic day 14.5, were treated with 1μM amyloid β. Using a Hoechst stain assay, amyloid β-treated neurons showed higher apoptotic cell death compared to controls. Additionally, following amyloid β treatment, immunoblotting showed a sustained increase in ATF4 protein levels and quantitative RT-PCR results demonstrated significant increases in the expression of pro-apoptotic transcripts, such as CHOP, Trib3, and Gadd45α ($p > 0.05$). In ATF4-null neurons ($ATF4^{-/-}$) treated with amyloid β, pro-apoptotic transcript levels and apoptotic cell death were both attenuated compared to $ATF4^{+/+}$ neurons. Therefore, ATF4 plays a necessary role in amyloid β-induced neuronal death. To conclude, these results suggest that targeting the ISR or ATF4 may be a potential therapeutic target for the treatment of Alzheimer's disease.

**Title:** Beta amyloid oligomer internalization via recently discovered nicotinic receptors may contribute to cholinergic cell death in Alzheimer's disease

**Authors: *G. WILLIAMS**[1], T. A. MURRAY[2]
[2]Biomed. Engin., [1]Louisiana Tech. Univ., Ruston, LA

**Abstract:** Central cholinergic neuron death and accumulation of beta-amyloid plaques are pathogenic features of Alzheimer's disease (AD). Despite scientific advances, the etiology of AD is not fully understood. The α7β2 nicotinic acetylcholine receptor (nAChR), a recently discovered neurotransmitter receptor subtype, is expressed in the septum and hippocampus of the brain regions of cell death early in AD. Research has shown that α7-nicotinic acetylcholine receptors (α7-nAChR) mediate β-amyloid peptide (Aβ) internalization and contribute to neuronal death. Studies have not yet focused on α7β2 nAChR mediated internalization of $A\beta_{1\text{-}42}$. Based on previous research, α7β2 is suspected to have a higher affinity for Aβ.Our study focused on comparing α7β2- to α7-nAChR mediated internalization of Aβ. SH-EP1 human neuroepithelial cell lines stably expressing α7-nAChRs (Fig 1A) or α7β2-nAChRs (Fig 1B), and wild type cells were incubated with oligomeric $A\beta_{1\text{-}42}$ or scrambled peptide (Fig 1C) followed by incubation with Amylo-Glo® dye (Biosensis). Aβ internalization was analyzed through a comparison of fluorescence intensity. Cell death assays were also performed.

Higher rates of Aβ internalization were displayed in cells expressing α7-nAChRs versus cells with α7β2-nAChRs, however both were markedly higher than cells incubated with scrambled $A\beta_{1\text{-}42}$ and wild type cells. Notably, cells expressing α7β2-nAChRs had a high rate of cell death. This suggests that internalization by α7β2-nAChRs could contribute to loss of function and cell death in AD.

These results provide new insights into mechanisms of intracellular Aβ accumulation and cytotoxicity. The α7β2 receptor is expressed in the septum and hippocampus where cholinergic cell death is observed in AD pathology. Because Aβ aggregation is a hallmark of AD pathology that contributes to neurodegeneration, further understanding the role of nicotinic acetylcholine receptors, particularly α7β2-nAChR, on β-amyloid is crucial to working towards treatment options and preventative measures.

**Title:** A novel thiourea possessing anti-inflammatory property rescues Aβ-induced bioenergetic dysfunction in microglia

**Authors: *Y.-S. SUN**[1,3], F.-S. SHIE[2], M.-H. CHAN[3], Y.-T. HSU[2]
[1]Ctr. For Neuropsychiatric Res., Natl. Hlth. Res. Inst., Zhunan town, Taiwan; [2]Ctr. for Neuropsychiatric Res., Natl. Hlth. Res. Inst., Zhunan Town, Taiwan; [3]Inst. of Neuroscience, Natl. Chengchi Univ., Taipei, Taiwan

**Abstract:** Alzheimer's disease (AD), a neurodegenerative disease, is characterized by the progressive neuronal loss and overactive microglia. Besides, amyloid-β (Aβ) is recognized as the biomarker in AD, which plays a crucial role in the pathogenesis of this disease. The imbalance between Aβ production and clearance leads to the accumulation of Aβ in extracellular and intracellular compartments. Growing evidence suggests that excessive amyloid-β (Aβ) accumulation instigates early deficits in mitochondrial function and causes a self-propelling cycle of microglial overactivation, eventually leading to neuronal damages. However, how Aβ affects mitochondrial function in microglia is still illusive. Here, we used the Seahorse XF$^e$24 Extracellular Flux Analyzer and the Seahorse XF Cell Mito Stress Test Kit to measure the oxygen consumption rate (OCR) as an indicator of mitochondrial functionality in microglia. The assay equipped with automatic drug delivery system targeting components of the electron transport chain (ETC) in the mitochondria provides us the key parameters of metabolic function, including ATP production, maximal respiration, and non-mitochondrial respiration. Our data show that Aβ induced a decline of the OCR in microglia as evidenced by significantly reduced maximal respiration and spare capacity. Intriguingly, the treatment of a novel thiourea rescued the abnormal OCR in microglia and improved the mitochondrial function. Our data further indicate that the rescuing effects of the novel compound on the aberrant bioenergetics elicited by Aβ are involved in the modulation of ERK activity that is highly associated with mitochondrial damages under the circumstances of Aβ toxicity. Taken together, our findings support the notion that Aβ undermines the mitochondrial bioenergetics in microglia. The beneficial effects of our novel thiourea on improving the mitochondrial function might aid the development of future treatments for AD.

**Title:** Neuroprotective effect of minocycline on mitochondrial mediated toxicity in Abeta-42 induced Alzheimer's disease using *Drosophila melanogaster* as an alternate model

**Authors: *R. KHATOON**
Jamia Hamdard, New Delhi, India

**Abstract:** Mitochondrial dysfunction is the foremost perpetrator of neurodegeneration in Alzheimer’s disease (AD). Studies suggest that minocycline have potential to reduce mitochondria mediated neurotoxity in AD but the exact underlying mechanism is not well explored. We investigated the protective effect of minocycline on Abeta-42 induced mitochondrial mediated neuronal dysfunction in *Drosophila melanogaster* at the organismal level by climbing, survival assay as well as cellular level through estimation of mitochondrial stress markers and apoptosis markers. Overexpression of Abeta-42 in the brain induced behavioral deficits in Drosophila *melanogaster* fruit fly. Deficits at a organisamal level were assessed by the using climbing, and survival behavior paradigms that is revealed by the Minocycline. Minocycline reduced the mitochondrial ROS and increases mitochondrial membrane potential determined by the Flow cytometer. Minocycline has also potential to decrease the denstometric ratio of Bax, Cleaved caspase 3 and cuts protein and increase in Bcl2 done by the western blotting. Moreover, our study suggests that minocycline shows a neuroprotective effect in Abeta-42 induced neuronal toxicity in AD.

**Abstract:** Neural activity is closely followed by a localised change in cerebral blood flow, a process termed neurovascular coupling. Impaired neurovascular coupling may be an early pathogenic factor in Alzheimer's disease (AD), which could also serve as a perfusion-based imaging biomarker of cerebral pathology. However, few studies have examined neurovascular dysfunction in AD mouse models, potentially due to the challenges of controlling physiological parameters in mice and profound effects of anaesthetics on vascular physiology. In the present study, we adapted an anaesthetic regime producing hemodynamic responses comparable to those in the awake mouse for use as a chronic anaesthetised preparation, to determine the onset and evolution of neurovascular alterations in the hAPP-J20 mouse model of AD and wild-type (WT) control animals. In addition, neuropathology was characterised relative to cognitive assessments in a separate cohort of animals. Animals were between 9 and 12 months of age at the start of the chronic imaging experiment. Optical imaging spectroscopy (OIS) produced functional maps of changes in tissue oxygenation and cerebral blood volume in response to whisker stimulation and vascular reactivity challenges. Following implantation of the imaging chamber, mice spent 7 days recovering before 3 chronic imaging sessions performed 30 days apart. A concurrent multi-depth electrophysiology and OIS acute experiment was performed to measure both neural activity and the hemodynamic responses. The hemodynamic response was largely preserved in the AD and WT groups, in contrast with previous reports. However, in the final acute experiments there was a distinct difference between these groups, similar to previous reports using acute preparations. This suggests that hAPP-J20 mice may be more susceptible to an acute CNS challenge, such as insertion of an electrode, compared to WT animals. The method of investigation may be a critical aspect in assessing neurovascular breakdown in mouse models of disease. Short-term recognition memory was preserved up to 12 months of age, but long-term recognition memory was impaired from 3 months of age. Aβ plaques were present from 6

months, with reactive microglia and astrocyte activation in the hippocampus significantly greater in the AD mice at 9 months, compared to WT. Preserved short-term but impaired long-term recognition memory therefore preceded Aβ deposition and glial activation. Defining early neurovascular, neuropathological, and cognitive changes could provide insight into new therapeutic targets early in the disease process, when intervention is most likely to effectively slow disease progression.

**Abstract:** Funding: NIH-NIA (AG054562)
Reduction of amyloid β (Aβ) is a key goal in the treatment of Alzheimer's disease. Sialic acid binds to Aβ with high affinity and exogenously-administered sialic acid improves cognition and attenuates neurotoxicity in several animal models. In this and our previous study, we used glycomacropeptide (GMP) from bovine milk to elevate levels of sialic acid and brain gangliosides.
In our previous study, administration of GMP in mouse chow had a positive effect on memory performance tasks and reduced both soluble and aggregated Aβ. The activated microglia and reactive astrocytes normally observed in cortical and hippocampal regions in 5xFAD transgenics were also significantly reduced in mice eating GMP.
Our current study uses male and female 5xFAD mice, which harbor human transgenes containing two PSEN1 and three APP mutations. Mice were given whey protein isolate either without (WPI group) or with GMP (WPI+GMP) in their drinking water, or water alone. In the first study, experimental diets were administered from 4 to 9 months of age and cognitive testing

was conducted before sacrifice at 9 months. The second study used a similar design, but with older mice starting experimental diets at 9 months and behavioral assessments at 14 months. The first cohort of younger mice treated with WPI+GMP demonstrated a modest improvement in cognitive and motor function compared to controls. Although preliminary, these results taken with our initial study suggest that dietary GMP may provide therapeutic benefit against Alzheimer's-related cognitive and neural impairments.

**Title:** High density awake recording of CA1 neurons in APP/PS1 mouse model of Alzheimer's disease

**Authors: *U. CHOCKANATHAN**, E. WARNER, L. TURPIN, M. O'BANION, K. PADMANABHAN
Univ. of Rochester, Rochester, NY

**Abstract:** Alzheimer's disease (AD) affects five million Americans and is the sixth leading cause of death in the United States. Individuals with AD often experience a loss of independence and decrease in quality of life stemming from the range of cognitive and behavioral symptoms caused by the disease. Despite substantial progress toward uncovering molecular and cellular hallmarks of AD and considerable work examining the behavioral consequences of that neuropathology, the alterations of neural activity patterns in the context of AD remain relatively unexplored and constitute a major gap in the understanding of the disease. Thus, interrogating changes in neural circuits is essential for linking the cellular pathology with behavioral changes and identifying potential loci for intervention. Using high density silicone array recordings in awake head-fixed animals, we recorded large populations of single neurons in the CA1 region of the hippocampus in the APP/PS1 transgenic mouse model of AD and in aged controls.

Extracellular recordings were made using 128-channel probes targeted to the dorsal CA1 (dCA1) region while the mice ran on a one-dimensional running wheel. 4 control and 4 APP/PS1 mice, all 11-12 months of age, were head-fixed and trained to run on a wheel for an hour per day for a 7-day period, after which the recordings were made. We analyzed first and second order statistics of neural activity and then linked the observed patterns to behavior. First, mean firing rates and inter-spike intervals were not significantly different between the two groups. However, our data showed that in the APP/PS1 mice, units were less correlated with each other, on average, than in control animals. Moreover, units from APP/PS1 mice were more correlated with running behavior than those from control mice. Additionally, population spike-train entropy, a measure of network disorder, was significantly higher in the APP/PS1 mice. These data show that dCA1 neuronal circuit activity is less structured in APP/PS1 mice; consequently, we have identified a potential link between the previously reported alterations in dendritic structure, synaptic connectivity, and neuronal excitability and network activity. Such a connection may provide insight into how the behavioral deficits that are a hallmark of the disease may arise from changes in the activity patterns of neural networks.

**Abstract:** Alzheimer’s disease (AD) is the most common form of dementia that involves neurodegenerative processes affecting synaptic function and memory formation. Mitochondrial dysfunction is widely related to the pathogenesis of AD, causing an increase in

cellular oxidative stress and, consequently, neuronal death. Several reports indicate that antioxidant supplementation has beneficial effects in animal models of AD. Lycopene is a potent antioxidant able to recover mitochondrial function in *in vitro* models, as well as in animals administered with the peptide Abeta1-42. However, the effect of lycopene in a transgenic model of AD has not been demonstrated. It should be noted that commercial lycopene is mainly extracted from tomatoes, which makes this product very expensive and not very accessible to the population. Therefore, in this project it is proposed to evaluate the therapeutic effect of lycopene obtained through a sustainable and economic process utilizing waste products from the process of beer production. **Objective:** To elucidate the mechanism by which lycopene improves cognition, synaptic density and mitochondrial morphology in APPPS1 mice. **Methods:** Lycopene (4 mg/kg, Sigma) or organic compound (4mg/kg) were given by oral cannulation to 4 month-old male APPPS1 (n=6) and WT mice (n=6), during 4 weeks. Vehicle (tween 5%) treated mice were included as controls (n=6). Cognitive performance was assessed 3 days before finalizing treatments. Animals were sacrificed and brain was immediately collected. Coronal hippocampal sections were used to assess amyloid pathology by BAM10 immunoreactivity, and spine density was evaluated after biolistic labelling. Mitochondria hippocampal morphology was evaluated by Transmission Electronic Microscopy (TEM). OPA1, DRP1 and PGC1-alpha proteins were measured in cortex samples. **Results:** We observed a significant improvement in short-term memory in APPPS1 mice treated with Lycopene (Sigma), while no recovery was observed with the organic compound. This behavioral recovery was accompanied by decreased Abeta load, increased spine density in hippocampus, recovery of mitochondria morphology, and OPA1, DRP1 and PGC1-alpha protein increases compared to APPPS1. **Conclusion**: Lycopene protects from cognitive alterations in APPPS1 by restoration of mitochondrial functioning, resulting in increased synaptic density. Hence we conclude that a nutritional supplementation with antioxidant compounds can be used as a therapeutic strategy against degenerative diseases, and may modulate the course of Alzheimer´s disease. *Study funded by Camara de la Industria de la Cerveza y la Malta, S.A. de C.V., and CONACYT-Mexico.*

**Title:** Evaluating the benefits of angiotensin-converting enzyme inhibition in *Drosophila* models of Alzheimer's disease

**Authors: *S. LEE**, S. GOMES[1], G. BOULIANNE[2,1]
[1]The Hosp. for Sick Children, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

**Abstract:** Alzheimer's disease (AD) is the most common cause of dementia in the aging population for which there is no cure. Through genetic studies of familial AD, mutations were identified in Presenilins (PS), which encode the catalytic component of the γ-secretase complex, which cleaves the amyloid precursor protein C-terminal fragment (APP-CTF) to produce amyloid peptides. Mutant forms of presenilin result in aberrant cleavage of APP-CTF to produce longer, more toxic forms of amyloid (Aβ42) that have been suggested as a major cause for AD-related neurodegeneration. Although several PS-targeting drugs have been developed, controversy remains as to whether this is an effective strategy as PS can also affect processing of many other proteins. One alternative strategy would be to target the interaction of PS with specific proteins such as APP-CTF.
Our lab used a genetic approach in *Drosophila* to identify proteins that specifically modulate the interaction between PS and APP-CTF. One such candidate is Angiotensin-converting enzyme (ACE), a metalloprotease of the renin-angiotensin system known to regulate blood pressure in humans. Interestingly, several recent studies have also shown that ACE inhibition can reduce the risk of AD, although the precise mechanisms are unknown. To determine whether ACE inhibitors are beneficial in AD and to identify the mechanism of action we utilized *Drosophila* lines that express three different AD-related human transgenes (APP/C99$^{WT}$; APP/C99$^{V717I}$; Aβ42) under the control of either an eye (GMR-GAL4), or CNS (ELAV-GAL4) specific promoter. We then examined whether Captopril, an ACE inhibitor or Losartan, an Angiotensin receptor blocker, had any effect on age-dependent, neurodegenerative phenotypes generated by expression of each AD transgene.
To date, we observed beneficial effects associated with inhibition of ACE in flies expressing APP/C99$^{V717I}$ including a reduction in cell death and an increase in lifespan. In contrast, ACE inhibition had no effect in flies expressing APP/C99$^{WT}$ or Aβ42. Moreover, neither Captopril or Losartan had any effect on Notch, a known target of γ-secretase, suggesting that these drugs are specific to AD related pathways. To determine the mechanism of action of Captopril and Losartan, we used western blots and ELISA assays to examine the effect of the drugs on the levels of C99 and amyloid peptides. We observed changes in the levels of C99 and the production of β-amyloid peptides only in APP/C99$^{V717I}$ expressing flies suggesting that ACE inhibition may affect the cleavage of APP-CTF by PS/γ-secretase. Future studies will focus on determining how ACE inhibition affects this interaction.

**Abstract:** Stress, likely due to hypothalamic-pituitary-adrenal (HPA) axis hyperactivity and excessive glucocorticoid secretion, is linked to the pathophysiology of Alzheimer’s disease (AD). For example, glucocorticoids worsen AD neuropathology (i.e., brain Aβ formation and tau accumulation) and cognitive impairment. Previous work from our laboratory indicate sex differences in glucocorticoid signaling in rats and mice in response to acute and chronic stress exposure. Notably, relative to men, women are twice as likely to suffer from stress-related disorders (e.g., depression) and AD. The goal of the present study was to investigate whether chronic variable stress (CVS) exacerbates and accelerates AD-related endpoints in a sex-dependent manner in young mice. This was accomplished using the triple transgenic mouse model of AD (3xTg), and their corresponding background strain (B6129SF2/J) as controls. Prior to CVS, 3xTg females, but not 3xTg males, showed a heightened corticosterone response to a restraint challenge. Observed at 4 months, this suggests that HPA-axis dysfunction may precede the onset of some AD-related endpoints in genetically vulnerable females. However, CVS exposure induced a persistent (6 weeks) elevation in basal corticosterone concentrations only in males, regardless of genotype. Together, these findings suggest sex differences in HPA-axis function prior to and following CVS exposure. Throughout the study, 3xTg mice of both sexes exhibited coat state deterioration, a depression-like phenotype. This finding supports the documented link between depression and AD. Cognitive deficits in AD encompass spatial, object, and social memory. Here, we evaluated social memory using the 3-chambered social preference and recognition test. At 6 months, male 3xTg mice did not display any observed cognitive deficits. However, female 3xTg mice displayed deficits in social memory, independent

of CVS history. This suggests a sex difference in amygdala-related memory vulnerabilities in the 3xTg mice. Based on these findings, CVS does not appear to negatively impact behavioral (i.e., cognition and depression-like) or endocrine (i.e., basal corticosterone) phenotypes in 3xTg mice at the observed age. However, given sex differences in HPA-axis responsivity and social memory, we will determine if CVS accelerates and exacerbates AD-related cellular anomalies (e.g., Aβ, phosphorylated tau) in a sex-dependent fashion. These data may further our understanding of how stress impacts neuroendocrine, behavioral, and cellular anomalies associated with AD in both sexes; thereby, shedding more light into the pathophysiology of this debilitating disease.

**Abstract:** Alzheimer’s disease (AD) is characterized by cognitive decline, the severity and rate of which are modulated by seizure activity. Although seizures are often infrequent, they contribute importantly to cognitive deficits in both AD patients and transgenic mice expressing human amyloid precursor protein (APP), and treatment with the antiepileptic drug levetiracetam improves cognition. We reported that even infrequent seizures in APP mice produce hippocampal accumulation of the transcription factor ΔFosB, which epigenetically alters expression of plasticity-related genes and drives persistent cognitive deficits. ChIP-sequencing and network profiling of genes bound by ΔFosB in APP and nontransgenic (NTG) mice demonstrated that the gene regulatory programs controlled by ΔFosB in the hippocampus undergo functional diversification in APP mice, revealing novel target genes involved in the regulation of neuronal excitability, glutamatergic signaling, and calcium homeostasis. In new

studies, we have focused on ΔFosB target genes that regulate excitability, aiming to investigate endogenous mechanisms by which neurons control excitability in conditions of recurrent seizures. We identified a number of novel, excitability-related ΔFosB targets that are suppressed in the hippocampus of APP mice, including a calcium-activated chloride channel that was not bound by ΔFosB in NTG mice, consistent with diversification of target genes in APP mice relative to NTG mice. AAV-mediated restoration of expression of the calcium-activated chloride channel revealed a worsening of neuronal alterations that are known to reflect the frequency and magnitude of seizure activity. These results and others suggest that ΔFosB-induced suppression of specific target genes may act to limit excitability in conditions accompanied by recurrent seizures, such as Alzheimer's disease and epilepsy.

**Authors: *J. J. NEIWORTH**, C. KWON
Dept of Psychology, Carleton Col., Northfield, MN

**Abstract:** Histological analysis of cotton top tamarin brain tissue showed that Alzheimer's Disease (AD) markers were present and increase with age of monkey. Labeling techniques using DAB staining and 6E10 antibody for beta amyloid, AT8 for neurofibrillary tangles, and GFAP for astrocytes were used, along with a light thionine stain for background tissue and to note cell volume and degradation. A separate lab was used with blind identification of age of monkey to corroborate findings. It was evident that there were beta amyloid plaques in monkeys around age 12-14, with levels increasing and pushing into vasculature with age. An abundance of neurofibrillary tangles were labeled in the oldest monkey post-mortem, who died at age 24. Less and/or rare levels of neurofibrillary tangles were present in tissue from younger monkeys. Double-labeling was used to study the relationship between astrocyte health, atrophy, hypertrophy, and adjacency to beta amyloid plaques. We discuss an interaction between levels of AD markers and immunological response based on age, and will correlate with cognitive

dysfunction to build a cognitive and neural description of aging, dysfunction, and AD-like symptoms in tamarins.

**Abstract:** Amyloid precursor protein (APP) is cleaved by a set of proteases including α-/β-/γ- and recently identified η-secretases, generating C-terminal fragments (CTFs) of varying lengths and amyloid β (Aβ) peptides, which are considered to play a pivotal role in Alzheimer's disease (AD) pathogenesis. Cellular cholesterol content/distribution can regulate the production/clearance of APP metabolites and hence modify AD pathology. To determine the functional relation between endosomal-lysosomal (EL) cholesterol sequestration and APP metabolism, we used our recently developed mouse N2a-ANPC cells that overexpress Swedish mutant human APP in the absence of cholesterol-trafficking Niemann-Pick type C1 (Npc1) protein. Here, we report that neither increased levels nor EL cholesterol sequestration altered APP holoprotein levels but caused the intracellular accumulation of APP α-/β-/η-CTFs and Aβ1-40/42 peptides. The levels of APP-cleaved products increased as a function of extracellular serum concentration in N2a-ANPC cells, which are more vulnerable to death than the control cells. Additionally, we show that pH of the lysosomal vesicles in N2a-ANPC cells shifted to a less acidic range with increasing serum concentrations, thus making them less efficient functionally. Interestingly, the addition of cholesterol to the culture media not only increased the levels of cellular cholesterol and APP-cleaved products but also rendered the cells more vulnerable to toxicity. Collectively, our results suggest that extracellular cholesterol

concentration in serum under conditions of Npc1 deficiency can influence intracellular cholesterol content/distribution and lysosomal efficacy, triggering the accumulation of toxic APP-cleaved products, eventually leading to cell death.

**Abstract:** While the role of β-amyloid (Aβ) in the loss of synapses and neurons contributing to Alzheimer's disease has been well-established, interventions that suppress Aβ have, to date, failed at translating into successful medicines. One contributing factor to these failures is the lack of an objective clinical biomarker that can detect the impact of early synaptic pathology on neuronal circuits, as these circuits give rise to proper encoding of sensory information leading ultimately to cognition and memory. In these sets of experiments, we recorded steady-state sensory EEG responses in wild-type and TG2576 mice which express high concentrations of the mutant Aβ due to a transgene coding for the isoform of Aβ precursor protein. These TG2576 mice exhibited abnormal sensory-evoked EEG activity which correlated with age and increasing Aβ-related pathology. Such low-level sensory-evoked responses may provide early insights into cortical pathologies that could be translated into patients as both an early measure of Aβ-driven synaptic dysfunction and as an objective measure of treatment response.

**Title:** Presenilin1 and 2 regulates zinc homeostasis and zinc dysregulation affects lysosomal dysfunction

**Authors: *H. LEE**[1], *Y. YOON[2], J.-Y. KOH[1]
[1]ASAN Med.Center, Seoul, Korea, Republic of; [2]Dept. of Ophthalmology, Asan Med. Ctr., Univ. of Ulsan Col. of Med., Seoul, Korea, Republic of

**Abstract:** Several mutations in presenilin 1 and 2 (PS1/2) genes cause familial Alzheimer's disease (FAD). While earlier studies focused on their role in Aβ-generating γ-secretase activity as a possible pathogenic mechanism, recent studies have reported that normal functions of PS1/2 include the regulation of the autophagy-lysosomal pathway, and the loss of PS1/2 function by their mutations hence causes defective autophagy-lysosomal degradation, a possible contributing mechanism in AD. Since zinc homeostasis is also likely involved in the regulation of autophagy lysosomal pathway, we examined the possible interaction between PS1/2, zinc homeostasis, and autophagy lysosomal degradation. In PS1/2 double knockout (DKO) mouse embryonic fibroblast (MEF) cells, levels of several autophagy-lysosomal proteins were increased, yet no further increases were induced by the addition of bafilomycin A1, an inhibitor of lysosomal acidification, indicating that lysosomal function was abnormal in PS1/2 DKO cells. Furthermore, when incubated with Aβ1-42, levels of accumulated Aβ in PS1/2 DKO cells were substantially greater than those in WT cells. Next intracellular free zinc levels were assessed with a zinc-specific fluorescent dye, FluoZin3-AM. Compared with intracellular free zinc levels in WT MEF cells, those in PS1/2 DKO MEF cells were significantly higher at the resting state. Furthermore, exposure to 100 uM zinc for 30 min, increased zinc levels more so in PS1/2 DKO cells than in WT cells. In contrast, lysosomal free zinc levels appeared lowered in PS1/2 DKO cells than in WT cells at resting state. However, exposure to zinc clioquinol increased lysosomal free zinc levels in PS1/2 DKO cells, which ameliorated lysosomal dysfunction and reduced levels of Ab in

these cells. Interestingly, while cytosolic zinc levels increased to a greater level in DKO cells, DKO cells were less sensitive to zinc toxicity than were WT cells. Consistent with this, with identical zinc exposure, zinc-induced lysosomal membrane permeabilization (LMP) was less pronounced in DKO cells than in WT cells. Present results support the idea that PS1/2 may regulate autophagy lysosomal pathway, likely by maintaining lysosomal acidification. At the same time, PS1/2 may contribute to cytosolic and lysosomal zinc homeostasis. The absence of PS1/2 may increase cytosolic zinc levels but decrease lysosomal zinc levels, which changes may contribute not only to autophagy lysosomal dysfunction in PS1/2 DKO MEF cells, but also to their diminished vulnerability to zinc-induced LMP and cell death.

**Abstract:** One of the major neuropathological hallmarks of Alzheimer’s disease (AD) is the extracellular deposition of amyloid β (Aβ) peptides as senile plaques. Many epidemiological and experimental studies have indicated that type 2 diabetes mellitus (T2DM) is a risk factor of AD. Some reports showed signs of insulin resistance in postmortem brains of patients with AD. Thus, insulin resistance has been considered as a common molecular pathological feature shared by AD and T2DM. In the mouse models of AD, however, Aβ deposition has been shown to be attenuated by knockout (KO) of *Irs2* encoding insulin receptor substrate-2 (IRS-2), a major signaling molecule that mediates the insulin effects. To gain insights into the molecular mechanism of the inhibitory effect of *Irs2* disruption on Aβ pathology, we examined *Irs2* deficient APP transgenic mice (A7 line). *Irs2* KO A7 mice exhibited hyperglycemia and systemic insulin resistance. The Aβ levels in the cortical homogenates of A7 mice measured by ELISA were not altered by *Irs2* deficiency by 6 months of age, whereas the levels of soluble and insoluble Aβ were both reduced at 9 months of age. Immunohistochemical staining of cortices of 15-month-old A7 mice revealed that *Irs2* deletion remarkably mitigated Aβ deposition.

However, the levels of APP fragments or APP processing enzymes in the cortical homogenates of 9-month-old *Irs2* KO A7 mice were similar to those in A7 mice, indicating that deletion in *Irs2* does not affect Aβ production. Furthermore, *in vivo* microdialysis showed that the Aβ levels of the interstitial fluid (ISF) of hippocampus as well as the half-life of Aβ42 (as determined by administration of a γ-secretase inhibitor Compound E) were not significantly different between genotypes in 9-month-old mice, suggesting that *Irs2* deletion does not modify Aβ clearance. Taken together, these results suggested that *Irs2* knockout does not affect production or clearance of Aβ; alteration in other aspects of Aβ dynamics, e.g., aggregation of Aβ, may be the cause of Aβ reduction in *Irs2* KO mice.

**Abstract:** The amyloid precursor protein (APP) is highly expressed by neurons compared to other cell types in the brain. APP is metabolized to numerous fragments including the amyloid beta (Aβ) peptides which are known to fibrillize and likely stimulate the degenerative and inflammatory changes characteristic of Alzheimer’s disease (AD) brains. Based upon the fact that enteric neurons also express APP and elderly are often afflicted with intestinal dysfunction such as constipation and fecal incontinence we hypothesized that the enteric nervous system may also produce Aβ production leading to an intestinal component of disease that may be temporally unique from the brain. To test this idea, we compared C57BL/6 wild type male and female mice to two models of AD, littermate control APP/PS1 mice and the newly characterized APP (NL-G-F) mice at 3, 6, and 12 months of age. Brain Aβ plaque deposition, microgliosis, astrogliosis, and

oligomeric and fibrillar Aβ deposition in APP (NL-G-F) and APP/PS1 mice were increased in an age-dependent manner. The increase in both male and female APP (NL-G-F) mice preceded that observed in the APP/PS1 mice, observable by 3 months of age. APP (NL-G-F) also demonstrated reduced Aβ 1-40 levels compared to the APP/PS1 mice at 3 months of age correlating with the Iberian mutation to promote a higher Aβ 1-42/1-40 ratio. Interestingly, female but not male APP/PS1 and APP (NL-G-F) mice demonstrated memory dysfunction at 3 months of age. In addition, 3 month old female APP (NL-G-F) mice also presented decreased intestinal motility as compared to the wild type and APP/PS1 mice. However, 3 month old female APP/PS1 mice demonstrated significantly increased intestinal permeability compared to wild type and APP (NL-G-F) mice. In addition, both APP/PS1 and APP (NL-G-F) males had increased mRNA expression of proinflammatory cytokines and the inflammation marker, Lipocalin-2, at 3 and 6 months of age while females had increased Lipocalin-2 at 3 months of age. These data demonstrate that both AD mouse models have cognitive and intestinal dysfunction by 3 and 6 months of age correlating with Aβ production and both mouse models present significant gender differences in their brain and intestinal inflammatory phenotype. The unique nature of Aβ production and deposition as well as intestinal changes across the two mouse models suggests that further study is required to better characterize the brain and peripheral disease progression for ultimate comparison to human disease.

**Abstract:** Introduction: Alzheimer’s disease (AD) is a progressive neurodegenerative disease that manifests as memory loss, learning dysfunction and dementia. Spatial learning and memory of AD rodent models is often assessed via navigational cues in mazes, most popular are the Morris water maze and the dry-land Barnes maze. Improved performance over sessions or trials is thought to reflect learning and memory.

Method: The Barnes maze is considered less stressful compared to water mazes and also useful for rodent models with minor motor deficits. The Barnes maze is a circular platform top with several holes equally spaced around the perimeter edge. Animals of $APP_{SL}$ and 5xFAD transgenic AD mouse models in a symptomatic age were analyzed in the Barnes maze test using a hippocampal learning protocol.
Results: Barnes maze results were analyzed for escape latency, speed, distance traversed, number of target entries, and the abidance in the target quadrant during the probe trial. Data of the two animal models were compared.
Conclusion/Summary: Our data show that the dry-land behavioral test apparatus of the Barnes maze is a valuable tool to analyze learning and memory deficits of different rodent AD models. This method might be an effective alternative to the Morris water maze while causing less stress to the animals.

**Abstract:** This study used a gene transfer approach to investigate the cardiovascular disease (CVD)-Alzheimer’s disease (AD) inter-relationship. A risk factor for the development of CVD, hypercholesterolemia, was induced in AD transgenic mice via gene transfer for mutant PCSK9 using a recombinant adeno-associated virus (AAV) vector in combination with a high fat diet. Cholesterol levels were dramatically elevated by 5-6-fold in the amyloid mice from 3 to 13 weeks after PCSK9 gene transfer compared to the control group of amyloid mice receiving a green fluorescent protein vector. We tested whether the robust hypercholesterolemia would exacerbate the deposition of amyloid-ß (Aß) plaques in the hippocampus and cortex at 7 months of age. Plaque burden was increased in the hippocampus of PCSK9 treated mice compared to the

control group though the increase was only modest compared to the large elevation in cholesterol. Studying the consequences of elevated cholesterol via gene transfer could be valuable in AD models as well as a variety of disease models involving the heart, the brain, and other tissues, as compared to making crosses with current germ-line transgenic mouse models of CVD.

**Title:** iSPECS: a proteomic method identifies the secretome of brain cells and novel substrates of the Alzheimer beta-secretase BACE1

**Authors: *J. TÜSHAUS**[1], S. A. MÜLLER[2], S. F. LICHTENTHALER[2]
[1]DZNE Munich, TUM Munich, Muenchen, Germany; [2]DZNE - German Ctr. For Neurodegenerative Dis., Munich, Germany

**Abstract:** Proteins secreted or proteolytically released from cells constitute the secretome and have a major function in the cell-cell communication in the nervous system, for example between neurons and glial cells or microglia. One of the contributing proteases is the beta-secretase BACE1 which cleaves the amyloid precursor protein (APP) and is a major drug target for Alzheimer's disease. However, BACE1 also cleaves numerous other substrates besides APP. A detailed understanding of the substrate repertoire as well as the function of the released ectodomains is necessary to predict potential side effects.
In a first step, we developed the 'improved secretome protein enrichment with click sugars' (iSPECS) method, which uses metabolic glycoprotein labelling and click chemistry and determines the secretome of (primary) cells, even in the presence of serum or serum-like culture supplements. To demonstrate the power of the method, we determined the secretome of the major brain cell types (neurons, astrocytes, microglia or oligodendrocytes) freshly isolated from mouse brain. This is a valuable resource for studying cell-cell communication in neuroscience. Next, we used iSPECS and determined BACE1 substrates in primary neurons in a brain region-

specific manner, such as from hippocampus and cortex. Several identified substrates were validated by immunoblots and are being functionally validated.
Taken together, we introduce iSPECS, a novel proteomic method used for secretome determination of the major brain cell types. Additionally, the identification of new BACE1 substrates has to potential to advance our fundamental knowledge of the function of BACE1 in the brain and to predict consequences of its inhibition when treating Alzheimer's disease.

**Abstract:** Alzheimer Disease (AD) is defined by the pathological lesions of senile plaques (SP) and neurofibrillary tangles (NFT) containing amyloid beta protein (Abeta) and microtubule-associated protein Tau (MAPT), respectively. Transgenic mouse models expressing familial AD (FAD) mutant *APP* and *PSEN1* cDNAs have provided a number of insights into genetic and environmental factors that drive Abeta aggregation and deposition of SP in AD and these changes correlate with human clinical AD. Our hypothesis was that overnutrition coupled with failure of homeostasis might drive conditions that favor SP formation. Reduced food or calorie intake is already known to benefit AD model mice. Restriction of Met, an essential amino acid, is known to increase longevity, without calorie restriction. We treated APP/PS1 transgenic mice with a 75% Met restricted (MR) diet and compared it with a isocaloric isonitrogenous complete diet (CD) for 12 months. Our data show that the treatment significantly drops brain soluble Abeta at 3 and 6 months. Older animals continue to show trends towards reduction of Abeta, but

the levels are not significantly different. Nevertheless, older mice show significant improvement in behavior in a novel object recognition task. In addition, MR diets significantly alter gut microbiota composition. As expected, the bacteria that metabolize Met and Cys are reduced significantly. Furthermore, several major species of bacteria were reduced significantly and the overall diversity of microbiota appears to be increased. This lack of concentration of some species may reduce inflammation. Thus, such diets may play an important role in strategies to prevent AD.

**Abstract:** The beta-secretase BACE1 is the enzyme responsible for amyloid beta generation and is a major drug target in Alzheimer’s disease. However, therapeutic BACE1 inhibition may cause unwanted side effects due to the loss of cleavage of additional BACE1 substrates besides APP. Different proteomic studies have identified more than 40 membrane proteins as potential BACE1 substrate candidates, but most of them have not yet been validated nor functionally characterized.

Here, we validate seizure protein 6 (SEZ6) as an exclusive BACE1 substrate both in primary neurons and in the brain of BACE1-deficient mice. In order to investigate the function of SEZ6 and the consequences of loss of SEZ6 cleavage by BACE1, we developed a novel proteomic technique to determine the surface proteome of primary neurons. Using this method, we found that SEZ6 specifically controls neuronal surface levels of a subgroup of glutamate receptors with key functions in neurotransmission. Mechanistic analyses suggest that SEZ6 is required for glutamate receptor transport along the secretory pathway and may influence synaptic transmission. Additionally, we demonstrate that the BACE1-generated soluble ectodomain of SEZ6 (sSEZ6) is strongly reduced in the CSF of BACE1-deficient mice. Importantly, sSEZ6 is reduced also in the CSF of BACE-inhibited monkeys in a dose dependent manner.
Taken together our results prove that SEZ6 is a major substrate of BACE1, both *in vitro* and *in vivo*. Moreover, we discover a novel function of SEZ6 as glutamate receptor regulator and we investigate the possibility to use sSEZ6 as a potential companion diagnostic to monitor BACE1 activity in patients treated with BACE inhibitors.

**Abstract:** Alzheimer’s disease (AD) is characterized by β-amyloid $(A\beta)_{42}$ plaques and neurofibril tangles. Evidence supports soluble $A\beta_{42}$ as the neurotoxic isoform precipitating AD

pathology and levels increase during AD progression in humans and mouse models of AD, including transgenic AβPP/PS1 and knock-in $APP^{NL-F/NL-F}$ mice. The abundance of soluble $A\beta_{42}$ strongly correlates with synaptic dysfunction and neurodegeneration supporting that AD lies on a continuum with dynamic neurobiological markers that are constantly in flux based upon genetic and modifiable lifestyle factors. For example, we have demonstrated that soluble $A\beta_{42}$ interacts with presynaptic neurons to elicit glutamate (Glu) release. As soluble $A\beta_{42}$ accumulation increases during AD progression, Glu dysregulation becomes more pronounced and eventually cascades into dementia associated with AD. To support this hypothesis, we present data from AβPP/PS1 and $APP^{NL-F/NL-F}$ mice that details the relationship between genetic and modifiable life style factors as it relates to Glu neurotransmission in AD. We observed an inverse relationship between basal and evoked Glu release in AβPP/PS1 mice compared to age-matched C57BL/6 controls. Evoked release was elevated prior to cognitive decline and plaque accumulation, but was similar during cognitive deficits and plaque formation. However, in these same mice, basal Glu was unchanged early on, but significantly elevated when pronounced AD pathology was present. Furthermore, we examined the relationship between obesity-induced insulin resistance and cognitive impairment. C57BL/6 mice fed a high fat diet (HFD) had impaired memory recall, whereas AβPP/PS1 HFD displayed deficiencies in both learning and memory, as determined by Morris water maze. Additionally, Glu neurotransmission, as well as VGLUT1 and GFAP density, were significantly elevated in the hippocampus of AβPP/PS1 low fat diet (LFD) compared to age-matched C57BL/6 LFD mice. HFD further elevated these levels compared to genotype matched controls. Finally, prodromal treatment with Riluzole, but not LY379268, in AβPP/PS1 mice prevented cognitive decline and restored hippocampal Glu neurotransmission with long-lasting effects, potentially demonstrating a viable treatment option in early AD. Initial examination of $APP^{NL-F/NL-F}$ mice are in agreement with studies in AβPP/PS1, further supporting the role of $A\beta_{42}$ in altered Glu neurotransmission and cognition associated with AD. The data presented here support Glu neurotransmission as a potential early biomarker and therapeutic target to alter disease outcome. 8-14 male mice/group were used for all data presented.

**Title:** Reversion of the Alzheimer's disease phenotype by reducing mitochondrial oxidative stress, restoring mitochondria respiration and decreasing tau accumulation and amyloid-beta fibrillation with polyprenols treatment

**Authors: G. DELL'ACQUA**[1], T. MC FADDEN[1], B. BLANC[2], R. LASSEUR[2], *N. COMPAGNONE[2]
[1]Sevda Cell Sci., Melbourne, Australia; [2]Translational medicine, ICDD, Gemenos, France

**Abstract:** The relationship between brain aging and Alzheimer's disease (AD) is contentious, yet extensive literature exists supporting a role for mitochondrial dysfunction and oxidative damage in the pathogenesis of AD. Using a patient-derived fibroblast model of AD, we investigated the activity of polyprenols studying the mitochondrial phenotype associated with AD. Polyprenols are the plant analogues and precursors of the transport lipid dolichol that play a crucial role in maintaining and protecting cell function. Dolichols are involved in protein glycosylation, controlling the regulation of protein synthesis and function. Found in the phospholipid bilayer, they modify the fluidity and permeability of membranes. We sought to determine how 3 escalading doses of polyprenols impacted mitochondrial functions associated with AD. We studied bioenergetics, redox status, mtDNA content, protein synthesis and ER stress through quantification of mitochondrial associated membranes (MAMs). We also quantified Tau, pTau expression level and amyloid beta fibrillation, hallmarks of the disease. In all experiments, polyprenols were able to dose-dependently restore a normal phenotype. In AD fibroblasts, induction of oxidative stress induced a higher oxidative response than in healthy cells. Polyprenols decreased $H_2O_2$-induced mtROS production, thus showing anti-oxidant properties at the two highest doses tested. This effect conveyed a 75-78% anti-oxidant rescue compared to a 43% generated by resveratrol. In AD fibroblasts, bioenergetics was impaired. Polyprenols normalized AD fibroblasts bioenergetics by improving: i) oxygen consumption; ii) ATP production; iii) lactate production and iv) the NAD+/ NADH ratio. Polyprenols also normalized mtDNA mass dose-dependently without affecting mtDNA content. Amyloid-beta fibrillation was increased in AD-fibroblasts compared to healthy cells. Polyprenols reduced amyloid fibril deposition in the extracellular space, in a dose dependent manner. They reduced Tau expression and the hyperphosphylorated form of Tau by 0.51-fold. Finally, in the AD fibroblasts there was an increase in MAMs, consistent with increased ER stress, and by using PLA we demonstrated that polyprenols normalized these interactions. In this work we confirmed the association between mitochondria dysfunction and AD. We also showed that polyprenols play an important role in reversing both mitochondria dysfunctions and pathological hallmarks of the disease, confirming their disease modifying capabilities. *The authors are grateful to Prenolica Ltd. for providing Bioeffective® R ("Ropren®), a concentrated extract of polyprenols.*

**Title:** Saturated free fatty acids increase amyloid precursor protein levels in exosomes: A novel mechanism for the increased risk of Alzheimer’s disease in metabolic syndrome

**Authors: *B. KIM**, F. E. MENDELSON, C. FIGUEROA-ROMERO, E. L. FELDMAN
Neurol., Univ. of Michigan, Ann Arbor, MI

**Abstract:** The prevalence of metabolic syndrome (MetS), including obesity and diabetes, among US adults aged 18 years or older has risen by more than 35% in last 20 years. In 2015, 30.3 million Americans had diabetes and more than 2 in 3 adults were considered overweight or obese. Multiple studies report that patients with MetS have an increased risk of developing Alzheimer’s disease (AD) compared to age- and gender-matched controls. An increase in free fatty acids (FFAs), especially saturated FFAs (sFFAs) such as palmitate, is one of the main characteristics found in obese people. Furthermore, higher levels of sFFAs in plasma is inversely correlated with cognitive function and are a significant risk factor for developing AD.
Exosomes are extracellular vesicles secreted by virtually all mammalian cells, including neurons, and they can be taken up by other cells. This exosome transfer allows intercellular communication but can also spread pathological proteins involved in neurodegenerative diseases such as AD, Parkinson’s disease, and prion diseases. Amyloid precursor protein (APP), β- & γ-secretases, and tau drive the progression of AD and are found in exosomes derived from AD neurons and microglia. These proteins accumulate in plaques in AD brains, and inhibition of exosome secretion reduces the plaque load in mouse models of AD. These findings indicate that exosomes not only deposit amyloid beta (Aβ), but also spread the ability to initiate plaques between cells.
Studies demonstrate that exosome production is increased in diabetes and obesity. In the current study we examined exosomes and their role in spreading APP pathology via FFAs. Treatment with the sFFAs, palmitate or stearate, increased APP levels in exosomes isolated from the cell culture supernatant of the HK-532 human cortical stem cell line or rat primary embryonic cortical neurons. APP levels in the cell lysates were not affected by sFFA treatment. In contrast, treatment with the unsaturated FFA, oleate, did not increase APP levels in exosomes and slightly

decreased the levels in the cell lysates. Metformin is an anti-diabetic medicine that modulates AMP-activated protein kinase (AMPK). We found that activation of AMPK by metformin or AICAR reduced APP levels in the lysates as well as in exosomes of basal and palmitate-treated neurons.
Overall, increased levels of APP in exosome following sFFA treatment suggest a possible explanation for the increased risk of AD in MetS.

**Abstract:** A number of tauopathies, including the most prevalent form of dementia – Alzheimer's disease (AD), have been described, but there are no approved therapies targeting tauopathies that are currently available. The common feature of this group of neurodegenerative disorders is accumulation of tau protein aggregates in neurons and/or glial cells. Notably, onset and severity of clinical symptoms in AD and some other tauopathies have been shown to correlate with the degree/stage of tau pathology, making modulation of tau propagation pathways an approach for therapeutic development.
Our screening efforts for tau propagation inhibitors led us to the identification of a brain permeable small molecule – cambinol – that is a known inhibitor of the neutral sphingomyelinase 2 (nSMase2). nSMase2 is a known gatekeeping enzyme involved in ceramide-

mediated exosome production. According to our data, cambinol inhibits cell-to-cell spread of tau oligomers derived from AD brain synaptosomes (P2) in tau biosensor-based D+R assay ($EC_{50}$ = 14 μM) and in the EV-mediated secondary assay. Interestingly, P2-seeded biosensor cells released 3.5 times more extracellular vesicles (EVs) compared to cells treated with empty liposomes. Biochemical examination of known exosome markers CD63, CD9 and syntenin-1 in the EV fractions by immunoblotting suggests that tau aggregation may interfere with some but not other exosome biogenesis pathways. An initial *in vivo* study shows that cambinol can reduce the level of the nSMase2 activity in the brain after oral administration at a dose of 100mg/kg. These data suggest that cambinol can engage the target, nSMase2, in the brain and is therefore a promising molecular probe to further evaluate this mechanism in tauopathy models. Our molecular docking and simulation analysis reveal that cambinol can target the DK-switch in the nSMase2 active site, and modulate the interaction between Asp430 (D430) and Lys435 (K435) involved in nSMase2 enzyme activity. Discovery of this novel molecular mechanism of the interaction between cambinol and nSMase2 has implications in the rational design and synthesis of novel nSMase2 inhibitors with superior drug-like properties that could inhibit propagation of pathologic forms of tau.

**Title:** Aβ aggregation modulator MRZ-99030 reverses synaptotoxic effects of $Aβ_{1-42}$ on LTP even following serial dilution to 1000:1 stoichiometric excess of $Aß_{1-42}$, suggesting a beneficial prion-like seeding mechanism

**Authors: *G. RAMMES**[1], H. RUSS[2], A. PEARLMAN[3], C. G. PARSONS[4]

**Abstract:** Recent evidence indicates that soluble oligomers of β-$amyloid_{1-42}$ ($Aβ_{1-42}$) rather than plaques are the major cause of early synaptic dysfunction and neurodegeneration in Alzheimer's disease (AD). This has furthermore been hypothesised to progress by the self-replication and spreading of toxic Aβ oligomers through a prion-like mechanism. Recently we identified MRZ-99030, as a small molecule that promotes the formation of off-pathway, non-toxic aggregates

thereby reducing the amount of intermediate toxic soluble oligomeric Aβ species. When applied at a 10:1 stoichiometric excess to Aβ, MRZ-99030 clearly reversed the synaptotoxic effects of $A\beta_{1-42}$ oligomers on synaptic plasticity and cognitive performance (Parsons et al., 2015; Rammes et al., 2015). Based on long lasting beneficial "trigger" effects observed in *in vivo* models, we hypothesised that MRZ-99030 might be able to seed a beneficial self-replication of non-toxic Aβ aggregates. To test this hypothesis, we prepared a serial dilution of MRZ-99030 starting with a 10:1 stoichiometric excess to $Aß_{1-42}$ (100nM). After incubating the $Aß_{1-42}$/MRZ-99030 mixture for 20 mins 10% (5mL) was transferred to a freshly prepared solution with Aβ (100nM). This dilution step was repeated 5 times finally resulting in a 1000:1 stoichiometric excess of $Aß_{1-42}$ over MRZ-99030. The final solution was then tested for its ability to impair long-term potentiation (LTP) in CA1 neurons. In this study we show that serial dilution of MRZ-99030 applied for 90 mins to acute murine hippocampal slices at room temperature reversed the synaptotoxic effect of $Aß_{1-42}$ on CA1-LTP after tetanic stimulation (100Hz/1s) of the Schaffer collaterals (LTP control=154±4%, n=24; with 100nM $Aß_{1-42}$=117±2%, n=7; in the presence of (1000:1) $Aß_{1-42}$/MRZ-99030=139±6%, n=13). Since the rate of $Aß_{1-42}$ oligomer formation has a steep linear temperature dependence we performed the same experiments also under physiological temperature (37°C). Under these conditions control LTP reached 151±6% (n=8) of baseline which was reduced by 100nM $Aß_{1-42}$ to 15±2% (n=5). When slices were incubated with (1000:1) $Aß_{1-42}$/MRZ-99030, the detrimental effects of $Aß_{1-42}$ on LTP reversed to 44±11% (n=6). In summary, the present results demonstrate that MRZ-99030, when serially diluted, even at very low concentrations neutralizes the synaptotoxic effects of Aβ oligomers on hippocampal LTP. We hypothesise that MRZ-99030 acts via a "beneficial prion-like" mechanism which promotes non-toxic structural variants of Aβ aggregates that propagate their conformations through template-directed folding of naïve Aβ peptides, thereby reducing synaptotoxic effects.

**Abstract:** The autophagy-lysosome system is one of the major intracellular protein degradation systems. Dysregulation of autophagy contributes to neuronal cell death in Alzheimer's Disease (AD). β-site amyloid precursor protein cleaving enzyme 1 (BACE1) is the β-secretase that initiates generation of beta amyloid (Aβ), a major toxic species in AD. Recent studies illustrated that BACE1 can be recruited to autophagic vacuoles(AVs) for further degradation in lysosomes via the autophagy-lysosome pathway. However, whether modulating autophagy would delay or prevent the progression of AD via regulating BACE1 remains to be determined. We used a recently developed small molecular compound, YS620, to regulate autophagy flux in vitro and found this regulation occurs in an autophagy-related protein 5(Atg5)-dependent manner. This novel autophagy inducer remarkably reduces the level of BACE1 expression and decreases Aβ generation in N2aAPPswe cells, an AD cellular model. We further verified the effect of YS620 using an in vivo transgenic (Tg) animal model of AD. After daily treatment with YS620 from 8-weeks until 5-months of age, the learning and memory impairment of female TgCRND8 mice, were improved compared to vehicle-treated female Tg mice, as measured by Morris Water Maze. [WW1] The YS620-treated Tg mice also had a reduction in hippocampal amyloid burden at 5 months old.Taken together, these results illustrate that YS620 can prevent cognitive malfunction in a transgenic mouse model of Alzheimer's Disease and that at a cellular level, this process involves the autophagy-mediated regulation of BACE1. Thus, YS620, a novel autophagy inducer, may be a potentially effective therapeutic agent for the treatment of AD.

**Abstract: Aims:** Alzheimer's disease (AD) is an incurable neurodegenerative disorder characterized by global cognitive impairment with accumulation of amyloid-beta peptides (Aβ) in the brain. Herbal approaches can be used as alternative medicines to slow the progression of AD. This study aimed to determine the beneficial effects and potential mechanisms of total flavonoid extract from *Dracoephalum moldavica* L. (TFDM) for attenuating Alzheimer-related deficits induced by Aβ.
**Main methods:** We used the amyloid precursor protein (APP) and presenilin 1 (PS1) double transgenic mouse and copper-injured APP Swedish mutation overexpressing SH-SY5Y cells to demonstrate the beneficial effects of TFDM. Further, the mechanisms were conducted on anti-amyloidogenic and neurotrophic transductions both *in vitro* and *in vivo*.
**Key findings:** Our results indicated that TFDM treatment ameliorated cognitive impairments and neurodegeneration and improved antioxidant defense system in APP/PS1 mice. TFDM also reduced Aβ burden by relieving Aβ deposition, decreasing insoluble Aβ levels and inhibiting β-amyloidogenic processing pathway involving downregulation of β-secretase and β-C-terminal fragment in the brain. In the AD cell model, TFDM protected injured cells, combined with the beneficial effects of decreasing APP levels, lowering $A\beta_{1-42}$ and regulating the redox imbalance. Moreover, TFDM preserved the extracellular signal-regulated kinase/cAMP response element-binding protein/brain-derived neurotrophic factor pathway both *in vitro* and *in vivo*.
**Significance:** In conclusion, TFDM clearly demonstrated neuroprotective effects by restoring the anti-amyloidogenic and neurotrophic transductions in the context of AD-associated deficits. These findings raise the possibility of using herb-based substances as supplement or potential alternative supplement for attenuating progression of AD.

**Abstract:** Alzheimer's disease (AD) is the most prevalent form of dementia in the elderly, which affects about 5.4 million individuals in the US. Current AD treatments are limited to temporary and mild alleviation of cognitive and behavioral symptoms in a subset of patients; there is no cure, effective prevention therapy or treatment which alters the course of AD. The pathological features of AD include β-amyloid (Aβ) plaques and neurofibrillary tangles in the cerebral cortex and hippocampus. Aβ peptides are the product of the amyloid precursor protein (APP) proteolysis by BACE1 (β-site APP cleaving enzyme 1) to produce the membrane-bound C-terminal fragment C99, which is further processed by γ-secretase to generate a number of distinct Aβ species. Aβ40 is the most abundant secreted Aβ peptide; however, the more fibrillogenic Aβ42 is the primary constituent of Aβ plaques. Our group developed and tested a series of small molecule γ-secretase modulators (GSMs), with BPN15606 emerging as the leading candidate for clinical development. BPN15606 demonstrates excellent in vivo PK/PD properties, highly significant dose-dependent biochemical efficacy and dose proportional exposures. At higher doses, this compound can almost completely eliminate Aβ42 levels in both brain and in CSF. In the current study, we evaluated the benefit of a combinational therapy using BPN15606 and a BACE1 inhibitor, LY2886721, in multiple *in vitro* assays and in an animal study. We present the biochemical, behavioral and pathological results of the treatments in two age groups, pre- and post-plaque formation PSAPP mice.

**Abstract:** Several lines of evidence suggest that the aggregation and deposition of amyloid-β peptide (Aβ) are associated with the pathogenesis in Alzheimer disease (AD). Therefore, the inhibition of Aβ aggregation and clearance of deposited Aβ have been focused as the therapeutic strategy for AD. We previously found that the photooxygenation of synthetic Aβ by small compound catalysts, which are activated by irradiation of light, reduced the aggregation potency and neurotoxicity of Aβ *in vitro* (Taniguchi et al., Nat Chem 2016; Ni et al., Chem 2018). To verify the effects of oxygenation of Aβ *in vivo*, we carried out the photooxygenation experiment using APP knock-in (NL-G-F; Saito et al., Nat Neurosci 2014) mice, and analyzed the brain Aβ amyloid by biochemical methods.
First, we analyzed the effect of photooxygenation on the aggregated synthetic Aβ *in vitro*. One to four oxygen adducts in Aβ were detected by MALDI-TOF-MS. Notably, the mobility of Aβ was shifted to 10 kDa on SDS-PAGE/immunoblot analysis, suggesting that the photooxygenation changed the conformation and/or biochemical character of Aβ. Next we performed the photooxygenation reaction using brain lysate obtained from 7-months old AD model mouse. Upon irradiation, 10 kDa Aβ was appeared in a similar manner to that observed in the experiment using synthetic Aβ, indicating that Aβ amyloid was successfully oxygenated in the brain. Finally, to photooxygenate the deposited Aβ in living mice, we injected the catalyst into hemi-hippocampus of 7-months old mice followed by irradiation by LED fiber. After 7 times of reactions, we collected the hippocampus and analyzed by immnoblotting. We found that 10 kDa Aβ was also detected under the reaction, indicating that oxygenation reaction occurred in the brains of living mice. In addition, this photooxygenation reaction decreased the total amount of Aβ in the brain.
These results indicate that the catalyst could photooxygenate not only synthetic Aβ but also Aβ deposited in the AD model mice brain. Moreover, the photooxygenation in living AD model mice significantly decreased the Aβ level, suggesting that photooxygenated Aβ was metabolized faster than naive Aβ. Thus, artificial photooxygenation by the catalyst would be a novel strategy for AD prevention and treatment.

**Abstract:** Pathological insults instigating self-propelling neuro-inflammation in the brain might occur many years before the presence of clinical manifestations in Alzheimer’s disease (AD). The severely compromised functioning of the brain due to such chronic insults makes AD treatment more difficult. Thus, intervention using a multi-functional treatment at the early stage of the disease is emerging as a promising therapeutic paradigm. However, preclinical diagnosis and effective cure for AD are not available so far. Recently, we have newly developed an antibody in both mouse and fully humanized versions, which recognizes various Aβ species and N-terminally modified pyro-glutamate Aβ. We found that this novel antibody can be used for early detection of cerebral Aβ levels and exerts multifaceted functionality in alleviating the AD-like pathology in APP/PS1 mice. This antibody exerts an ability of Aβ plaques engagement across blood-brain barrier through intraperitoneal injection and is able to transform over-activated microglia into ramified microglia with a healthy morphology, while enhancing microglial Aβ phagocytosis. Our data further indicate that treatment of this novel antibody appears to improve neuronal functions in APP/PS1 mice. For early detection of cerebral Aβ, intraperitoneal injection of this antibody triggered a robust efflux of cerebral Aβ into the bloodstream. The escalating Aβ levels in the serum were positively correlated with the cerebral Aβ levels in both Aβ plaques-laden and non-Aβ plaques-bearing APP/PS1 mice, which can be used to predict Aβ levels in the brain by monitoring the antibody-induced Aβ in the circulation. Data suggest that this novel antibody might exert theranostic potential for AD.

**Title:** Genetic and pharmacological inhibition of calcium-sensing receptor (CaSR) prevents amyloid pathologies and neuronal degeneration and restores cognitive deficits in mouse models of familial Alzheimer's disease

**Authors: *K. KURISU**[1], Z. CHANG[2], A. MIZUMA[1], C.-L. TU[2], M. YENARI[1], W. CHANG[2]
[1]Neurol., [2]Endocrine Unit, Univ. of California, San Francisco and VA Med., San Francisco, CA

**Abstract: Background and objective:** Alzheimer's disease (AD) is a growing nerurodegenerative disease that causes cognitive dysfunction in aging populations. The extracellular calcium sensing receptor (CaSR) was originally found in parathyroid cells where it senses minute changes in extracellular [Ca(2+)] by raising intracellular Ca(2+) concentrations to control secretion of parathyroid hormone and mineral metabolism. We reported previously that increased CaSR expression in hippocampus neuron underlies neuronal apoptosis and degeneration in ischemic condition. The current study tested the role of CaSR in the pathogenesis of AD, as soluable Amyloid-beta was reported to activate this receptor directly, by examining the impact of pharmacological or genetic inhibition of CaSR activity in 5XFAD mice, an animal model with accelerated development of AD pathology. **Materials and Methods:** The 5XFAD mice were daily injected with a CaSRantagonist (NPS2143, 1mg/kg) from 3-6 months of age or bred with mice with targeted Casr gene KO (CaSR-/-) in hippocampal neurons by expressing CamKIIa-Cre transgene and homozygous floxed-CaSR alleles. Cognitive functions were assessed monthly by Y-maze test and novel objective recognition tests and brain histology was performed at 6-month age. **Results:** While significant worsening of cognitive functions ($p<0.01$) and loss of hippocampal neurons ($p<0.01$) were observed in the 5XFAD mice from 3 to 6 months of age, daily NPS2143 injections ($p<0.01$) and CaSR KO ($p<0.01$) completely prevented these adverse effects. In line with this, neuronal apoptosis assessed by caspase 3 staining were significantly increased ($p<0.05$) in 5XFAD mice, but suppressed by NPS2143 injections ($p<0.05$) and CaSR KO ($p<0.05$) in the latter mice. Furthermore, accelerated amyloid-β deposition assessed by immunohistochemistry in the 5XFAD mice was significantly reduced by NPS2143 injections ($p<0.05$) and CaSR KO ($p<0.05$). **Conclusion:** Suppression of CaSR expression and/or activity preserves cognitive function and prevents neuronal degeneration in the AD mouse model potentially by preventing a feed-forward 'amyloid cascade' that may cause neuronal hyperactivity and subsequent cell death. Because CaSR antagonist, calcilytics, has been used clinically for treatments of mineral diseases, this receptor represents a highly translatable therapeutic target for prevention and/or treatment of AD.

**Abstract:** Structural characterization and in vitro effects of amyloid beta variants on citotoxicity, apoptosis and autophagy.
Alzheimer´s Disease (AD) is the most common type of senile dementia that affects human health. Deposition of Amyloid beta (Aβ) peptide in the brain is one of the most important events in AD progression. Soluble oligomers are now considered as primary toxic agents in amyloid diseases. Preventing formation of these soluble oligomers could stop amyloid β-sheet self-assembly. For that reason, formation of Aβ oligomers is being considered a target for therapeutic strategies for AD. Aβ peptide amino acid sequence is essential for its aggregation properties, oligomer formation, leading to the amyloid plaque and ultimately causing cell death. In this work, we used three variants of Aβ peptide: One containing amino acids 1-42 which is the whole sequence of Aβ, another one with amino acid 1-40 and other restricted to amino acids 25-35 known as it's hydrophobic core. We inserted point mutations at positions: A30W, K28A and M35C to assess the effect of the amino acids in these positions in Aβ-peptide oligomer formation and their in vitro effects on citotoxicity, apoptosis and autophagy. We used AFM and Western blot to determine in vitro formation of oligomers. AFM results show that A30W, K28A and M35C variants of Aβ (25-35), Aβ (1-42) and Aβ (1-40) A30W generated oligomers with different structure comparing with WT peptide. Aβ (1-40)-K28A and Aβ (1-40) M35C generated more fibrils. Western blot showed that oligomers of WT and the variants were capable of cell

internalization. We tested the effects of the mutant peptides on citotoxicity, apoptosis and autophagy using the rat C6 glioma cell line. Aβ (25-35) mutants did not change in vitro effects of citotoxicity, apoptosis and autophagy comparing with WT peptide. But Aβ (1-40) and Aβ (1-42) mutants produced less cell death comparing with WT peptides. Our results demonstrate that point mutations are capable to change oligomer structural characteristics, cytotoxicity, apoptosis and the effect on autophagy compared to the Aβ WT peptide. The strategy of introducing these point mutations could be used to modulate or prevent cell death in Alzheimer's disease.

**Abstract:** Our transgenic mouse lines express one gene with AD mutations, i.e., APPswe/dutch/iowa. They develop plaques at about four months of age, and we have described that two types of deposits are present, plaques, and diffuse deposits around blood vessels. Both plaques and blood vessel deposits are surrounded by activated glial cells. We have treated these mice with both D3 and RD2, anti Aβ42 oligomer targeted D-peptides, and improved cognitive deficits. We studied labeling of these deposits following single and double intracerebral (hippocampus) D3 and/or RD2 fluorescently labeled injections in these mice. We sacrificed and transcardially perfused the mice at two days following the injections. The brains were cut and immunohistochemically stained for Aβ species, and GFAP and Iba-1. Following the two day survival time the AD mice displayed a clear labeling of Aβ in the overlying cortex and hippocampus. No change was present between the labeling pattern following either D3 or RD2 injections. Labeled Aβ is present in lysosomes in neurons near the injection site, but surprisingly no labeled Aβ is present in astrocytes or microglia. Following double injections of both D3 and RD2 there are different labeling patterns, however, these are caused by the attached fluorophore,

not the different peptides. Furthermore, combined injections of unlabeled D-peptide and labeled D-peptide show that D3 limits uptake of labeled D3 but not RD2, and vice versa. Thus, likely the uptake of the D-peptides is through slightly different mechanisms, and, the choice of fluorophore significantly changes the properties of the combination. Finally it is likely that the two D-peptides target slightly distinct oligomers, suggesting a combination therapy.

**Abstract:** This talk introduces a new class of antibodies generated against structurally defined homogenous oligomers derived from the β-amyloid peptide Aβ. Polyclonal and monoclonal Aβ antibodies have been important tools for probing the structures of the toxic Aβ oligomers that are central to the pathogenesis of Alzheimer’s disease. Although the structures of Aβ oligomers remain unknown, “conformation dependent” antibodies have allowed researchers to probe oligomeric and fibrillar Aβ structures *in vitro* as well as in mouse and human brain tissues and fluids. Conformation dependent antibodies for Aβ oligomers are most commonly generated against Aβ oligomers and Aβ fibrils prepared *in vitro* from recombinantly expressed or chemically synthesized Aβ that are then used to immunize rabbits or mice. The antigenic Aβ oligomers in these preparations are heterogeneous in structure and stoichiometry and contain a vast diversity of conformational epitopes with inherently undefined structure, making it challenging to identify the exact epitopes that these conformation dependent antibodies recognize. These challenges demonstrate the need for more homogeneous and structurally defined Aβ oligomers for use in generating conformation dependent antibodies and in identifying and characterizing molecular targets for Alzheimer’s disease.
Our laboratory has elucidated the X-ray crystallographic structures of trimers, hexamers, and dodecamers composed of peptides derived from Aβ. These oligomers are the first ones derived

from Aβ in which the three-dimensional structures are known at high resolution, and are stable and homogeneous in solution. These oligomers are antigenic and contain conformationally distinct epitopes that have thus far been unexplored in Aβ structural biology. This talk will focus on monoclonal and polyclonal antibodies that specifically recognize these oligomers and how we have used these antibodies to correlate the high-resolution structures of our Aβ-derived oligomers with disease-relevant assemblies of the Aβ peptide. Western blotting and immunofluorescence studies in transgenic mouse and human brain tissue demonstrate that these antibodies recognize low-molecular-weight soluble Aβ oligomers, such as trimers, hexamers, and dodecamers and do not recognize the insoluble fibrils or plaques. These studies provide insights into the structures of soluble low-molecular-weight Aβ oligomers and pave the way for designing new therapies and diagnostics for Alzheimer's disease.

**Title:** Anti degenerative effectiveness by blocking multiple steps in the amyloid beta toxicity cascade

**Authors: *L. G. AGUAYO**[1], C. PETERS[2], F. BURGOS[2], D. BASCUÑAN[2]
[2]Physiol., [1]Univ. Concepcion, Concepcion, Chile

**Abstract:** The main neurotoxic agent of Alzheimer´s disease corresponds to diffusible oligomers of the β amyloid peptide (Aβ) released to the extracellular compartment and that subsequently associate to the neuronal membrane forming "pore-like" structures. These early membrane perforations can cause delayed alterations in calcium homeostasis leading to synaptic failure and death. Current therapies are not effective at curing or deterring disease progression, thus new approaches are needed. The importance of the C terminal region of Aβ in the association and perforation of the neuronal membrane was previously demonstrated. Using a pentapeptide derived from the primary sequence of Aβ, we were able to block multiple toxic steps of Aβ such as aggregation, association, membrane insertion, intracellular calcium increase and synaptotoxicity.
We are now examining a library of synthetic compounds in order to find small molecular weight peptidomimetic molecules that have similar neuroprotective effects, but with higher

pharmacological potential. A group of molecules having high *in silico* interaction with Aβ were selected and analyzed for their effects on Aβ aggregation, association, mitochondrial function and membrane perforation in PC12 cells and/or rat hippocampal neurons.
One of the new compounds examined, at low micromolar concentrations, was able to inhibit Aβ aggregation, membrane association, and intracellular calcium increase without producing an intrinsic toxic effect. It also blocked the synaptotoxicity and mitochondrial toxicity induced by Aβ. Experiments with Aβ injected in the hippocampus showed that the compound also blocked in vivo toxicity.
In conclusion, the present results indicate that it is feasible to develop peptidomimetic molecules that exert protective actions against Aβ at multiple steps similar to those reported with the G33LMVG37 pentapeptide.

**Abstract:** Alzheimer’s disease (AD) is a neurodegenerative disorder characterized by progressive memory decline and loss of cognitive functions. AD is histologically characterized by the pathological aggregation of beta amyloid (Aβ) and tau neurofibrillary tangles. Monomeric soluble Aβ can switch from helicoidal to β-sheet conformation, promoting its assembly into toxic oligomers. These oligomers have been reported to induce neuronal death and synaptic transmission impairments. However, there is now considerable evidence that in normal healthy brains, soluble oligomeric Aβ functions as a neuromodulator. Our laboratory has shown that at low concentrations (pM-nM) a naturally produced N-terminal Aβ fragment (N-Aβ fragment) is nearly twice as effective as full-length Aβ as a neuromodulator, stimulating receptor-linked increases in $Ca^{2+}$, enhancing long-term potentiation (LTP) and enhancing contextual fear conditioning. In addition, we have recently shown that N-Aβ fragment protects against $Aβ_{42}$-induced neurotoxicity. We further identified a hexapeptide core sequence within the N-Aβ fragment, YEVHHQ (N-Aβcore), which is found to be equally as effective in $Ca^{2+}$ signaling and was shown to also be neuroprotective against $Aβ_{42}$-induced oxidative stress and neuronal death.

Here, we investigated the neuroprotective role of the N-Aβcore on synaptic plasticity in rodent hippocampal slice LTP and LTD. Additionally, we utilized inhibitors of kinases and phosphatases implicated in LTP and LTD, respectively, to understand the neuroprotective action of the N-Aβcore. We examined changes on various kinases in the MAPK pathway and proteins that have been linked with $A\beta_{42}$-induced toxicity and implicated in learning and memory upon NMDAR activation. Lastly, we compared the differential gene expression induced by N-Aβcore to that by full-length Aβ, in order to gain insights into the underlying mechanisms of neuroprotection by N-Aβcore over beta amyloid-induced neurotoxicity. The differentially modulated genes included, most notably, Rcan3, Parp1, Apba3, Rab11 and Kif1c. Elucidating the molecular pathway of the N-Aβcore provides a better understanding of its neuroprotective mechanism and its role at the synapses in the context of accumulating Aβ in AD. The neuroprotective action of the N-Aβcore suggests the possibility of using this core sequence as a scaffold for optimization of a potential biologic for protection against Aβ -induced toxicity.

**Title:** Intranasal delivery of human iPSC-derived neural stem cells as a novel strategy for AD therapy

**Authors: *Y. FU**, J. ZHAO, M. DAVIS, Y. CHEN, C.-C. LIU, G. BU
Mayo Clin., Jacksonville, FL

**Abstract:** Alzheimer’s disease (AD) is the most common cause of dementia, characterized by deposition of amyloid-β (Aβ) plaques and neurofibrillary tangles in the brain, accompanied by synaptic dysfunction and neuronal loss. Stem cell-based therapy has recently been explored as a promising treatment option for AD as it offers the potentials to provide a trophic environment for neuronal survival and cell replacement. The human induced pluripotent stem cells (iPSCs) reprogrammed from somatic cells offer versatility for stem cell-based therapy. However, optimizing cell delivery method to the central nervous system remains a challenge. Accumulating evidence has suggested that direct intranasal delivery of drugs, peptides, and nanoparticles to the central nervous system can bypass the blood-brain barrier and thus has

emerged as a non-invasive alternative to oral and parenteral routes. Here we investigated the feasibility of intranasal administration of iPSC-derived neural stem cells (NSCs) to mouse brain. Following intranasal delivery of GFP-labeled NSCs, we found that they effectively integrated into mouse brain as differentiated neurons and astrocytes. We thus plan to extend these studies to addressing therapeutic potentials of human iPSC-derived NSCs in AD model mice. As apolipoprotein E (*APOE*) ε4 allele is the strongest genetic risk factor for late-onset AD, we plan to test the effects of delivering NSCs with different *APOE* genotypes into the brains of 5xFAD amyloid model mice. We hypothesize that intranasal delivered human iPSC-derived NSCs will reduce amyloid pathology, rescue the neuronal loss, and slow down cognitive decline in 5xFAD mice in an *APOE* genotype-dependent manner. Behaviors and AD-related pathology will be evaluated at different time points after intranasal delivery of different dosages of cells. The successful completion of this project will not only address promises and limitations of stem cell-based therapy but also provide guidelines for the design of human clinical trials to treat AD.

**Abstract:** Alzheimer’s Disease (AD) is the most common cause of memory loss and associated dementia symptoms for which an effective treatment is still unavailable. The greater the understanding of the neurodegenerative processes of the AD brains, the more emphasis has been placed on the role of intracellular amyloid beta (Aβ) in the resulting pathological entities such as increased amyloid burden and neurofibrillary tau tangles leading to neurodegeneration. A most recent focus on the pathological interdependence of cellular toxicity events related to AD

pathology reveals the pathological trio of intraneuronal Aβ, oxidative stress and mitochondrial dysfunction as main causes of cognitive decline in AD. It is therefore imperative to explore avenues to disrupt the correlation between the factors leading to progression of disease. Here we explore the ability of a bi-functional small molecule to reduce aggregation of intracellular Aβ and attenuate oxidative stress in cultured neurons. Structurally, this small molecule is comprised of a nitroxide spin label linked to an amyloidophilicfluorene and is known as spin-labeled fluorene (SLF). The effect of the SLF on intracellular Aβ accumulation and oxidative stress was measured in MC65 cells, a human neuronal line with inducible expression of the Aβ precursor protein APP. Super-resolution microscopy imaging showed SLF decreases accumulation of intracellular Aβ. Confocal microscopy imaging of MC65 cells treated with a reactive oxygen species (ROS)-sensitive dye demonstrated SLF significantly reduced the intracellular Aβ-induced ROS signal. In order to determine the contributions of the separate SLF moieties to these protective activities, experiments were also carried out on cells with nitroxides lacking the Aβ targeting domain or fluorene derivatives lacking the nitroxide functionality. These findings support a synergistic effect of SLF in counteracting both the conformational toxicity of Aβ and its promotion of ROS.

**Abstract:** Alzheimer's disease (AD) is the most common form of age-related dementia and is pathologically characterized by amyloid-β (Aβ) peptide deposition in brain parenchyma as plaques and in cerebral blood vessels as cerebral amyloid angiopathy (CAA). We have previously investigated the effect of clusterin (CLU), a genetic risk factor for AD, on amyloid pathology using the APP/PS1 mouse model of AD amyloidosis on a Clu wild-type (*$Clu^{+/+}$*) and Clu knock-out (*$Clu^{-/-}$*) background. We have found that loss of CLU led to abundant CAA with the simultaneous reduction of parenchymal amyloid deposits. Surprisingly, despite the several-fold increase in CAA, mice lacking CLU had significantly less hemorrhage and inflammation. Although, our previous study suggests that CLU is a key player in regulating the balance between Aβ deposition and clearance in the brain, additional mechanisms underlying the pathogenesis of AD and CAA are still poorly understood. Here, we performed a single-cell transcriptomic study to characterize the brain vascular cell types and states using a transgenic mouse model of amyloidosis with differential CLU expression. We uncovered novel genes and cell-type specific pathways involved in CLU-dependent and/or amyloid-dependent vascular changes. Additional bioinformatics analyses and validation that aim to identify functionally different cell subpopulations based on their transcriptional profiles and CLU expression are currently being explored. This study significantly improves our ability to define the complex mechanisms of amyloid deposition in brain cerebrovasculature and its consequences.

**Title:** The effect of depressive symptoms on neuronal reward processing in apolipoprotein E4carriers

**Authors: *E. A. KAPOULEA**[1,2], C. MURPHY[3,1]
[1]UCSD, San Diego, CA; [2]Psychology, San Diego State Univ., San Diego, CA; [3]Psychology, San Diego State Univ., San Diego State, CA

**Abstract: Background:** Apolipoprotein (APOE) E4 is a well-established genetic risk factor for Alzheimer's Disease (AD), a devastating neurological disease that afflicts 46.8 million people globally. AD is characterized by a decline in memory, language, problem-solving, and other cognitive skills. Previous studies have reported synergistic interactions between depressive symptoms and APOE E4 on risk of AD. To our knowledge, this phenomenon has not yet been

evaluated in relation to processing taste stimuli. The objective of this study was to use functional magnetic resonance imaging (fMRI) to investigate the effects of depressive systems on neural reward processing in E4+ and E4- individuals when responding to taste stimuli. **Methods:** Blood-oxygenation-level-dependent (BOLD) activations (N=35) were measured during an fMRI scan. Participants were divided into one of two groups: E4- (n =22) and E4+ individuals (n = 12), based on results from genomic testing. Participants were orally and randomly administered three different aqueous solutions of caffeine, saccharine, and sucrose and asked to rate the intensity and pleasantness of each tastant using a general Labeled Magnitude Scale (gLMS). Participants were also asked to answer questions on the Beck Depression Inventory-II (BDI-II) to measure levels of depressive symptoms. The imaging data were processed using AFNI software. Beta coefficients were extracted from a priori regions of interest (ROIs) implicated in taste and reward processing. For each stimulus, partial correlation analyses, controlling for age, were performed between a priori ROIs and BDI scores. **Results:** A one-way ANOVA showed no significant differences between the groups in age, odor threshold, taste threshold, BDI scores, and hedonic ratings of caffeine pre and post scan. In the E4+ group, during the hedonic evaluation of caffeine, BDI scores positively correlated ($r(12) = .789$, $p = .004$) with activation in the anterior cingulate cortex (ACC). In the E4- group, during the hedonic evaluation of caffeine, BDI scores negatively correlated with ACC activation($r(22) = -.547$ , $p = .010$). **Conclusions:** Results suggest differences in neuronal activation in response to taste stimuli between E4+and E4- individuals. As BDI scores increased, those in the E4+ group had increased activation in the ACC, while those in the E4- group had decreased activation as BDI scores increased. The ACC has been associated with reward processing by encoding general task values and received rewards. Results suggest that E4+ individuals with higher depressive symptoms may need to rely on a greater neural network to process reward stimuli in comparison to E4- individuals.

**Authors: *I. KAWAKAMI**, A. S. POZO, E. HUDRY, B. T. HYMAN
Dept. of Neurol., Massachusetts Gen. Hospital/Harvard Med. Sch., Charlestown, MA

**Abstract:** ***Introduction*** *APOEε4* is well known to be the genetic factor for late onset Alzheimer disease (AD). Previous studies have suggested that *APOEε4* increases amyloid beta

accumulation in human brains, but the correlation between the APOE status and tau pathology remains uncertain. ***Methods*** In the present study, we used a stereological approach to investigate the distribution of intraneuronal apoE in the hippocampus and temporal/occipital neocortex of normal aged controls in comparison with pathologically confirmed AD cases, stratifying the results by *APOE* genotypes. In addition, we examined whether there was a correlation between the presence of apoE in neurons and the presence of neurofibrillary tangles (NFTs). ***Results*** In control cases, we observed consistent and widespread intraneuronal apoE immunoreactivity in the hippocampus, especially within the CA1 region (less so in cortices). By contrast, AD brains displayed milder immunoreactivity in hippocampus but also in the cortices. ApoE positive neurons could occasionally be identified as pre-tangle and ghost tangle neurons, while most did not show any immunoreactivity for pathological tau. *APOEε4* carriers had lower neuronal apoE as compared with other genotypes, which resulted in a lower apoE/NFTs ratio. ***Conclusions*** Our findings suggest that the presence of apoE in neurons may be neuroprotective, and that the presence of *APOEε4* is negatively correlated with neuronal apoE in AD brains with a high burden of NFTs.

**Title:** The apolipoprotein E4 allele renders corpus callosum microcirculation and cognitive function more susceptible to cerebral hypoperfusion

**Authors: *S. AHN**[1,2], Y. HATTORI[1], L. PARK[1], C. B. SCHAFFER[2,1], C. IADECOLA[1]
[1]Feil Family Brain and Mind Res. Inst., Weill Cornell Med., New York, NY; [2]Meinig Sch. of Biomed. Engin., Cornell Univ., Ithaca, NY

**Abstract:** The apolipoprotein E4 (ApoE4) allele is an emerging risk factor for the subcortical white matter (WM) injury underlying vascular cognitive impairment. Supplied by terminal arterioles in overlapping arterial territories, the subcortical WM is particularly vulnerable to vascular dysfunction and reduced cerebral perfusion. However, little is known about the microcirculation of the deep cortical WM and the impact that cerebral hypoperfusion exerts on WM microvascular flow and cognition. We sought to determine if the ApoE4 genotype is associated with alterations in WM microcirculation that may render the WM more susceptible to injury and produce more severe cognitive deficits. We used isoflurane-anesthetized human ApoE

targeted replacement mice (ApoE4-TR and ApoE3-TR) (Sullivan et al., JBC, 272:17972, 1997) (males; age 3-4 months; n=4-5/group). Bilateral carotid stenosis (BCAS) was induced by placing 0.18 mm microcoils around the common carotid arteries. Red blood cell (RBC) speed and vessel diameter were evaluated in the CC microcirculation at baseline and 4 weeks after BCAS in the same mice by three-photon excited fluorescence microscopy (3PEFM), which enables deeper penetration into the WM of the corpus callosum (CC) (≥1mm below the pial surface). At baseline, microvascular diameter in CC did not differ between ApoE4-TR (4.6±0.1 μm) and ApoE3-TR mice (5.0±0.1 μm; $p>0.05$), but RBC speed was slower in ApoE4-TR mice (ApoE4, 1.5±0.1; ApoE3, 1.9±0.1 mm/sec; $p<0.05$). Following BCAS, RBC speed decreased in both strains of mice, but the flow reduction was more severe in ApoE4-TR than in ApoE3-TR mice (ApoE4-TR, -48±8%; ApoE3-TR, -30±13%; $p<0.05$). However, microvascular diameter remained unchanged (ApoE4-TR, 4.9±0.1 μm; ApoE3-TR, 4.7±0.1 μm; $p>0.05$). Next, to assess the impact of the greater CC flow reduction in ApoE4-TR mice, we investigated the WM damage produced by BCAS and the attendant cognitive deficits. BCAS resulted in more marked CC demyelination in ApoE4-TR than in ApoE3-TR mice ($p<0.05$). BCAS also impaired cognition more severely in ApoE4-TR mice, examined with Y maze arm alternation and novel object recognition ($p<0.05$). These data suggest that the ApoE4 genotype is associated with more severe alterations in CC flow and cognitive function in the setting of cerebral hypoperfusion. Such alterations may play a role in the increased susceptibility to subcortical WM damage observed in individuals carrying the ApoE4 allele.

**Title:** Alzheimer's disease associated APOE4 regulates gene expression in the genomic vicinity of apolipoprotein E

**Authors: *R. URFER**, A. URFER-BUCHWALDER
Selonterra, Inc., Belmont, CA

**Abstract:** Alzheimer’s disease (AD) affects millions of people worldwide. AD is caused by a combination of a subject’s genes, lifestyle and medical condition, as well as environmental factors. The single most important genetic contributor to AD is APOE4, a variant of the apolipoprotein E gene. We previously showed that the single nucleotide polymorphism rs429358 that defines APOE4 creates a recognition motif for the transcription factor nuclear respiratory

factor 1 (NRF1 ; UniProt Q16656). We hypothesized that this recognition motif acts as a transcriptional enhancer and thereby affects the expression of genes in the genomic vicinity of APOE4. In order to test this hypothesis, we performed a gene expression analysis in genetically defined human neurons. To this end, we built a custom gene array to probe genes located within 2 Mb of APOE on human chromosome 19 by quantitative polymerase chain reaction (qPCR). We measured differential gene expression in iPSC-derived human neurons homozygous for either the APOE4 (E4E4 ; AD-patient derived), APOE3 (E3E3 ; healthy control subject) or APOE2 (E2E2 ; healthy control subject) variants. qPCR analysis identified genes that are specifically regulated in E4E4 neurons but were unregulated between E3E3 and E2E2 neurons. Most of the E4E4-regulated genes were downregulated compared to the levels measured in E3E3 or E2E2 neurons. This finding is in line with known effects of enhancers that can both stimulate and inhibit gene expression. In conclusion, our data suggests that genes located in the genomic vicinity of APOE4 are regulated by this genetic variant in human AD neurons and may represent AD-causing genes.

**Abstract:** Since cerebral blood vessels play a critical role in maintaining brain homeostasis, cerebrovascular dysregulation leads to neuronal damage and diffuse white matter lesions, resulting in vascular cognitive impairment and dementia (VCID). VCID and Alzheimer's disease (AD) are the major causes of dementia in the aged population, while they often co-exist.

Accumulating evidence has shown that the ε4 allele of the apolipoprotein E (*APOE4*) gene increases the risk for VCID as well as AD, where *APOE4* disturbs cerebrovascular function and cerebrovascular endothelial integrity. In addition, a major apoE receptor, low density lipoprotein receptor-related protein 1 (LRP1), abundantly expressed in vascular mural cells including pericytes and smooth muscle cells. Thus, we investigated how the deletion of LRP1 in vascular mural cells, and apoE isoforms, affect the cerebrovascular system and cognitive performances using vascular mural cell specific LRP1 knockout mice (*smLrp1*$^{-/-}$) with *APOE3* or *APOE4* background. These mice were generated by breeding *Lrp1* floxed mice, sm22α-driven Cre recombinase mice and *APOE3*- or *APOE4*-targeted replacement (TR) mice. Morris Water Maze test revealed that spatial learning and memory ability was significantly impaired in *smLrp1*$^{-/-}$ mice compared to control mice with *APOE4* background, but not with *APOE3* background. We also found that the density of collagen IV, which is a main component of the vascular basement membrane, was lower in the brains of *APOE4; smLrp1*$^{-/-}$ mice than those of *APOE4* control mice when analyzed by immunohistochemistry. However there was no difference between *APOE3; smLrp1*$^{-/-}$ and *APOE3* control mice. The coverage of pericyte, tight junction proteins and astrocyte end-feet on cerebrovascular endothelial cells did not differ among the four groups. Taken together, our results suggest that LRP1 dysfunction in vascular mural cells contributes to cerebrovasculature dysregulation and related cognitive impairment in an apoE isoform-dependent manner.

**Title:** Effects of diet induced obesity and APOE genotype on Alzheimer-related pathology in female EFAD mice

**Authors: *A. CHRISTENSEN**[1], C. J. PIKE[2]
[1]Dept. of Gerontology, [2]USC Leonard Davis Sch. of Gerontology, USC, Los Angeles, CA

**Abstract:** Alzheimer’s disease (AD) risk is significantly influenced by genetic and environmental risk factors. The greatest genetic risk factor for late onset AD is APOE genotype, with E4 carriers being at a greater risk than E2 or E3 carriers. This increased risk in APOE4

carriers is exacerbated in females. Further, obesity in midlife has been shown to significantly increase AD risk in late life. To investigate whether APOE genotype and obesity interact to affect AD pathogenesis in females, we studied the effects of diet-induced obesity in the EFAD mouse model of AD. EFAD mice have knock-in of human APOE3 (E3FAD) or APOE4 (E4FAD) in the presence of 5xFAD genes. Female EFAD mice were maintained on either Western diet (WD; 45% fat, 21% sugar) or a control diet (10% fat, 7% sugar) for 12 weeks. E3FAD mice showed greater metabolic impairments after WD including increased glucose dysfunction and increased circulating leptin. E4FAD mice did not show impairments after WD, but had poorer metabolic function at baseline than E3FAD mice. E3FAD mice on WD were impaired on cognitive tasks and showed increased beta-amyloid pathology. E4FAD mice were more impaired on the behavior tests and had greater beta-amyloid neuropathology in comparison to E3FAD mice, but showed no further impairment by WD. Microglia are believed to play an important role in the progression of AD neuropathology and are implicated in the effects of both APOE4 and obesity. We assessed the activation of microglia in the hippocampus. As with beta-amyloid pathology, E3FAD mice showed increased microglial activation after WD. E4FAD mice had more activated microglia than E3FAD mice, but no further impairment after WD. Overall, these findings demonstrate significant gene-environment interactions between APOE and obesity in female EFAD mice.

**Abstract:** Although inheritance of APOE4 allele is a major genetic risk factor for late-onset Alzheimer’s disease (AD), the mechanisms underlying this association remain elusive. APOE

can differentially modulate amyloid β (Aβ) aggregation and clearance through blood brain barrier, or by astrocytic and microglial degradation. Microglia involvement in response to neurodegenerative processes and maintaining brain homeostasis is achieved through their ability to rapidly interact to changes in the brain microenvironment, enabling adequate phenotypic transformations. We hypothesize that APOE interacts with Aβ in an isoform-dependent manner, differentially impacting neuroinflammatory processes, particularly microglial response, influencing the progression of AD pathology. To test the hypothesis we infused co-incubations of Aβ with APOE3 or APOE4 native particles into the brains of WT mice to determine changes in microglial phenotypes. Utilizing magnetic-activated cell sorting we isolated microglia and neurons followed by RNA-seq to determine the impact of APOE isoform in the presence of Aβ on the transcriptomics of the two cellular populations. Utilizing FACS sorting we isolated the microglial into population which contain or lack infused fluorescently tagged Aβ and performed RNA-seq to determine changes in microglial response. Furthermore, using flow cytometry we determined the number of microglia containing Aβ for the Aβ+APOE3 and Aβ+APOE4 groups. Lastly, we utilized immunohistochemistry to confirm the RNA-seq results and further classify the microglial phenotypes of the two groups. We first show that microglial gene expression is more significantly impacted by the native APOE lipid particles when compared to neurons. Microglia in the Aβ+APOE3 group display significantly increased complexity and projections oriented toward the infusion site when compared to the Aβ+APOE4 group. Furthermore, microglia from the Aβ+APOE3 group show increased markers for chemotaxis. Microglia that contain Aβ in the APOE4 group display a unique transcriptome while displaying decreased phagocytic capacity. Infusion of Aβ+APOE3 or Aβ+APOE4 into $Trem2^{ko}$ mice further illustrate the importance of Trem2 in the microglial response to Aβ, Trem2 dependent mechanisms and differential impact of the APOE isoform even in microglia lacking Trem2. This study increases our understanding of the isoform-dependent effect of APOE on the microglial response to Aβ. Moreover, it provides a mechanism by which APOE isoform impacts the progression of AD and associated neuroinflammation.

**Abstract:** As the number of older Americans grow rapidly, there is a dire need to identify and validate early pre-clinical markers for Alzheimer's disease (AD). Recent studies have shown that abnormalities in olfactory structure and function may precede overt symptomatic development of AD by more than a decade. However, the molecular mechanisms of olfactory neural dysfunctions in AD are poorly understood. In our recent review article we presented preclinical research revealing persuasive evidence that Apolipoprotein E (APOE) impacts olfactory neuronal structure and function and AD pathogenesis. However, this finding has not yet been demonstrated in living human subjects. In this preliminary analysis, we examine olfactory pathways in transgenic murine models of AD and APOE mice and APOE4 human carriers. We used 6-9 month old knock in (APOE3 and APOE4) and 5X-FAD mice and collected both Olfactory Bulb (OB) and Olfactory Mucosa (OM) for microarray and protein analysis. Gene, sex, and phenotype interactions were correlated with pathology of OM and OB. Initial findings show APOE4 variant had significant effects on the level of oxidative stress, mitochondrial dysfunction, Tau and collapsin response mediator protein 2 (CRMP2) phosphorylation in the olfactory tissues of AD mice. In our human study, we used our platform of human derived olfactory tissue to explore differences in molecular signatures comparing olfactory neuronal isoforms derived from APOE4 carriers (n =2) and isoforms derived from non-carriers of APOE4. More specifically, we were interested in exploring protein expression of CRMP2 (n=2), a microtubule-associated protein that is specifically hyperphosphorylated in AD. We have optimized the protocol and trouble shooting strategy in the study of protein and molecular signatures in human olfactory neuronal isoforms of APOE4 and non-APOE4 carriers. We found that both total and phosphorylated CRMP2 levels were increased in olfactory neurons from APOE4 carriers compared to non-carriers of APOE4. Our findings illustrate the utility of olfactory epithelial and neuronal platform as a model to study preclinical development of AD in those at high clinical risk. We anticipate extending this platform for detailed morphologic, molecular and proteomic studies that would define mechanisms of AD development and progression in preclinical populations. Although further validation is warranted, results indicate that analysis of olfactory structure in relation to pre-clinical markers may have important translational potential in the near future.

**Abstract:** Emerging genetic, pathological, and mechanistic studies have provided strong evidence supporting a critical role of microglia in the pathogenesis of Alzheimer's disease (AD). Although known as the primary immune defense system in the brain, microglia and the inflammatory responses can play beneficial and/or detrimental roles upon neuronal injury and during disease progression. The ε4 allele of the apolipoprotein E (*APOE*) gene is the strongest genetic risk factor for late-onset AD, whereas *APOE* ε2 is protective compared to ε3 allele. Although apoE isoforms have been implicated in microglial functions, a direct comparison of how the three apoE isoforms impact microglial responses to neuronal injury is lacking. Here, we demonstrated dramatic differences of apoE isoforms in the activation and function of microglia upon cuprizone-induced demyelination. In particular, microglia in human apoE2-targeted replacement (apoE2-TR) mice are more efficient, whereas those in apoE4-TR mice are less efficient in the clearance of myelin debris compared to apoE3-TR mice. Deficiency of microglia in apoE4-TR mice was also evident morphologically as they exhibited a dystrophic phenotype. Importantly, several key molecules known to mediate microglial activation, migration, phagocytosis, and lipid catabolism were upregulated in the corpus callosum of cuprizone-treated mice in an apoE isoform-dependent manner. Our findings indicate that differential effects of apoE isoforms in microglia might contribute to their distinct ability to limit neuronal damages and/or facilitate repairs upon injuries, providing a novel pathway by which apoE2 reduces and apoE4 increases the risk of neurological diseases such as AD.

**Title:** Spatial learning and memory in murine models: Examination of gender, genotype and their interaction in 5xFAD and APOE transgenic mice

**Authors: *J. N. O'NEIL**, R. RAYHAN, M. M. MISIAK, K. F. MANAYE
Dept. of Physiol. & Biophysics, Howard University, Col. of Med., Washington, DC

**Abstract:** Alzheimer's disease (AD) is the most common cause of elderly dementia with women having a higher incidence than men do. Genome-wide association studies have shown that the apolipoprotein Ɛ4 (APOE 4) allele is the strongest genetic risk factor for developing late-onset AD along with age and sex. Individuals with APOE Ɛ4 allele are predisposed to develop an accelerated decline in cognition compared to non-carriers, due to underlying changes in brain structure. Using APOE knock-in mice (APOE 3 and APOE 4) and 5xFAD transgenic mice that overexpress mutant human APP(695) with the Swedish (K670N, M671L), Florida (I716V) and London (V717) familial mutations, we investigated the impact of human APOE alleles (Ɛ3, Ɛ4) and human Alzheimer's mutations (5xFAD) on cognitive performance. Mice aged (6-9 months) were trained on the Barnes maze apparatus for 4 days followed by a 72-hour probe to assess long–term spatial memory. In this preliminary study, we determined whether significant differences due to gender, genotype, and their interactions effected spatial cognition and long-term memory throughout the protocol. During training day 1 there was no significant difference in latency times, however, from training day 2- 3 both wild type and APOE 3 found the target hole at a faster and more significant rate than 5xFAD and APOE 4 mice. On training day 4, APOE 4 mice found the target hole at a similar rate as APOE 3 and WT. In contrast, 5xFAD did not show any learning and was significantly different from all three groups. On the 72-hr probe assessing long-term spatial memory these differences persisted. All behavior data will be further correlated with pathology studies, Understanding the cognitive performance in this model will be important in developing treatment strategies for AD in the near future.

**Title:** A clinically tested HDL mimetic peptide mitigates apoE4 associated lipidation and memory deficits

**Authors: *D. S. CHERNICK**[1], S. ORTIZ-VALLE[1], A. GRAM[2], L. LI[2]
[1]Pharmacol., [2]Exptl. and Clin. Pharmacol., Univ. of Minnesota, Minneapolis, MN

**Abstract:** The apoE ε4 allele is the primary genetic risk factor for late-onset Alzheimer's disease (AD), while apoE ε2 is protective, and apoE ε3 is neutral in this context. ApoE found in the brain is primarily produced and secreted by astrocytes, whereupon it binds lipids to form high-density lipoprotein (HDL)-like particles in the interstitial and cerebrospinal fluid. While the mechanisms by which apoE4 affects the development of AD are not completely understood, compelling evidence indicates that the pathogenic effects of apoE4 are mediated by lipid-related pathways. ApoE4 is known to be deficient in lipidation and formation of HDL in the brain, when compared to apoE3, while apoE2 is lipidated most effectively. ApoE directly interacts with amyloid-β (Aβ), and the level and lipidation state of apoE affects Aβ aggregation and clearance pathways. Our previous studies showed that a clinically tested 18-aa HDL mimetic peptide, 4F, increases the secretion and lipidation of apoE from wild-type primary murine astrocytes and mitigates Aβ-induced lipidation deficiency. Current results using primary murine astrocytes expressing the human apoE variants, as well as primary human astrocytes, confirm the relevance of our earlier work to human physiology. 4F restores apoE4 lipidation to a level similar to that of apoE2. Further, our studies indicate that apoE4 may be uniquely susceptible to the detrimental lipidation-inhibitory effect of Aβ, while apoE2 is protected against this insult. Our ongoing efforts seek to determine whether treatment with 4F can reverse the lipidation deficiency of apoE4 and improve memory and cognition *in vivo*. Aged mice expressing human apoE2, apoE3, or apoE4, were administered a once-daily I.P. injection of 2.5mg/kg D-4F for 3 weeks. 4F treatment was found to mitigate apoE4-associated memory deficits in this pilot study. Biochemical analyses of these animals are underway. Future studies will investigate the role of

4F in mitigating amyloid pathology in the context of the human apoE variants using mouse models of AD.

**Abstract:** The prevalence of dementia tends to increase with the aging society. To deal with this problem, early detection and treatment of dementia is important. For diagnostic support and screening, intelligence test, biomarkers and image diagnosis such as CT, MRI, PET are used as the conventional method. However, these methods have problems such as high inspection cost, invasiveness, requirement for dedicated equipment.
Our relevant research was to estimate health conditions, such as depression and stress state using voice. Analysis using voice is advantageous in terms of providing diagnostic support for physicians, it is non-invasive, it can be performed remotely and it doesn't require special equipment. In this paper we examined pilot study to detect dementia based on vocal analysis.
In the experiment, we collected voice (96kHz, 24bit, wav file) using an IC recorder and a pin microphone from healthy subjects (n=18) and patients with Dementia (n=39) in a hospital's consulting room. The voices were collected when the subjects read 13 fixed phrases. Informed consent was obtained from the subjects.
In the evaluation, extracted 600 acoustic features from each phrase's speech using the openSMILE software. Then, to develop an algorithm using the J48 decision tree-induction algorithm (Weka implementation of C4.5) with 10-fold cross validation for classifying healthy subjects and patients with Dementia. As a result, the classification performance of the algorithm relative to healthy subjects, patients with a dementia is 79.6% with recall of 0.679 and 0.847, respectively, and precision of 0.659 and 0.858, respectively.
Consequently, the algorithm performed well in classifying healthy subjects and patients with dementia, which suggest the utility of the classification algorithm in estimating disease

conditions based on speech. Future studies will subdivide dementia into Alzheimer's type, Lewy body type, etc., verify with voice collected at other hospitals, and improving its accuracy.

**Title:** Functional connectivity profile during inter-task resting state in dementia with Lewy bodies

**Authors: *E. CHABRAN**[1], D. ROQUET[2], D. GOUNOT[2], F. BLANC[2,3]
[1]Icube Lab. CNRS, Strasbourg, France; [2]IMIS team, ICube Lab. CNRS, Strasbourg, France; [3]Memory resources and research centre (CMRR), Univ. Hosp. of Strasbourg, Strasbourg, France

**Abstract: *Aims*:** Limited research has been done on the functional connectivity in visuoperceptual regions in dementia with Lewy bodies (DLB) patients. This study aimed to investigate the functional connectivity differences between a task condition and an inter-task resting-state condition within a visuoperceptual paradigm, in DLB patients compared with Alzheimer’s disease (AD) patients and healthy elderly control subjects.
***Methods*:** 26 DLB, 29 AD and 22 healthy subjects underwent a detailed clinical and neuropsychological examination along with a functional MRI during the different conditions of a visuoperceptual paradigm. Functional images were analyzed using group-level spatial independent component analysis and seed-based connectivity analyses.

***Results*:** While the DLB patients scored well and did not differ from controls and AD groups in terms of functional activity and connectivity during the task conditions, they showed decreased functional connectivity in visuoperceptual regions during the resting-state condition, along with a temporal impairment of the default-mode network activity. Functional connectivity disturbances were also found within two attentional-executive networks, and between these networks and visuoperceptual regions.
***Conclusion*:** We found a specific functional profile in the switching between task and resting-state conditions in DLB patients. This result could help better characterize functional impairments in DLB and their contribution to several core symptoms of this pathology such as visual hallucinations and cognitive fluctuations.

**Title:** Chronic suppression of monoacylglycerol lipase improves adult neurogenesis in septal but not temporal part of DG in a mouse model of Down syndrome

**Authors: D. FOZOONMAYEH**[1], J. YU[1], M. SANKARAN[1], M. WALSH[1], M. SAWA[1], A. TYRTYSHNAIA[1,2], M. KHOTIMCHENKO[2], *A. M. KLESCHEVNIKOV[1]
[1]Neurosciences, Univ. of California San Diego, La Jolla, CA; [2]Sch. of Biomedicine, Far Eastern Federal Univ., Vladivostok, Russian Federation

**Abstract:** Chronic treatment with the selective monoacylglycerol lipase (MAGL) inhibitor JZL184 restores hippocampal long-term potentiation and improves cognition of aged Ts65Dn mice, a genetic model of Down syndrome (DS) (Lysenko et al, 2014). To assess possible mechanisms responsible for these improvements, here we examined the effects of JZL184 treatment on adult neurogenesis in the Ts65Dn dentate gyrus (DG). JZL184 (8 µg/kg, i.p.) or vehicle were injected in 9 months old trisomic and control euploid (2N) mice once a day during 20 days. BrdU was injected on days 11-14 of the JZL184 treatment. Total number and density of BrdU-positive cells were significantly reduced in the vehicle-treated Ts65Dn mice indicating reduced adult neurogenesis. JZL184 treatment increased the rate of adult neurogenesis in Ts65Dn but not in 2N mice. Analysis of DG subregions showed that the changes were mostly similar in the septal, middle, and temporal portions of Ts65Dn *vs*. 2N DG. However, the effects of the JZL184 treatment in Ts65Dn mice were mostly confined to the septal part of the dentate gyrus. Thus, in the septal portion of DG, the BrdU+ cell density was reduced in Ts65Dn Veh group to 41.7 ± 11.9% ($p = 0.03$) and restored in Ts65Dn JZL group to 99.5 ± 34.7% ($p = 0.78$) of the corresponding values in the vehicle-treated 2N control mice. In the temporal portion of DG, the BrdU+ cell density was also reduced in Ts65Dn Veh group to 58.4 ± 6.7% ($p = 0.03$) but remained reduced in Ts65Dn JZL group at 57.9 ± 3.6% ($p = 0.03$) of the 2N Veh controls. Selective restoration of adult neurogenesis in the septal but not temporal DG may explain previous observations that JZL184 treatment improved cognition but had no effect on anxiety related behavior in Ts65Dn mice. Thus, chronic treatment of aged Ts65Dn mice with the selective MAGL inhibitor JZL184 selectively improved adult neurogenesis in the septal portion of Ts65Dn DG. Together with previous data, these results indicate that JZL184 treatment have several beneficial effects in the Ts65Dn model of DS and, therefore, can be regarded as a prospective approach for pharmacotherapy of cognitive impairment in DS.

**Authors: *B. KEPPLINGER**[1,2,3], H. BARAN[1], C. KRONSTEINER[1]
[1]Karl Landsteiner Res. Institute, Mauer, Mauer-Amstetten, Austria; [2]Neurolog., Neurolog. Department, Neuropsychiatric Hosp., Mauer-Amstetten, Austria; [3]Neurolog. Department, Gen. Hosp., Amstetten, Austria

**Abstract: Background** Symptomatic normal pressure hydrocephalus is a potentially reversible neurodegenerative disease commonly characterized by gait and urinary disturbance and occurrences of dementia. There is also hydrocephalus e-vacuo characterized by occurrence of dementia but without gait and/or urinary disturbance and no cerebrospinal fluid (CSF) pressure elevation. Since kynurenic acid (KYNA) is suggested to be involved in dementia present study aimed to investigate KYNA levels in the CSF of patients with hydrocephalus.
**Material and Methods** Clinical parameters in the CSF and serum of hydrocephalus patients (N=9) and of control subjects (CO, N=30), obtained from Neurological Department General Hospital Amstetten, Austria were evaluated. In addition by using HPLC method we measured KYNA levels in the CSF. Study was carried out according to ethical rules of the Lower Austrian Government.
**Results** We found significant increase of protein in CSF of patients with normal pressure hydrocephalus (207.2 % of CO; $p<0.01$) but not with hydrocephalus e-vacuo, comparing to control subjects. Furthermore, also albumin in CSF, IgG CSF, ratio CSF:serum IgG and ration CSF:serum albumin were significantly increased in the patients with normal pressure hydrocephalus (217, 290, 270 and 230 % of CO; $p<0.01$, respectively) but not in patients with hydrocephalus e-vacuo. KYNA levels in CSF of patients with normal pressure hydrocephalus were moderately but significantly increased (141 % of CO, $p<0.05$) and in patients with hydrocephalus e-vacuo significant increase of KYNA levels in CSF was found (225 % of CO, $p<0.01$), comparing to control subjects.
**Conclusion** KYNA levels are moderately but significantly increased in CSF of patients with normal pressure hydrocephalus and in hydrocephalus e-vacuo the increase was markedly higher. Measurement of KYNA levels in CSF might be interesting additional approach distinguishing patients between normal pressure hydrocephalus and hydrocephalus e-vacuo. We suggest that an enhancement of KYNA in CSF found in patient with normal pressure hydrocephalus and e-vacuo might play a role for the occurrence of dementia. All authors have no conflict of interest.

**Abstract:** The progressive loss of brain matter in neurodegenerative diseases leads to impairments in numerous autonomic, motor, and cognitive functions. An easy-to-measure method that is increasingly used in clinical investigations to assess cognitive function is pupillometry. In addition to global luminance and arousal, pupil size is also modulated by converging bottom-up sensory and top-down cognitive signals. Furthermore, the circuitry for pupil control is suggested to be linked to the saccade generation system. We hypothesize that disruptions in neural circuitry due to neurodegeneration or brain injury can affect pupil control and its relationship to the saccade system. Here, we examined pupil dynamics in patients diagnosed with one of 6 neurodegenerative diseases (Alzheimer’s disease, mild cognitive impairment, Parkinson’s disease, amyotrophic lateral sclerosis (ALS), frontotemporal dementia (FTD), vascular cognitive impairment) during an interleaved pro-/anti-saccade task, and hypothesized that specific components of the pupil response should be altered due to neurodegeneration. Pupil size and eye position were recorded while subjects performed the task. The pupil response following the presentation of the fixation cue consisted of an initial constriction component, which was mainly driven by the change of luminance level from fixation cue onset, followed by a dilation component that has been previously linked to saccade suppression and voluntary saccade preparation. Analysis revealed distinct differences between patient groups and age-matched controls in pupil dynamics. Pupil constriction was reduced in the patient groups compared to controls as was pupil dilation, suggesting changes in the light reflex pathway and the top-down preparation signals, respectively. Furthermore, there were differences in pupil measurements among the patient groups that may reflect disease differences in

neurological deficits. Reduction in pupil dilation was smallest in ALS and greatest in FTD, which was in line with anti-saccade performance where FTD showed the highest error rate among patient groups. The results demonstrated changes in pupil dynamics linked to neurodegeneration, showing that pupil measurements in visuomotor tasks have the potential to provide relevant early behavioural biomarker for diagnosis of neurodegenerative diseases and tracking disease progression.

**Abstract:** In older adults hyperintense signal is often found in the cerebral white matter on T2-weighted magnetic resonance imaging. These white matter lesions are found to be clinically associated with a cognitive, mood, and functional disturbances. These lesions are believed to have heterogenous origin, including both inflammatory and ischemic components. However, histopathologic correlations are limited since the WMLs are only seen on in-vivo scans and not on the postmortem ex-vivo MRI. Thus, alignment from in-vivo to ex-vivo MRIs is essential for improved understanding of the histopathology of WMLs. In the current study we address this challenge by developing an automated alignment method to register the in-vivo MRI to ex-vivo histopathology. Further WMH histological characterization is a long term goal that this method would facilitate. We scanned subjects (N=3, age during in-vivo scan= 87 (SD 1), age at death = 91(SD 1)) in-vivo and at postmortem (left hemisphere (LH)) to obtain T1-weighted, T2-weighted fluid attenuated inversion recovery (FLAIR) 7T MRIs. The ex-vivo tissues were cut into slabs of

1cm thickness and photographs were obtained. The ex-vivo MRI LH was reoriented into the same orientation as the in-vivo LH using FSL linear affine registration (flirt). The ex-vivo LH was mirrored to also create a full-brain ex-vivo image. Both ex-vivo and in-vivo whole brains were run through the SPM segmentation feature to acquire their forward and inverse deformation fields into MNI template. Spatial normalization within SPM12 was then used to apply the deformation fields to the original images. The forward deformation fields were applied to their corresponding MRIs to normalize them to the MNI template, while the ex-vivo inverse deformation field was applied to both the in-vivo and ex-vivo MRI. This method was applied to both the FLAIR MRI and the corresponding white matter segmentations. This produced a registration across the in-vivo, ex-vivo, FLAIR and white matter hyper intensities. The alignment allows us to view the WMLs on both the ex-vivo MRI and the postmortem histology.

**Abstract: Introduction:** Rapid eye movement sleep disorder (RBD) is a neurological disorder characterized by the loss of atonia during REM sleep. We investigated disease-specific features of event-related electroencephalograms (EEGs) during visuospatial attention task, and applied them to classify RBD patients from healthy controls using deep neural network. **Methods:** Nineteen healthy subjects (63.47 ± 7.37 years) and 16 drug-naïve idiopathic RBD patients (64.94 ± 6.92 years) participated in the study. Subjects performed Posner's cueing task. Valid and invalid stimuli were presented at 50:50 ratio, and the interval between cue and target was set to 200 ms and 1000 ms, respectively. Subjects were instructed to press a button when the target stimuli appeared. During the experiment, 60 channel EEG was recorded. Source localization analysis was performed. A 5-layer feedforward neural network was used as a pattern classifier. The inputs for the classifier were constructed from the time-samples of single-trial event-related current density time-series (-200 ms to 900 ms around the target onsets) . Layer-wise relevance propagation was used to find important time interval and brain area for classification from the trained neural network. **Results:** The classification accuracy was 83.29 ± 1.07%, and the sensitivity and specificity were 80.23% and 84.65%, respectively. The most important features for the classification were found to be the cortical currents within occipital and frontal regions at 200-350 ms poststimulus. **Discussion:** The temporal and spatial characteristics of the features crucial for the classification of RBD imply dysfunction of inhibitory attentional process of RBD patients. This is in accordance with the lack of the inhibition of return (IOR) associated with RBD.

**Title:** Sex-dependent effects of prediabetes in mouse models of Alzheimer's disease and mixed dementia

**Authors: *L. S. ROBISON**[1], O. GANNON[1], A. E. SALINERO[1], M. THOMAS[2], A. TYSON[1], K. L. ZULOAGA[1]
[1]Albany Med. Col., Albany, NY; [2]Rensselaer Polytechnic Inst., Troy, NY

**Abstract:** Alzheimer's Disease (AD) and vascular dementia are the two most common forms of dementia, and it has been estimated that 60% of individuals with AD have underlying cerebrovascular pathology/mixed dementia (MD). Diabetes increases the risk for both vascular and non-vascular dementia (including AD). Less is known about the effects of prediabetes, insulin resistance and glucose intolerance in the absence of hyperglycemia. This is a critical gap in knowledge, as prediabetes is 3x more common than diabetes and affects 38% of Americans. Prediabetes has been linked to early indicators of dementia, including hippocampal atrophy and memory deficits. Despite strikingly high prevalence and rates of comorbidity, much less is known about the effects of prediabetes on vascular and AD pathology and symptomology, particularly when these pathologies co-occur. In addition, since females have higher rates of dementia and faster rates of decline in cognition, sex differences must be explored. Therefore, the aim of the current study was to determine whether sex differences in the effects of prediabetes (modeled by chronic high fat diet) exist in mouse models of AD and MD. Male and female 3xTg-AD mice received either sham (AD model) or right unilateral common carotid artery occlusion (rUCCAO) surgery (MD model) at ~2.5 months of age; these were compared to wild-type (WT)/sham surgery (control) mice of both sexes. Mice were then placed on either low fat (LF; 10% fat) or high fat (HF; 60% fat; prediabetes model) diet for 3 months, then subjected to a glucose tolerance test (GTT), and used for either assessment of neurogenesis or behavior/cognition. Additional aspects of neuropathology (e.g. cerebral blood flow, amyloid, inflammation, cell death, and integrity of white matter, vasculature, and blood brain barrier integrity) are also being assessed. rUCCAO resulted in ~20% reduction in blood flow to the right hemisphere immediately after surgery. HF diet increased body weight gain and visceral fat mass, and impaired glucose tolerance, across groups. These metabolic deficits appear to be greater in females compared to males, and in 3xTg-AD mice regardless of surgery (AD and MD models) compared to WT mice. HF diet did not affect novel object recognition performance in WT mice; however, most AD and MD groups were impaired on this task. HF diet generally impaired spatial memory in the Morris water maze across mouse models, and MD (regardless of diet) also

hindered performance. This study will be critical for understanding sex differences in the effects of prediabetes on Alzheimer's disease and mixed dementia, and may point to pathways that could be targeted to enhance functional outcomes.

**Title:** Microglia engulfment of Purkinje cell dendrites precedes neurodegeneration in the NPC1$^{nmf164}$mutant mouse

**Authors: L. KAVETSKY**[1], K. GREEN[2], *I. SOTO[1]
[1]Mol. and Cell. Biosci., [2]Biol. Sci., Rowan Univ., Glassboro, NJ

**Abstract:** In Niemann Pick Type-C (NPC) disease, progressive and severe degeneration of neurons in different regions of the brain, but more severely in the cerebellum, is accompanied by neuroinflammation. Although neuroinflammation is considered a pathological hallmark of NPC, the temporal activation and its contribution to neuronal degeneration have not been elucidated. The aim of this study was to determine the sequence of neuroinflammation and its correlation with Purkinje cell (PC) loss and behavioral deficits in the NPC1$^{nmf164}$ mouse model of the disease. At early stages of NPC disease (4wk), when no signs of motor dysfunction were detected, microglia reactivity and activation were already evident in the molecular layer (ML) where PCs synaptic connections reside. Significant changes in IBA1+ cell number and morphology in the ML were remarkable even without loss of PCs at this early stage. Also, accumulation of CD68+ phagosomes in microglial cells was already evident at early stages of the disease in the mutant mice. At stages of moderate (8wk, ~50%) and severe (12wk, ~80%) degeneration of PC, the number of IBA1+ microglia/macrophages was significantly elevated and the morphology of these cells was found less ramified and more amoeboid shape. In addition, the accumulation of CD68+ phagosomes and autofluorescent material in these cells was remarkably higher when compared with younger NPC1$^{nmf164}$ mice, indicating increased phagocytic activity and lack of proper lysosomal function in these cells. For instance, more PC dendrites were found to be engulfed by microglia/macrophages in the mutant mice, suggesting that dendrite degeneration and engulfing by phagocytes precede neuronal death. We also found that the majority of these phagocytic cells were negative for the resident microglia marker TMEM119, suggesting that the majority of IBA1+ myeloid cells in the cerebellum at these stages of NPC disease are infiltrating monocytes. The increased neuroinflammation found in the late stages of

NPC was directly correlated with the loss of Purkinje cells and motor deficits in the NPC1$^{nmf164}$ mutant mouse. Our findings suggest that neuroinflammation in the cerebellum of NPC1$^{nmf164}$ mutant mice is a pathological event that precedes the death of PC and that is involved in the degeneration of PC dendrites.

**Title:** Identification and characterization of frontotemporal dementia risk factor TMEM106B interacting proteins

**Authors: *R. CHARAN**[1], T. L. UNGER[2], D. AMADO[2], J. MAK[2], M. P. HERNANDEZ-CON[2], A. S. CHEN-PLOTKIN[2]
[2]Neurol., [1]Univ. of Pensylvania, Philadelphia, PA

**Abstract:** Frontotemporal lobar degeneration (FTLD) is characterized by selective degeneration of the frontal and temporal lobes of the brain, and is one of the leading causes of early-onset dementia. However, the pathological mechanisms underlying this disorder are not very well understood. Common variants at the gene encoding Transmembrane Protein 106B (*TMEM106B*) have been shown to increase genetic risk for FTLD with TAR DNA-binding Protein 43 (TDP-43) inclusions (FTLD-TDP-43). Variants associated with increased TMEM106B expression associated with greater disease risk. We have previously demonstrated that TMEM106B localizes to endosomes/lysosomes, and disease-associated-increases of TMEM106B expression result in lysosomal abnormalities and accumulation of enlarged vacuoles in various cell types, including neurons. In the present study, we sought to understand the molecular mechanisms underlying these cellular phenotypes by identifying the interacting partners of TMEM106B. Using immunoprecipitation in combination with mass spectrometry (IP-MS), we identified 329 proteins that interact with TMEM106B in HEK293 cells. Pathway analysis suggested enrichment in proteins involved in the SNARE complex, and the vesicle-associated membrane protein 8 (VAMP8), a SNARE protein known to play a role in lysosomal and autophagosome function, was verified to interact with TMEM106B. Increased expression of TMEM106B also induced the localization of endogenous VAMP8 to the enlarged vacuoles in mouse primary cortical neurons. Finally, knockdown of VAMP8 rescues multiple abnormalities induced by TMEM106B over-

expression, suggesting that VAMP8 and TMEM106B may function in the same pathways in cellular health and disease.

**Title:** Lead (Pb) exposure causes hypertension and cognitive dysfunction in a mouse model of vascular cognitive impairment and dementia (VCID)

**Authors: K. KOHLER**[1], T. MACHEDA[2], D. M. NIEDOWICZ[2], A. M. HELMAN[3], M. M. HOBBS[2], L. R. FARRIS[2], A. RODRIGUEZ[2], T. L. BECKETT[2], *M. P. MURPHY[3]
[1]Sanders-Brown Ctr. on Aging, [2]Univ. of Kentucky, Lexington, KY; [3]Molecr & Cell. Biochemi, Univ. Kentucky, Lexington, KY

**Abstract:** Although lead (Pb) has long been known as a neurotoxic agent in children, recent epidemiological research indicates that cumulative, low-level Pb exposure likely causes age-related neurologic dysfunction in adults as well. In fact, environmental Pb exposure in adulthood has been linked to risk of late-onset Alzheimer’s disease (AD) and dementia. Although the biological mechanism underlying this link is unknown, it has been proposed that Pb exposure may increase the risk of AD via altering the expression of AD-related genes and, possibly, activating the molecular pathways underlying AD-related pathology. APPxPS1 knock-in mice were exposed to 0.2% Pb Acetate in drinking water for three months, and the concentration of Pb in the blood and brain measured by ICP-MS. Expression of AD-related genes was determined by two-step qRT-PCR, amyloid pathology was measured by ELISA, and AD-protein levels were measured by Western or spot blot. Cognitive performance was evaluated in using the Morris Water Maze (MWM). Our data convincingly shows that Pb exposure in adulthood impairs cognitive function in an APPxPS1 mouse line, and that this effect occurs in the absence of significant increases in AD-related pathology or gene expression. Chronic Pb exposure caused significant hypertension, which is a well known risk factor for both dementia and cerebrovascular disease (CVD). Angiotensin receptor (AT1R) antagonists are widely used as anti-hypertensives, but also improve cerebrovascular health and function in a variety of neurological diseases. The mechanisms underlying this protection are unclear. In order to

examine AT1R as a possible target for reversing the consequences of Pb exposure and for treating CVD in general, we used a mouse line created by our lab that is obese and diabetic, and has both vascular and AD-related neuropathology. These mice (db/AD) are cognitively impaired by 12 months and display extensive cerebrovascular pathology, such as aneurysms and infarcts. In this study, db/AD mice were treated with telmisartan, an AT1R antagonist and partial PPAR gamma activator, for up to 6 months (0.5 mg/kg/day, in drinking water). Telmisartan had some benefit on improving CVD in these mice, and reversed changes in signaling pathways that were caused by Pb exposure. Since telmisartan is an approved blood pressure medication, we believe that it could be used to treat not only the cognitive dysfunction associated with Pb exposure, but could also be used to mitigate the CVD complications of AD.

**Title:** Neurovascular coupling in cerebrovascular disease through aging: Impact for functional brain imaging

**Authors: *M. BOUROUROU**, M. KHOUIDER, A. MACHADO, C. LECRUX, E. HAMEL
Lab. of Cerebrovascular Res., Montreal Neurolog. Institute-Mcgill Univ., Montreal, QC, Canada

**Abstract:** ***Background:*** Neuronal activity is supported by the supply of glucose and oxygen from cerebral blood flow (CBF), a tight relationship known as neurovascular coupling (NVC). NVC forms the basis of functional brain imaging techniques, such as fMRI BOLD. fMRI is increasingly used as a diagnostic tool in brain diseases, including in Alzheimer's disease (AD) and other forms of dementia associated with cerebrovascular alterations. However, the challenge in discriminating the respective contribution of neuronal dysfunction from comorbid cerebrovascular disease in NVC responses in AD has recently been recognized.
***Hypothesis and Objectives***: As NVC requires an intact neurovascular unit, we hypothesize that a compromised brain circulation may potentially lead to misinterpretation of fMRI data. Hence, using a transgenic mouse model of cerebrovascular alterations reminiscent to those found in AD, we assessed the reliability of NVC in detecting changes in neuronal activity by concurrently

measuring sensory-evoked neuronal and hemodynamic responses.
***Methods*:** Whisker-evoked changes in neuronal activity (local field potentials), cerebral blood flow (CBF, laser-speckle contrast imaging and laser Doppler flowmetry) and cerebral blood volume (CBV, optical imaging of intrinsic signals) were measured at 3, 6 and 9 months of age in the somatosensory cortex of transgenic mice overexpressing transforming growth factor-β1 (TGF mice) and wild-type (WT) controls instrumented with a chronic cranial window and an intracortical microelectrode. Spatial and executive memories were measured in the Morris water maze and novel object recognition tests, respectively.
***Results:*** At three months of age, TGF mice displayed impaired hemodynamic responses to whisker stimulation compared to WT mice. Particularly, the evoked responses in oxy- and deoxyhemoglobin were reduced and delayed in TGF mice, together with decreased CBF responses. These differences were exacerbated with aging. In contrast, whisker-evoked neuronal responses were similar in TGF and WT mice, at all ages. At corresponding ages, TGF mice did not develop cognitive deficits.
***Conclusions:*** Cerebrovascular alterations without neuronal dysfunction resulted in age-dependent alterations in NVC responses in TGF mice which progressed through aging, pointing to a lack of correlation between hemodynamic and neuronal signals. The results underscore that caution is warranted in the use and interpretation of clinical brain imaging data in patients with cerebrovascular diseases.

**Title:** Strain-specific expression and accumulation of human transgenic tdp-43 in a mouse model of frontotemporal lobar degeneration

**Authors: R. SHAHIDEHPOUR**[1], L. KUKREJA[1], G. KIM[1], K. SADLEIR[2], H. DONG[3], J. CSERNANSKY[3], M. MESULAM[1], R. VASSAR[2], *C. GEULA[1]
[1]Cogn Neurol & Alzhei Dis Cent, [2]Dept. of Cell and Mol. Biol., [3]Dept. of Psychiatry and Behavioral Sci., Northwestern Univ. Med. Sch., Chicago, IL

**Abstract:** Accumulation of TDP-43 in inclusions is one of the pathological hallmarks of frontotemporal lobar degeneration (FTLD). Mouse models have shown that overexpression of wild-type or mutant human TDP-43 (hTDP-43) results in the formation of inclusions and

neuronal loss. To investigate the temporal sequence of inclusion formation and degeneration, we employed a conditional transgenic mouse model expressing hTDP-43 under the control of tetracycline operator sequences. Past studies have shown that in certain strains of mice, tetracycline transactivator (tTA) possesses toxicity independent of hTDP-43, which was rescuable by moving the transgene onto a congenic C57BL/6 background (B6). Brains of TDP conditional transgenic mice were harvested and immunohistochemically stained using antibodies against phosphorylated TDP-43 (pTDP-43) and hTDP-43. The number of TDP-43-positive inclusions were quantified in the frontal, temporal and parietal cortices after 5 and 14 days, as well as 4, 8, and 24 weeks of transgene expression. TTA and hTDP-43 transgenic mice were bred on 129SVE and FVB backgrounds respectively, which are among the mouse strains susceptible to neurodegeneration from tTA. To avoid tTA-specific degeneration, we backcrossed hTDP-43 overexpressing mice with B6 mice for 5 generations and bred animals with B6 mice expressing the tTA transgene. Pups were weaned, and brains examined after 14 and 28 days, as well as 8, 15, and 24 weeks of TDP expression. Brains were cut and stained for pTDP-43 and hTDP-43. Double transgenic mice on the 129SVE/ FVB background showed inclusions as early as 5 days after TDP-43 expression, followed by a gradual increase in the number of inclusions, peaking at14 days of post-weaning expression. After 8 and 24 weeks of transgene expression, inclusions were rarely encountered, but the brains showed the most severe degeneration. Transgenic mice on the B6 background showed a decrease in hTDP expression and in the size and number of inclusions, as well as a delay in their formation. Staining for human TDP-43 confirmed that although double transgenic B6 mice overexpress TDP-43, there is a significant reduction in hTDP-43 immunoreactivity compared to the original 129SVE/ FVB mice. These observations suggest that after prolonged transgene expression, TDP-43 inclusions disappear as neurons are lost. They also indicate that backcrossing hTDP-43 overexpressing mice onto a B6 background decreases the expression of TDP and delays inclusion formation. Our TDP-43 mouse model serves as a valuable tool in examining the temporal sequence of TDP-43 inclusion formation and its association with neuronal degeneration.

**Abstract:** Dementia is a common disease and Alzheimer's Disease(AD) is one of the most known causes of dementia. 43 million people worldwide suffer from this devastating neurogenerative disease. Mild cognitive Impairment (MCI) is known as a precedent stage of AD. Patients with MCI can be categorized as amnestic MCI(aMCI) and non-amnestic MCI(naMCI). Patients with aMCI show predominant memory loss and it is associated with high risk of conversion to AD. Patients with naMCI show impairments in other domains than memory and they are at higher risk to convert to other types of dementia. Different types of MCI can lead to different dementia forms that require varying approaches of treatment.Therefore, it is very important to differentiate aMCI and naMCI to prevent further conversion to either AD or other forms of dementia. Resting-state functional connectivity is one of promising biomarker for MCI. In this study, we used functional connectivity multivariate pattern analysis (fcMVPA) to classify aMCI and naMCI. aMCI participants (n=22, 15 female, mean age 60, range 45-80) and naMCI participants (n=22, 15 female, mean age 60, range 45-80) participated in the study. Resting-state data were collected with fMRI. Blood-oxygen-level dependent (BOLD) signal was extracted and cross-correlation coefficients of each region of interest (ROI), which represent functional connectivity, were calculated. Support vector machine (SVM) was trained to classify correlation coefficients of aMCI and naMCI groups. (ROI). fcMVPA showed an optimistic performance with a high cross-validation accuracy. Parahippocampal gyrus was used the most out of 6670 features among 116 ROI following automated anatomical labeling(AAL) format. Hippocampus and amygdala also showed relatively high usage. Regional homogeneity (REHO) and Amplitude of Low Frequency Fluctuation (ALFF) were also analyzed with Data Processing Assistant for Resting-State fMRI (DPARSF). ROI that showed the most significant difference between aMCI and naMCI in both REHO and ALFF was amygdala. aMCI group showed higher activity of amygdala, insular, and putamen. Amygdala is known to be the integrative of emotion and emotional behavior. Memory impairment and emotion regulation are found to be correlated in many studies. The result of this study suggests that aMCI group might suffer more emotional problems than naMCI group.

**Abstract:** Abstract: Mutations in the gene for the serine/threonine protein kinase *PTEN-induced putative kinase 1* (*PINK1*) are the second most frequent cause of autosomal recessive Parkinson's disease (PD). Via its kinase activity, PINK1 regulates neuronal cell survival and mitochondrial quality control. Numerous reports have revealed that PINK1 has diverse and physiologically significant functions, and therefore its activity should be tightly regulated. However, the molecular mechanisms regulating PINK1 stability and the modulator(s) involved have not been elucidated. In this study, we demonstrate that the U-box- containing and chaperone-associated ubiquitin E3 ligase STUB1 (also known as CHIP) promotes PINK1 ubiquitination and decreases its steady-state levels. Moreover, PINK1 levels were strongly reduced in dopaminergic neuroblastoma SH-SY5Y cells exposed to the apoptosis-inducer staurosporine. Of note, we found that this reduction resulted from STUB1-mediated PINK1 ubiquitination. Accordingly, siRNA-mediated *STUB1* knockdown reduced susceptibility to staurosporine-induced cell death. Taken together, these findings suggest that STUB1 plays a role in negative regulation of PINK1 stability and may suppress PINK1's cytoprotective effect during staurosporine-induced mammalian cell death. We propose that this PINK1 regulatory pathway might contribute to PD pathogenesis.

**Title:** Mitochondrial regulations by pyrroloquinoline quinone prevented rotenone-induced neurotoxicity in Parkinson’s disease models

**Authors: *Q. ZHANG**, L. WEI, J. LU, F. DING
Nantong Univ., Jiangsu, China

**Abstract:** Pyrroloquinoline quinone (PQQ), a redox cofactor in the mitochondrial respiratory chain, has been reported to protect SH-SY5Y cells from cytotoxicity induced by rotenone, a mitochondrial complex I inhibitor. In this study, we aimed to investigate the mitochondrial mechanisms involved in the neuroprotection of PQQ both *in vitro* and *in vivo*. The cultured human SH-SY5Y neuroblastoma cells were exposed to different concentrations of PQQ (1, 10 and 100 μM) for 24 h after which the cells were treated with 100 μM rotenone for another 24h. Electron microscopy images showed that PQQ could prevent the mitochondrial morphology damage. Real time PCR showed that PQQ could inhibit the down-regulation of TFAM, PGC-1α, Mfn2 and Drp1 mRNA expressions in rotenone-injured SH-SY5Y cells. Western blot indicated that PQQ could promote the expressions of Mfn2, Drp1, LRRK2 and DJ-1 in the mitochondria. In addition, PQQ could promote the co-localization of mitochondria and lysosome in rotenone-injured SH-SY5Y cells. Rotenone was injected into the left medial forebrain bundle of SD rats to establish a PD model *in vivo*, after which 2 ml of different doses of PQQ (0, 0.05, 0.25, or 1.25 mg/ml) or Edaravone (1.25 mg/ml) were given intraperitoneally once daily for 8 weeks, respectively. PQQ could up-regulate the mRNA levels of TFAM, PGC-1α, Mfn2 and Drp-1 in the midbrain of PD rats. Our findings indicated that PQQ could prevent the mitochondrial morphology damage, promote the mitochondrial biogenesis and mitophagy, as well as regulate mitochondrial dynamics.

**Title:** The mitochondrial phosphatase, PTPMT1, regulates immune responses in *Drosophila*

**Authors: *A. M. PAPAKYRIKOS**, X. WANG
Stanford Univ., Stanford, CA

**Abstract:** In a *Drosophila*-based screen for mitochondrial proteins with roles in Parkinson’s disease, we identified protein tyrosine phosphatase, mitochondrial 1 (PTPMT1). PTPMT1 is a highly conserved mitochondrial phosphatase, which is involved in the synthesis of the mitochondrial-specific phospholipid, cardiolipin. Cardiolipin regulates various mitochondrial functions and was recently found to be decreased in PINK1 mutants. Here, we demonstrated that PTPMT1 plays a role in regulating the immune system of *Drosophila melanogaster*. Lack of PTPMT1 caused early lethality, indicating that PTPMT1 is an essential gene. We discovered signature responses of immune activation in PTPMT1 mutants, prior to death. These responses include an upregulation of antimicrobial peptide expression and melanization of the tracheal system. Using the GAL4-UAS system, we knocked down PTPMT1 in a tissue-specific manner and found that among the various tissues we tested, the tracheal tissue was most critical for PTPMT1’s function. Our study provides a previously unexplored link between mitochondria and localized immune responses through PTPMT1 and substantiates the multifaceted roles of mitochondria in cellular survival.

**Abstract:** Parkinson's disease related proteins kinase PINK1 and ubiquitine ligase Parkin coordinate ubiquitination of mitochondrial proteins marking mitochondria for degradation. Miro1, an atypical GTPase involved in mitochondrial trafficking, is one of the substrates tagged by Parkin after mitochondrial damage. Here we demonstrate, that Parkin translocation to the mitochondria induced by inhibitors of mitochondrial respiratory chain is decreased and delayed when Miro expression is supressed. We find, that Parkin recruitment is a two step process where initial Parkin translocation occurs independently of Miro1 ubiquitination at K572, but stress-induced ubiquitination is disturbed when Miro1 is mutated. Moreover, we show the importance of Miro1 ability to sense calcium through EF hands. Mutations in EF hands decrease and delay Parkin translocation, diminish ubiquitination of Miro1 and disturb calcium provoked mitophagy in neurons. Together, our results suggest that Miro1 function as a calcium-sensitive regulatory docking site for Parkin on mitochondria.

**Abstract:** Mitochondrial dysfunction has been implicated in Parkinson's Disease (PD) progression; however, the mitochondrial factors underlying the development of PD symptoms remain unclear. One candidate is gadd45, which controls translation and membrane insertion of 13 mitochondrial proteins involved in oxidative phosphorylation. Here, we found that gadd45 mRNA and protein expression were significantly reduced in postmortem brains of elderly PD patients compared to normal controls. To evaluate the effect of *gadd45* deficiency, we produced mice lacking the *gadd45* gene in dopaminergic neurons (DAT- gadd45-KO mice). From 5 weeks of age, DAT- gadd45-KO mice began to show decreased dopamine production with progressive neuronal degeneration in the nigral area. At ~10 weeks of age, they developed PD-like behavioral deficits, including gait abnormalities, rigidity, and resting tremor. L-DOPA, a medication used to treat PD, ameliorated these defects at an early stage, although it was ineffective in older animals. Taken together, the observation that gadd45 expression is reduced in human PD brains and deletion of gadd45 in dopaminergic neurons leads to early-onset PD with stepwise PD progression support the conclusion that gadd45-mediated mitochondrial function is important for the survival of dopaminergic neurons.

**Abstract:** Impairments in the clearance of damaged mitochondria via autophagy, known as mitophagy, has been implicated in Parkinson's disease (PD). Mutations in the serine/threonine kinase PINK1, and the E3 ubiquitin ligase parkin cause impairments in mitophagy, and have been implicated in familial PD. In the event of mitochondrial damage, PINK1 is stabilized on the outer mitochondrial membrane where it phosphorylates multiple substrates including parkin and ubiquitin. Parkin then translocates from the cytosol to the damaged mitochondria and initiates selective clearance of the organelle via the autophagy-lysosome system. The co-chaperone protein Bcl-2 Associated Athanogene 5 (BAG5) interacts with several PD associated proteins including parkin and PINK1; and has been shown to enhance protein aggregation and dopaminergic neurodegeneration in the substantia nigra. Therefore, we hypothesize that BAG5 is a regulator of PINK1 and parkin dependent mitochondrial quality control. We have previously shown that BAG5 directly interacts with parkin and Hsp70, and now we have confirmed that BAG5 also interacts with PINK1 by co-immunoprecipitation. The functional consequences of this interaction with BAG5 was assessed in cell culture models utilizing the protonophore, carbonyl cyanide m-chlorophenyl hydrazine (CCCP) to dissipate mitochondrial membrane potential, cause mitochondrial dysfunction and induce parkin recruitment followed by mitophagy. Western blotting of mitochondrial enriched fractions demonstrated that BAG5 overexpression and knockdown modulates PINK1 protein levels in response to CCCP treatment with opposing effects. In U2OS cells stably expressing GFP-parkin, overexpression and siRNA mediated knockdown was found to modulate parkin recruitment following mitochondrial depolarization. Finally, BAG5 was found to affect downstream PINK1 and parkin mediated mitophagy, in U2OS cells stably expressing GFP-parkin or a kinase dead C431S mutant GFP-parkin. Overall our work implicates BAG5 as a novel regulator of PINK1 and parkin mediated mitochondrial control.

**Title:** DJ1 deficiency disrupts mitochondrial inner membrane coupling to cause neuronal dysfunction in familial Parkinson's disease

**Authors: *R. CHEN**[1], H.-A. PARK[1], N. MNATSAKANYAN[1], Y. NIU[1], P. LICZNERSKI[1], J. WU[1], P. MIRANDA[1], M. GRAHAM[2], W. J. MANDEMAKERS[3], V. BONIFATI[3], K. ALAVIAN[4], E. A. JONAS[1]
[1]Dept. of Intrnl. Med., [2]Dept. of Cell Biol., Yale Univ., New Haven, CT; [3]Erasmus MC, Rotterdam, Netherlands; [4]Imperial Col., London, United Kingdom

**Abstract:** Parkinson's disease (PD) is a progressive neurodegenerative disorder characterized by loss of dopaminergic (DA) neurons in the substantia nigra pars compacta (SNpc). DJ-1 is a peptidase C56 family protein with known and uncharacterized cellular functions, mutations of which are linked to early onset familial PD. We now find that DJ-1 is associated with the mitochondrial $F_1F_O$ ATP synthase and binds directly to the ATP synthase β subunit. WT DJ-1 decreases inner membrane permeability to $H^+$ ions, decreases the overall conductance of the inner membrane in patch clamp recordings, increases the enzymatic activity of the ATP synthase and enhances the efficiency of ATP production. In contrast, mutations in DJ-1 or DJ-1 knock out cause dysfunctional metabolism and loss of mitochondrial inner membrane coupling, resulting in decreased growth in mouse neurons and human cells. In DJ-1 mutant or deleted cells, levels of the ATP synthase β subunit, a key component of the $F_1$ gate of the ATP synthase c-subunit leak channel, are dramatically decreased, causing opening of the leak channel and mitochondrial membrane depolarization. The findings are conserved in mouse neurons and human fibroblasts. In further study, we find that CsA, which depends on the F1 for its actions, increases the level of the mitochondrial ATPase β-subunit in WT but not DJ1 mutant fibroblasts. The loss of $F_1$ function explains why the decreased neurite extension in DJ1-/- dopaminergic neurons is only partially ameliorated by Dex treatment, while in contrast with normal F1 levels Dex enhances ATP production efficiency by decreasing the inner membrane leak. It also explains the different effects of CsA in amelioration of the rate of the fibroblast death in WT and DJ1 mutant upon forced mitochondrial metabolism. Our data suggest that DJ-1 maximizes inner membrane efficiency by decreasing the opening of the ATP synthase c-subunit leak channel and that DJ-1 is required for maintaining a highly efficient and functional ATP synthase complex by transcriptional, translational and possibly chaperone regulation of a main component of the $F_1$ gate of the channel, the β subunit. Our findings provide novel insights into PD pathogenesis and future therapeutic options.

**Abstract:** It has been almost 40 years since mitochondria were discovered to be key players in the pathogenesis of Parkinson's disease (PD) - the most common movement neurodegenerative disorder. Mitochondrial dysfunction leads to energy deprivation and death of dopamine (DA) neurons in the substantia nigra (SN) of the mibdrain, leading to the hallmark motor phenotypes observed in PD patients. The vast majority of PD cases (~90%) are idiopathic (iPD) while less than a tenth of affected individuals carry mutations to genes associated with PD. Postmortem iPD SN neurons exhibit somatic mitochondrial DNA (mtDNA) deletions, fewer mtDNA molecules undergoing transcription or replication, lower abundances of mitochondrial transcription factors (TFAM and TFB2M) and respiratory chain complex deficiencies, suggesting that mtDNA integrity is compromised in iPD. Interestingly, the E3 ubiquitin ligase Parkin, coded by the *PARK2* gene, was shown to be protective of the mitochondrial genome from oxidative insults, and mutations to *PARK2* cause the most common form of early-onset PD. Moreover, Parkin is a putative interacting partner of TFAM and increases mtDNA gene expression upon overexpression, supported by detection of elevated mtDNA concentration and mtDNA-encoded proteins. Although mostly known for its role in mitophagy, a novel role for Parkin in mtDNA maintenance is thus postulated. To study Parkin's function in mtDNA maintenance on an endogenous level, we generated induced pluripotent stem cell (iPSC)-derived neurons from patients with mutations to *PARK2* (c.1072Tdel/delEx7 and c.1072Tdel/c.1072Tdel) and controls. Compared to controls (n=3), neurons lacking Parkin (n=2)

exhibit significantly more mtDNA deletions and significantly less mtDNA transcription/replication. These findings were replicated in SH-SY5Y Parkin-knockout (KO) cells. SH-SY5Y Parkin-KO cells also mirrored reduced protein abundances of TFAM and complex I of the respiratory chain, while mitophagy was unaltered between controls and Parkin-KO cells under baseline conditions. These data support a novel role for Parkin in the pathogenesis of PD which may be as important as its role in mitophagy, opening avenues and targets for therapeutic intervention.

**Title:** Alpha-synuclein interplays with Miro to delay mitophagy and contribute to Neurodegeneration in Parkinson's models

**Authors: *C.-H. HSIEH**, M. KIM, A. SHALTOUKI, X. WANG
Stanford Univ., Palo Alto, CA

**Abstract:** Alpha-synuclein aggregation, composing Lewy bodies, is a hallmark of Parkinson’s disease (PD) pathology. Mutated forms of this protein are indicative in familial forms of PD; however, its role in pathogenesis still eludes need for exploration. It has been previously found that alpha-synuclein co-localize with mitochondria, and associated proteins. Miro is a part of the motor/adaptor complex on the outer mitochondrial membrane crucial in regulating mitochondrial motility and proper clearance of this protein is important in allowing the facilitation of mitophagy in the face of damage. Here, we show an upregulation of Miro protein levels results as alpha-synuclein accumulates by using fly models, patient brains and neurons. In PD patients, elevated levels of mitochondrial surface Miro leads to a delay in mitophagy. These mitophagy phenotypes and neurodegeneration of human neurons and flies can be rescued by partial reduction of Miro. Additionally, we show that Miro upregulation occurs by interaction with the

N-terminus of alpha-synuclein. This project indicates the importance of understanding mitochondrial phenotypes in concurrence to alpha-synuclein as a potential therapeutic target through Miro.

**Abstract:** Mitochondrial loss of function is a critical factor in multiple neurological disorders including Parkinson Disease (PD) and amyotrophic lateral sclerosis (ALS). One regulator of mitochondrial function is peroxisome proliferator-activated receptor gamma coactivator-1alpha (PGC-1α), a transcriptional co-activator that drives multiple gene programs related to metabolism and mitochondrial function. In general, a reduction in PGC-1α expression and/or function associates with disease progression and cell loss, but it is not clear how PGC-1α dysfunction contributes to disease or how PGC-1α-dependent pathways can be targeted for intervention. To identify potential transcription factors that mediate PGC-1α's function in neurons, we searched for transcription factor consensus binding sites in PGC-1α-dependent genes recently identified by our laboratory using RNAseq in SH-SY5Y neuroblastoma cells overexpressing PGC-1α. The promoters of PGC-1α-dependent genes exhibited an enrichment of consensus binding sites for members of the estrogen-related receptor (ERR) family of transcription factors. Then, to explore the relevance of these factors for neuronal function, we investigated the expression of PGC-1α-dependent genes in mice lacking ERRα. We found that ERRα knockout mice show deficiencies in previously-identified PGC-1α-dependent genes related to metabolism and neuronal function and that acute inhibition of ERRα in SH-SY5Ys blocks PGC-1α-mediated gene expression. These studies suggest that PGC-1α drives expression of genes via ERRα and that the potential involvement of ERRα pathways in the process of neurodegeneration warrants further exploration.

**Abstract:** Parkinson's Disease (PD) is the second most common neurodegenerative disorder, affecting over 1 million individuals in the U.S. alone. The disease is characterized pathologically by a selective loss of Dopamine neurons within the substantia nigra, resulting in progressive loss of voluntary coordinated motion. While work in recent years has uncovered genes and cellular pathways involved in the disease, the underlying mechanism of neurodegeneration remains incompletely understood. Mitophagy is a cellular process by which damaged mitochondria are cleared from the cell via autophagic mechanisms. This mitochondrial quality control process has been found to be dysregulated in PD patients, and may play a role in the pathogenesis of the disease. A key step in mitophagy initiation is the ubiquitylation of critical mitochondrial-associated substrates which leads to their proteasomal degradation and guides clearance of the mitochondrion. Our therapeutic hypothesis is to develop small molecules to increase this ubiquitylation signal and ultimately increase mitophagic flux, restoring homeostasis. We have developed several assays that reflect sequential steps of mitophagy at progressive temporal points of the process, namely Parkin translocation, ubiquitylation and degradation of key mitochondrial substrates, and engulfment of mitochondria by lysosomes. The development and validation of these assays, as well as their potential use in the discovery of novel modulators of mitophagy, will be presented.

**Title:** Pink1 and pka regulates bdnf signaling to stimulate dendrite outgrowth and mitochondrial function

**Authors: *R. K. DAGDA**, M. DAGDA, M. SWAIN, R. DAGDA
Pharmacol., Univ. of Nevada Sch. of Med., Reno, NV

**Abstract:** PTEN-induced kinase 1 (PINK1), which is linked to Parkinson's disease, is a neuroprotective kinase that regulates dendrite remodeling, mitochondrial trafficking and function. The molecular mechanisms by which PINK1 stimulates dendrite outgrowth remain to be elucidated. Like PINK1, brain-derived neurotrophic factor (BDNF) is a potent stimulator of dendrite outgrowth and maturation. Therefore, we surmised that PINK1 regulates dendrite outgrowth by stimulating BDNF signaling. Immunohistochemistry analyses of brain slices derived from 10 month old PINK1 knockout mice show that PINK1-deficient cortical and hippocampal neurons have reduced intracellular levels of BDNF and a concomitant reduction in dendrite length. *In vitro*, time-dependent analyses of dendrite length and complexity revealed that PINK1-deficient primary neurons exhibit significantly decreased outgrowth rates upon reaching maturation in culture. Treating PINK1-deficient neurons with recombinant human BDNF was able to restore dendrite length in PINK1-deficient cortical neurons to similar levels as wild-type neurons. Conversely, treating PINK1-overexpressing SH-SY5Y cells with inhibitors of the BDNF receptor (TrkB) blocked the ability of PINK1 to enhance neurite outgrowth. These results suggest that PINK1 stimulates dendrite outgrowth through BDNF-mediated activation of TrkB. Mechanistically, PINK1 activates PKA signaling to regulate mitochondrial function and BDNF signaling as transfecting neuroblastoma SH-SY5Y cells with an inhibitor of Protein Kinase A (PKI) was able to block PINK1's ability to enhance intracellular levels of BDNF and regulate mitochondrial trafficking and content. Primary neurons treated with human recombinant BDNF (2-24 hours) showed enhanced oxygen consumption rates (basal, maximal and ATP-linked OCRs), increased rates of glycolysis, increased anterograde mitochondrial trafficking,

increased mitochondrial content and fusion suggesting that BDNF phenocopies the ability of PINK1 to enhance the bioenergetics status of the cell. Overall, our data suggest the existence of a new neuroprotective signaling axis in which PINK1 stimulates BDNF by activating PKA signaling as a positive feedback loop to modulate dendrite outgrowth and enhance mitochondrial structure/ function in neurons.

**Title:** Familial LRRK2 G2019S Parkinson's disease patient fibroblasts have reduced mitochondrial clearance

**Authors: *R. THOMAS**[1], J. A. KORECKA[1], D. P. CHRISTENSEN[1], M. L. HASTINGS[2], P. J. HALLETT[1], O. ISACSON[1]
[1]McLean Hospital/ Harvard Med. Sch., Belmont, MA; [2]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

**Abstract:** Human induced pluripotent stem cells (iPSCs)-derived neurons from LRRK2 G2019S mutation carriers exhibit disrupted mitochondrial movement and increased vulnerability to chemical stressors of mitochondrial function (Cooper, Seo et al. 2012). We and others have also uncovered changes in mitochondrial phenotypes in fibroblasts derived from LRRK2 G2019S carrying PD patients. Utilizing a static co-localization based assay we have shown that LRRK2 inhibition with IN-1 normalizes LRRK2 mutation-mediated changes in mitophagy (Smith, Jansson et al. 2015) but the dynamics of mitophagy are largely unknown in patient fibroblasts harboring the LRRK2 G2019S mutation. To study the temporal changes in mitophagy, we performed live cell imaging of mitophagic flux with a pH sensitive dual fluorescence reporter containing a mitochondrial target sequence (a variant of the Rosella bioprobe) in human fibroblasts. There was a decreased rate of mitophagy at baseline and upon treatment with valinomycin (mitochondrial complex I inhibitor) in human fibroblasts derived from PD patients carrying the LRRK2 G2019S mutation compared to fibroblasts from healthy subject controls.

Pharmacological (using IN-1 LRRK2 inhibitor) and genetic (using antisense oligonucleotides) inhibition of the LRRK2 kinase activity normalized this phenotype. For further investigation of the stage of mitophagy (initiation, transport, autophagosome maturation, and degradation by the lysosome) affected by the LRRK2 G2019S mutation, we analyzed expression levels of various proteins that regulate each phase, in control and LRRK2 G2019S cells, at baseline and upon treatment with valinomycin and bafilomycinA1. There was a significant increase in the mitochondrial marker Tom20, mitophagy initiator Optineurin, lysosomal content regulators TFEB and non-glycosylated LAMP1, and a decrease in the autophagosomal load associated LC3 (A & B) I/II ratio. The increased expression of proteins associated with initiation of mitophagy and lysosomal load, coupled with decreased mature autophagosome load in LRRK2 G2019S cells, indicate that the reduced rate of mitophagy could be due to defective vesicular transport. These data show that the LRRK2 G2019S mutation alters mitophagy rates, which may have important implications for understanding the cell biology leading to pathology in vulnerable cells carrying the mutation.

**Abstract:** Mitochondrial dysfunction, which is primarily associated with respiratory chain complex I (CI) impairment, has a pivotal role in the etiology of both familial and idiopathic forms of Parkinson’s disease (PD). Impaired mitochondrial function is linked to an increased

oxidative cellular burden and bioenergetic failure, which can elicit the loss of midbrain dopaminergic neurons, resulting in the classical motor symptoms of the disease. However, the underlying molecular orchestration of this mitochondrial dysfunction remains unresolved. Recent analysis in blood and at single-neuron level linked this deficit to depletion of the mitochondrial DNA (mtDNA). Strengthening these findings, our own previous experiments indicate a tight correlation between complex I deficiency and reduced protein levels of the mitochondrial transcription factors A (TFAM) and 2B (TFB2M) in postmortem SN neurons from idiopathic PD patients (IPD). To further interrogate the mechanisms of this mitochondrial dysfunction in IPD, we made use of i) postmortem brains from IPD patients. ii) *In vitro* modeling of IPD, with the derivation of iPSC from patients and controls, and the subsequent generation of 2D dopaminergic neuron cultures and 3D midbrain organoids. The *in vitro* modelling of PD has the additional advantage of allowing mitochondrial phenotypes (including respiratory complex activities and mtDNA dynamics) to be functionally monitored in a longitudinal manner. Our studies included single-cell mtDNA deletion and replication/transcription rate detection as well as transcriptomics and proteomics analyses. Through our midbrain organoid experiments, we identified differential dynamics of neuronal dopaminergic specification in IPD patients. We are now exploring if this implicates higher susceptibility of IPD neuronal cultures to stress. Overall, with this project, we aim to further dissect the molecular mechanisms of mitochondrial dysfunction in IPD.

**Abstract:** Parkinson’s Disease (PD) is a neurodegenerative disorder linked to the loss of dopaminergic neurons in the midbrain. A key pathological marker of PD is the presence of Lewy

bodies, which are mainly composed of misfolded *α*-synuclein protein. *α*-synuclein is a highly post-translationally modified protein. While phosphorylation and nitration of *α*-synuclein are well-studied in the context of PD pathology, less is known about sumoylation, which is proposed to be neuroprotective based on limited studies. The majority of sumoylation takes place on the lysine-96 and lysine-102 residues of *α*-synuclein, and it increases the protein's solubility. The goal of this research was to better understand the role of sumoylation in regulating *α*-synuclein toxicity, and we performed four studies towards it. First, we evaluated the effects of blocking sumoylation on *α*-synuclein in the well-established budding yeast model for PD and found that *α*-synuclein becomes more aggregated, gains toxicity, and loses localization at the plasma membrane. Second, we evaluated the effects of altering sumoylation pathways by using yeast strains with reduced (*ulp1*$^{ts}$) or excessive sumoylation (*smt3*$^{ts}$), and found that *α*-synuclein aggregates more with reduced sumoylation, but becomes less toxic with increased sumoylation. Third, we asked how altering phosphorylation of *α*-synuclein would alter sumoylation's protective role and found that blocking phosphorylation reduced the protein's toxicity in the absence of sumoylation. Finally, we began evaluating whether blocking sumoylation and altering phosphorylation on familial PD mutant versions of *α*-synuclein would exacerbate its toxicity. In the future, we will conduct further studies to understand how sumoylation affects other variants and modifications of *α*-synuclein.

**Abstract:** Parkinson's disease (PD) is characterized by α-synuclein misfolding and the death of midbrain neurons. PD can be described as familial, or sporadic, both of which are influenced by a multitude of environmental and genetic factors. Familial PD is directly caused by a mutation in one of at least ten genes, including *SNCA*, *DJ-1*, *VPS35*, and *ATP13A2*. *SNCA*, which encodes α-synuclein, has six identified missense mutations (A30P, E46K, H50Q, G51D, A53E, and A53T) that each cause aggressive PD. Sporadic PD is linked with several risk genes and loci, including *VPS13*, the Sac I domain of *SYNJ1*, and the Swa2 domain of *DNAJC6*. Using our previously

established budding yeast model system for α-synuclein, we first show that wild-type (WT), E46K, A53T, H50Q, and A53E α-synuclein are toxic to yeast and show varying degrees of membrane binding and aggregation, while A30P and G51D α-synuclein are relatively non-toxic and shows cytoplasmic diffuse localization. What is still not well understood is whether the other PD-causing and risk genes mentioned above can influence toxicity and localization properties of WT α-synuclein and these six familial PD mutants. To test the hypothesis that they do influence α-synuclein, WT and familial mutant forms of α-synuclein were studied in haploid yeast strains that were singly deleted for these six PD-linked genes (all of which are linked to loss-of-function in PD). Results show that some gene deletions increase (*Δhsp31)* or decrease (*Δatp13, Δvps35*) α-synuclein toxicity and alter its localization in a highly familial mutant specific way, while others more broadly increase α-synuclein toxicity or aggregation (*Δvps13, Δsac1)*, while still others show no effect (*Δswa2)*. Our findings suggest that WT and each familial mutant of α-synuclein create cellular toxicity and alter localization in distinct ways and that each is likely regulated by different subsets of genes, opening doors for mutant-specific mechanistic insight into the varying modes of α-synuclein toxicity.

**Abstract:** Parkinson’s disease (PD) is associated with the aggregation and misfolding of alpha-synuclein in midbrain dopaminergic neurons. The gene for alpha-synuclein has six known mutations that cause early-onset familial forms of PD. The pathological determinants of three of these mutants (A30P, E46K, and A53T) are well characterized in diverse model systems and they reveal that each mutant affects cellular toxicity in distinctive ways. The three more recently discovered familial mutants (H50Q, G51D, and A53E) are not extensively studied. We expressed H50Q, G51D, and A53E mutants in budding and fission yeasts model systems and hypothesized that each would generate toxicity by altering their membrane association and aggregation

properties, and by disrupting cellular pathways including nitrative stress responses and endocytosis, but each would do so in distinctive ways. First, we found that the H50Q and A53E mutants were toxic to yeast, and bound membranes and aggregated within yeast, while G51D was cytoplasmically diffuse and nontoxic. Secondly, we asked whether the loss of the original amino acid or the gain of the new amino acid in each new familial mutant is responsible for disease. We created four substitution mutations for H50Q, G51D, and A53E in both yeasts models corresponding to the four functional classes of amino acids. We found that H50D was cytoplasmically diffuse and nontoxic, G51A bound membranes and aggregated like WT, G51E was cytoplasmically diffuse and nontoxic like G51D, and A53R was cytoplasmically diffuse and nontoxic, suggesting both the loss of the original amino acid and the gain of the new amino acid are key. Thirdly, we found that some of these new familial mutants had increased toxicity in yeast strains altered for nitrative stress (particularly G51D), sumoylation, and endocytosis. Collectively, this work adds insight into the pathogenicity of different familial PD mutants of alpha-synuclein.

**Title:** Treatment with GM1 ganglioside is neuroprotective in a progressive Parkinson's disease model in the rat produced by AAV1/2-induced overexpression of A53T-alpha-synuclein

**Authors: *J. S. SCHNEIDER**, C. WILLIAMS, R. ARAS
Dept Pathol, Anat. & Cell Biol, Thomas Jefferson Univ., Philadelphia, PA

**Abstract:** Previous studies using MPTP-induced Parkinson’s disease (PD) models in mice and non-human primates showed GM1 ganglioside to have neuroprotective and neurorestorative effects on dopaminergic neurons in these models. Based on these data from our and other labs, we conducted clinical trials of GM1 in PD patients. Our double-blind placebo controlled delayed start study of GM1 in PD found that GM1 had an early-appearing symptomatic effect and significantly slowed symptom progression over a 2 year period. While these clinical data are encouraging and validate pre-clinical studies with the MPTP models, questions remain regarding the mechanism(s) through which GM1 exerts its effects on PD. To explore some of these

potential mechanisms and to validate the use of GM1 in a non-MPTP model, studies examined effects of GM1 on a progressive PD model linked to α-synuclein toxicity. Male Sprague Dawley rats received unilateral intranigral injections of AAV1/2 expressing human A53T α-synuclein. Some animals received daily saline injections (vehicle controls) or GM1 (30 mg/kg, IP) beginning 24 hrs. (early start) or 3 wks. (delayed start) post surgery. Spontaneous paw use, examined with the cylinder test, was performed prior to surgery and at 3 and 6 wks. post surgery (early start group) or 3 and 8 wks. post surgery (delayed start group). At the end of the study, brains were removed and striatal sections were taken for dopamine (DA) or synuclein measurements. Immunohistochemistry was performed for visualization of tyrosine hydroxylase (TH) and synuclein in the striatum and substantia nigra (SN), cell counts were obtained from the SN, and indices related to synuclein pathology were assessed. Results from the cylinder test showed expected asymmetry in paw use at 3 and 6 wks. in α-synuclein/vehicle animals and significantly reduced asymmetry in GM1-treated animals (early start), that approached baseline levels by wk. 6. In delayed start animals, asymmetry appeared at 3 wks. and was significantly reduced at 8 wks, following 5-6 wks. of GM1 treatment. Striatal DA levels were significantly higher in both early and late start GM1-treated animals, compared to vehicle controls. Cell counts and studies of indices of synuclein pathology are in progress. The data collected to date indicate that GM1 ganglioside is an effective neuroprotective therapy in the α-synuclein overexpression model of PD. Other putative neuroprotective therapies were effective in PD toxin models but failed to be effective in an α-synuclein toxicity model. Thus, GM1 is the first drug to show efficacy in both MPTP and α -synuclein models, as well as in PD patients, and deserves further development as a treatment for PD.

**Abstract:** Aggregation of insoluble alpha-synuclein (α-syn) in Lewy bodies and Lewy neurites is a pathological hallmark of Parkinson disease (PD), PD with dementia, dementia with Lewy bodies, and multiple system atrophy (MSA). Postmortem human tissue pathology-staging studies suggest Parkinson's disease correlates with the pathological spread of α-synuclein-immunoreactive Lewy body and Lewy neurite pathology. Currently, α-syn deposition can only be studied at autopsy or inferred from plasma/CSF levels. Through longitudinal determination of protein aggregate severity and regional distribution, an α-syn PET ligand would enable in vivo quantification of disease progression and as such, provide an important tool for patient selection and evaluation of the therapeutic potential of clinical candidates. A suitable α-syn PET ligand candidate that is selective over pathological tau or amyloid does not exist. Further, identification of potential PET ligands is hampered by the lack of appropriately validated tool molecules and the assays needed to profile them.
Here, we report the development and validation of key in vitro and ex-vivo assays used to profile molecules that bind to α-syn aggregate species. Initially, in vitro experiments were designed to determine the affinity of molecules binding to recombinant α-syn fibrils and molecules were prioritized for fibril binding affinity and selectivity over binding to monomeric, non-aggregated α-syn protein. Molecules were then profiled for binding to pathological tau and amyloid in Alzheimer's disease brain tissue. Compounds with selectivity for α-syn fibrils over tau and amyloid binding were further profiled for affinity to pathological α-syn aggregation using a cellular pre-formed fibril α-syn model in SHSY5Y cells and transgenic mice. Molecules displaying suitable in vitro binding characteristics were then prioritized for autoradiography experiments in post-mortem human PD brain tissue. Taken together the data describe methods and assays used to identify and profiling novel chemical α-syn PET ligand candidates and validate binding to Lewy-bodies in post-mortem PD human tissue.

**Title:** Layer-specific axonal degeneration of serotonergic fibers in the prefrontal cortex of aged α-synuclein expressing mice

**Authors: *J. WIHAN**[1], J. GROSCH[1], C. MÜLLER[2], J. WINKLER[1], Z. KOHL[1]
[1]Dept. of Mol. Neurol., [2]Dept. of Psychiatry and Psychotherapy, Erlangen Univ. Hosp., Erlangen, Germany

**Abstract:** Aggregation of α-synuclein (α-syn) plays an important role in the pathogenesis of Parkinson's disease (PD), the second most common neurodegenerative disorder worldwide. Intriguingly, axonal pathology of dopaminergic projections precedes cell loss in the substantia nigra in PD indicating a retrograde axonal degeneration of nigrostriatal projections. While most attention focused on the dopaminergic system, increasing evidence suggests the involvement of further neurotransmitter systems, particularly, the serotonergic system. However, the precise impact on this system is still not well understood. The prefrontal cortex (PFC) is one major target region of the raphe nuclei linked to crucial psycho-emotional and cognitive functions and is affected in the prodromal stage of PD. Thus, we investigated the impact of α-syn on the prefrontal serotonergic system in aged mutant α-syn expressing mice (A53T mice). By combining immunohistological and biochemical approaches, we identified a profound layer-specific reduction of the serotonergic input to the PFC layers II and V of aged A53T mice, sparing PFC layer I. While residual axons were characterized by enlarged varicosities, prefrontal serotonin levels were not affected. However, we detected a transcriptional upregulation of tryptophan hydroxylase 2 in the raphe nuclei of A53T mice, indicating an increased serotonin biosynthesis. In line with this finding, aged A53T mice showed an elevated expression of the anterograde vesicle transport protein kinesin family member 1a (Kif1a) and the vesicle packaging protein vesicular monoamine transporter 2 (vMAT2) in the PFC. In conclusion, a profound layer-specific axonal degeneration of prefrontal serotonergic projections in A53T mice was observed paralleled by compensatory mechanisms such as increased serotonin synthesis, vesicle packaging and transport capacity. Broadening our knowledge of axonal degeneration and compensatory mechanisms during the long-lasting prodromal phase of PD is an important prerequisite for the development of disease-modifying therapies.

**Abstract:** Synucleinopathies are neurodegenerative diseases characterized by the presence of α-synuclein-positive intracytoplasmic inclusions into the central nervous system. Increasing evidence indicates that impairment of lysosomal function may contribute to the pathogenesis of the synucleinopathies, including Parkinson's Disease and Multiple system atrophy (MSA). The transcription factor EB (TFEB) is a master gene of lysosomal biogenesis which coordinates the expression of lysosomal genes leading to an induction of autophagy. It has been demonstrated that overexpressing TFEB in a rat parkinsonian model triggers the restauration of the lysosomal machinery which leads to an enhancement in the clearance of α-synuclein, finally leading to neuroprotective effects. To investigate the efficiency of TFEB overexpression as a common therapeutic strategy for all synucleinopathies, we used a viral-based approach to overexpress TFEB under a neuronal or an oligodendroglial promoter into a transgenic mouse model of MSA, the PLP-Syn mice, which overexpresses in oligodendroglial cells the human WT-α-synuclein under the mouse myelin proteolipid protein (PLP) promoter. We here report that overexpressing TFEB under an oligodendroglial promoter leads to some neuroprotective effects regarding the dopaminergic nigro-striatal pathway. This neuroprotection is associated with an increased clearance of α-synuclein in the substantia nigra of the TFEB-injected PLP-Syn mice. Finally, we report some TFEB-mediated neurotrophic effects which can potentiate the neuroprotective effects observed in TFEB-injected mice.

**Title:** Behavioral and dopaminergic changes in double mutated human α-synuclein mouse model of Parkinson´s disease

**Authors: *U. JULKU**, T. KILPELÄINEN, R. SVARCBAHS, T. T. MYÖHÄNEN
Div. of Pharmacol. and Pharmacotherapy, Univ. of Helsinki, Helsinki, Finland

**Abstract:** Alpha-synuclein (aSyn) is the main component of the Lewy bodies, a histopathological finding of Parkinson's disease. Familial mutations in aSyn gene correlate with early onset of Parkinson´s disease. Misfolded aSyn aggregates and oligomers are believed to have toxic effects on neurons. aSyn regulates dopamine transporter function indicating that misfolded aSyn can alter synaptic dopamine recycling and be a possible cause to dopaminergic neurodegeneration in Parkinson´s disease. Richfield at al (Exp Neurol, 2002) introduced a novel double mutated human A30P*A53T aSyn transgenic mouse strain (C57BL/6J-Tg(Th-SNCA*A30P*A53T)39Eric/J) to model Parkinson´s disease. Heterozygous transgenic mice expressed human aSyn in cell bodies, axons, and terminals of the nigrostriatal system. Mice had decreased locomotor activity at age of 7-9 and 13-23 months, and lowered concentration of dopamine and its metabolites in the striatal tissue at the age of 16-18 months. Younger mice did not have significant changes in locomotor activity or in the striatal dopamine concentration.The aim of our study was to characterize behavioral and dopaminergic changes in homozygous A30P*A53T aSyn transgenic mice. We created a novel genotyping protocol to identify homozygous transgenic mice because genotyping method used in the previous studies was not able to separate heterozygous and homozygous mice. We measured 22 hour locomotor activity and amphetamine induced locomotor activity every 3 months until the age of 18 months and extracellular dopamine in 12 months and in 18 months old homozygous mice by microdialysis. Night time activity in 22 hour locomotor experiment was decreased in 6 months, 9 months and 12 months old transgenic mice compared to wild-type littermates but increased in 18 months old transgenic mice. Baseline level of extracellular dopamine was similar in transgenic and wild-type mice at the age of 12 months and 18 months. Amphetamine-induced dopamine release caused higher extracellular level of dopamine in 12 months old wild-type mice than in 12 months old transgenic mice indicating altered dopamine transporter function but there was no difference in amphetamine-induced dopamine level in 18 months old mice. In conclusion, homozygous aSyn transgenic mice have age-dependent changes in locomotor activity and in the striatal dopaminergic function that are partly different than in heterozygous mice. Altered dopaminergic function needs to be studied further but this mouse strain could be a useful animal model to study treatments for Parkinson´s disease.

**Abstract:** The locus coeruleus (LC) is a small nucleus among the catecholaminergic cell groups, but it has extensively branched axons, and it innervates broad areas in the brain. According to the most widely accepted Parkinson's disease (PD) staging model of Braak, the LC is the second brain area affected by alpha-synuclein (αSyn) pathology, but the possible neurochemical changes induced by axonal αSyn-transmission from the LC have never been investigated. Therefore, we overexpressed human wild-type αSyn (WT-αSyn) or the control protein luciferase (luc) in the mouse LC via unilateral stereotactic delivery of the recombinant adeno-associated virus (rAAV), and subsequent pathological alterations were investigated in a time-dependent manner. Stereology results demonstrated that the LC neurons were not vulnerable to WT-αSyn overexpression, yet rigorous microgliosis and astrogliosis occurred as early as 3 weeks post-injection. Intriguingly, the number of anti-choline acetyltransferases (ChAT) immunoreactive (ir) neurons in the dorsal motor nucleus of the vagus (DMnX) and in the nucleus ambiguus (nAmb) significantly decreased in the αSyn group post 3 and 9 weeks. The putative axonal connectivity between the LC and the cholinergic motor nuclei and the loss of ChAT-ir were further elucidated and reproduced by microinjection of Tyrosine Hydroxylase (TH) promoter-specific viral vectors (rAAV2/5-TH-WT-αSyn) in the LC. We found robust αSyn-ir axonal varicosities around the DMnX neurons, and remarkably, intraneuronal αSyn was present in ambiguus neurons in both hemispheres as early as 3 weeks post-injection. As nucleus ambiguus compact formation controls the esophagus, we investigated the cervical, thoracic and abdominal parts of the esophagus tissues of these mice. As a result of aSyn overexpression in the LC, we observed αSyn-ir cells and varicosities in the muscle layers, and notably, some of these αSyn-ir neurons co-localized with Protein Gene Product 9.5 (PGP 9.5)-ir myenteric plexus ganglia post 3 and 9 weeks. Furthermore, we also found that, unlike the majority of the Vesicular Acetylcholine Transporter (VAChT) signals, some motor nerve endings were weak and dispersed from the motor receptors. Our data reveal that LC neurons induced the transsynaptic and transneuronal presence of αSyn in the vagal motor nuclei and suppressed cholinergic efferents terminating on motor endplates in the esophagus. It appears that αSyn can travel via the anatomically connected brain regions as proposed in the early staging model of PD, implying α-synucleinopathy in noradrenergic neurons may potentially disturb the cholinergic modulation of the upper gastrointestinal tract.

**Abstract:** GBA1 encodes the lysosomal enzyme glucocerebrosidase (GCase) which metabolizes the lipids, glucosylceramide (GlcCer) and glucosylsphingosine (GlcSph). Mutations in GBA reduces trafficking of GCase to the lysosome resulting in loss of enzyme activity and lipid accumulation and significantly increase the risk of PD. In several preclinical in vitro paradigms, pharmacological or genetic inhibition of the enzyme and lipid elevation is capable of exacerbating α-syn aggregation in pre-formed fibril and overexpression models of PD. However, it remains unclear whether reduction of glycolipid content is capable of ameliorating or reducing α-syn aggregation. Pharmacological inhibition of glucosylceramide synthase (GCSi's) is a promising therapeutic approach for treating PD, however, more work is required to understand the mechanism of action of these molecules and profile their therapeutic potential. In the present studies, we utilize a preformed fibril (PFF) in vitro model of α-synuclein pathology to investigate the relationship between glycolipid biology and α-syn pathology. The PFF model uses recombinant α-syn PFFs to seed recruitment of endogenous α-Syn into insoluble, phosphorylated α-syn aggregates, similar to the pathology observed in PD. Consistent with previous findings, our data show pharmacological inhibition of GBA with a selective inhibitor, conduritol B epoxide (CBE) robustly modulates glycolipid levels in SH-SY5Y cells, rodent primary cultures, and human iDopa neurons. In addition to elevating glycolipid content, CBE also markedly increases detergent-insoluble phosphorylated α-syn aggregates. Consistent with these pharmacological studies, genetic inhibition of GCase (through GBA1 mutation) similarly causes accumulation of glycolipids and elevates insoluble phosphorylated α-syn. Lastly, we demonstrate GCSi (Ibiglustat) administration effectively decreases glycolipid content in SH-SY5Y cells, rodent primary cultures, and human iDopa neurons and can reduce αSyn pathology in PFF in

vitro models. Together, our data support the hypothesis that glycolipids promote aSyn pathology, and reduction of glycolipids through GCS inhibition provides a novel therapeutic approach for treating PD.

**Title:** Establishing a rat model to study the progression of sporadic Parkinson's disease

**Authors: *Y.-J. CHEN**[1], P.-C. CHEN[1], C.-T. WANG[1,2,3,4]
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

**Abstract:** Parkinson’s disease (PD) is the second most common neurodegenerative disease, clinically characterized by bradykinesia, resting tremor, and rigidity. The etiology of PD is attributed to the progressive loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc), further decreasing the release of dopamine (DA) through the nigrostriatal pathway to the striatum, where DA binds to different types of DA receptors, producing various responses (activation/inhibition) for the fine control of locomotor activity. Losing these DA neurons in SNpc results in insufficient dopamine and thus breaks the balance of neurotransmission in the striatum. Specifically, the hallmark in both familial and sporadic PD is the presence of intra-neuronal proteinaceous inclusions, termed “Lewy Bodies”, mainly composed by aggregation of alpha-synuclein (α-syn), which can be distributed across the whole brain during PD progression. However, how α-syn aggregates propagate across brain or other systems remains unclear. Current PD animal models are either induced by toxic agents causing rapid PD onset, or made by carrying inherited pathogenic genes resembling familial PD but not sporadic PD. In this study, we aim to establish a rat model to mimick sporadic PD during adulthood. Male Sprague-Dawley rats (~250 gw) were deep anesthetized for stereotaxic surgery. The 2 μL solution containing DNA plasmids (5 μg/μL) was microinjected into SNpc to deliver genes expressing membrane-bound green fluorescence protein (GFP). Five electric pulses were delivered by homemade

platinum electrodes via ear bars, with duration of 50 msec and intervals of 950 msec, yielding the electric field strength of 133 V/cm. After 14-16 days following *in vivo* electroporation, the rats were sacrificed to verify gene expression in the SNpc by immunofluororescence staining. Double stainings for GFP and tyrosine hydroxylase (TH) showed the colocalization of both signals, demonstrating the success of *in vivo* electroporation. Therefore, this *in vivo* electroporation technique can be used as a gene delivery method to introduce the human pathogenic α-syn mutant in adult rats, serving as a sporadic PD model.

**Title:** Evaluation of alpha-synuclein pathology and glycolipids in post-mortem parkinson’s disease brain samples

**Authors: *R. KESILMAN (KORN)**, L. YAO, A. RAMIREZ, J. SCHACHTER, N. HATCHER, R. DROLET, S. SMITH
Early Discovery Neurosci., Merck & Co., Inc., West Point, PA

**Abstract:** While the etiology and pathogenesis of Parkinson’s disease (PD) remain poorly understood, mutations in the genes that encode α-synuclein (αSyn) and glucocerebrosidase (GCase) proteins are the strongest genetic risk factors for the disease. Preclinical in vitro and in vivo experiments have depicted a biochemical relationship between αSyn and the glycolipid substrates of GCase. In some post-mortem brain experiments from PD patients, glycolipid content is altered in distinct brain regions compared to control patient samples. However, additional data is needed in this area to better characterize the role of glycolipids in PD, and further understanding of the relationship between GCase and αSyn in the disease pathogenesis. One limiting factor has been the availability of well-characterized post-mortem brain tissue that allows sampling across relevant brain regions that are vulnerable in the disease. Second, direct quantitation of a broad array of glycolipid species has been challenging and prevented direct comparison across laboratories.
To this end, the present studies utilized a validated LC-MS assay to quantitate several glycolipid species including: glucosylceramide (C16-24_1), glucosylsphingosine, and ceramide (C16-24) from several regions across the Braak neuraxis. Serial thin sections were prepared from distinct brain regions including, dorsal motor nucleus of the vagus (n=15), substantia nigra (n=30), temporal cortex (n=24) to allow for a robust characterization of αSyn pathology in adjacent sections to those evaluated for glycolipid content. αSyn pathology from adjacent sections was

determined using: histochemical staining of Lewy-bodies with H&E, immunohistochemical detection using LB509, and biochemically from detergent soluble and insoluble fractions using a validated alphalisa assay to quantify absolute amounts of αSyn phosphorylated at serine-129. Data from these studies suggest glycolipid content of certain species are altered in disease when compared to control patients. αSyn pathology, while robust in many patients, is variable across brain region and from patient to patient. Together, these studies expand on the current data available in the field, and continue to define a role for glycolipids in PD pathogenesis.

**Abstract:** Parkinson’s disease (PD) is a slowly progressing neurodegenerative disorder. The pathological characteristics of PD are the degeneration of dopaminergic neurons in the Substantia nigra pars compacta as well as neuronal protein inclusions called Lewy bodies (LBs). LBs mainly consist of misfolded and aggregated variants of the small presynaptic protein alpha-synuclein (α-syn). Aggregation processes of α-syn result in the formation of α-syn fibrils, being prone to propagate throughout the whole brain. So far, the mechanisms behind this spreading pathology of α-syn in PD are still elusive. In biophysical studies, iron was shown to bind to native α-syn, fostering its aggregation process. Therefore, iron and α-syn have become important targets to understand PD pathophysiology. The influence of iron brain load on the α-syn spreading pathology may be a key mechanism for new therapeutic approaches in the treatment of PD. In our current *in vivo* study with C57BL/6 mice, an iron intoxication paradigm combined with intra-striatal injections of pathogenic α-syn preformed fibrils (PFFs) was performed.

Increased iron accumulation in the brain was achieved by feeding mouse pups with different concentrations of carbonyl iron (60, 120 and 240 mg / kg body weight) from p10 to p17. Cognition was impaired in mice intoxicated with the highest iron dosage at 3 months post iron intoxication (N = 14 - 20). PFFs-injected mice showed also strong cognitive impairments at 90 days post α-syn PFFs injection (N = 27 - 28). Furthermore, we evaluated the effects of the different iron dosages on α-syn PFFs spreading throughout the mouse brain. Since the pathophysiology of PD cannot be entirely mimicked by the mouse model, we used postmortem midbrain tissue of PD patients and age-matched controls to investigate the distribution of iron and other elements on a subcellular level. Here, α-syn-positive LBs were analyzed using X-ray fluorescence and X-ray diffraction to identify PD-specific patterns of metal content and crystalline structures. Our results showed a high iron content and a reduction of copper in the LB, which has to be confirmed in a larger sample size. Our data from human tissue suggests a dyshomeostasis of iron and copper in α-syn-positive LBs of PD patients. Furthermore, the animal data supports a deleterious role of iron on cognition, but its influence on α-syn spreading remains to be determined in further experiments.

**Title:** Human Plasma Fraction reduces the detrimental effects of alpha-synuclein overexpression in mice

**Authors: *C. TUN**, H. HACKBART, S. REGE, M. K. CAMPBELL, A. LIU, E. CZIRR, S. BRAITHWAITE, S. S. MINAMI
Alkahest, San Carlos, CA

**Abstract:** We have previously demonstrated that treatment of aged immunocompromised mice with young human plasma improves aging-associated memory and motor deficits and enhances neurogenesis. We have now identified a novel human plasma fraction (PF) that enhances both cognition and neurogenesis beyond the levels seen with young plasma. Importantly, this newly identified plasma fraction, with only a portion of the complexity of whole plasma, can be administered to immune-competent mice with no deleterious side effects. This allowed us to test whether PF could ameliorate the motor and cognitive deficits observed in a mouse model of Parkinson’s disease, specifically, human alpha-synuclein overexpressing mice (Line 61). We treated transgenic mice with either vehicle or PF intravenously and found significant

improvements in motor function three weeks later in wire suspension, beam walk, and the pasta gnawing test for motor function. We further assessed whether neuronal survival was affected by immunohistochemistry and found significantly more NeuN-positive cells in the hippocampus and striatum of PF-treated mice compared to vehicle-treated mice. To determine whether these changes were associated with reduction in neuroinflammation, we assessed the same brain regions for Iba1-positive microglia and CD68-positive activated microglia and found significant reductions in both. These findings suggest that treatment of alpha-synuclein transgenic mice with a human plasma fraction ameliorates multiple Parkinson's disease-related symptoms, including motor deficits, neuronal loss, and neuroinflammation, and provides strong support for clinical evaluation of this plasma fraction in Parkinson's disease.

**Title:** Motor impairment due to alpha-synuclein-mediated dopaminergic neuron dysfunction in *C. elegans*

**Authors: S. K. KALIA**[1], K. MENEZES[1], N. TRAN[1], J. B. RODGERS[1], H. CHAU[1], K. FUJISAWA[1], K. CHEN[1], A. M. LOZANO[1], J. G. CULOTTI[1], S. SUO[2], W. S. RYU[1], *L. V. KALIA[1]
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Saitama Med. Univ., Saitama, Japan

**Abstract:** Parkinson's disease is a neurodegenerative movement disorder characterized by motor impairment due to death of dopaminergic neurons in the substantia nigra pars compacta. Accumulation of the protein alpha-synuclein is implicated in the initial dysfunction and eventual loss of these neurons. To date, transgenic *C. elegans* have been used to model the later stages of alpha-synuclein-mediated neurodegeneration in which neurite retraction or complete cell loss is already evident. To develop a *C. elegans* model of earlier alpha-synuclein-mediated dopaminergic neuron dysfunction, we ectopically expressed alpha-synuclein in dopaminergic neurons and identified a motor impairment using quantitative phenotyping with high-resolution worm tracking, custom imaging processing, and machine learning. This motor phenotype preceded the onset of prominent loss of dopaminergic neurites or cell bodies but was associated with impaired dopaminergic signalling as measured by a green fluorescent protein reporter. The

motor phenotype was not due to neuromuscular junction abnormalities or alterations in lifespan. We developed an unbiased, semi-automated, quantitative method for multi-worm measurements of the motor phenotype. The severity of the motor phenotype correlated with alpha-synuclein protein levels. Treatment of alpha-synuclein transgenic *C. elegans* with dopamine reduced the motor impairment whereas treatment of non-transgenic *C. elegans* with a $D_2$ dopamine receptor antagonist induced the motor impairment. Together, our findings demonstrate that alpha-synuclein causes dopaminergic neuron dysfunction associated with motor impairment in this *C. elegans* system. The motor impairment occurs in advance of severe dopaminergic neurodegeneration and thus models an earlier stage of alpha-synuclein cytotoxicity.

**Authors: F. LAFERRIERE**[1], B. DEHAY[2], C. SANDT[3], E. DOUDNIKOFF[1], *W. MEISSNER[4], E. BEZARD[2]
[1]Inst. des Maladies Neurodégénératives, Bordeaux, France; [2]Inst. of Neurodegenerative Dis., Bordeaux, France; [3]Synchrotron SOLEIL, Gif-sur-Yvette, France; [4]Inst. Des Maladies Neurodégénératives, Bordeaux, France

**Abstract:** Synucleinopathies are neurodegenerative diseases characterized by the presence of α-synuclein-positive intracytoplasmic inclusions in the central nervous system. α-synuclein protein shares key features with prions such as i) conformational change of physiological α-synuclein into misfolded pathological forms; ii) seeding of α-synuclein pathogenic properties; iii) cell-to-cell transmission and spreading of α-synuclein protein among neuronal regions. To model *in vivo* α-synuclein seeding and spreading afferent to PD pathogenesis, we inoculated human PD-derived samples into mice and monkeys. In that extent, after tissue homogenization, the autopsy

material was fractionated on sucrose density gradients allowing a fine separation of α-synuclein aggregates: Lewy bodies (LB), containing the majority of aggregated α-synuclein, and noLB fractions composed mainly of the monomeric form of the protein and finely granular α-synuclein. In parallel to the analysis of the pathology induced by the injection of the extracted material, the aim of this study was to characterize biochemically and biophysically the nature of LB and noLB fractions. To unravel the physical properties of α-synuclein aggregates (i.e. LB vs noLB), we performed different and complementary assays. We first assessed their amyloid nature by measuring their binding of Thioflavin S labelling to the fractions, and by using the α-synuclein Cisbio detection kit to quantify the amount of aggregates through this FRET-like methodology. We also directly observed the assemblies using electron microscopy examination. Then, taking advantage of a collaboration with Synchrotron SOLEIL, we were able to resolve their secondary structure (i.e. α-helix and β-sheet composition). We then directly estimated the size and density of these assemblies by sedimentation and floatation ultracentrifugation techniques. Lastly, we determined the prion-like biochemical properties of the α-synuclein aggregates by measuring their resistance to Proteinase K digestion, and to detergent solubilisation and denaturation (SDS-Urea treatment). Overall, this study represents a crucial step in understanding the composition and nature of LB and noLB fractions in terms of α-synuclein aggregated species, allowing us to directly relate their pathogenic propensity to the quaternary structure of their α-synuclein content. More than a physical characterization, it will allow a better understanding of synucleinopathies pathogenesis, and help us moving towards the development of therapeutic approaches

**Abstract:** Alpha-synuclein (α-syn) is a presynaptic protein which progressively accumulates in neuronal and non-neuronal cells in neurodegenerative diseases such as Parkinson's disease (PD), Dementia with Lewy bodies (DLB), and Multiple system atrophy. In addition to accumulation of oligomers and fibrils, the mechanisms of neurodegeneration in these synucleinopathies might involve propagation to neuronal and non-neuronal cells such as astrocytes and microglia leading to neuro-inflammation. To understand the role of immune cell involvement in PD, we evaluated 10-11 months old α-syn mouse model which overexpress human wild type α-syn (α-syn Tg: Thy1 promoter line 61) comparing its littermates non-transgenic mice (non-Tg). We collected organs including brain, spleen, liver, lymph node and thymus. Over all, α-syn Tg showed tendency of smaller body weight, as well as spleen and liver weight, hence the total cell number in these organs in the α-syn Tg decreased when compared to non-Tg mice. Flow cytometric analysis of immune cells revealed that α-syn Tg showed significant decrease of NKT cells in the spleen, liver and lymph nodes, and an increase of NKT cells in the brain in α-syn Tg mouse. Immunohistochemical analysis of brain sections revealed significant increase of CD3 and CD4 (T cells), but not CD20 (B cells) in cortex, hippocampus and striatum of α-syn Tg compare to non-Tg mouse. Macrophage marker CD68 also increased in the same brain regions in α-syn Tg mouse as well as microglia and astrocytes. These results suggest alterations in the balance between innate and adaptive immune responses play an important role in neuroinflammation and neurodegeneration in synucleinopathies and that modulating such responses might be a viable therapeutic target.

**Abstract:** Alpha-Synuclein (α-syn) is a presynaptic neuronal protein linked genetically and neuropathologically to Parkinson's disease (PD). PD is associated with severe motor symptoms, however, they are often accompanied and even preceded by debilitating non-motor symptoms (NMS) such as olfactory deficits, cognitive decline, anxiety, depression and psychosis that significantly impact the quality of life of patients. Furthermore, beyond nigrostriatal dopaminergic dysfunction, there is a widespread deregulation of other neurotransmitters. The aim of this study was to evaluate the progression of NMS in male and female α-syn BAC transgenic rats, generated by Olaf Riess, Tubingen University (Nuber et al. 2013), using a behavioral test battery [open field (locomotor activity), elevated plus maze (anxiety), buried pellet test (olfaction), prepulse inhibition (sensorimotor gating), Morris water maze (learning & memory), forced swim test and sucrose preference (depressive-related behaviors)], neurochemical analysis (catecholamines, glutamate and GABA) with HPLC and electrochemical detection and α-syn biochemistry at 3, 6, 9, 12 and 18 months. α-syn BAC males exhibit reduced food consumption and body weight, increased locomotor activity and reduced anxiety starting at 3 months. Furthermore, both females and males exhibit an early onset olfactory deficit and depressive-like phenotype at 3 months, a spatial learning deficit at 6 months and sensorimotor impairment at 12 months, with males presenting an overall worse phenotype. Neurochemical correlates indicate dopaminergic dysfunction in the striatum and glutamatergic and GABAergic dysfunction in the amygdala and hippocampus, possibly related to observed locomotor hyperactivity, reduced anxiety and cognitive impairment, respectively. In addition, phosphorylated and oligomeric α-syn species accumulate with age in relevant brain regions. Attempts to reverse specific behavioral phenotypes via 1) silencing of α-syn expression with microRNA stereotaxic injections in the ventral tegmental area and 2) pharmacologically modulating dopaminergic neurotransmission are currently underway. α-syn BAC rats provide a valuable translational tool to evaluate the role of α-syn in the pathogenesis of NMS and assess potential early therapeutic interventions for PD.

**Abstract:** Clinical trials of disease modifying treatments to target Parkinson's disease (PD) have thus far all failed. Evidence suggests that a key etiologic factor is membrane-associated oxidative stress. Lipid peroxidation plays a central role in oligomeric α-synuclein (α-syn) toxicity, mitochondrial dysfunction and neuronal degeneration, all key processes in the pathogenesis of PD. Poly unsaturated fatty acids (PUFAs), that make up synaptic and mitochondrial membranes, are often the first molecular targets attacked by reactive oxygen species, resulting in membrane dysfunction and generation of toxic reactive carbonyls and isoprostane-containing species. We examined a novel non-antioxidant based approach that makes PUFAs resistant to the non-enzymatic chain reaction of lipid peroxidation. The rate-limiting step of the chain reaction of ROS-initiated PUFA autoxidation involves hydrogen abstraction at bis-allylic sites. The rate of this step can be slowed down if hydrogens are replaced with deuteriums. D-PUFAs are considered safe and tolerable drugs, with no off-target activities, and are approved for human use. Here we show that overexpression of human A53T α-syn in the rat substantia nigra (SN) using an adeno-associated viral vector reproduces several of the neuropathological and biochemical features seen in PD patients, including nigrostriatal dopamine (DA) degeneration. Consistent with prior findings that dietary isotopic reinforcement with D-PUFA protects against MPTP-induced nigrostriatal damage in mice, chronic dietary supplementation with D-PUFAs improved behavioral deficits and preserved SN DA neurons and their striatal nerve terminals. D-PUFAs were also effective against axonal damage, oxidative stress, and inflammation produced by α-syn toxicity. These studies will support moving D-PUFAs forward into clinical trials to evaluate their efficacy as a neuroprotective therapy for PD.

**Authors: *A. KHAN**, M. MAILE, C. WITTMER, K. TATSUKAWA, D. PRICE, M. GILL, D. BONHAUS
Neuropore Therapies Inc., San Diego, CA

**Abstract:** Accumulation of aggregates of alpha-synuclein (ASYN) in brain is linked to several neurodegenerative disorders and synucleinopathies including Parkinson’s disease (PD) and Dementia with Lewy bodies (DLB). Transgenic (Tg) mouse models with overexpression of ASYN have proved useful in characterizing the behavioral, neuropathological, and biochemical consequences of ASYN aggregation.
The mThy1-ASYN Tg mouse model (commonly referred to as Line 61), overexpresses wild-type human ASYN and develops extensive accumulation of ASYN in brain and peripheral regions relevant to PD, neurodegeneration (including loss of tyrosine hydroxylase immunoreactivity in the striatum), inflammation, and both motor and non-motor functional deficits. Neuropore Therapies Inc. has licensed and established a colony of mThy1-ASYN transgenic mice and here we report the results of efforts to confirm and extend a detailed characterization of the motor and non-motor phenotype of this PD model.
Body weight, spontaneous locomotor activity, grip strength, and hind limb clasping were measured at the ages of 1, 3, 6, 9 and 12 months in separate cohorts of age matched non-transgenic and transgenic mice (Line61 tg). A transgenic phenotype on these measures emerged between 3-6 months of age consisting of decreased body weight, increased locomotor activity, decreased grip strength and increased hind limb clasping. The changes in transgenic body weight and grip strength were stable after 6 months of age. The hyper locomotor activity resolved between 9 and 12 months of age (back to non-transgenic levels). Hind limb clasping deficits were progressive between 3 and 9 months of age and then stable from 9 months through 12 months of age.
A separate cohort of age matched animals was used to conduct repeated measurements of colonic motility and whole gastrointestinal (GI) transit starting at 3 months of age and including 6, 9, 12 and a separate cohort tested at 16 months of age. A decrease in colonic motility (utilizing bead expulsion test) was present in L61 tg mice starting at 3 months of age. A statistically significant deficit in colonic motility (increased time to expel glass bead) was also present at 6 and 12 month of age. There was no evidence for slowed GI transit (timed dye gavage) at any age tested.
Taken together, these data confirm and extend observations of motor and non-motor deficits in Line 61 tg mice as early as 3 month of age with some persistent or progressive changes through 12-16 months of age. Efforts are ongoing to characterize ASYN pathology (brain and periphery) and translatable markers in samples collected from these subjects.

**Abstract:** We developed a High-Content Screening (HCS) assay aimed at detecting and profiling candidates (i.e. genes or drugs) capable of interfering with both the onset and the progression of *α*-synucleinopathy. In order to maximize the probability of eventually ending up with an assay meeting the minimal robustness requirements for screening, we focused on wild type mouse cortical neurons challenged with exogenous *α*-synuclein assemblies. Indeed, late embryonic cortical neurons are easily isolated in large quantities and are amenable to standardized 96-well culture, and (ii) additions of exogenous *α*-synuclein assemblies allows to control the exact amount brought to the target neurons. Setting up this assay allowed us to explore dose/response and time-dependent effects of exposure to α-synuclein assemblies, using a variety of readouts based on immunofluorescence (IF) staining, and taking into account the different phases of the *α*-synuclein-neuron interaction. We exposed neurons to low concentrations (10 nM) of *α*-synuclein and applied machine learning strategies with random forest algorithms to treat the resulting IF images: this allowed us to observe and quantify the early formation of scattered hybrid *α*-synuclein speckles at the level of the target neurons. These speckles were big (in the 100nm-1µm size range) and consisted in the apposition of exogenous human *α*-synuclein clumps with endogenous synuclein counterparts on the processes of most neurons. Later on, and only in a fraction of the neurons bearing these speckles, extensive phosphorylation of endogenous *α*-synuclein took place, showing this time a "whole cell" pattern instead of a scattered one. Investigation of the nature and of the causal relationship between hybrid speckles and extensive *α*-synuclein phosphorylation is underway *in vitro* as well as *in vivo* and an update will be presented in the poster.

**Title:** α-synuclein post-translational modifications are not only markers of pathology but are also key regulators of lewy body formation and maturation; implications for therapies targeting α-syn and pathology spreading

**Authors: *A.-L. MAHUL-MELLIER**[1], F. ALTAY MELEK[1], J.-C. COPIN[1], J. BUTSCHER[1], N. MAHARJAN[1], N. AÏT BOUZIAD[1], S. VINGILL[2], R. WADE-MARTINS[2], R. HAMELIN[1], S. DEGUIRE[1], R. BURAI[1], H. LASHUEL[1]

**Abstract:** Parkinson's disease (PD) is the second most common neurodegenerative disorder characterized by the neuronal accumulation of misfolded alpha-synuclein (α-syn) into intracellular inclusions named Lewy bodies (LB). Despite increasing evidence indicating that α-syn plays a central role in PD pathogenesis, the molecular and cellular mechanisms that trigger the conversion of soluble α-syn to its aggregated form and regulate LB formation and the role of these processes in PD are still elusive. Recent findings have demonstrated that misfolded α-syn can be transmitted to recipient neurons, and serve as efficient seeds to initiate aggregation, thus spreading the pathology throughout the brain in a prion-like manner. Taking advantage of the seeding capacity of pre-formed fibrils (PFFs) to induce the formation of intracellular LB-like structures, we sought to decipher the role of post-translational modification in 1) the processing of α-syn PFFs; 2) α-syn seeding capacity and fibril formation**;** and 3) the formation and maturation of LB-like inclusions in primary neurons. Using an integrative imaging and proteomic approaches, including correlative light electron microscopy imaging, temporal proteomic analyses and biochemical characterization, we were able to uncover novel mechanisms that govern the initiation of α-syn misfolding in neurons and identify specific PTMs that occur during the various stages of α-syn seeding, aggregation and LB formation. First, temporal proteomic profiling of the LB-like inclusions formed in neurons revealed similarity with the proteins content related to the *bona fide* LB detected in human brain reinforcing the physiological relevance of the seeding model for studying the biogenesis of LBs. Second, our temporal proteomic studies revealed that treatment with α-syn fibrils induces the activation of specific enzymes that regulate α-syn PTMs during the initiation of the seeding process and later

during the growth and maturation of the newly formed aggregates. Third, we showed that C-terminal modifications are required for the efficient packaging of fibrils and LB maturation. Finally, our results point towards a potential failure of the protein degradation machinery to clear off these inclusions leading to the intracellular accumulation of LB as failed aggresomes-like inclusions. In conclusion, our work helped to uncover new mechanisms that possibly contribute to the origin of the LBs and the development of PD. Furthermore, this work represents the first comprehensive biochemical and structural characterization of α-syn aggregation, interactome and inclusion formation in a neuronal seeding model of PD and synucleinopahties.

**Title:** Perivascular macrophages control synucleinopathy spreading and toxicity in mouse models of Parkinson’s disease

**Authors: *S. HUNOT**, J. FUENTEALBA, E. C. HIRSCH
Cell. and Mol. Neurosciences, ICM - Brain & Spine Inst., Paris, France

**Abstract:** Parkinson’s disease (PD) is a movement disorder characterized by the loss of dopaminergic neurons (DN) in the substantia nigra (SN) and the presence of intraneuronal inclusions (Lewy bodies and neurites) enriched in alpha-synuclein (alpha-syn), a protein believed

to have prion-like propagation/aggregation properties. The mechanisms underlying the progression of neurodegeneration remain poorly understood, but probably involve both cell-autonomous and non-cell autonomous processes. Indeed, accumulating evidence suggests that pathological neuro-immune interactions could play a critical role in PD pathogenesis. In particular, microglial activation and T-cells are found in the SN of PD patients, but also in several animal models of the disease. The presence of circulating cells within the diseased brain may indicate alterations of the blood-brain barrier (BBB), as reported by several studies. The structural and functional properties of the BBB are tightly controlled by perivascular elements such as pericytes and perivascular macrophages (MPVs). The importance of MPVs in pathophysiological mechanisms of the CNS is a recent concept that has notably found echo in proteinopathies and in particular Alzheimer's disease. However, their response and pathogenic role in PD have, so far, never been investigated. Our present data suggest that PVMs may play a role in PD pathophysiology. Using a mouse model of degenerative synucleinopathy we found that the number of PVMs dynamically increases within the SN during the course of neurodegeneration. We further demonstrated that local cell proliferation accounted for this PVM recruitment with no involvement of peripheral immune cell engraftment. Importantly, similar increase in PVM density was observed in the *postmortem* brain of PD patients. The specific ablation of PVMs aggravates the demise of DN in our animal model, revealing their neuroprotective potential. This feature is very likely associated to their immunomodulatory properties and their ability to clear toxic molecules from the perivascular space. In line with this, we found that PVM depletion dramatically increases synucleinopathy spreading in mice injected with toxic α-syn assemblies. Overall, our results highlight the importance of PVMs in regulating the toxicity and spreading of synucleinopathy and suggest that immunotherapeutic approaches in PD could be oriented selectively to maintain or even boost the beneficial functions of immune cells like PVMs.

**Abstract:** ***Background:*** Dysfunction of the ubiquitin-proteasome system (UPS) has been implicated in the pathogenesis of a wide range of neurodegenerative disorders, which are characterized by the accumulation of misfolded proteins in affected neurons. In the context of Parkinson's disease (PD), impairment of the catalytic activity of the 26S proteasome has been reported in post-mortem sporadic PD brain tissue, various rodent models and in cultured cells lines overexpressing mutant alpha-synuclein. It remains unclear whether proteasome inhibition is associated with functional impairment of the UPS *in vivo* and whether this could contribute to an early loss of dopaminergic neurons. ***Aim:*** To measure UPS activity at different stages of dopaminergic neurodegeneration following viral-mediated expression of A53T alpha-synuclein in rat substantia nigra ***Methods:*** Adult female rats received unilateral co-injection of adeno-associated viruses (AAVs) expressing human A53T alpha-synuclein and the $Ub^{G76V}$GFP reporter substrate into the substantia nigra. Timed-culls were performed at different stages of disease progression and *in vivo* UPS activity measured by immunofluorescence and fluorogenic peptide cleavage assays. ***Results:*** Expression of A53T alpha-synuclein was associated with accumulation of the $Ub^{G76V}$GFP reporter in both dopaminergic and non-dopaminergic cell populations in the substantia nigra. In contrast, dopaminergic neurons in the neighboring ventral tegmental area did not show evidence of UPS dysfunction, despite accumulation of misfolded A53T alpha-synuclein. ***Conclusion:*** Expression of mutant alpha-synuclein is associated with functional impairment of the UPS in a rodent model of PD. As a result, strategies to upregulate UPS activity could have therapeutic benefit in PD and related protein misfolding disorders.

**Abstract:** Parkinson's disease (PD) is a multifactorial synucleinopathy with selective vulnerability of the nigral dopaminergic system. Current models of PD pathology fail to recapitulate the temporal sequence of disease progression or exhibit comprehensive phenotype. With this study, we aimed to generate a model to define the effects of combining two primary pathogenic factors, mitochondrial deficits and proteostatic stress, on the formation of protein aggregates and nigrostriatal intregrity. We employed the heterozygous Engrailed 1 (*En1*$^{+/-}$) mouse that features progressive loss of nigral dopamine neurons, striatal dopamine deficiency, axonal dysfunction and neuroinflammation. *En1*$^{+/-}$ mice display significant mitochondrial deficits and lysosomal deficiencies which are akin to phenomena observed in clinical PD. We tested the hypothesis that mitochondrial deficits underlying the *En1*$^{+/-}$ phenotype will enhance the effects of intrastriatal injections of pathogenic human α-synuclein (α-syn) fibrils (hPFFs). We unilaterally injected 4 week-old *En1*$^{+/-}$ and control wild-type mice with hPFFs and sacrificed animals at 3 months of age for post-mortem analysis. Using immunohistochemistry and stereology, we established the effects of *En1*$^{+/-}$ on the propagative dynamics of synucleinopathy. Following the intrastriatal PFF injection, *En1*$^{+/-}$ mice exhibited a near-threefold increase in pS129-α-syn-positive neurons in the substantia nigra when compared to wild-type mice injected with hPFFs, as assessed by unbiased stereology. To compare this exacerbation of pathology to another anatomical region with direct projections to the striatum, we counted the number of pS129-α-syn-positive neurons in the amygdala. *En1*$^{+/-}$ mice also featured a significant increase in amygdala inclusions compared to control mice, although not as dramatic as the enhanced nigrostriatal pathology. Additionally, we assigned pathology scores in regions throughout the neuraxis to assess widespread propagative potential. We observed amplified pathological aggregation in *En1*$^{+/-}$ animals along multiple bilateral cortical pathways including, but not limited to, motor cortex, perirhinal/entorhinal cortices, and somatosensory cortex. In conclusion, we found that following intrastriatal injection of hPFFs, mitochondrial dysfunction is more permissive to the aggregation of pathological α-syn, with heightened insult selectively along the nigrostriatal pathway. Here, we present our updated characterization of the *En1*$^{+/-}$-hPFF model. We anticipate that this double-hit model may be more predictive of pre-clinical therapeutic development and success for PD than existing mouse models.

**Title:** Optimising a rat model of Parkinson's disease based on AAV vector-mediated alpha synuclein transfer in the nigra

**Authors: *J. MUDANNAYAKE**[1], T. BJORKLUND[2], F. P. MANFREDSSON[3]
[1]Lund Univ., Lund, Sweden; [2]Mol. Neuromodulation, Wallenberg Neurosci., Lund, Sweden; [3]Translational Sci. & Mol. Med., Michigan State Univ., Grand Rapids, MI

**Abstract:** Animal models based on α-synuclein overexpression that replicate a range of disease pathology represent a more clinically relevant alternative to toxins-based Parkinson's disease (PD) models. However, the inability to faithfully reproduce the temporal and neurochemical patterns of pathology and behavior of published work on these models hinders its wide applicability in the research setting. To generate a replicable, 'standardized' adeno-associated virus (AAV) vector-mediated α-synuclein model, we aim to first comparatively analyze commonly used AAV serotypes coupled with various DNA promoter and post-transcriptional regulatory elements, prior to characterizing pathology and behavior deficits of a PD model generated with the optimal vector construct. The below expression plasmids were cloned: ssAAV-CBA-αSyn-WPRE-bGHpA, ssAAV-Syn-αSyn-WPRE-lateSV40pA, scAAV-CBh-αSyn-WPRE3-enSV40pA, scAAV-Syn-αSyn-WPRE3-enSV40pA, scAAV-CMV/Syn-αSyn-WPRE3-enSV40pA, and scAAV-PGK-αSyn-WPRE3-enSV40p. All constructs were packaged into AAV5, while scAAV-CBh-αSyn-WPRE3-enSV40pA was additionally packaged into AAV2 and 6. Titer-matched vector constructs will be unilaterally injected into the wild-type rat nigra and brains histochemically assessed four weeks post-injection to determine the vector construct generating optimal levels of protein expression. The selected vector construct, together with a control construct expressing the fluorescent tagBFP2 protein will be then tested as per above and pathology and behavior deficits assessed at 4, 8, and 12 weeks post-injection.

**Abstract:** Background:
Parkinson's disease (PD) is the second most common neurodegenerative disease affecting approximately 1% of the population over the age of 60 years. α-Synuclein is a key molecule in the pathogenesis of PD and genetic studies have linked the level of α-synuclein with the risk of developing PD. The level of α-synuclein is therefore a possible target as a disease modifying treatment for PD.
Findings:
We have recently published that Polo-like kinase 2 is able to regulate α-synuclein protein and mRNA levels in mice, brain slices and primary neurons (Kofoed et al., 2017, Neurobiol. Dis.). Following this, we have obtained data showing the involvement of two additional PD-associated kinases in the pathway. Our data presents a novel approach for decreasing α-synuclein levels using small molecule compounds.
Perspectives:
Decreasing α-synuclein levels can decrease α-synuclein pathology and motor dysfunctions in PD animal models, however, these treatments often relies on viral injections in the brain for siRNA expression. The ability to decrease α-synuclein using small molecule compounds therefore holds the potential as disease modifying treatment for PD suitable for treatment of human patients.

**Title:** Andrographolide modulates the overexpression and aggregation of Alpha synuclein in an *in vitro* model of Parkinson's disease

**Authors: *S. BASTÍAS-CANDIA**, N. INESTROSA
Ctr. for Aging and Regeneration (CARE), Pontificia Univ. Catolica De Chile, Santiago, Chile

**Abstract:** Parkinson disease (PD) is one of the most common neurodegenerative disorders affecting up to the 0,5-1,0% of the current population and rising 1 to 3 percent among 80 years old people. PD has a multifactorial etiology, involving genetics and environmental causes, but even when its origin can be different they have a common feature, the overexpression and aggregation of the α-synuclein (SNCA) protein. SNCA correspond to a presynaptic protein involved in the dopamine release, synaptic vesicle formation, and recapture of the dopamine from the extracellular spaces. Because of its multiple functions, the overexpression and consequent aggregation of SNCA has been related with neuronal dead through oxidative stress, neuroinflammation and interference with the dopamine synthesis and exocytosis, among others. Besides the substantial information about PD pathophysiology, currently there is no effective treatment. In the last years, natural compounds with neuroprotective effects have been proved against several neurodegenerative disorders, but only a few have shown to improve o reverse the selective neuronal damage. That is the case of Andrographolide (ANDRO), a labdane diterpene isolated from the plant Andrographis paniculata, with neuroprotective properties on oxidative stress and neuroinflammation. Its mechanism of action seems to involve the activation of Nrf2/ARE and NFκB pathways, but more important, its relationship with GSK-3β indicates a possible link with the Wnt/β-catenin signaling pathway. In this regard, ANDRO have demonstrated to have neuroprotective effect through the reduction of phosphorylated tau protein and amyloid β aggregate maturation in aged Octodon degus, a natural model of Alzheimer’s disease, with a clear recovery of cognitive impairment. We hypothesize that ANDRO can modulates the overexpression of SNCA in a sporadic in vitro model of PD. Rotenone, a classic PD-like model capable to generates mitochondrial dysfunction and SNCA overexpression was used in a SH-SY5Y neuroblastoma cell line. We assess the levels of SNCA and tyrosine hydroxylase as markers of PD, and the levels of Nfr2/HO-1 and NFkB as oxidative and inflammatory markers. The modulatory ANDRO effects were evaluated by Western blotting and

Immunofluorescence techniques. Thus, in the present work we postulate that ANDRO a natural compound, with modulatory effects on the Wnt signaling, is capable to exert neuroprotective activity on a sporadic model of PD.

**Title:** Disorganization of the brain extracellular matrix through microglial activation in the Lewy body-injected mouse

**Authors: *E. BEZARD**[1], F. N. SORIA[2], B. DEHAY[1]
[1]Inst. of Neurodegenerative Dis., Bordeaux, France; [2]Inst. Des Maladies Neurodégénératives, Bordeaux Cedex, France

**Abstract:** We wish to explore the interplay of the extracellular matrix and microglia in a murine model of Parkinson’s disease. The extracellular matrix (ECM) is an intricately arranged molecular framework comprised of secreted proteins and complex sugars that support cell function and survival. Changes in the highly-hygroscopic hyaluronan (HA) network, the structural scaffold of the ECM in the brain, can dramatically modify the extracellular space (ECS) volume. The neuropathological hallmark in Parkinson’s Disease (PD) is the presence of Lewy Bodies (LB), intraneuronal proteinaceous inclusions constituted, among other components, by alpha-synuclein (-syn). The ECS/ECM participate both in the spreading of toxic conformers of alpha-synuclein and in the regulation of inflammation, key events leading to the loss of dopaminergic neurons in the substantia nigra (SN).
Here we sought to explore the HA network in the SN of mice injected with LB fractions derived from PD patients containing a very small amount (pg) of human -syn. This inoculation induced 40% of neurodegeneration 4 months after surgery (Recasens et al., 2014). Since HA and microglia can be visualized with fluorescent probes, we analyzed its structure by confocal microscopy and quantified the extent of the HA network in the SN by image analysis.
We found a substantial alteration of the HA network in LB-injected mice compared to controls, as well as microglial invasion of the SN. No changes were detected in HA synthesis and degradation enzymes. However, we observed increased expression of inflammation markers TNF-alpha and CD68, and the glial HA receptor CD44. Interestingly, we observed engulfment of HA structures by activated microglia in LB-injected mice.

These results suggest a role of microglia in the alteration of the ECM in a context of alpha-synuclein-induced neurodegeneration. Our results provide insight on a crucial and underexplored component of the brain and adds to our understanding of the pathophysiology of PD

**Abstract: Background:** The neuropathological hallmarks of Parkinson’s disease (PD) are the appearance of alpha-synuclein (αSYN)-positive Lewy bodies and the extensive loss of catecholaminergic neurons. Although αSYN is primarily localized in neuronal cytosol, it has also been detected in extracellular fluid, suggesting that a mechanism promoting the uptake of extracellular αSYN in susceptible neurons may exist. In this study, we focused on a membrane-associated protein, flotillin-1 (FLOT1), which is highly expressed in brainstem catecholaminergic neurons and is strikingly upregulated in PD. The FLOT microdomain is known to provide endocytic platforms that are involved in the uptake of cell surface molecules including dopamine transporter (DAT). **Objective:** The main purposes of this study were to determine whether extracellular αSYN could influence on the endocytic process of FLOT1 and DAT. **Methods:** HEK 293 cells expressing GFP-DAT and induced pluripotent stem cells derived dopaminergic neuron were incubated with conditioned medium containing recombinant human αSYN monomer. Distinct endosomal structures including early endosomal autoantigen 1 (EEA1), Rab7A, and Rab11A were investigated by immunohistochemistry. Time-lapse imaging was performed to explore the spatiotemporal distribution of monomeric αSYN and DAT. Co-immunoprecipitation was adopted to demonstrate the molecular interaction between αSYN, FLOT1 and DAT. **Results:** We found that FLOT1 co-assembled with extracellular monomeric αSYN on the cell surface, thereby facilitating the endocytic uptake of monomeric αSYN.

Furthermore, extracellular monomeric αSYN triggered the internalization of DAT via FLOT1-assisted endocytosis and downregulated DAT activity. Surprisingly, αSYN was concomitantly endocytosed into cells by hijacking endocytic trafficking of DAT. **Conclusion:** (1) extracellular αSYN has a regulatory role on FLOT1-assisted DAT trafficking. (2) αSYN internalizes into cells by hijacking the endocytic process of DAT.

**Title:** Systematic analysis on the seeding activity of familial mutant forms of α-synuclein

**Authors: *N. XU**[1], G. ITO[2], A. TARUTANI[1], T. TOMITA[1,2]
[1]Lab. of Neuropathology and Neurosciences,Graduate Sch. of Pharmaceut., [2]Lab. of Brain and Neurolog. Disorders, Graduate Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

**Abstract:** Parkinson disease (PD) is one of the most common neurodegenerative diseases characterized by loss of dopaminergic neurons in the midbrain. PD is pathologically characterized by the deposition of aggregated α-synuclein proteins as Lewy bodies and Lewy neurites. Six missense mutations in the α-synuclein gene (i.e., A30P, E46K, H50Q, G51D, A53E, and A53T) have been identified in familial PD cases, implicating the pathological importance of α-synuclein. Recently, interneuronal propagation of amyloid protein has emerged as a common paradigm explaining how the pathology spreads in the patient brains of neurodegenerative diseases. However, it remains unclear how pathogenic mutations in α-synuclein alter the propagation. In this study, we examined seeding and propagation activities of α-synuclein mutants in in vitro fibrillization assays, primary cultured neurons and wild-type mouse brain. These α-synuclein mutants were produced in E. coli, and incubated at 37 ℃ with agitation for several days to induce aggregation. The formed aggregates were then sonicated and used as seeds for subsequent experiments. First, the seeded aggregation with mouse α-synuclein monomer was measured by a thioflavin assay. We found that all the mutants, but not G51D, showed a seeding activity. Next, rat cortical primary neurons were treated with the α-synuclein seeds for 7 days, and induction of phosphorylation of S129 in endogenous α-synuclein, which represents the formation of aggregated α-synuclein, was examined by an immunocytochemical analysis. All mutants were able to induce phosphorylation of endogenous α-synuclein. Finally, we tested the propagation of α-synuclein pathology in wild-type mouse brains unilaterally injected with the α-synuclein seeds into the striatum. One month after injection of wild-type α-

synuclein seeds, we confirmed the induction and spreading of phosphorylated α-synuclein. The result of systematic in vivo experiment using α-synuclein mutants will also be presented. These results will elucidate the difference between wild-type and mutant α-synuclein in terms of the seeding activity both in vitro and in vivo, which might explain the pathogenicity of the mutations.

**Abstract:** In α-synucleinopathies, such as Parkinson's disease, dementia with Lewy bodies (DLB) and multiple system atrophy (MSA), the presence of abnormal α-synuclein (α-syn) aggregates in neuronal and/or glial cells is a defining neuropathological feature. A growing body of evidence strongly suggests that these forms of α-syn have prion-like properties, and self-amplify by conversion of normal α-syn and spread throughout the brain by transmission between cells. However, it is not yet clear whether such prion-like pathogenic α-syn poses a risk of secondary infection to humans, as is the case for certain prion diseases, such as iatrogenic Creutzfeldt-Jakob disease. In this study, we investigated in detail the prion-like seeding activities of several kinds of pathogenic α-syn, including synthetic fibrils and detergent-insoluble fractions extracted from brains of patients with α-synucleinopathies. We determined the minimum amounts of these pathogenic α-syn species required for induction of seeded α-syn aggregation in SH-SY5Y cells and non-Tg mice. Exposure to synthetic α-syn fibrils at concentrations above 100 pg/mL caused seeded aggregation of α-syn in SH-SY5Y cells, and seeded aggregation was also observed in C57BL/6J mice after intracerebral inoculation of at least 0.1 μg/animal. α-Syn aggregates extracted from brains of MSA patients showed higher seeding activity than those

extracted from patients with DLB, and their potency was similar to that of synthetic α-syn fibrils. We also examined the effects of various methods that have been reported to inactivate abnormal prion proteins ($PrP^{SC}$), including autoclaving at various temperatures, exposure to sodium dodecyl sulfate (SDS), and combined treatments. The combination of autoclaving and 1% SDS substantially reduced the seeding activities of synthetic α-syn fibrils and α-syn aggregates extracted from MSA brains. However, single treatment with 1% SDS or generally used sterilization conditions proved insufficient to prevent accumulation of pathological α-syn. In conclusion, α-syn aggregates derived from MSA patients showed a potent prion-like seeding activity, which could be efficiently reduced by combined use of SDS and autoclaving.

**Abstract:** Aggregated forms of the proteins alpha-synuclein (a-syn) and tau constitute the pathological hallmarks in the brain of patients with Parkinson’s and Alzheimer’s disease. Although discovered at least 20 years ago, we still lack an understanding of the cellular mechanisms that contribute to the complex and dynamic protein aggregation process, heavily restricting our possibilities to rationally target either the aggregation process itself or the cellular ability to degrade these aggregates. The hypothesis that aggregated forms of either a-syn or tau are not only affecting neuronal function and survival, but also actively contributing to spreading of the disease in the brain was a breakthrough for modelling disease pathology.
With current model systems, it is possible to initiate the intracellular aggregation by adding pre-aggregated forms of a-syn and tau to the media. Taking advantage of seeding model systems and recent advances in quantitative proteomics, we set out to conduct an in-depth analysis of a-syn and tau aggregate-associated proteins at their distinct aggregation stages. In addition, our analysis incorporates information on the posttranslational modification (PTM) status of the aggregate proteins focusing on ubiquitylation and phosphorylation. We believe that by dissecting

aggregate interactomes and PTM signatures throughout aggregation stages across experimental models, we will increase our understanding on how intracellular inclusion formation and clearance (degradation or release) are regulated and can be modulated.

**Abstract:** Alpha-synuclein is a central component of Lewy bodies present in Parkinson’s disease (PD) patients. The consequences of synucleopathy in neuronal function remains unclear and preclinical therapy testing targeting alpha-synuclein are needed. To help identify biomarkers, we utilized whole-cell patch clamp in brain slices to evaluate alterations in synaptic properties in the dorsal striatum from Line 61 transgenic mice overexpressing human wild-type alpha synuclein. Brain slices were prepared from Line 61 mice at ages where they display significant impaired motor behavior and synuclein pathology. Analysis of striatal spiny projection neurons (SPNs) showed a robust decrease in the frequency of miniature excitatory synaptic events in Line 61 compared to wild-type littermates. This phenotype was the same between 2-month and 6-month old Line 61 mice, suggesting a stable readout throughout aging. Analysis of paired-pulse ratio in 6-month old Line 61 corticostriatal synapses revealed no changes in the probability of release, indicating a decrease in excitatory drive in Line 61 is related to synapse loss. The reduction in the frequency of synaptic events was accompanied by a significant increase in the amplitude of synaptic events. This suggests that striatal SPNs from Line 61 underwent synaptic scaling to compensate for the loss of synapses. To further support the synapse loss and scaling phenotype in Line 61, alterations in levels of different synaptic protein markers in the striatum from Line 61 mice will be analyzed using western blotting. Altogether, we have a stable and robust synaptic deficit in the Line 61 model that we can offer for preclinical testing, supporting and translatable to the loss of dendritic spines reported in PD patients and rodent models.

**Abstract:** Parkinson's disease (PD) is characterized by the aggregation of endogenous α-synuclein into fibrillar inclusions in the brain. Although its native function remains elusive, evidence supports that α-synuclein plays an important role in neurological function under normal physiological conditions. The aggregation of α-synuclein under pathologic conditions involves misfolding of the intrinsically disordered monomer into oligomers which can aggregate to form the fibers that make up the insoluble inclusions seen in the brains of PD patients. There has been significant effort to identify small molecule inhibitors of α-synuclein fibrillization. However, recent evidence suggests the kinetically unstable oligomeric species, and not fibrils, are the source of α-synuclein cytotoxicity.
We have developed a set of cell-free FRET based biosensors that monitor monomer-monomer interactions and fibril formation through fluorescence lifetime. Using fluorescence lifetime provides a 30-fold increase in sensitivity over more traditional FRET measurements. We are currently optimizing these biosensors for use in high-throughput screening to identify inhibitors of oligomer and fibril formation. We have achieved an optimal FRET of 14.99% for WT oligomeric interactions and a seeded induced change in FRET of 15.34%. HTS hits will be validated for FRET dose response, biophysical changes in aggregation kinetics via thioflavin T assays and AFM characterization, and functional properties via cell death assays.

**Abstract:** Synucleinopathies, including Parkinson's disease (PD), Dementia with Lewy bodies (DLB), and multiple system atrophy (MSA) are all characterized by aggregation and deposition of α-synuclein in the brain. Developing reliable biomarkers that can distinguish among the synucleinopathies is an urgent public health need. Multiple observations suggest that misfolding

and self-association of α-synuclein into oligomers and aggregates cause neural dysfunction and neurodegeneration in these diseases. Nonetheless, diagnosis of synucleinopathies is challenging due to overlapping symptoms among the synucleinopathies themselves and with other atypical parkinsonian syndromes. Exosomes are nano-vesicles shed by most cell types, which carry cell- and cell-state-specific proteins and nucleic acids and provide a rich source of biomarkers. Recently, α-synuclein was shown to transfer via exosomes between different brain cells suggesting that measuring α-synuclein in brain-derived exosomes isolated from patient blood could serve as a potential biomarker for synucleinopathies. In this study, we used antibody-coated magnetic beads to immunochemically isolate exosomes released by neurons or oligodendrocytes from serum of healthy individuals and patients with PD and MSA and measured biomarker concentration in them by a highly sensitive electrochemiluminescence ELISA. The aims of the study were: 1) To determine if measuring α-synuclein in serum exosomes from neurons and oligodendrocytes can distinguish between healthy controls and patients with PD or MSA, 2) To test whether analyzing α-synuclein in neuronal and oligodendroglial exosomes can distinguish between PD and MSA. Neuronal and oligodendroglial exosomes were isolated from serum of 50 controls, 50 patients with PD, and 30 patients with MSA. Significantly higher concentrations of α-synuclein were found in both neuronal and oligodendroglial exosomes from patients than in controls. α-Synuclein in oligodendroglial exosomes distinguished patients with MSA from healthy controls with 100.0% sensitivity and 96% specificity. The absolute values of α-synuclein in neuronal and oligodendroglial exosomes provided moderate separation between the PD and MSA groups, yet the ratio between the two cell types allowed separating the two disease groups with 90.0% sensitivity and 90.0% specificity. Thus, α-Synuclein in brain-derived blood exosomes provides a sensitive biomarker for distinguishing patients with MSA from healthy controls and from patients with PD using a blood test and suggest that the method can be expanded further for other neurodegenerative diseases.

**Abstract:** Parkinson Disease (PD) is a neurodegenerative movement disorder that is characterized by post-mortem observation of two pathological hallmarks including loss of dopaminergic (DAergic) neurons of the substantia nigra (SN) and alpha-synuclein aggregates (Lewy bodies and Lewy neurites). Current therapies for PD focus on managing symptoms after substantial loss of DAergic neurons with no current method of prevention of neurodegeneration. Elucidation of the underlying causes of neuronal cell dysfunction has the potential to provide new therapeutic targets to prevent loss of DAergic neurons. Post-translationally modified alpha-synuclein is the major component of filamentous inclusions in neurons throughout the brain in PD. It is not known how DAergic neurons respond to inclusion formation; defining their transcriptional profile during the cell death process could identify pathways for preventing cell death. To understand how levels of gene transcription change in neurons with Lewy pathology, we use the fibril model. According to this model, addition of alpha-synuclein preformed fibrils *in vivo* or in culture leads to corruption of endogenous alpha-synuclein over time, resulting in inclusions, defects in neuronal function, and cell death. To enable quantification of transcripts in cells containing alpha-synuclein aggregates, we optimized a new technique combining RNAscope fluorescent *in situ* hybridization with immunofluorescence for phosphorylated alpha-synuclein. With this protocol, we demonstrate that neurons with inclusions always express mRNA for alpha-synuclein, consistent with the model that inclusion formation requires cell-autonomous endogenous alpha-synuclein expression. Interestingly, inclusions were only observed in glutamatergic neurons and were not observed in GABAergic neurons, which express very low levels of alpha-synuclein mRNA. In the future, we will use this method to track transcriptional changes in a cell-specific manner during the process of inclusion formation and cell death.

**Title:** Alpha-synuclein and tau abnormalities caused by lipids in neurodegenerative aging

**Authors: *O. R. BREKK**, O. ISACSON, P. J. HALLETT
McLean Hosp., Belmont, MA

**Abstract:** Aging is the most significant risk factor for developing genetic and sporadic neurodegenerative disorders, including Parkinson's disease (PD) and Alzheimer's disease (AD). The connections between aging and disease-associated gene products, for example GBA1, alpha-synuclein (aSYN), or Tau, are not fully understood. We have previously observed age-dependent reductions in glucocerebrosidase (GCase) activity (encoded by GBA1) in normal aging in the human (Rocha et al., 2015, Ann. Clin. Trans. Neurol.) and mouse (Hallett & Huebecker et al., 2018, Neurobiol. Aging) brain, with concurrent accumulation of a variety of glycosphingolipids (GSLs) including glucosylceramide and glucosylsphingosine. As glucosylceramide has recently been shown to induce aSYN aggregation and attenuate neurotoxicity *in vitro* (Zunke et al., 2018, Neuron), we wish to investigate the impact of age-related lipid impairments on disease-associated proteins aSYN and Tau. In wildtype (WT) mice aged 2-24 months of age, presenting with elevated GSL content, we investigated lipid modifications of aSYN and Tau through biochemical lipid-extraction assays of whole-brain homogenates and assessed how these modifications affect protein structure and posttranslational state. Using fluorescent labeling and automated colocalization analysis, we determined the localization of these proteins within the neuronal lipid membrane compartment with known lipid membrane markers including vesicular membranes, to identify likely binding partners. Lastly, we will assess any correlation between GCase function and lipid homeostasis on aSYN burden in human sporadic PD. As an alternative to the classic view of proteinopathy, these findings illuminate the interplay between age-associated changes in lipid homeostasis and the risk for neurodegenerative disease.

**Title:** The role of biological membranes in the alpha-synuclein/Nedd4-1 interaction

**Authors: *R. V. STAHELIN**, J.-C. ROCHET
Purdue Univ., West Lafayette, IN

**Abstract:** Neuropathological and genetic evidence strongly suggests that aggregation of the presynaptic protein alpha-synuclein (aSyn) plays a central role in Parkinson's Disease (PD) pathogenesis. In healthy neurons, aSyn exists in an equilibrium state between a natively unfolded, non-membrane-bound form and a form physically associated with synaptic vesicles that adopts an amphipathic alpha-helical structure upon lipid binding. Although both forms can produce aggregates, the rate of aSyn aggregation is accelerated ~1,000-fold in the presence of vesicles. Additionally, it has found that familial aSyn mutants (e.g. A30P, G51D) with a high propensity to adopt a membrane-bound conformation with a short, lipid-bound N-terminal segment and unbound central and C-terminal segments (referred to here as an 'exposed' conformation) and an enhanced ability to undergo membrane-induced aggregation elicit greater neurotoxicity. These findings support a model in which the aggregation of exposed membrane-bound aSyn conformers is a key target in PD. Accordingly, cellular perturbations that stimulate the degradation of membrane-bound aSyn could alleviate aSyn neurotoxicity in the brains of PD patients.
The E3 ligase Nedd4-1 catalyzes the Lys-63-linked ubiquitylation of intracellular aSyn and degradation by the endolysosomal pathway. Nedd4-1 harbors an N-terminal lipid binding C2 domain that regulates its interactions with membranes in a calcium dependent manner. The current study will present the mechanism by which aSyn and Nedd4-1 interact on membrans to favor aSyn ubiquitylation and degradation. Additionally, the interaction mechanism with Nedd4-1 will also be presented for familial PD aSyn mutations (A30P and G51D).

**Abstract:** Vacuolar protein sorting 35 (*VPS35*) has been reported as a pathogenic gene for late-onset autosomal dominant Parkinson's disease (PD). To date, several *VPS35* variants (D620N,

M607V, R524W, et al) have been demonstrated to be prevalent in PD patients, but the mechanisms underlying how endosomal pathway defect leads to impaired protein trafficking and degradation is still not clear. In this study, we discovered that *VPS35* c.1858G>A D620N variant leads to excessive cytoplasmic alpha synuclein accumulation in comparison with other variants. In stable expressed *VPS35* D620N SH-SY 5Y cell lines, punctate aggregation of Golgi complex in the peri-nuclear region was demonstrated and aggravated after alpha synuclein pre-formed fibrils (PFF) incubation. One of the crucial lysosomal enzyme for alpha synuclein degradation, cathepsin-D was demonstrated to be trapped in the Golgi complex rather than be trafficked to the lysosomes in the *VPS35* D620N variant. With PFF incubation, chaperon-mediated autophagy and exosome release increased to compensate for inadequate alpha synuclein degradation. Cation-independent Mannose-6-phophate receptor (M6PR) is the major sorting cargo of VPS35-associated retromer and functions as the carrier of lysosomal enzymes. A reduction in the membrane fraction of M6PR, as well as co-localization of cytoplasmic fraction with multi-vacuolar bodies hint in endosomal recycling defect and the detention of Cathepsin-D. The defect can be restored by a Glucagon-Like Peptide-1 Receptor Agonist (GLP-1 RA) Exendin-4 through increasing M6PR expression and thus reduce cytoplasmic alpha synuclein accumulation. <!--EndFragment-->

**Abstract:** Accumulation of alpha-Synuclein (AS) aggregates in neurons, dendrites and glial cells are the staple of many synucleinopathies. Although various therapeutic strategies are available to alleviate the motor and cognitive deficits, none of these therapies slows aggregation of the AS. We have recently demonstrated accumulation of AS in the hippocampal and nigral neurons due to chronic stimulation of adenosine A1 receptor (A1R). We hypothesize that pharmacological inhibition of A1Rs or administration of the drug, 1-aminoindan, which was previously implicated in preventing AS misfolding (Jakova et al., 2016), can prevent the neurotoxicity-enhancing effects of increased AS in hippocampal and SNc neurons. Using male postnatal 28-35-day old Sprague-Dawley rats, we administered an adenosine-mimicking compound (AMC) for 7 days by intraperitoneal injection and tested the effects of novel neuroprotective agents in hippocampal and SNc neurodegeneration. Behavioural tests were conducted after day 8. Animals were then euthanized and used for acute tissue slicing or perfused with 4% paraformaldehyde for subsequent immunohistochemical and confocal imaging with Zeiss confocal microscope. Additional biochemical and biophysical techniques, such as nanopore analysis and electrophysiology, were used to determine the binding sites of our compounds to AS, as well as to measure the effects of these compounds on synaptic transmission by fEPSP recordings. Additionally, co-immunoprecipitaion experiments were conducted to determinate if AS forms a protein-protein complex with A1R. From western blot analysis and confocal images, the two proteins appear to interact together. Using nanopore and confocal imaging analyses, we determined that the neuroprotective compounds 1-aminoindan and DPCPX exerted their effects by binding directly to AS and preventing AS interaction with A1R. These data suggest that

adenosine signalling plays a major role in synucleinopathy and that AMC agonists/antagonists may also directly regulate alpha synuclein conformation and expression.

**Abstract:** Cell-to-cell transfer of αlpha-synuclein (α-syn) is thought to underlie the stereotypical progressive pattern of α-syn pathology and symptoms in Parkinson´s Disease (PD). In this process, α-syn is suggested to trigger an immune response through transfer from neurons to astrocytes and through activation of microglia leading to increased secretion of proinflammatory cytokines and chemokines. The activation of microglia depends on α-syn conformation, i.e. oligomers, but not monomers, induce microglial activation and increase the levels of MHCII expression. However, little is known about how the coexistent activation of microglia influences the propagation of α-syn pathology. We have previously shown that genetic variants regulating the expression levels of Mhc2ta, the major regulator of MHCII transcription, lead to a modified microglial activation profile in response to overexpression of human α-syn in the rat substantia nigra pars compacta (SNpc). DA.VRA4 congenic rats, with lower transcriptional activity of Mhc2ta and MHCII genes compared to DA rats, display enhanced denervation of the nigro-striatal system and significant behavioral deficits after nigral α-syn overexpression. To answer

how activation of microglia influences α-syn pathology, we used an α-syn seeding model, with low-dose of rAAV-α-syn injected into the SNpc followed by intra-striatal administration of α-syn pre-formed fibrills (PFFs) two weeks later. We found that seeding with PFFs induced widespread a-syn pathology and microglial activation compared with rAAV-α-syn only. The impact of Mhc2ta expression on α-syn-induced pathology was assessed by comparing DA.VRA4 and DA rats with regard to microglial, lymphocyte and cytokine profiles, aggregation and propagation of α-syn, dopaminergic axonal pathology and fiber density in the striatum, dopaminergic cell survival in SNpc and motor impairments.

**Abstract:** We have generated a structure-dependent FingR (**F**ibronectin **in**trabody **g**enerated with m**R**NA display) that binds to membrane-bound α-Synuclein. In “synucleinopathies”, such as Parkinson’s disease, the overexpression or mutation of α-Synuclein leads to the formation of toxic aggregates that impair neuronal function. Although progress has been made in identifying the cellular processes that are disrupted by misfolded α-Synuclein, its physiological functions and the pathways that trigger its pathogenic state are not well understood. The binding of α-Synuclein to synaptic vesicles and its putative interactions with synaptic proteins suggest that it has roles at the synapse. However, elucidation of these functions has been problematic for several reasons: (i) Even low-level exogenous expression of α-Synuclein alters its localization and the levels of multiple presynaptic proteins; and (ii) α-Synuclein exists in at least two structure-dependent states in neurons, a membrane-bound form that is localized to the outside of synaptic vesicles and an unstructured form that is diffuse in the surrounding cytosol. Thus, there is a need for tools that enable different endogenous states of α-Synuclein to be distinguished, so that their individual roles in neurodegeneration can be studied. When expressed in neurons the α-Synuclein FingR localizes in a punctate pattern to presynaptic terminals with α-Synuclein and

the synaptic vesicle proteins Synaptophysin, Synapsin 1/2, and VGLUT1. In cell bodies the α-Synuclein FingR associates with membranous structures, suggesting that it does not recognize the unbound form of α-Synuclein in the cytosol and nucleus. Furthermore, KCl-induced excitation of neurons results in changes in the localization of the FingR that are similar to those reported for endogenous α-Synuclein, indicating that it does not impede function. In addition, the α-Synuclein FingR co-immunoprecipitates α-Synuclein from cell lysate, but not a FingR that has its binding domains randomized. Lastly, whereas fluorescently tagged Synaptophysin, a popular probe for labeling presynaptic sites, enlarges presynaptic terminals and causes toxicity, the α-Synuclein FingR can be expressed in neurons for several weeks without producing effects on presynaptic terminals. We plan to use the FingR to visualize membrane-bound α-Synuclein at synapses in culture and *in vivo*, with the aim of identifying and dissecting pathways that control its function as well as those that can lead to its aggregation and transformation into toxic protein complexes.

**Abstract:** Parkinson’s Disease (PD) is pathologically characterized by the progressive loss of nigrostriatal dopaminergic neurons and aberrant accumulation of the presynaptic protein αSynuclein (αS). Several factors have been proposed to trigger αS aggregation, resulting in αS-induced neurotoxicity. One of them is 3,4-dihydroxyphenylacetaldehyde (DOPAL), a toxic dopamine metabolite, which covalently modifies lysine residues of proteins. *In vitro* and cellular studies demonstrated that DOPAL triggers αS oligomerization, prevents αS association to

synaptic vesicle membranes and affects synapse physiology. Interestingly, the release of aS toxic oligomers from diseased neurons is considered a relevant pathological mechanism in the spreading of neurodegeneration in PD. Therefore, we studied DOPAL-aS oligomers secretion and propagation by extracellular vesicles and their impact on recipient neurons. aS-containing exosomes where purified from HEK293T cells and the presence of SDS non-resistant oligomers and, upon DOPAL treatment, also SDS-resistant oligomers was confirmed. To explore the effect of aS and DOPAL-aS oligomers uptake, primary mouse cortical neurons where incubated for 24 hours with aS-containing exosomes. After exosomal uptake, neurons displayed significant neurite retraction, redistribution of synaptic vesicles pools and reduced synaptic markers after incubation with DOPAL-modified aS containing exosomes. Finally, we are conducting an ultrastructural analysis by using markers for correlated light and electron microscopy to distinctly label aS oligomers. We also aimed to determine whether DOPAL-aSyn oligomers release is due to impaired proteostasis of donor neurons and altered aS clearance. Indeed, our previous LC-MS studies revealed that some lysines of αS are preferentially modified by DOPAL; most of them are also reported as ubiquitination sites. Hence, aS half-life was measured in catecholaminergic BE(2)-M17 cells, revealing an accumulation of monomeric aS after DOPAL treatment but no significant variation in degradation kinetics. In parallel, we generated stable BE(2)-M17 cell lines with an inducible and dose-dependent aS over-expression to finely assess any synergistic effect of DOPAL and aS on cytotoxicity. Concluding, our study combines different biochemical and imaging approaches to shed light on the crucial contribution of altered dopamine metabolism in αS-associated neurodegeneration in PD.

**Title:** Rab27b modulates alpha-synuclein spread and toxicity

**Authors: *R. N. UNDERWOOD**
Neurol., Univ. of Alabama At Birmingham, Birmingham, AL

**Abstract:** Alpha synuclein (αsyn) is the primary component of proteinaceous aggregates termed Lewy Bodies that pathologically define Parkinson’s Disease (PD). αSyn is hypothesized to

spread through the brain in a prion-like fashion by misfolded protein forming a template for aggregation of endogenous αsyn. The release and uptake of αsyn from cell to cell are essential processes for this prion-like spread. αSyn does not have a signal peptide for classical secretion and is thought to be released through non-classical secretion mechanisms regulated by a family of proteins called Rab GTPases. Rab27b is one of several GTPases essential to the endosomal-lysosomal pathway and is necessary for the proper localization of endosomal compartments. We have developed an *in vitro* doxycycline-inducible αsyn model in M17 neuroblastoma cells (termed ISYN cells). Induction of αsyn expression by doxycycline in ISYN cells causes a corresponding increase in the release of αsyn into the conditioned media (CM). When transferred to separately-cultured primary neurons, thisαsyn-enriched CM is toxic to these neurons. We found that upon αsyn induction Rab27b protein expression increased by ~2 fold in the ISYN cells. Similarly we observed a ~2 fold increase in Rab27b expression in the postmortem human brain lysates from PD patients compared to healthy controls. To examine the impact of Rab27b dependent pathways on αsyn release and toxicity, we knocked down Rab27b expression by lentiviral transfection of shRNA. shRNA knockdown of Rab27b decreased αsyn release into the CM by ~40%. Surprisingly, despite the reduction in αsyn release, CM from induced ISYN cells in which RAB27b was knocked down cells induced greater toxicity in separately cultured SH-SY5Y cells compared to control. These data indicate a potential role for Rab27b in the release and toxicity of αsyn and ultimately in PD pathogenesis.

**Abstract:** Parkinson’s disease (PD) is the second most common age-related neurodegenerative disorders with uncertain etiology worldwide. The hallmark of PD is the endogenous protein alpha-synuclein abnormal accumulation and progressively forms Lewy bodies within oligodendroglial cells leading to neuronal death. To date, no universal diagnostic biomarker and disease-modifying treatment are available for Parkinson’s disease. In this study, we aim to reveal a new method that could measure alpha-synuclein for potential PD diagnosis and map the

toxicity domain of alpha-synuclein. The Human alpha-synuclein full length and different fragments fusion proteins produced by *Escherichia coli*. All the fusion proteins were studied for aggregation progress. Proteins were studied also tested by the MTT assay for cytotoxicity. Here we investigated that the N-terminal 1-65 domain induced the aggregation of alpha-synuclein and increase the toxicity of alpha-synuclein. Aggregated alpha-synuclein were observed been dissociated by some organic solvent. This treatment method could be used for PD diagnosis as a potential application.

**Title:** Mesenchymal stem cells modulate seeding with vesicle-associated á-synuclein in Parkinson's disease

**Authors: S. OH**, *J.-H. PARK
Dept. of Neurosci., Mayo Clin., Jacksonville, FL

**Abstract:** Ample evidence suggests that α-synuclein (α-syn) is released from cells and propagated to others via cell-to-cell transmission. In terms of their prion-like behavior, α-syn propagation plays key roles in the pathogenesis and progression of α-synucleinopathies. We have found evidence to suggest that α-syn can form oligomers in the extracellular space that are associated with small extracellular vesicles (EVs) explaining the paradoxical clinical and research observations that α-syn can be found in grafted neurons in Parkinson’s disease (PD) patients after transplant, and broaching the possibility that α-syn-containing EVs could represent a mechanism for disease progression. Here, we isolated EVs from mid-frontal gyrus of neuropathologically confirmed Multiple system atrophy (MSA) brains or temporal gyrus of Dementia with Lewy bodies (DLB) brains and incubated EV particles with stable cells overexpressing reporters of α-syn oligomerization. EVs from DLB and MSA brain were capable of inducing α-syn aggregation and increasing phosphorylated α-syn compared to EVs from control brains.
Mesenchymal stem cells (MSCs) secrete various cytotropic factors, including neurotrophic growth factors, chemokines, cytokines, and extracellular matrix proteins which, in turn, exert neuroprotective effects on neighboring cells. Here we investigated if MSCs could exert a neuroprotective effect on cells treated with MSA or DLB brain exosomes. α-Syn stable cell lines treated with brain MSA or DLB exosomes and cocultured with MSCs for 24 hours had less α-

syn aggregation and decreased α-syn phosphorylation compared to exosome treated cells. Further investigation indicated that MSC coculture decreased uptake of EVs into cells. These data suggest that MSCs may inhibit α-syn transmission by blocking uptake of EVs containing α-syn, inducing a prosurvival effect, and halting the spread of pathology. Because MSCs exert neuroprotective properties by inhibiting α-syn transmission they may represent a potential target for disease-modifying therapies for PD.

**Title:** α-Synuclein on tau aggregation in synucleinopathies

**Authors: *U. SENGUPTA**[1], J. GERSON[2], N. PUANGMALAI[2], A. ELLSWORTH[2], N. BHATT[2], S. MCALLEN[2], M. CARRETERO-MURILLO[2], D. CASTILLO-CARRANZA[2], R. KAYED[2]
[1]Neurol., [2]Univ. of Texas Med. Br., Galveston, TX

**Abstract:** Neurodegenerative diseases are age-related disorders that are characterized by specific set of clinical symptoms and pathological hallmarks. Parkinson’s disease (PD), dementia with Lewy bodies (DLB) and multiple system atrophy (MSA) are the three major synucleinopathies, which are pathologically characterized by the accumulation of α-Synuclein protein into Lewy bodies and Lewy neurites. A growing body of evidence suggests that the intermediate aggregation state, oligomers, are the acutely toxic species, disrupting multiple cellular functions. Studies also suggest that soluble oligomers of pathogenic proteins self-propagate in a prion-like manner, thus spreading disease pathology. Neurodegenerative disease-associated pathogenic proteins often interact with one another and modulate downstream activities that disrupt their

normal functions. The co-occurrence of α-Syn and tau in multiple diseases suggests their orchestrated method of toxicity. Our laboratory and other groups have demonstrated that α-Synuclein cross-seeds tau protein, promoting its aggregation. We have previously demonstrated that PD and DLB brain tissues contain tau oligomers and they co-localize with α-Synuclein oligomers. In this study, I am investigating the ability of α-synuclein oligomers inducing tau aggregation, resulting in the formation of a disease specific aggregate. We observed that *in vitro* α-Synuclein oligomers induce tau to a more toxic aggregate. Additionally, co-aggregates of tau and α-Synuclein derived from PD (synucleinopathy) brain tissues demonstrated more toxicity than tau aggregates derived from progressive supranuclear palsy (PSP; tauopathy) brain tissue. Furthermore, we observed that brain-derived α-Synuclein oligomers are the toxic species, but the question remains as how they exert their toxicity. Thus, interactions between α-Synuclein, Tau and other amyloid proteins may be critical for the formation of disease-specific pathogenic aggregates, indicating multiple targets for disease-modifying therapeutics.

Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Accumulation of α-synuclein (α-syn) and tau aggregates are neuropathological hallmarks of Parkinson’s disease (PD) and Alzheimer’s disease (AD), respectively. Post-mortem brain investigations have reported co-morbid AD and PD in more than 35% of PD and 50% of AD patients. Interestingly, these patients show more severe motor and cognitive phenotypes and shorter disease durations, suggesting crosstalk between α-syn and tau. In addition to their coexistence in the human brain, α-syn and tau are both partially unfolded in their native states and capable of forming toxic oligomers or hetero-oligomers under pathological conditions. Previous studies have shown that α-syn and tau promote the fibrilization of one another in-vitro and in-vivo. However, the nuances of this deleterious feed-forward loop, in particular the consequence of each protein for the other, are poorly understood.
Here, we model co-morbid AD/PD pathology in-vitro and in-vivo. While previous studies have

shown the ability of exogenously applied α-syn and tau to seed and promote spreading in-vivo, we show increased accumulation and spreading of α-syn and tau aggregates in a co-pathology induced scenario. Our data points to a synergistic effect of α-syn on tau in different models and we explore the underlying mechanism that might be implicated in potentiating α-syn effect on tau.

**Abstract:** Parkinson's disease (PD) is the second most common neurodegenerative disease. Central to PD is the extensive and progressive loss of dopamine (DA) neurons in the substantia nigra and the subsequent depletion of striatal DA. This loss results in the cardinal symptoms, bradykinesia, resting tremor, and rigidity that are limited to only symptomatic treatment. Evidence show remaining DA neurons stain positively for alpha-synuclein (aSyn)-rich Lewy bodies, implicating aSyn in PD. Furthermore, aSyn can undergo aggregation, particularly under conditions of oxidative stress, forming neurotoxic oligomers. Data from our lab, and others, suggest toxic biogenic aldehydes may also play a pivotal role in PD. Mice deficient in aldehyde dehydrogenases, Aldh1a1 and Aldh2, result in an aldehyde load with elevated levels of the dopamine aldehyde, 3,4-dihydroxyphenylacetaldehyde (DOPAL), and the lipid peroxidation end product, 4-hydroxynonenal (4HNE). As a result, these mice display degeneration of tyrosine hydroxylase-immunoreactive neurons and deficits in motor performance. Importantly, *in vitro* studies suggest both DOPAL and 4HNE are capable of stabilizing toxic αSyn oligomers. However, the interaction of biogenic aldehydes with aSyn *in vivo* is lacking. The selective generation of DOPAL in dopamine neurons and the ability of DOPAL and 4HNE to stabilize

neurotoxic αSyn oligomers, led us to hypothesize that, αSyn is mechanistically related to the neurochemical and behavioral manifestations of PD that result from elevated biogenic aldehydes. To test this hypothesis, we generated mice deficient in Aldh1a1 and Aldh2 crossed them to mice that overexpress the human wildtype αSyn. We found that overexpression of αSyn in the presence of elevated levels of DOPAL was associated with increased expression of neuroinflammatory markers and exacerbation of deficits in motor performance. The results of neurochemical assays and treatments will be discussed.

**Title:** Regulation of α-synuclein expression in Parkinson′s disease by locus-specific epigenetic remodeling of SNCA

**Authors: *S. GUHATHAKURTA**, E. ADLER, S. BASU, G. JE, L. ADAMS, Y.-S. KIM
Burnett Sch. of Biomed. Sciences, UCF Col. of Med., Univ. of Central Florida, Orlando, FL

**Abstract:** Histone post-translational modifications (PTMs) are the major epigenetic regulators of gene expression in the cell. Perturbation in epigenetic regulation of α-synuclein encoding gene (*SNCA*) plays significant role in pathogenesis of Parkinson′s disease (PD). Enhanced transcription of *SNCA* leading to production of higher amount of protein, has been linked with severity and early onset of the disease. Epigenetic deregulation also relates to generation of higher transcript and has been shown to be associated with PD.
Two important histone marks that regulate transcriptional activation or repression of gene are histone H3 lysine 4 trimethylation (H3K4me3) and H3 lysine 27 trimethylation (H3K27me3). In the NIH Roadmap epigenomics data from adult human substantia nigra (SN), it was shown that H3K4me3 is heavily enriched at transcriptionally important regions of *SNCA* along with a relatively less enrichment of H3K27me3 at the same region. In spite of its significant implication in regulation of *SNCA*, nothing has been studied so far to demonstrate their role. Remarkably, we found that normal balance between H3K4me3 and H3K27me3 is disrupted in PD brain samples with significantly higher occupancy of H3K4me3 at regulatory areas of *SNCA*. Moreover, the higher level of α-synuclein in the patients is positively correlated with this higher enrichment of permissive H3K4me3. This finding has also been replicated in PD patient-derived iPSCs. Modulation of this histone mark by overexpressing their specific histone lysine demethylase, JARID1A led to significant alteration in α- synuclein in the cell. Based on these strong scientific

premises, our objective is understand whether deregulated expression of α-synuclein in PD is mainly contributed by perturbation in the occupancies of H3K4me3 at *SNCA*. Recent advancement in CRISPR technologies has made it possible to alter gene-specific epigenetic environment without disturbing entire cellular epigenome. Using SunTag system, multiple molecules of JARID1A was recruited at the promoter of *SNCA* to effectively reduce the H3K4me3 from there. Removal of H3K4me3 reduced α-synuclein expression in the cell. Additionally, H3K4me3 was enriched more at *SNCA* promoter under oxidative stress in neuronal cells, which also supported higher expression of α-synuclein. The locus-specific removal of H3K4me3 under oxidative stress was able to control α-synuclein expression at basal level. This study has identified a novel epigenetic mechanism towards deregulated expression of *SNCA* in PD. It also paved a new strategy for locus-specific regulation of gene expression by employing novel epigenetic modulation.

**Title:** Alpha-synuclein deregulates the expression of COL4A2 and impairs ER-Golgi function

**Authors: *T. F. OUTEIRO**[1], I. PAIVA[2]
[2]Exptl. Neurodegeneration, [1]Univ. Med. Ctr. Goettingen, Goettingen, Germany

**Abstract:** Alpha-synuclein (aSyn) is the major protein component of Lewy bodies and Lewy neurites, the typical pathological hallmarks in Parkinson’s disease (PD) and Dementia with Lewy bodies. aSyn is capable of inducing transcriptional deregulation, but the precise effect of specific aSyn mutants associated with familial forms of PD, remains unclear. Here, we used transgenic mice overexpressing human wild-type (WT) or A30P aSyn to compare the transcriptional profiles of the two animal models. We found that A30P aSyn promotes strong transcriptional deregulation and increases DNA binding. Interestingly, COL4A2, a major component of basement membranes, was found to be upregulated in both A30P aSyn transgenic mice and in dopaminergic neurons expressing A30P aSyn, suggesting a crucial role for collagen related genes in aSyn-induced toxicity. Finally, we observed that A30P aSyn alters Golgi morphology

and increases the susceptibility to endoplasmic reticulum (ER) stress in dopaminergic cells. In total, our findings provide novel insight into the putative role of aSyn on transcription and on the molecular mechanisms involved, thereby opening novel avenues for future therapeutic interventions in PD and other synucleinopathies.

**Abstract:** c-Abl is a nonreceptor tyrosine kinase that is activated in human Parkinson’s disease (PD) brain and in α-synuclein mouse models of PD. c-Abl phosphorylates α-synuclein and inhibits Parkin’s ubiquitin ligase activity, both of which promote α-synuclein aggregation. Disruption of cell redox state - e.g. by exogenous toxins, mitochondrial dysfunction, or impaired oxidant scavenging - is also known to drive pathogenesis in PD. Here we show that α-synuclein aggregates induce c-Abl activation by a mechanism involving disruption of cell redox state. Studies in primary cortical neurons were performed to evaluate the role of α-synuclein mediated stress in c-Abl activation. Incubation with human alpha synuclein fibrils (hu-synPFF) induced both oxidative stress and c-Abl activation in these cultures as measured by western blotting and immunocytochemistry. Co-treatment with N-acetyl cysteine, which promotes glutathione formation, suppressed both oxidative stress and c-Abl activation. Effects of glutathione depletion were evaluated in the $EAAT3^{-/-}$ mouse, which has reduced glutathione levels selectively in neurons. Neurons in these mice showed increased level of c-Abl activation, which was reduced back to normal by addition of N-acetyl cysteine to drinking water. These results suggest that oxidative stress induces c-Abl activation in PD brain, that α-synuclein aggregates contribute to the oxidative stress, and that treatment with thiol repletion agents such as N-acetyl cysteine can effectively prevent c-Abl activation. NAC may thus be a viable alternative to direct c-Abl inhibitors as a therapeutic agent, as NAC can cross the human BBB and does not have the toxicities associated with direct c-Abl inhibitors.

**Title:** Molecular linking of influenza infection to cellular pathology of protein misassembly: The case of alpha-synuclein

**Authors: *C. KORTH**[1], R. M. MARREIROS[2]
[1]Heinrich Heine Univ. Dusseldorf, Dusseldorf, Germany; [2]Dept. of Neuropathology, Heinrich Heine Unive, Düsseldorf, Germany

**Abstract:** **Appeal:** There have been repeated reports [1] describing that viral infection of the brain may be linked to triggering neurodegenerative diseases. The influenza pandemic 1916-1926 led to a significant number of cases of post-encephalitic Parkinsonism and individuals born during that time had an increased risk of developing Parkinson's disease (PD). Our main hypothesis is that influenza infection leads to impairments of cellular proteostasis affecting aggregation of alpha-synuclein (α-Syn) underlying PD. **Background:** Neurodegenerative diseases are associated with disrupted proteostasis and hallmarked by deposits of disease-specific proteins such as Lewy-bodies consisting of α-Syn in PD, extracellular beta-amyloid plaques and intraneuronal tangles of hyperphosphorylated tau in Alzheimer's disease, or TDP-43 aggregates in amyotrophic lateral sclerosis. During acute phases of infections with neurotropic viruses, neurological symptoms can occur, however the long-term effects can persist after the main infection is over. Previous studies with human post-mortem brains and rodent models suggested an association of influenza infection with molecular hallmarks of PD [1,2]. In the present study, Human dopaminergic neurons were used as an *in vitro* model to study the disturbances in the cell proteostasis that leads to α-Syn aggregation after influenza infection. **Methods:** Differentiated Lund Human MESencephalic cells were infected with the WSN33 influenza (H1N1 strain). The effect of viral infection was investigated by immunocytochemistry, biochemical and functional assays. Immunohistochemistry in a Rag-/- mice infected for 28 days with WSN33 influenza was performed. **Results:** Influenza infection of dopaminergic neurons triggered α-Syn aggregation, which was not the case for control proteins like TDP-43. Appearance of α-Syn aggregates was dependent on the viral infections titer. Functional consequences of influenza-induced α-Syn misassembly will be reported, as well as our investigations on which cellular pathways are

targeted by influenza infection that lead to α-Syn aggregation. In infected mice with Influenza virus, increased α-Syn expression and deposition was visualized in the brain regions where virus was present. **Conclusions:** We conclude that influenza virus assembly by host factors interfers in a direct way with cellular pathways that regulate α-Syn proteostasis and thus demonstrate a novel molecular mechanism of how viral infection may trigger neurodegenerative disease.

**Title:** Prefrontal d1 dopamine-receptor neurons and delta resonance in interval timing

**Authors: *Y.-C. KIM**[1], N. S. NARAYANAN[2]
[1]Neurol., Univ. of Iowa, Iowa City, IA; [2]Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

**Abstract:** Prefrontal neurons expressing D1-type dopamine receptors (D1DRs) are critical for cognitive processes such as working memory, flexibility, and timing, leading to the hypothesis that these neurons directly encode cognitive processing. During timing tasks, one form this cognitive processing might take is time-dependent ramping activity — monotonic changes in firing rate over time. Thus, we hypothesized the prefrontal D1DR+ neurons would strongly exhibit time-dependent ramping during interval timing. We tested this idea using an interval-timing task in which we used optogenetics to tag D1DR+ neurons in the mouse medial frontal cortex (MFC). While 23% of MFC D1DR+ neurons exhibited ramping, this was significantly less than untagged MFC neurons. By contrast, MFC D1DR+ neurons had strong delta-frequency (1-4 Hz) coherence with other MFC ramping neurons. This coherence was phase-locked to cue onset and was strongest early in the interval. To test the significance of these interactions, we optogenetically stimulated MFC D1DR+ neurons early vs. late in the interval. We found that 2-Hz stimulation early in the interval was particularly effective in rescuing timing-related behavioral performance deficits in dopamine-depleted animals. These findings provide insight into MFC networks and have relevance for disorders such as Parkinson’s disease and schizophrenia.

**Authors: *A. SINGH**[1], A. ESPINOZA[1], D. JUNG[1], N. S. NARAYANAN[2]
[1]Univ. of Iowa, Iowa City, IA; [2]Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

**Abstract:** Non-invasive neuromodulation techniques such as transcranial magnetic stimulation (TMS) is important tools in cognitive and motor neuroscience because this method is able to reveal the relevance of certain neuronal activity patterns for a given brain function. It is feasible to combine TMS with electrophysiological techniques (electroencephalography; EEG). Scalp EEG recordings can guide TMS neuromodulation approach, providing the required information to optimize when to stimulate the target brain structure. This approach can close the loop between measuring the real-time brain activity and modulating brain signals with stimulation. Motor cortical beta band oscillations are thought to be crucial component of motor encoding. To understand the role of these oscillations in normal or movement disorders motor system, computation of instantaneous amplitude and phase are required. Phase of the identified oscillation could be a better approach to modulate its pattern. Here, we exploited the benefits of phase-locked adaptive TMS to improve motor performance. Scalp EEG recording were collected in normal subjects during key-board pressing task while TMS was delivered at GO cue in-phase (90 or 270 degree) to beta (13-30 Hz) oscillation recorded from the motor cortex. Results showed that phase-locked stimulation improved motor task performance as compared to random phase-locked or sham stimulation. We present here a proof-of concept evaluation that adaptive phase-locked stimulation could be an effective approach to modulate brain activity and to induce behavioral effects.

**Title:** Targeting frontostriatal circuits to rescue prefrontal dysfunction during interval timing

**Authors: *E. EMMONS**[1], B. J. DECORTE[2], N. S. NARAYANAN[3]
[2]Neurosci., [1]Univ. of Iowa, Iowa City, IA; [3]Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

**Abstract:** Prefrontal dysfunction and cognitive impairment are common in human diseases such as schizophrenia but remain untreatable. Information processing in the prefrontal cortex and its primary subcortical target, the striatum, are central to this problem. We approach this knowledge gap by using an interval-timing task, which involves working memory and attention. Previous work from our lab has found evidence of robust temporal activity in rodent medial frontal cortex (MFC) and dorsomedial striatum (DMS) during interval-timing behavior. One possible form of temporal activity at the neuronal level is that of "time-dependent ramping" activity. Our lab has found that temporally-guided behavior and DMS ramping activity both depend on the MFC. To further probe the role of these circuits in interval timing, we asked whether optogenetic stimulation of frontostriatal circuits could compensate for impaired timing behavior. Here, we bilaterally injected a viral vector expressing ChR2 optogenetic protein in the MFC. Animals were also implanted with an optrode (integrated microwire electrode and fiberoptic cannula) in the DMS and bilateral infusion cannulae in the MFC. After waiting 4 weeks for viral expression, we optogenetically stimulated MFC to DMS projection terminals with 473-nm light during the interval-timing task. In order to model "prefrontal dysfunction" and impair timing behavior, we inactivated the MFC with muscimol (a $GABA_A$ agonist). On subsequent days, we experimented with different parameters of frontostriatal-projection stimulation while the MFC was either active or inactive. We tested three conditions of optogenetic stimulation: no stimulation, 2-Hz stimulation, and 20-Hz stimulation. As described above, MFC inactivation impaired behavior on the interval-timing task. Surprisingly, we were able to rescue this impairment with frontostriatal 20-Hz stimulation but not with 2-Hz stimulation or no stimulation. This finding suggests that frontostriatal circuits are essential to basic cognition and that information processing may occur in specific frequency domains. These data help elucidate the role of frontostriatal circuits in cognitive processing and could guide strategies to compensate for prefrontal dysfunction in human disease.

**Title:** Differential parkinsonian deficits and basal ganglia output in stimulus-guided and memory-guided movements

**Authors: *A. TEKRIWAL**[1], M. J. LINTZ[2], J. A. THOMPSON[3], G. FELSEN[4]
[1]Dept. of Physiol. and Biophysics; Dept. of Neurosurg., [2]Dept. of Psychiatry, [3]Dept. of Neurosurg., [4]Dept. of Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

**Abstract:** Parkinson's disease (PD) is a progressive neurodegenerative disorder caused by loss of dopaminergic neurons (DANs) in the basal ganglia (BG). The link between loss of DANs and onset of PD motor symptoms is well substantiated; however, the degree of impairment depends on the context of the movement (e.g., whether it is habitual). Although well documented in the clinical literature, the underlying neural mechanism leading to some movements being more impaired than others is not well understood. To investigate, we record neural activity from BG output nuclei of hemi-PD and control mice trained on a two-alternative forced choice task. We elicited unilateral DAN loss via 6-hydroxydopamine infusion into the left substantia nigra pars compacta. To acquire neural recordings, we implanted drivable tetrodes into a principal output nucleus of the BG, the substantia nigra pars reticulata (SNr), ipsilateral to DAN loss. Control mice were similarly implanted. We compared behavior and neural activity between two conditions requiring otherwise-equal orienting movements: stimulus-guided or memory-guided. Under the stimulus-guided condition, the direction of movement (left vs. right) was selected based on the identity of the stimulus. Under the memory-guided condition, the direction of movement was selected based on recent history of movements (left vs. right) and whether they were rewarded. Blocks of stimulus-guided and memory-guided trials were interleaved within the behavioral session, allowing for within-session comparisons of behavior and neural activity between the two conditions. We hypothesized that the BG differently process memory-guided and stimulus-guided movements. Consistent with this hypothesis, we found that DAN loss led to greater behavioral impairment on stimulus-guided than on memory-guided trials. We predict that this behavioral difference will be reflected in altered movement-related SNr activity between the

two conditions. In control mice, we found that SNr activity depended more strongly on movement direction (i.e., activity was more direction selective) in memory-guided than stimulus-guided trials. We are currently analyzing neural data in mice with DAN loss. We expect that, in memory-guided trials, direction selectivity of SNr activity in hemi-PD mice will resemble that recorded in control mice, while in stimulus-guided trials, direction selectivity will be weaker in hemi-PD mice than in control mice. Ultimately, these studies will contribute to elucidating how the BG control different forms of movement under normal and pathological conditions.

**Title:** The effect of alpha-synuclein overexpression on calcium dynamics and dendritic spines in cortical neurons

**Authors: *G. M. ALDRIDGE**[1], C. A. WARWICK[2], S. M. NATHWANI[2], Y. M. USACHEV[3], N. S. NARAYANAN[4]
[1]Neurol., [2]Univ. of Iowa, Iowa City, IA; [3]Dept Pharmacol, Univ. of Iowa Dept. of Pharmacol., Iowa City, IA; [4]Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

**Abstract:** Lewy Body dementias, which include Parkinson's disease dementia (PDD) and Dementia with Lewy Bodies (DLB), are characterized by intracytoplasmic protein accumulations. These "Lewy Bodies" consist mainly of alpha-synuclein, and in Lewy Body dementia are often found in cortical neurons. While overexpression of alpha-synuclein in patients with genetic multiplications is associated with these diseases and leads to Lewy body accumulation, it is not known whether overexpression of alpha-synuclein directly affects neurons in the cortex. There is also evidence that alpha-synuclein can alter calcium dynamics in neurons in culture, but it is unknown if this mechanism leads to pathologic changes in vivo. We hypothesize that overexpression of alpha-synuclein has a direct effect on calcium homeostasis, leading to altered spine turnover and abnormal calcium dynamics. To test this hypothesis, we are utilizing an AAV-6 viral vector coding for full length human alpha-synuclein to induce targeted overexpression of this protein locally in the prefrontal cortex of adult mice. Furthermore, by using a P2A linker, mCherry protein is co-expressed in neurons expressing alpha-synuclein, allowing us to examine infected and neighboring neurons in vivo during live animal imaging.

Our preliminary data in post-mortem animals 3 months after viral injection shows that overexpression of alpha-synuclein leads to alterations in dendritic spine number and morphology, with the effect modulated by cortical layer. To test the hypothesis that overexpression of alpha-synuclein leads to calcium abnormalities in vivo, we have injected viral vector into mice genetically expressing gCAMP6s in cortical neurons. We then implant a cortical window to allow live animal, awake, in vivo, 2-photon imaging of calcium dynamics in freely-walking, but head fixed mice. We are able to examine calcium dynamics both in cell bodies of layer 2/3 cortical neurons, as well as subcellular calcium dynamics of spines and boutons in layer 1. These experiments will help determine whether local overexpression of alpha-synuclein, which is causative of disease in human patients, can induce pathology through direct action at cortical neurons.

[1]Neurobio., [2]Technion Med. Sch., Haifa, Israel; [3]Electrical Engin., Technion, Haifa, Israel

**Abstract:** Parkinson's Disease (PD) is a common neurodegenerative disease, which markedly disrupts motor performance. The basal ganglia, the main brain system affected by PD, exert their physiological effects mostly by modulating neocortical activity via the cortico-basal ganglia loop. In the cortico-basal ganglia loop data is streamed from the neocortex to the striatum, processed along several parallel pathway, to finally sent back to the neocortex to modulate the activity of the neocortical network. The primary motor cortex M1, and especially layer-5 pyramidal tract (PT) neurons, integrate data from multiple brain regions, including the cortico-basal ganglia loop, to generate motor output commends that are transmitted to the brain stem and spinal cord. Thus, although PD primarily targets the basal ganglia, the motor consequences of cortico-basal ganglia disruption leading to motor disability must be mediated by impairment of the M1 network dynamics. Based on these assumptions, in this study we took a novel M1 centric approach to study PD focusing on the primary motor cortex. After training our head fixed mice

to perform a complicated motor task, hand reaching for food pallets, we monitored the activity of multiple neurons in layers 2-3 and 5 using two photon in-vivo imaging of GCaMP6 expressing pyramidal neurons in head fixed awake behaving mice. Experimental PD was induced by injection of 6 hydroxydopamine (6OHDA) into the striatum. Our findings show that experimental PD dramatically disrupts both motor behavior and the activity dynamics of M1 neurons. Changes in the cortical dynamics in M1 were seen both at the level of individual neurons, as well as at the cortical network level. Moreover, PD resulted in disruption of the network dynamics in both layers 2-3 and layer 5 of M1. These findings shed new light on the mechanisms underlying motor disabilities in PD, and identifies novel potential therapeutic targets in PD.

**Abstract:** Parkinson's disease (PD) is a severe neurodegenerative disorder characterized by progressive loss of dopaminergic neurons. Administration of the dopamine precursor levodopa helps restore dopamine levels in the striatum - the brain region targeted by dopamine neurons - and thereby ameliorates motor symptoms in PD patients. However, as the disease progresses, the efficacy of levodopa decreases and leads to uncontrolled motor side effects known as dyskinesia. While several models have been proposed to explain how loss of dopamine affects downstream striatal circuits, technical limitations have prevented direct and simultaneous observation of striatal neuron populations in vivo during disease progression. Using two-photon $Ca^{2+}$ imaging in awake behaving mice, we simultaneously monitored the activity of striatal direct and indirect pathway neurons over the course of weeks under control conditions, following 6OHDA-mediated loss of dopamine neurons and upon levodopa-induced dyskinesia. Our work sheds light on the aberrant circuit dynamics that develop in the striatum during the progression of parkinsonism and dyskinetic episodes, and forms the basis for future experiments aimed at better alleviating PD symptoms.

**Abstract:** Parkinson's disease (PD) is characterized by the progressive loss of dopamine in the basal ganglia that drastically alters circuit physiology and motor function. Individuals with PD do not develop motor symptoms until late stages of the disease. This robustness of motor function is thought to reflect compensatory changes within the basal ganglia or dopamine system. But most studies of compensatory plasticity have focused only on the input stage of the basal ganglia, with little information about how or if compensation impacts the progression of pathophysiology in basal ganglia output. To assess how basal ganglia output pathophysiology progresses under different compensatory conditions, we recorded from basal ganglia output neurons in the substantia nigra pars reticulata (SNr) during progressive dopamine loss induced at rates of 3 days - 6 months using toxin or neurodegenerative models. Because compensatory changes within the basal ganglia can take several days to weeks to stabilize, slow dopamine depletions provide more time for compensatory mechanisms to engage than rapid depletions. In vivo recordings from SNr were performed in awake, head-restrained mice at various stages of progressive dopamine loss. Surprisingly, we found that independent of the time course or mechanism of dopamine depletion, SNr pathophysiology developed at early stages of dopamine loss, when as little as ~20-40% of dopamine had been lost. The nature and severity of these pathophysiological changes, including reduced firing rates, increased firing irregularity, bursting, and synchrony, were largely independent of the mechanism or duration of dopamine depletion, and emerged well before the onset of motor symptoms. These results challenge long-standing assumptions about the role of compensatory plasticity within the basal ganglia and suggest that circuit compensations leading to the robustness of motor function occur at sites outside of the basal ganglia.

**Title:** Responses of the substantia nigra pars reticulata to synaptic inputs from the direct and indirect pathways: A computational modeling study

**Authors: *R. S. PHILLIPS**[1], A. H. GITTIS[2], J. RUBIN[1]
[1]Dept. of Mathematics, Univ. of Pittsburgh, Pittsburgh, PA; [2]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

**Abstract:** The substantia nigra pars reticulata (SNr) serves as the primary output nuclei of the rodent basal ganglia (BG). Multiple synaptic input streams are integrated within the SNr, as it is targeted by synaptic excitation from the subthalamic nucleus and synaptic inhibition from direct pathway striatal neurons and indirect pathway globus pallidus (GP) neurons. Due to the convergence of these synaptic inputs, the SNr is well position to transfer pathological BG activity to downstream targets. Consistent with this idea, the SNr develops abnormal levels of burst firing in dopamine depleted (DD) conditions that is associated with behavioral impairments. Despite these important roles, computational modeling of the SNr has been limited. In this work, we developed a conductance-based differential equation model of SNr neurons. The model was tuned to reproduce key experimental observations including increased spike rates under apamin application and enhanced irregularity under block of TRPC3 channels known to exist in mouse SNr. With this data-based calibration, the model serves as a resource that we are using to test hypotheses about possible mechanisms underlying several recent findings on SNr from the literature and from the Gittis lab. First, in a version of the model including dendritic and somatic compartments to represent different sites of synapses from striatum and GP, we consider the diversity of experimentally observed SNr responses to synaptic inputs. In particular, we test four distinct proposed mechanisms to explain the paradoxical increases in SNr activity, and generally heterogeneous responses across the SNr population, following optogenetic activation of inhibitory synapses emanating from GP neurons. Second, by including short-term depression and tracking chloride concentration and potassium-chloride pump activity in the model, we provide a possible explanation for remarkable motor rescue experiments in akinetic DD mice published by the Gittis lab, in which multiple minutes-long epochs of optogenetic stimulation targeting various GP neuronal subpopulations could, for some targets but not others, lead to hours-long motor recovery associated with diminished burstiness in SNr.

**Title:** Disruption of homeostasis of the Basal Ganglia circuit in Parkinson's disease

**Authors: J. SCHMALZ**, *G. KUMAR
Chem. and Materials Engin., Univ. of Idaho, Moscow, ID

**Abstract:** We developed a computational model of the basal ganglia circuit that integrates chemical-level description with the electrical-level description of the basal ganglia dynamics to investigate the dynamical transition from the healthy state to the Parkinson's Disease (PD) state as a function of the depletion of dopamine neurons. A recent hypothesis in PD suggests that the beta-oscillation in the subthalamic nucleus (STN) arises from an imbalance in the direct and indirect pathways that originate in the striatum of the BG. The disruption of the striatum homeostasis creates an imbalance in the activity of neurons in the direct and indirect pathway, which are the D1 and D2 medium spiny neurons (MSNs), respectively. Recent experimental data suggests that the asymmetric activity of the D1 and D2 medium spiny neurons (MSNs) may be due to a combination of factors, such as, a difference in the dopamine binding concentration of D1 and D2 receptors, the excess release of acetyl choline, and the different muscarinic (acetyl choline) receptors on the MSNs. Based on these experimental results, we expanded the existing multi-compartment model of basal ganglia by including detailed chemical-level descriptions of dopamine and acetyl choline dynamics in the striatum as well as the projection of dopamine neurons from the substantia nigra (SN) to the striatum. To simulate the progression of PD, neurons in the SN were sequentially removed from the BG network. A key finding of this work is the emergence of beta-oscillation in the STN upon removal of SN dopamine from the healthy BG model. Our computational model of the BG shows that the removal of dopamine neurons results in a neurochemical imbalance in the striatum that disrupts the overall homeostasis of the BG. The neurochemical imbalance leads to an asymmetric activation of the direct and indirect pathways and drives the BG network from the healthy state to the PD state.

**Authors: *T. IKUTA**, T. C. MYERS, M. C. INGE, A. W. COCHRAN
Communication Sci. and Disorders, Univ. of Mississippi, University, MS

**Abstract:** The dorsolateral prefrontal cortex (DLPFC) has been found to be downregulated in Parkinson’s disease (PD). Transcranial stimulation has been shown to improve balance, functional mobility, and problem solving performance in PD. The DLPFC is one of the cortical regions significantly affected by PD. However, the underlying mechanism of DLP hypofunction is not clear, especially in the context of the progression of the disease. In this study, we sought to elucidate functional connectivity reduced through the course of PD. We used resting state functional magnetic resonance imaging (rsfMRI) data from Parkinson's Progression Markers Initiative. Sixty-one patients (60.2±10.36 years old) had two sessions (15.59±5.96months apart) of rsfMRI data, and we analyzed them in a pairwise fashion to examine the longitudinal change of DLPFC functional connectivity. In a whole brain voxel-wise analysis, the right DLPFC showed significant decrease in its connectivity to the posterior cingulate cortex (PCC) and precuneus (corrected $p<0.05$). The PCC and precuneus are both a part of the default mode network. The current finding may suggest that influence of the default mode network to the DLPFC is reduced as the PD progresses. Connectivity between the DLPFC & PCC and between the DLPFC & precuneus may predict executive function, problem solving, balance, and functional mobility. Finding behavioral correlates of the functional connectivity would reveal the symptoms for which the reduced connectivity underlies.

**Authors: *E. BRAZHNIK**, N. NOVIKOV, M. W. PRESTON, Jr, A. R. WEISS, A. J. MCCOY, J. R. WALTERS
Neurophys/Pharmacol Section, NIH NINDS, Bethesda, MD

**Abstract:** Loss of dopamine and associated excessive beta frequency synchronization in the basal ganglia (BG)-cortical motor circuits in both Parkinson's disease (PD) patients and animal models of PD are thought to contribute to parkinsonian motor dysfunction. However, the neural mechanisms and circuitry underlying these oscillations remain uncertain. Recently, we reported that synchronized activity in the substantia nigra pars reticulata (SNpr) of hemiparkinsonian rats entrains activity in the ventromedial thalamus (VM) and promotes the transmission of 25-35 Hz oscillations throughout BG-thalamocortical circuits (Brazhnik et al., 2016). The parafascicular thalamic nucleus (PF) receives inputs from the BG, cortex, and cerebellum and provides

feedback to the subthalamic nucleus (STN) and striatum (STR) and thus could be implicated in the pathophysiology of PD. Unlike the VM, however, exaggerated beta oscillations are not evident in recordings from the PF in the behaving, hemiparkinsonian rat. Instead, our latest results call attention to the potential role of PF output in tonic modulation of STR and STN activity and support the idea that reductions in PF activity may have a therapeutic effect on motor dysfunction in PD (Brazhnik et al., SFN Abst. 2015, 2017). In the present study, two groups of hemiparkinsonian rats received infusion of different inhibitory DREADD viruses into the PF: AAV2-hSyn-hM4D(Gi)-mCherry (hM4D, n=10) to inhibit PF output and AAV8-hSyn-dF-HA-KORD-IRES-nCitrine (KORD, n=3) to selectively inactivate striatal projections from the PF. Recording electrodes were implanted targeting motor cortex (MCx), STR, and SNpr. Histological analyses revealed modest DREADD virus expression in the PF with some spread to surrounding areas. Similar to previous studies, exaggerated high beta power in the MCx and SNpr and coherence between these regions were observed during treadmill walking. At 3-4 weeks post-surgery, clozapine-N-oxide (1-5 mg/kg, ip.) and salvinorin B (1-2 mg/kg, sc.), both of which activate the receptors expressed by the corresponding DREADD virus, substantially improved circular treadmill walking in the clockwise direction without modifying cortical or nigral high beta oscillations. Results suggest that selective inactivation of PF terminals in the STR reduces motor deficit in a rodent model of PD. Ongoing DREADDs experiments are further exploring the contribution of the PF to high beta oscillations in BG-cortical motor circuits as well as spiking activity in the STR, SNpr, and MCx during treadmill walking.

**Abstract:** Recent work has shown that Cross-Frequency Coupling (CFC) is generated in several brain circuits with different architectures, and is associated with various physiological and pathological conditions. In particular, Phase-Amplitude Coupling (PAC), observed in oscillatory neuronal activity, is an important variant of the CFC phenomenon, in which the amplitude of a higher frequency band is modulated by the phase of another band with a lower frequency content. The PAC phenomenon has been reported in many frequency ranges using various techniques for recording neuronal activity and algorithms for the quantification of the CFC. In Parkinson's disease (PD), beta-gamma PAC has been observed in the local field potentials in the primary motor cortex. It has been found that it is exaggerated compared to patients without movement disorders. The reported evidence suggests that this excessive coupling is probably a manifestation of an excessive synchronization in the basal ganglia and may be related to motor dysfunction in PD. Although several works support the association of PAC with the parkinsonian state, the origin of PAC in this context has been poorly explored. In this work, we investigate the generation of PAC in models of neuronal populations whose architecture has already been proposed for the generation of pathological oscillations associated with PD. Our model is composed of three populations. They represent the motor cortex, sub thalamic nucleus (STN) and external globus pallidus (GPe). The interaction among these populations gives rise to an architecture that incorporates the hyperdirect, direct, indirect and STN-GPe loops. To describe and quantify PAC in different conditions, we have characterized, in the parameter space, the behavior of the oscillations using the Phase Locking Value (PLV), which characterizes plain PAC, and Time Locked Index (TLI), which quantifies the presence of harmonics. We have found two situations. In the first one the appearance of PAC is linked to a Hopf-Hopf bifurcation. In this case high values of PLV are associated with high values of TLI, indicating that PAC is generated by the harmonics in the non-sinusoidal shape of the waveform. In the second case PAC is associated with a secondary bifurcation by which a system that is already oscillating generates an additional frequency. In this case we obtain high values PLV and low values of TLI. This corresponds to the case of a sinusoidal waveform modulated in amplitude by a slower frequency. These results show that the proposed architecture can lead to different types of PAC. Both are linked to the dynamics of interacting populations and are informative regarding the conditions of the system.

**Title:** CSF proteins and longitudinal functional connectivity network changes in Parkinson's disease

**Authors: *M. C. CAMPBELL**[1], J. JACKSON[3], A. SNYDER[2], P. KOTZBAUER[1], J. PERLMUTTER[1]
[1]Neurol., [2]Radiology, Washington Univ. Sch. of Med., Saint Louis, MO; [3]Psychological and Brain Sci., Washington Univ. in St. Louis, Saint Louis, MO

**Abstract: Background:** Parkinson disease progression reflects ongoing pathological proteinopathy and deficits in multiple neurotransmitter systems. Resting-state functional connectivity, as a measure of brain function, may provide a non-invasive marker of Parkinson disease progression.
**Objective:** The present study examined the relationship between baseline CSF protein levels and longitudinal changes in cortical resting-state functional connectivity networks in Parkinson disease participants compared to healthy controls.
**Methods:** Non-demented Parkinson disease (N = 64) and control (N = 27) participants completed longitudinal resting-state magnetic resonance imaging scans and clinical assessments. Participants also completed baseline lumbar punctures for CSF protein levels. Parkinson disease participants completed neuroimaging and behavioral testing after overnight withdrawal (OFF) of Parkinson disease medications.
**Results:** Functional connectivity within the sensorimotor network and the interaction between the dorsal attention network with the frontoparietal control network significantly decreased over time in Parkinson disease participants. Baseline CSF alpha-synuclein protein levels predicted decline in the sensorimotor network.
**Conclusions:** These results indicate that cortical motor and association network functional connectivity declines over time in Parkinson disease prior to dementia onset. Further, brain protein levels may contribute to longitudinal declines in functional connectivity networks.

**Abstract:** Rest tremor is one of the most common and disabling symptoms of Parkinson's Disease (PD). There is good evidence that rest tremor may have a pathophysiology different from most other PD symptoms. To date, the pathophysiology of rest tremor is not clearly established. Understanding the neural origin of parkinsonian rest tremor will help us not only to optimize the existing treatment strategies such as Deep Brain Stimulation but also to develop alternative treatment strategies for rest tremor reduction. There are broadly two categories of theories that are gaining prominence to explain the origin of Parkinsonian rest tremor. The first category is the Central Oscillator Theory (COT) which proposes that the rest tremor is driven by oscillatory signals originating from the brain. These could be produced either by a nucleus with spontaneous rhythmicity or by instability in the local (central) feedback loop consisting of neuronal populations or different nuclei and their axonal connections in the brain. The second category is the Feedback-induced Instability Theory (FIT) which proposes that the rest tremor is a limit-cycle oscillation that occurs due to feedback-induced instability in the sensorimotor loop caused by increased response time (delay in the sensorimotor loop). We attempt to contrast these theories with the help of elementary simulation examples and compare the simulation trends with established clinical observed trends.

**Title:** Blocking GABAergic input to the subthalamic nucleus improves motor deficits and modulates beta burst activity in the motor cortex of the hemiparkinsonian rat

**Authors: *M. W. PRESTON, JR**, H. BERMUDEZ CABRERA, N. NOVIKOV, J. R. WALTERS
Neurophysiological Pharmacol. Section, NIH NINDS, Bethesda, MD

**Abstract:** Parkinson's disease (PD) is characterized by the progressive loss of dopamine (DA) neurons in the basal ganglia (BG), and is associated with abnormal local field potential (LFP) synchrony in the beta frequency range (15-35Hz) coincident with motor dysfunction. Although these phenomena are well established, the link between them remains debated. Traditionally, LFP data is averaged across trials and subjects, giving the impression of continuously robust beta power during a given behavioral state. However, on a trial-by-trial basis, beta power emerges as transient bursts and the characteristic features of these bursts may provide information about underlying pathology. Unilateral injection of 6-hydroxydopamine into the rat medial forebrain bundle ablates DA neurons in the BG, resulting in both motor dysfunction and excessive beta oscillatory activity throughout the BG-thalamocortical circuit, providing a model for the study of PD. The goal of this study was to examine the characteristics of beta bursts in the motor cortex (MCx) of the hemiparkinsonian rat in conjunction with the expression of motor deficits. LFP activity was recorded from the MCx of the lesioned hemisphere of hemiparkinsonian rats, during circular treadmill walking. Results show that the distribution of beta bursts and their features periodically fluctuate as the animals walk. Specifically, bursts are less likely to occur around the time that an animal exhibits a step with the hindlimb contralateral to their lesioned hemisphere. In addition, the bursts that do occur proximal to these step times are characterized by significantly reduced amplitude. These results suggest that desynchronization of beta activity coincides with initiation of hindlimb stepping. To further investigate the relationship between MCx LFP activity and motor function, the effects of pharmacological manipulation of the subthalamic nucleus (STN) were tested. Infusion of GABA antagonist picrotoxin into the STN during treadmill walking had no significant effects on total beta power; however, results show significant modulation of beta burst features coincident with improved motor function (n=5). Additional studies with muscimol and assessment of STN LFP activity are ongoing. These results support the view that beta burst duration is an effective biomarker for parkinsonian dysfunction, and are consistent with observations in PD patients showing that adaptive deep brain stimulation of the STN both ameliorates motor dysfunction and reduces the average duration of beta bursts (Tinkhauser G, et al., 2017).

**Title:** The development of synchronized beta activity in the anterior cingulate cortex and its effects on executive function and pain processing in the hemiparkinsonian rat

**Authors: *A. R. WEISS**, Y. YANG, A. YIM, E. BRAZHNIK, N. NOVIKOV, M. W. PRESTON, Jr., A. J. MCCOY, J. R. WALTERS
Neurophysiological Pharmacol. Section, NINDS, Bethesda, MD

**Abstract:** The motor symptoms of Parkinson's disease (PD) have been linked to the emergence of exaggerated oscillatory activity in the 13 - 35 Hz beta range in local field potentials (LFP) recorded in the basal ganglia (BG) and motor cortex (MCx) of PD patients and parkinsonian animal models. Patients and animal models also exhibit cognitive dysfunction and increased pain sensitivity in PD, but the electrophysiological correlates of these non-motor symptoms are not well understood. As the prefrontal cortex (PFC), like the MCx, receives afferent input from the BG, prior studies have hypothesized that the PFC also develops synchronized beta in PD. These studies revealed synchronized beta activity in the PD anterior cingulate cortex (ACC) but not in the prelimbic or infralimbic cortices during a treadmill walking task (Weiss *et al.*, SFN Abst. 2016, 2017). We hypothesize that dopamine (DA) loss and the subsequent synchronization of beta activity in the ACC may be implicated in the non-motor symptoms of PD. Here, we investigate the development of synchronized low (20 - 29 Hz) and high (30 - 36 Hz) beta activity in the ACC of awake, behaving 6-OHDA-lesioned hemiparkinsonian rats in both executive function (responding to salient cues signaling the onset of expected or unexpected treadmill-induced walking) and pain processing (injection of formalin into the hind paw). Interactions between the ACC, the subthalamic nucleus (STN), and the ventral medial thalamus (VM) of the BG-thalamocortical circuit were also investigated.

Electrode bundles were implanted in the ACC, STN, and VM of rats with either unilateral DA cell lesions or saline controls. In an executive function task, LFPs and spiking activity were recorded during epochs centered on auditory stimuli and treadmill walking in DA-lesioned and non-lesioned rats, wherein beta activity was shown to be coherent between the ACC, STN, and VM of DA-lesioned rats. Further, beta spectral power, peak frequency, and coherence all increased with increasing alertness and were modified by the expectedness of treadmill walking trials. In the formalin injection test, behavioral responses, spiking, and LFP activity were recorded for 2 hours following injection. Formalin injection experiments are ongoing but initial results show that after injection, beta band spectral power is less modulated by behavior (as opposed to before injection).

Our results suggest that the transmission of synchronized oscillatory activity from the BG, through the VM, to the ACC in parkinsonian conditions may disrupt normal ACC function; and provide further insight into the significance of excessive oscillatory activity in PD, cognitive, and pain systems.

**Abstract:** Parkinson's Disease (PD) is the second most common neurodegenerative disease, affecting ~1% of the individuals over the age of 65 and is characterized by the loss of dopaminergic neurons in the substantia nigra. Recent studies suggest a link between the pro-inflammatory profile associated with PD and alterations in the gut microbiota. We examined the impact of ablating the gut microbiota through antibiotic treatment in animal models of PD on motor deficits, dopaminergic integrity in the basal ganglia, and the inflammatory profile in the central nervous system and periphery. Our results demonstrate that chronic treatment with an antibiotic cocktail ameliorate the neurotoxicity of 6-hydroxydopamine in a unilateral lesion model. Motor dysfunction was reduced in antibiotic-treated groups as measured by paw-rearing measurements in the cylinder test and ipsilateral rotations observed in the amphetamine-induced rotation test. Immunohistochemistry against dopaminergic neuron marker tyrosine hydroxylase shows reduced dopaminergic neuron degeneration in antibiotic treated animals as well as a reduction in the expression of pro-inflammatory markers in the basal ganglia, but not in the periphery. These results implicate the gut microbiota as a potential source of pathology in the development of PD. However, further studies are necessary to understand the specific mechanisms involved in transducing alterations in the gut microbiota to changes in dopaminergic neuron vulnerability.

**Abstract:** Patients with Rapid Eye Movement Sleep Behaviour Disorder (RBD) have a high risk of developing Parkinson's Disease (PD) or a closely related disorder and therefore represent an opportunity to study prodromal neurodegeneration. Recent studies in PD highlighted the utility of measures extracted from neuromelanin-sensitive MRI (NM-MRI) in identifying pathological changes in the substantia nigra (SN) and locus coeruleus (LC), two key sites involved early in the disease process.We sought to apply this technique in patients with RBD by firstly developing an automated method to extract measures from NM-MRI in SN and LC, and, secondly, by comparing these measures in terms of their ability to: 1) differentiate healthy controls (HC) from RBD patients; 2) differentiate RBD with normal or abnormal Dopamine transporter (DaT) SPECT/CT scan (current gold standard for assessing dopaminergic neurodegeneration); 3) correlate with clinical risk.Thirty-two patients with RBD underwent neuromelanin-sensitive MRI (NM-MRI) and DaT SPECT/CT imaging (reported as normal/abnormal by an experienced nuclear medicine radiologist). Clinical risk was calculated for each RBD patient using the Movement Disorders Society Research Criteria for Prodromal Parkinson's Disease (MDS). Twenty-five healthy controls (HC) were scanned with NM-MRI. SN and LC measures were calculated using an automated method: we defined search and reference regions of interest (ROIs) for the SN and LC on a study-specific NM template in MNI space. For each subject, the ROIs defined on the template were registered on the individual NM images to derive SN and LC volumes and other measures used in the literature (Chen et al.,2014; Sasaki et al.,2006, Schwarz et al.,2011; Isaias et al.,2016; Ohtsuka et al.,2013). NM-MRI measures were compared between

HC and RBD, between RBD with normal vs abnormal DaT SPECT/CT, and correlated with the MDS score.Compared to HC, RBDs had a significant reduction in SN volume (p=0.02) and LC volume (p=0.001). RBD patients with abnormal DaT SPECT/CT (n=17;46%) had significantly reduced peak signal intensity (p=0.002) and contrast ratio (p=0.001) within the SN compared to those with normal DaT SPECT/CT. Amongst RBDs, both SN and LC volumes correlated inversely with MDS prodromal probability scores (SN:r=-0.44, p=0.03; LC:r=-0.60, p=0.001).These results suggest that NM-MRI allows extracting quantitative measures of prodromal neurodegeneration that predict dopaminergic deficits and clinical PD risk in patients with RBD. The use of this fully automated methodology should further facilitate the replication of findings and enable the objective identification of longitudinal changes.

**Abstract:** While motor symptoms are prominent clinical and disabling features of Parkinson’s disease (PD), nonmotor symptoms such as sleep deficits start early in the course of the disease. Deterioration of basal ganglia (BG) cortical circuits affects the regulation of sleep and wakefulness. Among the multiple physiological functions of sleep, glymphatic system (GS)

activation may protect the brain from neurodegenerative decline. The GS consists of a flow of cerebrospinal and interstitial fluid through the brain parenchyma and is assumed to clean toxins and waste from the brain and spinal cord during sleep. We performed a pilot imaging study of a free-water (FW) compensated diffusion tensor imaging scan for measures of interest regarding the function of the GS and also acquired task-activated multiband fMRI to measure neurofunctional activity in relation to motor skill in nine patients with moderate PD and nine age-matched healthy control subjects (HC). In addition to experiencing clinical motor symptoms as quantified with the Unified Parkinson's Disease Rating Scale, PD patients reported more sleep problems, daytime sleepiness and dozing than HC. For GS measures, we found increased FW fraction in BG regions in PD relative to HC that was correlated with the duration of the PD diagnosis and motor symptom severity. Testing the neurofunctional correlates of motor skill using a procedural memory task, we found on average normal motor skill acquisition; both PD and HC continuously improved performance with motor skill sequence repetition, but not when performing non-repeating random sequences (control condition). Individual motor symptom severity in PD adversely affected this motor skill acquisition, in particular, bradykinesia correlated with slower learning curves. Our pilot task-activated fMRI results showed frontal hypoactivation in PD relative to HC, when performing the motor skill (learned) sequences compared to random sequences. Sleep quality and frontal FW fraction were related to the frontal activation pattern during motor performance. Together our findings provide preliminary evidence for a role of sleep and regional FW fraction measures of the GS for motor symptom severity and regional neurofunctional correlates of motor skill in PD. More and larger studies are warranted to advance our understanding on the implication of sleep and the GS for disease severity and progression. **Abstract:** Treatments for Parkinson's disease (PD) do not stop the progress of the disease.In this context,the idea has arisen that it is necessary to recover the dopaminergic system as an alternative for the treatment of PD. Recently, the importance of BDNF in the regulation of various processes of dopaminergic neurons has been reported, so maintaining their levels would produce a beneficial effect;given the background that points to melatonin (MTL) as an effective antioxidant that also increases BDNF levels and is able to increase the levels of dopamine synthesis,while the activation of the D3 receptor is able to increase BDNF levels;because it would produce a beneficial environment in which the levels of BDNF are maintained,the oxidative environment is reduced and the cell survival processes are stimulated,consequently reversing the symptoms of PD.In this study we evaluated the efficacy of co-administration of MTL and dopamine agonist(7-OH-DPAT) as inducers of BDNF production and its effect on the motor performance of pharmacologically treated animals.Sixty male Wistar rats were used;they were divided into 2 groups:the lesion group consisting of 48 rats that were injected unilaterally with 6-OHDA(8μg/μl) and fifteen days later both groups were evaluated for turning behavior with apomorphine(0.25 mg/kg) for ensuring dopaminergic loss.The lesion group was divided into three groups:the first one to which the dopamine agonist was administered, the second the melatonin and the third co-administration of both treatments.It is important to mention that the dopamine agonist was administered through a microdiffusion pump that was implanted by surgical methods subcutaneously, the pump is active for 3 months releasing 1mg/kg/day,and melatonin was administered 10mg/kg per day orally daily in the morning. The three afore mentioned groups,once the treatments were initiated, were injected with BrdU 500mg/Kg /ip(1 month daily) and they were tested for beam and stairway behavior prior to the injury and every 15 days during the treatment.Once at the end of the treatment time, the organisms were sacrificed by intracardiac perfusion for immunohistochemistry method(TH/BrdU) and Golgi technique.Preliminary behavioral results show that the effect of the co-administration of MTL/7-OH-DPAT drastically recover the motor activity,this could be happening because that treatment could be potentiating the effect of both drugs; possibly because it has been reported that melatonin recovers dopamine levels as well as increases the sensitivity of the D2 family receptor,while the D3 agonist favors the presence of BDNF,allowing a more permanent effect with treatment.

**Abstract:** Parkinson’s disease (PD) is a common neurodegenerative disorder characterized by loss of striatal dopaminergic neurons due to oxidative stress and localized neuroinflammation. Neuroinflammation results in microglial activation and release of several proinflammatory mediators. Being one of the major controllers of the immune response, the kynurenine pathway (KP) of tryptophan catabolism is also likely to be involved in the neuroinflammatory and neurotoxic cascade in Parkinson’s disease. With this background, this study is designed to evaluate the neuroprotective potential of 1-Methyltryptophan (1-MT) in 6-OHDA mouse model of Parkinson’s disease. The effect of different doses of 1-MT on oxidative stress, neuroinflammation, apoptosis, mitochondrial dysfunction, neurotransmitters levels, biochemical and behavioral alterations was assessed after induction of Parkinson’s disease by unilateral administration of 6-OHDA to the striatum. 1-MT significantly alleviates the neuromotor deficits produced by 6-OHDA in rotarod and open field test. Further, 1-MT has been found to be neuroprotective as indicated by reduced oxidative damage, neuroinflammation, mitochondrial dysfunction and neuronal apoptosis. Restoration of neurotransmitter levels and increased brain BDNF levels has been observed following treatment with 1-MT. The overall findings suggested that 1-MT, an indoleamine-2,3-dioxygenase (IDO-1) inhibitor could be an alternative in the pharmacotherapy of PD.

**Abstract:** Parkinson's disease (PD) is one of the most affected neurodegenerative diseases in the world. Deregulation of cyclin-dependent kinase 5 (Cdk5) is believed to play an important role in neurodegenerative diseases including PD. p25 is a cleavage peptide of p35, a physiologic activator of Cdk5. p25 combines to Cdk5 and leads to the hyperactivity of Cdk5, which in turn hyperphosphorylates downstream substrates and leads to neuroinflammation and apoptosis of neurons. Previously, we have demonstrated that adeno-associated virus serotype-9 (AAV9) mediated Cdk5 inhibitory peptide (CIP) inhibits the activity of Cdk5/p25 complex and alleviates pathologic and behavioral changes in Alzheimer's disease mouse model. In this study, we evaluated whether AAV9-CIP protected dopaminergic neurons in 1-methyl-4-phe-nyl-1,2,3,6-tetrahydropyridine-probenecid (MPTP/p) induced PD mouse model. The data showed that administration of AAV9-CIP by intracerebroventricular injection one week before MPTP/p exposure protected dopamine neurons from apoptosis in substantia nigra compact of the model mice. Importantly, AAV9-CIP also alleviated the motor and anxiety-like symptoms of the disease animals. In summary, AAV9 mediated CIP might be a potential intervention for PD.

**Abstract:** Parkinson disease is (PD) a debilitating motor disorder affected million of the population worldwide. The underlying cause for the loss of substantial nigra pars compacta (SNc) neurons with several different theories have been implicated for the years but still, the actual fact is undetermined and vague. However, oxidative stress is being considered to be the most important contributing factor in neurodegeneration. With huge oxygen demand brain always remain prone to the oxidative stress. To combat this oxidative stress the body has sets of endogenous antioxidants counteracting and managed the raised oxidative stress conditions. As the intolerable limit of radical species cause redox imbalance and resulting in the pathogenesis leading neuroinflammation and neurodegeneration. Previous reports found with the involvement of sulfiredoxin-peroxiredoxin (Srx-Prx) axis role in carcinogenesis, cell proliferation, migration, and metastasis. This potential axis gets overexpressed in cancer but less express in the dopamine region of SNc and striatum. Earlier reports also suggested the peroxiredoxin (thiol-based peroxidase) isoforms if overexpress or knockout in animal or cells lead to altering the pathogenesis in PD. This peroxiredoxin with 6 isoforms serves an important function with peroxidatic activity and chaperone alike activity in hyperoxidized form (sulfonic acid; PrxSO3). The ATP and sulfiredoxin-1 (Srx-1) mediate as a key player for the restoration of reduced Prx with its peroxidatic activity in neutralizing the peroxides. For understanding the mechanistic approach we studied the effect of neurotoxins such as 6-hydroxydopamine (6-OHDA), MPP+ induced reactive oxygen species leading inflammation role in neuroblastoma and microglia cells. Moreover, we also investigated the effect of 7,8-dihydroxyflavone (7,8-DHF) on sulfiredoxin and peroxiredoxin axis. We utilized the potential Nrf2 activator (D3T; 3H-1,2-Dithiole-3-thione) we found the increased expression of sulfiredoxin-1 and with the combination of 7,8-DHF provided the add on effect that confirms the 7,8-DHF role in increasing genes and protein expressions of Srx-1 and Prx (2,3,4,6) in cells and the animal mouse model of MPTP. The tunnel assay also confirms the prevented death by 7,8-DHF in the striatum and nigral region of mice. Thus, TrkB agonist may be the future drug candidate or adjunct in treating Parkinson's disease with multiple potentials of neurogenesis and augmenting the antioxidant status.

**Title:** Is brain-derived neurotrophic factor signaling critical for mediating the benefits of vagus nerve stimulation in preclinical Parkinson's disease?

**Authors: *A. FARRAND**[1], K. HELKE[2,3], R. GREGORY[2], M. GOOZ[4], V. HINSON[5], H. BOGER[1]
[1]Neurosciences and Ctr. on Aging, [2]Comparative Med., [3]Pathology and Lab. Med., [4]Drug Discovery and Biomed. Sci., [5]Neurol., Med. Univ. of South Carolina, Charleston, SC

**Abstract:** We have previously shown that vagus nerve stimulation (VNS) alleviates motor impairment and neuronal degeneration in a rodent model of Parkinson's disease (PD). In addition, preliminary results from our lab demonstrated that VNS increased brain-derived neurotrophic factor (BDNF) in target regions of the locus coeruleus (LC) and substantia nigra (SN), findings similar to previous studies using a model of depression that suggest VNS exerts its beneficial effects via BDNF-TrkB signaling. Therefore, we wanted to determine if the effects of VNS in our PD model are dependent on a BDNF-TrkB signaling mechanism. To test our hypothesis, we used our double lesion rat model of PD (combining N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP-4)/6-hydroxydopamine (6-OHDA)) and implanted VNS cuffs and headcaps. To block the TrkB signaling pathway, rats also received a daily injection of either the potent TrkB inhibitor, ANA-12, or vehicle prior to the VNS session in which locomotor activity was recorded. We found that TrkB inhibition alone was not sufficient to prevent the beneficial locomotor effects of VNS; however, ANA-12 administration did prevent the VNS-induced increase of tyrosine hydroxylase (TH)-positive neurons in the LC and SN and the increase of TH-immunoreactivity in the striatum. In order to determine which TrkB-induced signaling pathway is involved, Western blot analysis of pAkt (Ser473), pERK, and pPLCγ was conducted. Interestingly, results showed increased phosphorylation of all three proteins following ANA-12, suggesting that TrkB inhibition alone in our model is insufficient to prevent activation of these cell-signaling proteins. Since Akt, ERK, and PLCγ can be activated through numerous pathways including inflammatory cytokine production and even crosstalk with each other, it is possible that phosphorylation of these proteins is occurring through an alternative signaling cascade. While overall our results suggest TrkB signaling does play a role in the beneficial effects of VNS, as demonstrated by ANA-12's prevention of VNS effects on TH-positive neurons, our findings suggest additional mechanisms are also involved. Therefore, current studies are ongoing to determine the cause of increased Akt, ERK, and PLCγ phosphorylation. These data will elucidate the contribution of TrkB signaling to our observed symptomatic and neuroprotective VNS effects in the PD model, thus aiding in a potential therapeutic target for PD motor dysfunction and neuropathology.

**Title:** Chronic caffeine treatment protects against α-synucleinopathy by reestablishing autophagy activity in the mouse striatum

**Authors: L. YANAN**[1], *R. XIANGPENG[1], Z. WU[1], G. YINGZI[1], H. ZHIDONG[1], C. JIANG-FAN[1,2]
[1]The Eye Hosp. of Wenzhou Med. Univ., Zhejiang, China; [2]Dept. of Neurol., Boston Univ. Sch. of Med., Boston, MA

**Abstract:** Despite converging epidemiological evidence for the inverse relationship of regular caffeine consumption and risk of developing Parkinson's disease (PD) with animal studies demonstrating protective effect of caffeine in various neurotoxin models of PD, whether caffeine can protect against mutant α-synuclein (α-Syn) A53T-induced neurotoxicity in intact animals has not been examined. Here, we determined the effect of chronic caffeine treatment using the α-Syn fibril model of PD by intra-striatal injection of preformed A53T α-Syn fibrils. We demonstrated that chronic caffeine treatment blunted a cascade of pathological events leading to α-synucleinopathy, including pSer129 α-Syn-rich aggregates, apoptotic neuronal cell death, microglia and astroglia reactivation. Importantly, chronic caffeine treatment did not affect autophagy processes in the normal striatum, but selectively reversed α-Syn-induced defects in macroautophagy (by enhancing microtubule-associated protein 1 light chain 3, and reducing the receptor protein sequestosome 1, SQSTM1/p62) and chaperone-mediated autophagy (CMA, by enhancing LAMP2A). These findings support that caffeine—a strongly protective environment factor as suggested by epidemiological evidence—may represent a novel pharmacological therapy for PD by targeting autophagy pathway.

**Title:** The neuroprotective effects of sumoylation in Parkinson's disease *in vitro* and mouse models

**Authors: *Y.-H. KIM**, D. WILLIAMS, E. CARTIER, J. VIANA
Biol. Sci., Delaware State Univ., Dover, DE

**Abstract:** The Small Ubiquitin-like Modifier (SUMO) is a form of post-translational modification that may regulate protein function and stability. The SUMO ligase, Ubc9 conjugates SUMO to its target proteins. The role of SUMOylation in dopaminergic neurons in brain remains unclear for Parkinson's disease (PD) pathology. We hypothesize that the overexpression of Ubc9 protects dopaminergic neurons against oxidative stress. In cell viability (MTT) and cytotoxicity (LDH) assay, the Ubc9-EGFP overexpression protected N27 rat dopaminergic cells against $H_2O_2$ or MPP+ induced toxicities, compared to EGFP overexpressing control cells. We tested if the protective effects are mediated by reducing reactive oxygen species (ROS) production that is derived from oxidative stress. Using CellROX® Deep Red Reagent (Thermo, C10422) as a fluorogenic probe, we found that cellular ROS level was significantly lower in Ubc9-EGFP cells than that in EGFP cells, after the exposure of 640 μM MPP+ for 24 hrs. Hereafter, we applied the Ubc9 up- or down-regulating *in vitro* and *in vivo* models to validate SUMOylation as a potential regulatory target in PD pathological models. In MPTP-lesioned mice, we also confirmed that ROS level was lower in Ubc9 transgenic mice than that in WT siblings after chronic MPTP injection. In *in vitro* Cycloheximide-based protein stability assay, higher protein level of alpha-synuclein was identified in Ubc9-EGFP cells than in EGFP only cells. Ubc9 knock-down by RNAi in N27 parental cells showed a decrease in alpha-synuclein protein level, suggesting that SUMOylated alpha-synuclein has higher protein stability than non-SUMOylated form. Furthermore, in immunohistochemistry using confocal microscopy, we identified that dopaminergic neurons in the striatum from Ubc9 overexpressing transgenic mice are more resistant to MPTP toxicities than those from WT siblings. Our findings support that Ubc9 overexpression significantly reduces the MPTP toxicity in the striatum. Currently we are confirming the findings in Western blots quantitatively in tyrosine hydroxylase (TH) as a dopaminergic marker and in synaptophysin as a synaptic marker, using tissues from the striatum and brain stem. The most intriguing observation is that chronic MPTP injection strips off the SUMO1 from alpha-synuclein in the striatum after immuno-precipitation, which can be a

detrimental process in reducing alpha-synuclein protein stability. Our studies suggest that Ubc9 overexpression can be a regulatory target to protect dopaminergic neurons against oxidative stress, implicating that high level of SUMOylation in dopaminergic neurons can slow PD pathology.

**Title:** SPG101, a novel compound with spinogenic activity, ameliorates early synaptic loss in a mouse model of Parkinson's disease

**Authors: *B. J. SPENCER**[1], V. F. SIMMON[3], S. T. SARRAF[3], P. W. VANDERKLISH[4,3], R. A. RISSMAN[2,5]
[1]Neurosciences, [2]Neurosci., UCSD, La Jolla, CA; [3]Spinogenix, Inc., San Diego, CA; [4]Mol. Med., The Scripps Res. Inst., La Jolla, CA; [5]VA San Diego Healthcare Syst., San Diego, CA

**Abstract:** α-synuclein is a major neuronal synaptic protein implicated in Parkinson's disease (PD), dementia with Lewy bodies (DLB), Multiple System Atrophy and the lysosomal storage disorder, Gaucher's disease. Multiplication, point mutations or post-translational modification of α-synuclein can promote its abnormal aggregation and accumulation into Lewy bodies and Lewy neurites which lead to neuronal death. The primary early event associated with increased α-synuclein accumulation is dendritic synaptic loss, preceding even neuronal loss or microglial activation. Recently SPG101, has been reported to increase spinogenesis in a mouse model of Alzheimer's disease. SPG101 readily crosses the blood-brain barrier and accumulates in the brain. In order to determine if this compound would be effective to treat the early dendritic spine loss in a model of PD / DLB, SPG101 was delivered daily for 4 weeks by intra-peritoneal injection to α-synuclein-tg mice. Compared to vehicle treated animals, SPG101 treated α-synuclein-tg and non-tg mice showed an approximately 50% increase in dendritic spine density in cortical neurons after 4 weeks of treatment without any pathological complications. In addition, there was a decrease in α-synuclein accumulation in the cortex and thalamus in the α-

synuclein-tg mice treated with SPG101. Thus, SPG101 increases spinogenesis in cortical neurons and may be a potential therapeutic for neurodegenerative diseases like PD, where loss of spine density is an early pathological event.

**Title:** Altered expression of genes involved in ganglioside biosynthesis in substantia nigra neurons in Parkinson’s disease brain and potential role in modulating vulnerability for neurodegeneration

**Authors: *M. VERMA**, J. SCHNEIDER
Thomas Jefferson Univ., Philadelphia, PA

**Abstract:** Reduced expression of GM1 and other major brain gangliosides GD1a, GD1b and GT1b have been reported in Parkinson’s disease (PD) brain. Yet, the mechanisms underlying these changes are unclear but may be related to a defect in ganglioside biosynthetic processes. The present study examined gene expression of key biosynthetic enzymes involved in synthesis of GM1 and GD1b (*B3galt4*) and GD1a and GT1b (*St3gal2*) in residual neuromelanin-containing neurons in the PD substantia nigra (SN). Since ganglioside expression is cell type-specific, interpretation of potential gene expression changes in whole SN homogenates from PD brain could be complicated due to various factors including variable loss of SN neurons, glial responses, and signals from white matter across different samples. Thus, the current study was performed using in situ hybridization histochemistry to examine *B3galt4* and *St3gal2* gene expression in neuromelanin-containing neurons in the SN of PD patients and non-PD controls. Fresh frozen human SN samples (8 normal controls, 61-92 yrs. and 7 PD subjects, 77-95 yrs.)

were obtained through the NIH NeuroBioBank and sourced from the NICHD Brain and Tissue Bank for Developmental Disorders at the University of Maryland, the Harvard Brain Tissue Resource Center, and from the Human Brain and Spinal Fluid Resource Center, VA Greater Los Angeles Healthcare System. The clinical diagnosis of Parkinson's disease was confirmed at autopsy. Tissues were sectioned at 14 µm thickness and mounted onto Superfrost Plus slides. In situ hybridization was performed using the RNAscope 2.5 HD Chromogenic Assay kit (Advanced Cell Diagnostics, Inc.) using the manufacturer's protocol, with slight modifications. For each gene, the number of dots/cell (each dot represents a single RNA molecule) was counted on coded slides, from at least 20 cells from each case that had neuromelanin clearly visible. There were significant decreases in both *B3Galt4* and *St3gal2* gene expression in residual neuromelanin-containing SN neurons in the PD brain compared to age-matched controls. In vitro studies were then performed to examine the extent to which a decrease in *B3Galt4* gene expression affects GM1 expression and potentially influences vulnerability to neurodegeneration. Exposure of differentiated SK-N-SH dopaminergic (DAergic) cells to *B3galt4* siRNA significantly decreased GM1 expression and resulted in significant cell death in response to an exposure (10µM $MPP^+$) that previously resulted in no cell loss. These results together suggest a defect in ganglioside biosynthetic processes in SN DAergic neurons in PD that may play an important role in the pathogenesis of PD.

**Title:** Neuroprotection and immunomodulation of progesterone in the gut in a MPTP mouse model of Parkinson's disease

**Authors: *T. P. DIPAOLO**, H. JARRAS, M. BOURQUE, M. MORISSETTE, A.-A. POIRIER, K. COULOMBE, D. SOULET
Ctr. de Recherche du CHUQ-CHUL, Quebec, QC, Canada

**Abstract:** Gastro-intestinal symptoms appear in Parkinson's disease (PD) patients many years before motor symptoms suggesting the implication of dopaminergic neurons of the gut myenteric plexus (MP). Inflammation is also known to be increased in PD. Our laboratories have previously shown neuroprotective activity of progesterone in the brain as well as estrogens in the brain and gut of the mouse model lesioned with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine

(MPTP). We hypothesize that progesterone also has neuroprotective activity in the gut. The objective of the present study was thus to investigate the neuroprotection and immunomodulation of progesterone in the MP of MPTP mice. A group of adult male C57BL/6 mice were administered 2 injections/day of progesterone (1µg) or vehicle for 10 days. At treatment day 5, 4 injections of MPTP (6.5 mg/kg) or a saline solution were administered. Another group of mice received first 4 injections of MPTP (6.5 mg/kg) or a saline solution. An hour after the first and last doses of MPTP and during the 5 following days, these mice received injections of progesterone (1 µg, 8 mg/kg or 16 mg/kg). Ilea were collected on day 10 of treatment and micro-dissected to isolate the MP. These tissues were processed for immunohistochemistry in order to count dopaminergic neurons and pro-inflammatory macrophages. A loss of about 60% of dopaminergic neurons, as well as an increase of about 50% of pro-inflammatory macrophages were measured in MPTP mice compared to intact controls. These changes were completely prevented in MPTP mice treated before and after MPTP injection with progesterone at a daily dose of 1 µg and normalized with a dose of progesterone of 8 mg/kg administered after MPTP. These results are similar to those that we previously reported for various dopaminergic markers in the brain of these mice, also showing neuroprotection with progesterone given before and after the MPTP lesion with a low dose of progesterone and at a higher dose given after MPTP. In conclusion, the present results showed neuroprotective and anti-inflammatory effects of progesterone in the MP of MPTP mice and extended our previous findings in the brain with this steroid. Progesterone is non-feminizing and thus could be used for both men and women in pre-symptomatic stages of the disease, as well as at disease diagnosis since we observed beneficial effects of progesterone when starting the administration before and after the lesion.

**Abstract:** The role of astrocyte elevated gene-1 (AEG-1) in nigral dopaminergic (DA) neurons has not been studied. Here, we report that the expression of AEG-1 was significantly lower in DA neurons in the postmortem substantia nigra of patients with Parkinson's disease (PD) compared to age-matched controls. Similarly, decreased AEG-1 levels were found in the 6-hydroxydopamine (6-OHDA) mouse model of PD. An adeno-associated virus-induced increase in the expression of AEG-1 attenuated the 6-OHDA-triggered apoptotic death of nigral DA neurons. Moreover, the neuroprotection conferred by the AEG-1 upregulation significantly intensified the neurorestorative effects of the constitutively active ras homolog enriched in the brain [Rheb(S16H)]. Collectively, these results demonstrated that the sustained level of AEG-1 as an important anti-apoptotic factor in nigral DA neurons might potentiate the therapeutic effects of treatments, such as Rheb(S16H) administration, on the degeneration of the DA pathway that characterizes PD.

**Abstract:** Motor symptoms in Parkinson's disease (PD) are often preceded by non-motor symptoms related to dysfunctions of the autonomic nervous system such as constipation, defecatory problems and delayed gastric emptying. These gastrointestinal disorders are associated with the alteration of dopaminergic (DA) neurons in the myenteric plexus (MP) of the gut. Studies in our laboratory have demonstrated the immunomodulatory effect of female sex hormones to prevent neurodegeneration in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse model of enteric nervous system degeneration in PD. We also showed that the 5α-reductase inhibitor dutasteride (DUT), but not finasteride (FIN), has a protective effect in the central nervous system. The objective of this project was therefore to evaluate the neuroprotective and immunomodulatory role of FIN and DUT in the MP by increasing endogenous levels of estrogen via the inhibition of 5α-reductase, thus preventing the conversion of testosterone to dihydrotestosterone. Adult C57BL/6 male mice received 1 daily injections of FIN or DUT (5 and 12.5 mg/kg) for 10 days. On day five, 4 injections of saline or MPTP (6.5 mg/kg) were administered. The brains of these mice were previously analyzed with positive results, hence supporting the chosen doses in this experiment. On day ten, mice were killed, the ileum was fixed and microdissected to isolate the MP. Immunohistochemistry with antibodies against tyrosine hydroxylase (TH) and ionized calcium-binding adapter molecule 1 (Iba-1) were performed for stereological counting of DA neurons ($TH^+$) and macrophages ($Iba\text{-}1^+$). Also, free radicals, nitric oxide and proinflammatory cytokines produced by treatment of 1-methyl-4-phenylpyridinium ($MPP^+$) were measured in human monocytic THP-1 and DA SH-SY5Y cells. We observed a loss of about 70% of $TH^+$ neurons in MPTP mice while control levels were maintained following FIN (12.5 mg/kg) and DUT (5 mg/kg) treatments. Moreover, we measured an increase of approximately 55% in the number of macrophages in MPTP mice, while control levels were maintained with DUT treatment (5 and 12.5 mg/kg), showing a significant anti-inflammatory effect of the drug in MPTP animals. In addition, DUT inhibited generation of free radicals in monocytes and DA neurons in culture treated with $MPP^+$, while FIN had no effect. Finally, $MPP^+$-induced nitric oxide and proinflammatory cytokines production were also prevented by DUT *in vitro*. Overall, the present results demonstrate that DUT treatment prevents damages to DA neurons in the MP in a MPTP mouse model of PD, mainly through anti-inflammatory effects.

**Abstract:** The path to bring new drugs to the clinic is long and costly, with very few candidates eventually being granted approval. Drug repositioning, the process by which drugs currently on the market for a given condition, might be useful for diseases other than their primary indication, is a way to expand the therapeutic tools against certain diseases, at a faster pace and a much lower cost. Here, we hypothesised that the clinically-available anti-depressant nefazodone, which bears affinity for serotonin 1A and 2A (5-$HT_{1A}$and 5-$HT_{2A}$) receptors, would alleviate L-3,4-dihydroxyphenylalanine (L-DOPA)-induced dyskinesia and psychosis-like behaviours (PLBs) in Parkinson's disease (PD), and assessed its benefit in the parkinsonian marmoset. Six common marmosets were rendered parkinsonian by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) administration. Following repeated administration of L-DOPA to elicit stable PLBs and dyskinesia, they were administered acute challenges of nefazodone (0.01, 0.1, 1 mg/kg) or vehicle, in combinaison with L-DOPA, after which motor activity was automatically detected and the severity of dyskinesia, PLBs and parkinsonian disability is being rated by a blinded observer. Analysis of motor activity reveals that nefazodone does not alter L-DOPA-induced motor activity. Full analysis of the effect of nefazodone on dyskinesia and PLBs is on-going and will be presented at the conference. However, at this stage, that nefazodone has no effect on motor activity suggests that it does not interfere with the anti-parkinsonian action of L-DOPA and that, conditional to anti-dyskinetic and/or anti-psychotic efficacy, it could be offered to alleviate symptoms of PD patients.

**Abstract:** Parkinson’s disease (PD) is characterized by a loss of dopamine (DA) neurons in the substantia nigra pars compacta (SNpc) and a decrease of their projections to the striatum. Previous studies in our laboratory have shown that a n-3 polyunsaturated fatty acids (n-3 PUFA) enriched diet prevents DAergic denervation in the MPTP mouse model. More recently, we found that n-3 PUFA dietary intake also exerts partial neurorestorative effects after an extensive 6-hydroxydopamine(6-OHDA)-induced lesion of the DAergic system. Since preclinical and clinical studies hint towards benefit of exercise in PD, we investigated whether the neurorestorative action of n-3 PUFA synergistically interacts with exercise to induce recovery of the nigrostriatal pathway. Male C57/BL6 mice were unilaterally lesioned by stereotactic injection of 6-OHDA, a toxic analog of dopamine, to induce a ~50% dopaminergic denervation, as confirmed with HPLC and Tyrosine hydroxylase (TH)-immunochemistry. Four (4) weeks following the lesion, animals were fed either a docosahexaenoic acid (DHA)-enriched or a control diet. At the same time, half of the mice underwent an exercise regimen (a free-access wheel). The treatments lasted 7 weeks until sacrifice. The mice performed an average number of 7823±236 wheel revolutions in 12h during the night and no significant difference was observed between lesioned and non-lesioned animals. Neither DHA or exercise altered the total travelled distance in the open field test, nor the percentage of unclockwise rotations following apomorphine administration. In the stepping test, however, an increase in the use of contro-lateral forepaw (vs. ipsilateral) was observed in lesioned animals exposed to both DHA and voluntary exercise compared to lesioned animals under either one of the treatments only. Although the combination of DHA and exercise did not improve the number of TH-positive cells in the SNpc, HPLC analysis revealed that DHA intake led to higher DA content in the striatum of 6-OHDA lesioned animals. Furthermore, the striatal rise in DOPAC/DA ratio observed in 6-OHDA-treated mice was prevented by exposition to both DHA and exercise. Our results support our previous report of partial neurorestorative effects of dietary DHA and suggest that the combination of voluntary exercise and DHA may improve additional motor behavioral components and reduce dopamine turnover.

**Title:** Voluntary physical exercise improves subsequent motor impairments in a MitoPark mouse model of Parkinson's disease

**Authors: Y.-H. CHIANG**[1,4], J.-H. LAI[1], S.-C. HSUEH[2], J.-C. WU[4,1], *K.-Y. CHEN[3]
[1]Dept. of Surgery, Sch. of Medicine, Col. of Med., [2]The Ph.D. Program for Neural Regenerative Medicine, Col. of Med. Sci. and Technol., [3]Taipei Med. Univ., Taipei, Taiwan; [4]Dept. of Neurosurg., Taipei Med. Univ. Hosp., Taipei, Taiwan

**Abstract: Aim:** Parkinson's disease (PD) is the second most common neurodegenerative disorder after Alzheimer's disease and is likely to impose an increasing social and economic burden on societies. It involves problems of movement, emotions, and cognition, affecting over 10 million people worldwide . Although a good deal is known about the pathophysiology of the disease, and information is emerging about its cause, there are no pharmacological treatments shown to have a significant, sustained capacity to prevent or attenuate the condition. Such treatments are urgently needed. Accumulating clinical evidence suggests that physical exercise is such a treatment, and studies of animal models of the DA deficiency associated with the motor symptoms of PD further support this hypothesis. Moreover, exercise is a non-pharmacological, economically practical, and sustainable intervention with little or no risk and with significant additional health benefits. In this study, we investigated the long-term effects of voluntary running wheel exercise on motor behavior as well as histology in a MitoPark mouse model of PD. **Methods:** The PD animals were separated into two groups, exercise (at the age of 6 weeks) and non-exercise, for evaluating the effects of voluntary running wheel exercise. For behavioral assessments, animals were subjected to novel object recognition test, beam walking, and rotational test. The dopamine neuron density was measured by dopamine transporter PET ([$^{18}$F]-FE-PE2I/ PET). The measurement of mitochondrial bioenergetics was performed with Seahorse XF systems. In addition, the molecular mechanisms of exercise on DA neuronal function were evaluated by immunohistochemistry and western blot analysis.
**Results:** We observed that, when compared with the non-exercise controls, four-week voluntary exercise improved the motor function, including a significantly improved beam walking speed and the latency on rotarod. However, the preference index on novel object recognition did not improved after exercise treatment. Furthermore, dopamine neuron density was higher in exercise treatment group, and the mitochondria dysfunction was also improved.

**Conclusions:** We first investigated the potential benefits after long-term exercise in the MitoPark mouse model of PD. Our findings suggest that long-term voluntary exercise reduces the progression of motor symptoms, preserves DA fibers, and elevates DA markers but does not prevent DA neuron loss in this PD mouse model.

**Title:** Progression of Parkinson's disease symptoms halted using dance over 3-years as assessed with MDS-UPDRS

**Authors: *J. F. DESOUZA**[1], K. A. BEARSS[2]
[1]Psychology & Biol., York Ctr. For Vision Res., Toronto, ON, Canada; [2]Psychology, York Ctr. for Vision Res., York University, ON, Canada

**Abstract: OBJECTIVE:** To determine the overall progression of motor, non-motor, and resting state electroencephalography (rsEEG) changes of Parkinson's Disease (PD) while participating in Dance for Parkinson's classes in Toronto. Our aim is to examine and potentially construct brain-related plasticity mechanism(s) as a function of dance using multimodal neuroimaging. **RATIONALE:** PD is characterized as a chronic, progressive, degenerative disease with deteriorating motor and non-motor function as well as a loss of nigrostriatal dopaminergic neurons ultimately increasing disability while creating a deficiency of dopamine in the striatum. Data suggests a fast progression of motor dysfunction within the first 5 years, with annual rates of progression of the UPDRS III (motor) score from 5.2-8.9 points. About 40-50% of dopaminergic neurons are lost within the first decade, causing excessive inhibition of thalamo-cotical nuclei via the direct and indirect striato-pallidal pathways. Areas which have been hypothesized to be involved with alpha rhythm organization, where people with PD (PwPD) have been shown to have lower individual alpha peak frequency. **METHODS:** 16 PwPD, mild-severity ($M_{H\&Y}$= 1.25, SD= 0.86), ($M_{age}$= 68.73, $SD$= 8.41, $N_{Males}$= 11, $M_{DiseaseDuration}$= 5.54, $SD$= 4.52) were tested before and after participating in dance class (Dance for PD®) using the standardized MDS-UPDRS (I-IV), H&Y, PANAS-X, MMSE, PD-NMS and rsEEG over 3 years. **RESULTS:** rsEEG global alpha power was highest after a single dance class in comparison to before, $F(1,26) = 6.928$, $p < .025$, $\eta 2 = .210$. There is no motor impairment (UPDRS part III)

progression of PD across 3-years ($p$ = .817). In addition, non-motor aspects of daily living (UPDRS part I), motor experiences of daily living (UPDRS part II) and motor complications (UPDRS part IV) show no significant impairment ($p$ = .329), ($p$ = .540), and ($p$ = .390) after 3 years of dancing once a week, respectively. We found the annual rate of decline in the motor function scores to be zero (slope=0.000146). **CONCLUSION:** Our results indicate positive benefits of dance for motor, non-motor and neural changes in PD. Previous longitudinal studies suggest a 5.2-8.9-point annual decline in motor function whereas our cohort suggests that the annual motor impairment is drastically lower, indicating participation in dance may delay the progression of motor impairment. These findings continue to support the benefits of dance in PwPD over three years.

**Authors: *P. C. CUNNINGHAM**[1], K. WALDECK[2], B. GANETZKY[3], D. T. BABCOCK[1]
[1]Lehigh Univ., Bethlehem, PA; [2]Univ. of Wisconsin-Madison, Madison, WI; [3]Univ. Wisconsin, Madison, WI

**Abstract:** Parkinson’s Disease (PD) is characterized by the loss of dopaminergic neurons, resulting in progressive locomotor dysfunction. Identification of genes required for the maintenance of these neurons should help to identify potential therapeutic targets. However, little is known regarding the factors that render dopaminergic neurons selectively vulnerable to PD. Here we show that *Drosophila melanogaster scarlet* mutants exhibit an age-dependent progressive loss of dopaminergic neurons, along with subsequent locomotor defects and a shortened lifespan. Knockdown of Scarlet specifically within dopaminergic neurons is sufficient to produce this neurodegeneration, demonstrating a unique role for Scarlet beyond its well-characterized role in eye pigmentation. Both genetic and pharmacological manipulation of the kynurenine pathway rescued loss of dopaminergic neurons by promoting synthesis of the free radical scavenger Kynurenic Acid (KYNA) and limiting the production of the free radical generator 3-hydroxykynurenine (3-HK). Finally, we show that expression of wild-type Scarlet is neuroprotective in a model of PD, suggesting that manipulating kynurenine metabolism may be a potential therapeutic option in treating PD.

**Abstract:** Growing evidence indicates that autophagy induction may have beneficial effects on neurodegenerative and psychiatric diseases. However, autophagy also shares signaling pathways with cell death. Therefore, prolonged use of autophagy inducers may also have serious consequences for cellular homeostasis. Recent studies indicate that dopamine D2R/D3R ligands may modulate autophagy, but mechanisms underlying the interaction between D2R and D3R and the autophagy machinery are still unknown. Here D2R and D3R overexpressing cells, and $D2R^{-/-}$, $D3R^{-/-}$ and wild-type mice were treated with pramipexole, a D2R/D3R agonist used in the treatment of Parkinson's disease and which has antidepressant effects. Assessment of autophagy markers and phosphorylation of mTOR and its downstream target p70S6K reveals that prolonged pramipexole treatment activates autophagy through mTORC1 inhibition mediated by a D3R-dependent D2R-independent mechanism. Given the differential distribution of D2R and D3R in the brain, the fact that autophagy is selectively activated by $D_3R$ directs our interest to compounds acting on specific neuronal populations through precise ligand-receptor interactions and signaling mechanisms. Interestingly, the activity of mTORC1 targets involved in translation, ribosomal protein S6 and 4E-BP1, along with cell viability, were preserved. This pattern of

mTORC1 inhibition contrasts with that of direct allosteric and catalytic mTOR inhibitors. Taken together, these findings open up new opportunities for G-protein coupled receptor ligands as autophagy inducers in the treatment of neurodegenerative and psychiatric diseases.

**Title:** A DJ-1, PD related gene, regulates the astrogliosis for repair of injured brain

**Authors: *D.-J. CHOI**[1,2], E.-H. JOE[1,2,3]
[1]Pharmacol. Lab. #401 Ajou Uni Med., Suwon, Korea, Republic of; [2]Chronic Inflammatory Dis. Res. Center, Ajou Univ. Med., Suwon, Korea, Republic of; [3]Dept. of Brain Sci., Suwon, Korea, Republic of

**Abstract:** In injured brain, astrocytes become activated and contribute to repair of the injury. Here, I report that DJ-1 positively regulates repair of injured brain. MRI analyses shows delayed repair of brain damage in DJ-1-knockout (KO) mice compared with wild-type (WT) mice. Accordingly, in injured KO brain, astrocytes become less reactive and fill damaged areas more slowly, and recovery of tyrosine hydroxylase-positive neurites is delayed. However, in pure cultures, neurite outgrowth of damaged DJ-1-KO neurons is comparable to that of WT neurons. Expression levels of GDNF and BDNF are lower in astrocytes in DJ-1-KO brain and slice cultures. Expectedly, WT slice culture conditioned media (SCM) exerts stronger effects on neurite outgrowth than KO-SCM. These results suggest that DJ-1 deficiency may contribute to the development of PD by attenuating astrocyte-mediated repair of brain damage.

**Abstract:** We previously showed that capsaicin (CAP), an agonist of transient receptor potential vanilloid subtype 1 (TRPV1), inhibits microglia activation and microglia-derived oxidative stress in the substantia nigra (SN) of $MPP^+$-lesioned rat. However, the detailed mechanisms how to regulate microglia-derived oxidative stress by CAP remain determined. Here we report that ciliary neurotrophic factor (CNTF) produced by CAP-activated TRPV1 on astrocytes, but not microglia inhibits microglia-derived oxidative stress through the CNTF receptor alpha (CNTFRα) located on microglia, which rescues dopamine neurons in the SN of $MPP^+$-lesioned rats and ameliorates amphetamine-induced rotations. Immunohistochemical analysis revealed a significant increase in levels of CNTFRα expression on microglia in the SN of tissue from humans with Parkinson's disease (PD) compared with age-matched controls, indicating that these findings may have relevance to this disease. Our results describe for the first time that CNTF endogenously produced by CAP-activated TRPV1 on astrocytes, not microglia inhibits microglia activation and microglia-derived oxidative stress *in vivo* and rescues dopamine neurons in a $MPP^+$-lesioned rat model of PD. These data suggest that TRPV1 on astrocytes may be a beneficial target in the treatment of neurodegenerative disease associated with neuroinflammation such as PD.

**Title:** The adaptive defense mechanism associated with HFE genotype and its response to paraquat-induced toxicity

**Authors: *I. SONG**[1], A. M. SNYDER[4], B. NEELY[2], J. R. CONNOR[3]
[1]Penn State Col. of Med., Hummelstown, PA; [3]Neurosurg., [2]Penn State Col. of Med., Hershey, PA; [4]Neurosurgery, MC H110, Penn State Univ. Coll Med., Hershey, PA

**Abstract:** Past research studies have identified the link between environmental toxins and mitochondrial dysfunction in Parkinson's disease. Recently, our laboratory reported protection from paraquat-induced motor impairment and cellular changes in HFE (H67D) mutant mice. The HFE protein regulates iron uptake by interacting with the transferrin receptor. Based on our previous study, we hypothesize that an antioxidant defense system is elevated in association with the HFE mutation. The candidate proteins chosen to begin to examine this hypothesis are Nrf2, cytosolic ferritins, and GSH. Because the Nrf2 pathway is preferably activated in astrocytes, we hypothesize that the HFE mutant astrocytes are responsible for the proposed neuroprotection. We performed immunostaining on primary astrocytes in cell culture that revealed an increase in both NRF2 and L-ferritin staining in the HFE mutant astrocytes compared to WT astrocytes at baseline. Paraquat treatment induced a loss of mitochondrial membrane potential as measured by TMRE assay in astrocytes of both genotypes, but the decrease in WT astrocytes (30%) was greater than that in the HFE mutant astrocytes (20%). Furthermore, paraquat exposure resulted in a greater increase in the astrocytic senescence marker B-galactosidase in the WT (300% increase) cells compared to H67D astrocytes (150% increase). To further elucidate the role of HFE mutant astrocytes in neuroprotection against paraquat-induced toxicity, we have developed a SH-SY5Y neuroblastoma model that is stably transfected with WT or H63D HFE and is further differentiated to express DAT, which is critical for paraquat uptake. Exposure to low dose (100uM) paraquat did not affect the viability of HFE mutant SH-SY5Y cells but decreased the WT SH-SY5Y cells by 20%. However, the WT and HFE mutant cells were equally affected (30% cell death) by a higher dose (200uM) of paraquat. To examine the interaction between astrocytes and neurons, astrocytes were treated with a sublethal dose of paraquat, and then the conditioned media from the paraquat-treated astrocytes was added to the neuronal cultures. A significant decrease in the viability of the WT SH-SY5Y cells was observed after treatment with WT astrocyte conditioned media (9% decrease), but there was no effect when the WT SH-SY5Y cells were treated with H67D astrocyte conditioned media. The results of our study suggest that there is a difference in vulnerability to paraquat toxicity associated with HFE genotype. The data further suggest that the difference in vulnerability is mediated by astrocytes that have adapted to the mutation by activating their antioxidant defense system.

**Title:** Increased ATP-derived extracellular adenosine is responsible for the over-activation of adenosine $A_{2A}$ receptors causing neurodegeneration in 6-OHDA-hemiparkinsonian rats

**Authors: *R. A. CUNHA**[1,2], M. CARMO[3], P. M. CANAS[1], F. Q. GONÇALVES[1], J.-P. OSES[1], F. D. FERNANDES[3], F. V. DUARTE[1], C. M. PALMEIRA[1], A. R. TOMÉ[1], P. AGOSTINHO[1], G. M. ANDRADE[3]
[1]CNC -Center for Neurosci. and Cell Biol., Coimbra, Portugal; [2]Univ. of Coimbra, Fac. of Med., Coimbra, Portugal; [3]Dept. of Physiol. and Pharmacol., Federal Univ. of Ceará, Fortaleza, Brazil

**Abstract:** Parkinson's disease (PD) involves an initial loss of striatal dopaminergic terminals evolving into a degeneration of dopaminergic neurons in the substantia nigra (SN), which can be modeled by 6-hydroxydopamine (6-OHDA) administration. The blockade of adenosine $A_{2A}$ receptor ($A_{2A}R$) attenuates PD, but the source of the adenosine responsible for $A_{2A}R$ over-activation is unknown. Since ATP is a general danger signal, we now tested if the extracellular catabolism of adenine nucleotides into adenosine (through ecto-5'-nucleotidase or CD73) is responsible for $A_{2A}R$ over-activation in PD. In dopamine-differentiated neuroblastoma SH-SY5Y cells, 6-OHDA bolstered ATP release (from 5 minutes up to at least 6 hours) and its extracellular conversion into adenosine through an up-regulation of CD73. This CD73/$A_{2A}R$ up-regulation was a precocious event, occurring 2 hours after exposure to 6-OHDA, thus pre-dating SH-SY5Y cell dysfunction. Removing extracellular adenosine with adenosine deaminase (2 U/mL), blocking CD73 with α,β-methylene ADP (AOPCP, 100 μM) or blocking $A_{2A}R$ with SCH58261 (100 nM) were equi-effective to prevent 6-OHDA-induced dysfunction and damage of SH-SY5Y cells. *In vivo* striatal unilateral exposure to 6-OHDA increased $K^+$-evoked ATP release and the extracellular formation of adenosine from adenosine nucleotides and up-regulated CD73 and $A_{2A}R$ selectively in synapses, but not in total membranes. Intracerebroventricular administration of AOPCP (100 μM, continuous exposure) phenocopied the effect of SCH58261 (0.1 mg/kg, ip), attenuating 6-OHDA-induced: 1) increase of contralateral rotations in the apomorphine test; 2) reduction of dopamine content in striatum and SN; 3) loss of tyrosine

hydroxylase staining in striatum and SN; 4) motor dysfunction in the cylinder test; 5) short-term memory impairment in the object recognition test. This suggests that increased ATP-derived adenosine formation is responsible for $A_{2A}R$ over-activation in early PD, prompting CD73 as a new target to manage PD.

**Title:** Promoter identification and transcriptional regulation of the anti-inflammation gene cd200r1 in Parkinson's disease

**Authors: *S. LIN**[1], R. SHEN[1], L. HE[1], C. WU[2], J. DING[1]
[1]Neurol., Ruijin Hospital, Shanghai Jiaotong Univ. Scho, Shanghai City, China; [2]Neurosci., Univ. of California San Diego, San Diego, CA

**Abstract:** Recent researches have been shown that abnormal activation of microglia plays an important role in pathogenesis of Parkinson's disease (PD). Microglia are normally inhibited in a stationary state almost by the contact inhibition between neuron and microglia. This contact inhibition recently has been found closely related to the interaction between CD200 (located in neuron) and its receptor CD200R1 (located in microglia). Normally, CD200R1 upregulates to increase CD200-CD200R1 inhibit signaling thus preventing microglia from overactivating when brain being attacked. Our previous studies showed, however, expression of CD200R1 could not increase in PD when received inflammation stimulation, which means abnormal regulation of CD200R1 expression happens in PD. However, no information about the regulatory element of the CD200R1 gene and its transcriptional regulation has been reported so far. Here we identified the CD200R1 promoter using a promoter luciferase construct that directs transcription of CD200R1. Our results show that the region from -485 to -267 (first base of CDS is +1) constitutes the core promoter and harbors motifs for the binding of NFKB1 as validated by analysis websites JARSPAR and P-MATCH. Knock down of NFKB1 dropped the promoter activity of CD200R1. Using chromatin immunoprecipitation assay and EMSA, we demonstrated the physical interaction of NFKB1 to the CD200R1 core promoter sequence. In human

peripheral blood mononuclear cell (PBMC), expression levels of NFKB1 correlated significantly to CD200R1 (P< 0.0001). Knock down of NFKB1 reduced CD200R1 expression in PBMC (P < 0.0001). Importantly, LPS stimulation led to increase expression of CD200R1 which was prevented when knock down of NFKB1 in human PBMC. Meanwhile, levels of NFKB1 showed a decrease in PD patients (P< 0.001). This is the first study identifying the CD200R1 promoter and its transcriptional regulation by NFKB1. Knowledge of the transcriptional regulation of the CD200R1 gene will implicate in enhanced understanding of its role in pathogenesis of PD.

**Title:** Small molecule recovery of mitochondrial injury by DOPAL-treated α-synuclein

**Authors: *J. B. WATSON**, A. YACOUB, A. KUNZ, B. ARANKI, G. SEROBYAN, W. COHN, J. P. WHITELEGGE, T. A. SARAFIAN
Dept Psychiatry & Biobehav Sci., David Geffen Sch. Med. UCLA, Los Angeles, CA

**Abstract:** We previously reported that overexpressed human α-synuclein can disturb mitochondrial function (Sarafian et al., 2013, PLoS One 8(5):e63557), but it was not clear which proteoform (monomer, oligomer, fibril?) was the active toxin. Since α-synuclein amyloid oligomers are likely the most neurotoxic form in Parkinson’s Disease (PD), the dopamine breakdown product, 3, 4-dihydroxyphenylacetaldehyde (DOPAL), was used to generate oligomeric α-synuclein from recombinant protein preparations [Watson et al (2017) Soc Neurosci Abstr 131.13]. DOPAL-oligomeric α-synuclein (DOS) significantly reduced by 15-30% the membrane potential in mitochondria isolated from mouse forebrain using fluorescent probes (JC-1, TMRM). Importantly, after survey of a large list (50 or more) of commercially available small molecules known to modulate mitochondrial function, multiple unrelated compounds provided complete recovery of DOS-induced mitochondrial injury. Additional HPLC/mass spectrometry studies by combined top-down/intact protein and bottom-up approaches showed that the mitochondrial inhibitory form of DOS is highly oxidized and contains multiple catechol and quinone covalent modifications. The results suggest that mitochondrial injury in brain cells, such as those in substantia nigra’s pars compacta containing dual high levels of DOPAL and α-synuclein, can be selectively rescued by cocktails of known small molecules. Experiments in progress seek to identify additional small molecules for rescue

and can provide additional clues to the mitochondrial targets of DOS injury. Overall the studies highlight DOPAL-mediated structural modification of α-synuclein as a possible mechanism underlying PD neuropathology.

**Title:** Rapid influx of extracellular $Zn^{2+}$ into substantia nigra pars compacta via AMPA receptor causes of paraquat-induced Parkinson’s disease

**Authors: *H. MORIOKA**, R. NISHIO, A. TAKEUCHI, H. TAMANO, A. TAKEDA
Univ. of Shizuoka, Shizuoka, Japan

**Abstract:** Neurodegenerative disorders like Parkinson's disease (PD) are said to be caused by oxidative stress. Exposure to environmental agents such as herbicide paraquat (PQ) has been reported that acting as a reactive oxygen species (ROS) generator and been implicated in sporadic PD from epidemiological studies. Here we first report a novel mechanism of nigrostriatal dopaminergic neurodegeneration, in which rapid dysregulation of intracellular $Zn^{2+}$ via PQ-induced ROS production causes PD in Rats. We have used the microdialysis technique to perfuse PQ (3 μg/μL) in the rat's Substantia Nigra pars compacta 4h after the implantation of a microdialysis probe. During the perfusion of PQ (3 μg/μL), the extracellular glutamate and $Zn^{2+}$ levels were respectively increase and decrease in the SNpc. These changes were ameliorated by the co-perfusion with Trolox, an antioxidative agent. Accordingly, we demonstrated in vivo slice experiments. PQ (3 μg/μL) injection caused the increase of intracellular $Zn^{2+}$ and ROS levels in the SNpc. In vitro slice experiments showed that rapid PQ (3 μg/μL) exposure occurred increasing extracellular $Zn^{2+}$ influx via AMPA receptor activation. Immunohistochemical analysis showed that PQ (3 μg/μL) injection in the SNpc lost tyrosine hydroxylase (TH) and increased of turning behavior to apomorphine. These dopaminergic neurons degeneration were markedly reduced by co-injection of PQ and intracellular $Zn^{2+}$ chelator, i.e., ZnAF-2DA into the SNpc. Furthermore, surprisingly loss of nigrostriatal tyrosine hydroxylase induced with a low dose of PQ (10 ng/μL), which did not induce any behavioral abnormality, was completely blocked by co-injection of ZnAF-2DA. Increasing of Intranigral $Zn^{2+}$ levels by the low dose of PQ (10 ng/μL) was also completely blocked by extracellular $Zn^{2+}$ chelator and antioxdative agent i.e., Ca-EDTA and Trolox. Taking into account all of the results, Intracellular $Zn^{2+}$ dysregulation

in dopaminergic neurons by the PQ is the cause of PQ-induced PD in Rats and the block of intracellular $Zn^{2+}$ toxicity leads to overcoming PQ-induced pathogenesis.

**Title:** Brain insulin distribution in rats following intranasal application

**Authors: *Y. PANG**, K. CARTER, L.-W. FAN, A. BHATT
Univ. of Mississippi Med. Ctr. / Dept of Pediatrics, Jackson, MS

**Abstract:** Background: Our previous work showed that intranasal insulin is neuroprotective in a 6-hydroxydopamine-based rat model of Parkinson's Disease (PD). The aim of this study was to assess brain insulin pharmacokinetics in rats following intranasal application. Methods: Male adult rats were anesthetized with isoflurane and recombinant human insulin was administrated to both side of nostrils (20 ug each). At 15 min, 1, 2, and 6 h, rats were perfused intracardially with ice-cold PBS and brain tissue from the olfactory bulbs, striatum, thalamus, hippocampus, subtantia nigra (SN) plus ventral tegmental area (VTA), cerebellum, brainstem, and cerebral cortex were dissected for insulin measurement. Control rats were given intranasal PBS (vehicle). A total of 6 rats were included in each group. Insulin was detected by an ultrasensitive, human-specific ELISA kit, and insulin levels was expressed as pg/mg wet tissue. Data were analyzed by two-way ANOVA followed by Bonferroni post-hoc test. For microscopic study, rats were given intranasal fluorescence-tagged insulin (Ins-Alex546). Results: Insulin was detected in a wide range of brain regions, with highest levels at 15 min in all regions ($p<0.05$ vs control) except the cerebral cortex ($p>0.05$ vs control). The brainstem retained the highest levels, followed by SN-VTA, olfactory bulb, striatum, hippocampus, and thalamus. The level of Insulin decreased overtime and at 2 h, it remained significantly higher in the olfactory bulb and brainstem but not other regions. By 6 h, insulin levels declined to the control level ($p>0.05$). Consistent with ELISA data, Ins-Alex546-binding cells were found widespread in the brain 15 min following intranasal administration. The olfactory bulb and brainstem showed highest density of Ins-Alex546-binding cells, while the cerebral cortex especially the superficial layer showed very little fluorescence. Those Ins-Alex546-binding on cell membrane was confirmed by immunostaining with anti-human insulin antibody. Moreover, Ins-Alex546 binding was exclusively co-localized with NeuN immunoreactivity, indicating that insulin binds exclusively

to neurons but not glial cells. Double labeling of tyrosine hydroxylase (TH) and pAkt showed that the Akt/PI3K signaling was activated in a subset of dopaminergic neurons in the SN. Conclusion: Intranasal insulin could be rapidly distributed into brain including the SN via olfactory and trigeminal pathways.

**Abstract:** Parkinson's disease related death of dopaminergic neurons has been linked to pathological aggregation of alpha-synuclein protein and its transcellular traffic through the dopaminergic system. Tetracyclines, such as minocycline and doxycycline have been shown to be neuroprotective in Parkinson's disease animal models. Neuroprotective activities of minocycline have been attributed to its inhibitory effects on microglia activation. On the other hand, doxycycline has been shown to protect cells by inhibiting the formation of toxic alpha synuclein species. However, the antibiotic activity of these compounds limit their prescription for chronic treatments such as neurodegenerative disorders. Thus, chemically modified tetracyclines with diminishing or reduced antibiotic activity could represent a more adequate therapy for long-term treatments. In this regard, it was recently reported that the chemically modified tetracycline lacks antibiotic activity but retains anti-inflammatory effects. In the present study we evaluate the ability of CMT inhibit alpha-synuclein aggregation using different biophysical techniques such as fluorescence techniques, SAXS and advanced microscopies. In

addition, we evaluate the ability of CMT to modulate the inflammatory response of microglial cultures mediated by different inflammogenic compounds and we demonstrate that CMT inhibits cytokine production and Iba-1 release, as well as expression of prototypical markers of microglial activation. Considering that incyclinide has reduced antibiotic activity compared to other tetracyclines and is a well tolerated drug according to cancer-related Phase I clinical trials, we conclude that it could be a “ready to use drug”. Due to its ability to diminish toxic aggregation of alpha synuclein as well as neuroinflammatory processes, we propose CMT is poised as an promising candidate for Phase I clinical trials in neuroprotection.

**Abstract:** Recent findings have highlighted the critical roles of iron accumulation and iron-induced oxidative stress in the pathogenesis of Parkinson's disease (PD). Removing accumulated iron and reducing oxidative stress are potential therapeutic strategies for PD. We discovered that GSK-J4, a histone demethylase inhibitor with the ability to cross blood brain barrier, is a potent iron suppressor, and may therefore exert beneficial effect on PD. We found that, in vitro, only a trace amount of GSK-J4 could significantly and selectively suppress cellular iron in the dopaminergic SH-SY5Y and MES23.5 cells but not in HEK293 and HepG2 cells. Importantly, GSK-J4 prevented 6-OHDA-induced cell death and apoptosis in PD cell model, and rescued dopamine neuronal loss and motor defects in 6-OHDA-induced PD rats and MPTP-induced PD mice. These effects were accompanied by inhibition of the increase in various reactive oxygen

species in 6-OHDA models. Consistently, GSK-J4 suppressed $H_2O_2$-induced cell death in SH-SY5Y cells. Further experiments showed that GSK-J4 rescued the abnormal changes of histone methylation (H3K27me3 and H3K4me3) and iron metabolism during 6-OHDA-treatment. The effects of GSK-J4 on iron metabolism and neuroprotection were suppressed by inhibitor of H3K4me3 but not inhibitor of H3K27me3. These results imply that upregulation of H3K4me3 caused by GSK-J4 treatment is involved in cell-specific regulation of iron metabolism and the subsequent antioxidant effect. Therefore, GSK-J4 is a potentially useful compound in suppressing PD pathogenesis.

**Title:** Tubacin, an HDAC6 inhibitor, induced neuroprotective effects in MPTP mice

**Authors: *Y. PARK**, S. SONG, T. KIM, J. KIM, H. SEO
Hanyang Univ., Ansan, Korea, Republic of

**Abstract:** Parkinson’s disease (PD) is caused by selective vulnerability of dopaminergic neurons in substantia nigra (SN). As an external cause, MPTP [1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine] targets specifically those dopaminergic neurons involved in PD pathology. Histone deacetylase (HDAC) has critical function to unwrap DNA from histone by deacetylation and regulates specific gene expression for cell fate determination. As administration of HDAC inhibitors has been reported as potential therapeutic target in several neurodegenerative diseases. We hypothesized that inhibition of HDAC6 (class IIB HDAC) with tubacin induces neuroprotection in MPTP PD mouse model. We found that tubacin significantly improved motor balance in MPTP mice. Tubacin increased the number of tyrosine hydroxylase (TH)-positive dopaminergic neurons in the SN regions and reduced the expression of proinflammatory markers. These results suggest that tubacin could be used to study neuroprotection mechanism and future therapeutic application for PD.

**Abstract:** Parkinson's disease is a complex neurodegenerative disorder characterized by the presence of alpha-synuclein (aSyn)-positive protein aggregates called Lewy bodies and the selective death of dopaminergic neurons in the substantia nigra region of the brain. Multiple cellular pathways that are dysregulated in PD have been identified, including protein clearance systems and oxidative stress responses. Manipulation of these systems by environmental insults or genetic perturbations causes increased aggregation of aSyn, which in turn causes increased oxidative and proteasomal stress, generating a vicious cycle culminating in the death of dopaminergic neurons. Thus, strategies to enhance protein clearance and antioxidant responses have the potential to reduce aSyn aggregation and halt neurodegeneration. Nuclear factor erythroid-derived 2-related factor 1 (Nfe2L1) is an ER associated transcription factor that translocates to the nucleus under conditions of proteasomal inhibition. Once in the nucleus, NFE2L1 upregulates the expression of Antioxidant Response Elements (ARE)-regulated genes, including genes involved in glutathione biosynthesis and proteasome assembly. Nfe2L1 has been recently shown to be downregulated in the brains of PD patients, and knockdown of Nfe2L1 causes sensitization to oxidative and proteotoxic stress. We identified a SNP associated with Nfe2L1 as one of the most significant hits in a PD GWAS meta-analysis study. Based on these observations, we hypothesize that Nfe2L1 protects against neurotoxicity elicited by PD-related insults by alleviating oxidative stress and proteasomal dysfunction. Consistent with this idea, we have found that Nfe2L1 is expressed in rat midbrain dopaminergic neurons and is upregulated

upon treatment with proteasome inhibitor MG132 in rat primary midbrain cultures. Current efforts are focused on examining effects of Nfe2L1 expression on neurotoxicity in cellular models relevant to PD (e.g. primary midbrain cultures and human iPSC-derived dopaminergic neurons over-expressing aSyn or exposed to the PD-related toxin rotenone) and in the rat rAAV model. The data from these studies will yield insight into neuroprotective effects of Nfe2L1 in PD models and set the stage for developing therapies that enhance Nfe2L1 function in the brains of PD patients.

**Abstract:** Parkinson's disease (PD) is a progressive motor disease of unknown etiology. The clinical features of PD emerge due to selective degeneration of dopamine (DA) neurons in the substantia nigra pars compacta (SNc), which project to the caudate putamen (CPu) where they release DA. In the current in vivo mouse model study, we tested acetyl-L-carnitine (ALC) for its ability to protect against 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP)-induced damage to DA neurons. ALC is an acetylated form of L-carnitine and is found as a small water-soluble peptide located in mitochondria. It is naturally produced in vivo and is often taken as a dietary supplement. ALC has a carnitine moiety which is important for the oxidation of fatty acids and an acetyl moiety that is required for the maintenance of acetyl-CoA levels and can promote the production of the antioxidant glutathione. Studies suggest that ALC can easily cross the blood-brain barrier. In the present study, we investigated whether ALC treatment can ameliorate the pathology seen in a chronic MPTP-induced PD mouse model. There were four treatment groups: probenecid only (250mg/kg, i.p; control), MPTP (25mg/kg-10 doses)

+probenecid (250mg/kg-10doses), and MPTP (25mg/kg-10 doses) + acetyl-L-carnitine (100mg/kg-daily i.p. for 38 days) and acetyl-L-carnitine (100mg/kg-daily i.p. for 38 days). MPTP-induced losses in tyrosine hydroxylase and DA transporter immunoreactivity in the ventral midbrain SNc and CPu were significantly reduced by ALC. HPLC data suggests that decreases in CPu dopamine and other DA metabolites level produced by MPTP were also attenuated by ALC. In addition, microglial activation and astrocytic hypertrophy induced by MPTP were greatly reduced by ALC, indicating protection against neuroinflammation. ALC only treated animals did not show any change in the DA or DA metabolites. Likewise, the glucose transporter-1 that is expressed exclusively in brain endothelial cells is also protected by ALC from MPTP-induced down-regulation. This study demonstrates protection afforded by ALC against MPTP-induced damage to endothelial cells and TH loss suggesting that ALC therapy may have the potential to slow or ameliorate the progression of PD pathology.

**Abstract:** Aggregation of the presynaptic protein, alpha-synuclein (aSyn), plays a major role in neurotoxicity in Parkinson’s disease (PD) and other synucleinopathy disorders. aSyn undergoes accelerated aggregation in the presence of phospholipid membranes by adopting an exposed alpha-helical structure, a state that favors membrane-induced self-assembly. In turn, aSyn aggregation at membrane surfaces may cause a disruption of dopamine vesicles, leading to preferential dopaminergic neuronal death. Endosulfine-alpha (ENSA) is a cAMP regulated

phosphoprotein that is expressed in the CNS and has been reported to interact with membrane-bound aSyn. Previously, we showed that ENSA is downregulated in the frontal cortex of patients with dementia with Lewy bodies (DLB) and shows a trend towards being downregulated in the substantia nigra (SN) region of PD brains. In primary midbrain cultures, WT ENSA, but not the S109E mutant that fails to interact with membrane-bound aSyn, alleviated aSyn-mediated dopaminergic cell death and neurite retraction. Collectively, these data provide a strong premise for the hypothesis that ENSA alleviates aSyn neurotoxicity by interfering with aSyn aggregation at the surface of phospholipid membranes. Current efforts are focused on testing this hypothesis in an *in vivo* model by determining the effects of co-expressing WT ENSA versus ENSA-S109E on aSyn neurotoxicity in the rat rAAV-aSyn model using behavioral and immunohistochemical approaches. In addition, we have developed a rat model of mild traumatic blast injury (mTBI) that shows evidence of aSyn aggregation in the SN and nigrostriatal degeneration, and this model opens new avenues for examining protective effects of ENSA against PD-related neuropathology. The results of these studies will provide new insights into the molecular underpinnings of aSyn neurotoxicity and ENSA-mediated neuroprotection and set the stage for designing therapies to slow nigrostriatal degeneration in PD or TBI patients.

**Title:** Dynamics of development of the synaptic processes in the substantia nigra and spinal cord on rotenon model of Parkinson's disease

**Authors: *V. SARGSYAN**[1], N. BEHNAM DEHKORDI[2]
[1]Orbeli Inst. Physiol, Yerevan, Armenia; [2]Head Neck Surgery Dept., Case Western Univ. Hosp., Clevland, OH

**Abstract: Abstract Objective:** The mechanism of neurodegeneration associated Parkinson’s disease (PD) continues to be complex and in many ways still needs further investigation. At least it is important that not only the lack of dopamine neurons in Substancia Nigra (SN) is responsible for characteristic motor symptoms to be subject to symptomatic therapy. At present to assess electrophysiological, neurochemical, behavioral and cognitive manifestations of PD successfully used the rotenon model which develops within 4 weeks after the intracerebral injection of rotenone. **Methods:** On the model of PD after 2-4 weeks (w) recording of the

activity of single neurons of SN to high frequency stimulation (HFS) of Caudate-Putamen (CPu), spinal cord (SC) motoneurons (MNs) (at L4-L5 segments), as well as activity of SN neurons evoked by HFS of flexor (G) and extensor (P) hind limb nerves revealed the formation of excitatory and depressor responses in the form of tetanic depression and potentiation (TD, TP) to be combined into uni - (TD post TD , TP post TP) and multidirectional ( TD post TP , TP post TD) post-tetanic sequences **Results:** It is established, that in the SN neurons to HFS of CPu, TD going with PTD at 2nd week was close to the norm, dropping by more than half at 4th week. With the use of vipera radei venom (VR), there was tendency of reducing the TD. It is believed the advancement of deepening the depressor tetanic reactions as a carrier of protective load during neurodegeneration of different origin in the initial stage of recovery, and to facilitate the restoration of the original ratio of excitatory and depressor processes. In the present study should be evaluated the significance of tetanic depressor manifestations of SC MNs and SNs activity, best expressed in the initial stage of recovery. As is known, depressor post stimulus manifestations of activity in the form of TD and PTD mediate the inhibitory GABA or Glycine monoamines. **Conclusion:** Apparently depressor mechanism of protection mediated by, inter alia, GABA-ergic structures at different origins of neurodegeneration, contributes to the restoration the initial ratio of excitatory and inhibitory processes Keywords*: Parkinson's disease, Substantia Nigra, spinal cord motoneurons, the extensor and flexor nerve , Caudate Putamen, single spike activity.*

**Abstract:** Parkinson’s disease (PD) is a neurodegenerative disease for which there is no known cure. Deep brain stimulation (DBS) is a surgical treatment that has been recognized as effective in reducing motor symptoms for PD patients. Previous work implicates DBS directly influences motor cortex through stochastic antidromic spikes. Here we developed a prototype of a multi-channel stimulating system to mimic the effects of stochastic antidromic activation on the motor cortex and assessed the efficacy in ameliorating motor symptoms in the rat PD model. The results showed that different combinations of frequency, amplitude and pulse width of electrical pulses exerted different effects on Parkinsonian rats. Among these, some stimulus patterns were able to produce transient beneficial effect on movement assessed by open-field locomotor activities. These results indicate that, in principle, cortical stimulation can achieve therapeutic outcome, and is a less invasive approach than standard DBS. More refined mode of stimulation to achieve long-lasting and more robust effect will be explored.

**Title:** The effects of growth hormone on motor findings and neuronal morphology in Parkinson model rats

**Authors: *O. KIRAZLI**, A. ARMAN, M. ÖZKAN, R. GULHAN, U. SEHIRLI
Marmara Univ., Istanbul, Turkey

**Abstract:** OBJECTIVE:Parkinson Disease is a neurodegenerative disease, characterized by the degeneration of dopaminergic neurons in Substantia nigra (SN). Growth hormone (GH) is a hormone that plays a role in the development of important functions in the control of brain development. There are studies showing that BH administration may be associated with recovery of neuronal functions after brain injury. Dendritic spines increases the surface area and causes the communication between all stimulating cells in the brain.There is a connection between the structural properties and functions of dendritic spines. This study aims to investigate the effect of GH therapy on motor function and neuronal morphology for 3 months.METHODS:Sprague Dawley rats; Treatment group (PD+GH) (n = 6) and Sham (PD+ Saline) (n=6) were injected with 4 µl 6-OHDA solution (Bregma AP: -2,1 mM, Lat: 2,0 mm and VL: -7,8 mm) stereotaxically. Following the injection GH and saline (0.15 mg / kg / day, s.c.) is administered daily. Rotation preferences and lesion grade are evaluated according to the rotation test. Golgi (FD Rapid Kit) and Tyrosine hydroxylase (TH) staining procedures are applied to sections of the striatum and substantia nigra (40 µm).Golgi staining was evaluated using Neurolucida

360(v2018).RESULTS:According the results of the rotation, the number of rotations in BH treatment group was significantly decreased (p = 0.0112). No significant difference was observed between the groups in SN and striatum in TH staining. Thin type dendritic spine density is significantly increased in the treatment group, which indicates restoration of neuron morphology.CONCLUSION:Long term GH administration has been shown to have positive effects on motor function and neuronal morphology.This study was supported by Marmara University Scientific Researches and Projects Committee (SAG-K-070617-0339)

**Abstract:** [Background] Tyrosine hydroxylase (TH), dopa decarboxylase (DDC) and nuclear receptor related 1 (Nurr1) are essential for nigrostriatal dopaminergic function. Here, we investigated an as-yet-unidentified mechanism for the coordinate expression of above three genes *in vitro* and *in vivo* to provide the first evidence for a novel regulatory system of TH/DDC/Nurr1 by a protein complex of V-1, a classical ankyrin repeat protein, and CP, an actin capping protein, the unique regulators of actin dynamics (PLoS Biol. 2010).

[Method] Lentiviral V-1 expression vectors (VSV-G/V-1) were prepared to analyze V-1/CP-regulated dopaminergic function. Wild-type (WT), mutated (D44R) or control (GFP)-conjugated VSV-G were injected into the substantia nigra of C57BL6 mice which were sacrificed 1 month after injection for the subsequent analyses. The aging-dependent failure of V-1/CP complex formation was analyzed by immunohistochemistry. Signaling pathway required for the V-1/CP function was analyzed by Rho/Rac pull-down assay and transfection of Rho, LIMK, cofilin, SRF constructs, or their mutants. A ChIP-PCR assay was employed to identify the SRF-binding site in the promoter region of TH, DDC, and Nurr1 genes. Human brains were analyzed with the approval by the ethics committee of Japan Sagamihara National Hospital.
[Results] Failure of V-1/CP complex formation by injecting mutant VSV-G/V-1(D44R, cannot bind to CP) into C57BL6 mice midbrain impaired the expression of TH/DDC/Nurr1 as well as VMAT2 and DAT in the nigrostriatum, accompanied by a reduction in dopamine levels. We also found that VSV-G/V-1(D44R) impairs RhoA/Rac1/ROCK/LIMK pathway. In cultured dopaminergic neurons, we identified that V-1/CP complex promotes RhoA/Rac1 activity, cofilin phosphorylation and facilitates actin polymerization, accompanied by enhanced MAL nuclear import to increase serum responsive factor (SRF)-mediated transcription. A ChIP-qPCR assay using an anti-SRF antibody showed the V-1/CP-regulated SRF-binding in the promoter region of TH/DDC/Nurr1 genes. Interestingly, MPP(+)-treatment impaired the association of V-1/CP, whereas VSV-G/V-1(WT) transfection to increase V-1/CP complex formation alleviated the MPP(+)-induced dopaminergic neurodegeneration by restoring the impaired TH/DDC/Nurr1/VMAT2 expression and dopamine content. Notably, we also found that the association of V-1/CP was weakened in aged C57BL6 mice and the human midbrain in Parkinson's disease (PD).
[Conclusion] We conclude that the V-1/CP complex is crucial for maintaining the adult dopaminergic system, implying that the V-1/CP complex is a novel potential target for fundamental therapy of PD.

**Title:** Extracellular $Zn^{2+}$ influx into nigral dopaminergic neurons plays a key role for pathogenesis of 6-hydroxydopamine-induced Parkinson’s disease in rats

**Authors: *A. TAKEDA**, R. NISHIO, H. MORIOKA, H. TAMANO
Univ. Shizuoka, Shizuoka, Japan

**Abstract:** Glutamate excitotoxicity is the pathological process through which neurons are damaged and killed after excess activation of glutamate receptors. The influx of extracellular $Ca^{2+}$ through N-methyl-D-aspartate (NMDA) receptors plays a crucial role in glutamate excitotoxicity. Even in dopaminergic neurons where the mechanism of glutamate excitotoxicity is poorly understood, $Ca^{2+}$ influx through NMDA receptors has been believed to be a trigger for neuronal death. In contrast, it is recognizing that most of the death signaling associated with neurological conditions is mediated by not only $Ca^{2+}$ toxicity but also $Zn^{2+}$ toxicity. Dopaminergic neurons express glutamate receptors in the substantia nigra pars compacta (SNpc). It has been postulated that excess activation of glutamate receptors on dopaminergic neurons in the SNpc may be involved in pathophysiology of Parkinson's disease (PD), which is a progressive neurological disease characterized by a selective loss of nigrostriatal dopaminergic neurons. To understand PD pathogenesis, it is important to clarify the significance of cytosolic $Zn^{2+}$ toxicity and its origin in nigrostriatal dopaminergic neurodegeneration. Here we report a unique mechanism of nigrostriatal dopaminergic neurodegeneration, in which extracellular $Zn^{2+}$ influx plays a key role for PD pathogenesis induced with 6-hydroxydopamine (6-OHDA) in rats. 6-OHDA rapidly increased intracellular $Zn^{2+}$ only in the SNpc of brain slices and this increase was blocked in the presence of CaEDTA, an extracellular $Zn^{2+}$ chelator, and CNQX, an α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptor antagonist, indicating that 6-OHDA rapidly increases extracellular $Zn^{2+}$ influx via AMPA receptor activation in the SNpc. Extracellular $Zn^{2+}$ concentration was decreased under in vivo SNpc perfusion with 6-OHDA and this decrease was blocked by co-perfusion with CNQX, supporting 6-OHDA-induced $Zn^{2+}$ influx via AMPA receptor activation in the SNpc. Interestingly, both 6-OHDA-induced loss of nigrostriatal dopaminergic neurons and turning behavior to apomorphine, an index of behavioral abnormality, were markedly ameliorated by co-injection of intracellular $Zn^{2+}$ chelators, i.e., ZnAF-2DA and TPEN. Co-injection of TPEN into the SNpc blocked 6-OHDA-induced increase in intracellular $Zn^{2+}$ but not that in intracellular $Ca^{2+}$. The present study suggests that the rapid influx of extracellular $Zn^{2+}$ into dopaminergic neurons via AMPA receptor activation in the SNpc causes nigrostriatal dopaminergic neurodegeneration, resulting in 6-OHDA-induced PD in rats.

**Abstract:** Parkinson's disease (PD) is a debilitating movement disorder resulting from the death of dopamine neurons. There is as of yet no stable and permanent treatment, leading to the necessity of developing new treatment method. Through optogenetic circuit dissection, we have revealed that inhibited thalamic neurons paradoxically yield rebound excitability and induce motor abnormalities associated with PD. This study focuses on the development of a new method for the cure of PD by controlling this rebound excitability. For that, we designed a method that can normalize the abnormally increased excitatory output in a desired number of neurons, and confirmed that it works properly as expected in vitro. Ultimately, we aim to find a new circuit-based therapy that can ameliorate Parkinsonian motor symptoms semi-permanently through clinical application experiments in mice and primate PD models.

**Title:** Modulation of PINK1 and PARK2 gene expression in rotenone induced Parkinson's disease model

**Authors: *Z. A. RAZZAK**[1], K. RAFI[2], G. ABBAS[3], S. SIMJEE[2]
[1]Dr Panjwani Ctr. or Mol. Med. and Drug Res., Intl. Ctr. for Chem. and Biol. S, Karachi University, Pakistan; [2]Dr. Panjwani Ctr. for Mol. Med. and Drug Res., Intl. Ctr. for Chem. and Biol. Sci., Karachi University, Pakistan; [3]H.E.J. Res. Inst. of Chem., Intl. Ctr. for Chem. and Biol. Sci., Karachi, Pakistan

**Abstract: BACKGROUND**
**Objective**
Parkinson's disease (PD) is the second most leading cause of death due neurodegenerative diseases, nearly affecting 1% of population worldwide. The posture instability and shaky movements happen due to motor impairment. The hallmarks of PD occur due to death of dopaminergic neurons in substantia nigra par compacta, due to the modulation of PARK2 gene

recruited by PTEN induce putative kinase1 (PINK1). PARK2 translate the Parkin protein which participates in the degradation of misfolded protein. During oxidative stress, mitochondria concomitantly reduce the performance of electron transport chain. As a result, PINK1 activation is ceased which in series halt the recruitment of PARK2 resulting in accumulation of protein which eventually cause death of dopaminergic neuron. Available PD therapies only provides symptomatic relief, so the aim of this study is to find new leads which can halt the death of dopaminergic neurons and slow down the progression of PD.

**Methods**

In this preliminary study, *in vivo* mice model of PD was developed by intra peritoneal (IP) administration of rotenone on alternate days for 60 days. Animals were grouped into three doses (i) low dose (ii) median dose (iii) high dose. Hind limb clasping test and grip strength test were conducted to grossly evaluate the disease progression. After the appearance of maximum symptoms animals were sacrificed. Mid brain and striatum was isolated and samples were processed for RT-PCR. Neurotransmitter analysis was done by HPLC to quantify the Dopamine and DOPAC turn over in striatum of brain.

**Results and Conclusion**

Based on the initial findings, we conclude that the median dose of rotenone has the maximal potential for decreasing dopamine turn out number; this was confirmed by comparing by all respective groups. RT-PCR analysis shows decrease level of PINK1 and PARK2 expression suggesting mitochondrial dysfunction (rotenone is mitochondrial complex 1 inhibitor) which further decreases the PARK2 gene expression which resulting in the accumulation of degraded protein causing the death of neuron. In future studies, we aim to screen the novel peptides to find the possible lead compound that can be used as a potential therapeutic agent for Parkinson's disease.

**Abstract:** This study was designed to assess the reproducibility of the amantadine anti-dyskinetic effect in the MPTP L-DOPA-Induced Dyskinesia (LID) macaque model for soundly defining the sample sizes required to test anti-dyskinetic compounds. Dyskinesia are side effects associated with chronic L-dopa treatment in Parkinson's patients that are partially alleviated by the weak NMDA antagonist amantadine. Although the current benchmark, response to amantadine is variable and effective only in a subset of patients. While recognizing that the MPTP macaque model is the gold-standard pre-clinical translational model, we provide critical information for designing and powering studies for testing of novel anti-dyskinetic strategies. We conducted the meta-Analysis of 11 studies (n ranging from 7 to 24 individuals) involving NHPs treated with vehicle and amantadine in combination with levodopa. The effect was calculated by the difference in total dyskinesia score between amantadine and vehicle. The primary objective was to quantify the reproducibility of the study responses and to understand the variability present between studies and between animals within the studies. Secondly, we determined the expected effect size and variation to ensure appropriate statistical design and power for future studies with new compounds. The mean profiles over all animals in all studies show a reasonable efficacy window between vehicle and amantadine response profiles. However, the profiles in individual studies are less consistent. The meta-analysis of the effect suggested a study-to-study heterogeneity (effect from -2.6 ± 1.45 to -15.3 ±1.03). The meta-analysis of the within-subject standard deviation suggested that the heterogeneity between-study is negligible relative to the size of the variability within-study. From the two meta-analyses, we obtained an estimate of the 'average' amantadine effect of -8.8 and an estimate of the potential size of the within-subject SD of 3.6. The number of animals required to detect 100%, 67% and 50% of the amantadine effect is 4, 6 and 12 with the corresponding power of 85%, 84% and 83% respectively. Result of this meta-analysis is of significance and confirms that the MPTP macaque model is a reliable translational model to assess the antidyskinetic ability of a novel mechanism. However, due to the intersubject variability using suitable sample size is essential to obtain consistent results.

**Title:** Resting-state brain small-world network property correlates with fatigue in PD patients

**Authors: *H. RAO**, X. ZHONG, R. BHAVSAR, E. MAMIKONYAN, F. YANG, H. LEI, J. A. DETRE, D. WEINTRAUB
Univ. of Pennsylvania, Philadelphia, PA

**Abstract: Introduction**: Parkinson's disease (PD) is a common neurodegenerative disease affecting millions of people world-wide. Fatigue is a highly prevalent and disabling non-motor symptom in PD. However, little is known about the neural mechanisms underlying fatigue in PD, and this lack of knowledge is a significant barrier to implementing prevention and management strategies. Accumulating evidence suggests that the human brain is topologically organized as a small-world network. Our previous neuroimaging study on healthy adults suggest that disruption of the brain small-world network properties (e.g., characteristic path length λ and small-worldness σ) may underlie increased fatigue after experimental sleep deprivation. In this follow-up pilot study we used resting-state functional magnetic resonance imaging (fMRI) to examine whether these brain network properties are associated with fatigue severity in a cohort of PD patients. **Method**: We scanned 11 PD patients (6 females, mean age = 67±10 years) using a standard multi-band EPI sequence on a Siemens 3T Prisma scanner. Patients' fatigue severity was assessed by both the Fatigue Symptom Inventory (FSI) and the Multidimensional Fatigue Symptom Inventory-Short Form (MFSI-SF). GRETNA toolbox was used to model the resting-state fMRI data with graph theory and calculate the brain small-world network properties. **Results**: Significant negative correlations were found between network characteristic path length λ and fatigue scores from both FSI ($r$=-0.777, $p$=0.008) and MSFI-SF (for general fatigue: $r$=-0.863, $p$=0.001; for total fatigue: $r$=-0.670, $p$=0.048). However, no correlations were found between network small-worldness σ and fatigue scores in PD (all $p$>0.05). **Conclusion:** The characteristic path length λ is a measure of the average shortest paths for information transport between nodes of the brain small world network. Correlations between λ and fatigue scores suggest that fatigue in PD may also be associated with disruption of the brain small-world network property and communication efficiency.

**Abstract:** Parkinson's disease (PD) is a neurodegenerative disorder characterized by movement disorder. Non-motor symptoms of PD have also been paid attention to in recent years, especially the somatosensory symptoms. The tactile motion perception of somatosensory, the movement sensation between the skin and the object, has become a research focus because of its close relationship with the motor performance. The goal of the study was to characterize tactile motion perception in PD patients to explore the somatosensory symptoms in PD. To this end, we used a lab-designed ball tactile stimulator to present a series of stimulations to the center of the subject's left index fingerpad. The stimulation parameters included 8 different directions and 6 speed levels of motion. Subjects directly drew a line on the touchpad to response the tactile motion velocity (direction and speed) of stimulations. In the current study, 24 subjects were divided into three groups: seven PD patients (55-65 y), ten young-age-healthy controls ($HC_Y$, 20-30 y) and seven old-age-healthy controls ($HC_O$, 55-65 y). All Parkinson's patients were evaluated by Unified Parkinson's Disease Rating Scale (UPDRS). Our data showed that the significant difference in perception of directions ($p<0.05$) and speed ($p<0.05$) among PD, $HC_Y$ and $HC_O$ groups. The bias of direction perception in PD group was largest in three groups. The speed perception in PD subjects was shown to be less sensitive than that in $HC_Y$ ($p<0.01$) and $HC_O$ subjects ($p<0.05$). Taken together, the results indicated that the widespread deficits in tactile motion perception of PD patients.

**Title:** The discovery of dopamine D1 positive allosteric modulators for the treatment of neuro-psychiatric disorders

**Authors: *K. A. SVENSSON**[1], J. P. BECK[1], J. HAO[1], J. SCHAUS[1], B. HEINZ[1], X. WANG[1], S. MITCHELL[1], K. WAFFORD[1,2], H. Y. MELTZER[2,3], C. R. YANG[3], R. F. BRUNS[1]
[1]Neurosci. Discovery Res., Eli Lilly and Co., Indianapolis, IN; [2]Psychiatry and Behavioral Sci., Northwestern Feinberg Sch. of Med., Chicago, IL; [3]Neurosci., ShangPharma, Shanghai, China

**Abstract:** The dopamine D1 receptor plays a critical role to maintain motor activity, reward and higher cognitive functions including working memory, attention and executive function. Increased cortical D1 activity could address critical unmet medical needs including cognitive impairment. Selective D1 agonists are active in animal models relevant to clinical applications for neuro-psychiatric disorders. However, development of D1 agonists for clinical use has not been successful due to issues with receptor desensitization, poor ADME properties, or dose limiting side effects (eg Arnsten 2016, but see Gray et al., 2018).
Objective: Test the hypothesis that a dopamine D1 positive allosteric modulator (D1PAM) could address some of these issues and offer a more physiological approach to activation of D1 receptors with temporal and spatial resolution related to endogenous dopamine release (cf. Svensson et al., 2017).
Methods: In vitro testing for potentiation of dopamine induced increase in cAMP was done using cloned human D1 cells. Mutagenesis and D1/D5 chimera studies identified the binding site for D1PAM. In vivo testing was done in human D1 receptor knock-in (hD1KI) mice due to a significant species difference in binding of D1PAM. Preclinical data will be shown for the two D1PAMs DETQ and LY3154207.
Results: DETQ shows high alpha-shift and D1 selectivity. Studies with chimeric receptors identified a novel allosteric binding site at the second intracellular loop. DETQ increased locomotor activity in hD1KI mice over a wide dose range without evidence for inverted U-shaped dose-response. DETQ reversed hypo-activity caused by pre-treatment with a low dose of the dopamine depleting agent reserpine. DETQ acted synergistically with L-DOPA to reverse the akinesia seen with a high dose of reserpine. Microdialysis studies showed that DETQ increases release of acetylcholine in the hippocampus where it had an additive effect together with rivastigmine. Testing in the novel object recognition model for cognition showed dose relate reversal of PCP induced deficits with DETQ.
Conclusions: Preclinical data support further development of D1PAMs for neuro-psychiatric

disorders. This includes LY3154207 which recently entered phase 2 studies in Parkinson's disease dementia.

Taipei Univ. of Technol., Taipei City, Taiwan

**Abstract:** To determine the influences of exercise on motor deficits and dopaminergic transmission in a hemiparkinson animal model, we measured the effects of exercise on the ambulatory system by estimating spatio-temporal parameters during walking, striatal dopamine (DA) release and reuptake and synaptic plasticity in the corticostriatal pathway after unilateral 6-OHDA lesions. 6-OHDA lesioned hemiparkinsonian rats were exercised on a fixed speed treadmill for 30 minutes per day. Controls received the same lesion but no exercise. Animals were subsequently analyzed for behavior including gait analysis, rotarod performance and apomorphine induced rotation. Subsequently, in vitro striatal dopamine release was analyzed by using FSCV and activity-dependent plasticity in the corticostriatal pathway was measured in each group. Our data indicated that exercise could improve motor walking speed and increase the apomorphine-induced rotation threshold. Exercise also ameliorated spatiotemporal impairments in gait in PD animals. Exercise increased the parameters of synaptic plasticity formation in the corticostriatal pathway of PD animals as well as the dynamics of dopamine transmission in PD animals. Fixed speed treadmill training 30 minutes per day could ameliorate spatial temporal gait

impairment, improve walking speed, dopamine transmission as well as corticostriatal synaptic plasticity in the unilateral 6-OHDA lesioned rat model.

**Title:** Biochemical and behavioral evidences for neuromodulatory properties of combination of ellagic acid, curcumin and mucuna pruriens against rotenone induced mice model of Parkinson's disease

**Authors: *D. K. KHATRI**[1], P. K. RANE[2], M. B. PANCHWADKAR[3]
[1]Pharmacol. Dept., [2]Pharmacol. lab, Dr. D. Y. Patil Inst. of Pharmaceut. Scienc, Pune City, India; [3]Pharmacol., Dr. D. Y. Patil Inst. of Pharmaceut. Sci. & Res., Pimpri Pune, India

**Abstract: Aim & Objectives** The present study was designed in order to explore the possible synergistic effect of three highly naturally occurring bio-active compounds viz. Ellagic acid (EA), Curcumin (Cur) and Methanolic extract of *Mucuna Pruriens* Seeds (MPM). The neuroprotective role of combinational therapy of EA, Cur and MPM was explored in rotenone induced behavioural, oxidative and mitochondrial dysfunction in mice model of Parkinson’s disease. **Background** Ellagic acid (EA) Curcumin (Cur) and *Mucuna Pruriens*, are natural polyphenolic, powerful bioactive compounds used word wide. They exhibited numerous biological and pharmacological activities including potent antioxidant, cardiovascular disease, anticancer, anti-inflammatory effects and neurodegenerative disorders in cell cultures and animal models. **Methods** Chronic administration of rotenone (1 mg/kg i.p.) for a period of three weeks significantly impaired behavioural paradigm (Memory, learning and locomotor activity), oxidative defence (Decreased activity of superoxide dismutase, catalase and reduced glutathione level) and mitochondrial Complex-II-Succinate Dehydrogenase (SDH), Complex III- MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-H-tetrazolium bromide) enzymes activities as compared to normal control group in the brain of mice. **Results** Three weeks of EA, Curc and MPM combination (50, 100 and 200 mg/kg, p.o) treatment significantly improved behaviour parameters ($P < 0.001$) oxidative damage ($P < 0.001$) and mitochondrial enzyme complex activities ($< 0.05$, $P < 0.01$, $P < 0.001$) as compared to negative control (rotenone treated) group. We found that combination of EA, Cur and MPM restored motor deficits and enhanced the activities of antioxidant enzymes suggesting its antioxidant and neuroprotective potential in vivo. **Conclusion** Collectively, these data suggest that combination therapy of natural bioactive compounds may provide neuroprotection may be primarily attributed to the restoration effect on

antioxidant defence and mitochondrial function which lead to improved locomotor phenotype. We propose that EA, Cur and MPM combination may provide new perspectives for the development of therapeutic strategies in protecting the brain against oxidative stress-mediated neurodegenerative disorders.**Key words:** Ellagic acid, Curcumin, *Mucuna Pruriens*,; Rotenone; Neuroprotective; Parkinson's disease; Mitochondrial Dysfunction; Oxidative Stress

**Title:** A new combination therapy of Curcumin and Ginkgo biloba for mitochondrial biogenesis Implications for Parkinson’s disease

**Authors: *P. K. RANE**[1], M. B. PANCHWADKAR[3], D. K. KHATRI[2]
[1]Pharmacol. lab, Dr. D. Y. Patil Inst. of Pharmaceut. Scienc, Pune City, India; [2]Pharmacol. Dept., Dr. D. Y. Patil Inst. of Pharmaceut. Scienc, Pune, India; [3]Pharmacol., Dr. D. Y. Patil Inst. of Pharmaceut. Sci. and Res., Pimpri Pune, India

**Abstract: Objective *** This study was designed with the objective to find out the possible synergistic effect of Curcumin (Cur) and Methanolic extract of Ginkgo biloba (EGB) Leaf in Parkinson’s disease (PD). Cur and EGB were explored for their neuroprotective effect in rotenone-induced neurodegeneration in mice model of Parkinson’s disease. **Background *** Both Cur and EGB, are natural polyphenolic, highly potent bioactive compounds. Cur has been used for centuries in traditional medicines in India. Curcumin showed several biological and pharmacological activities including potent antioxidant, cardiovascular disease, anticancer, anti-inflammatory effects and neuroprotective effect. Ginkgo biloba is one of the most widely used herbal remedies in the world to treat the symptoms of early-stage Alzheimer’s disease, vascular dementia, peripheral claudication, and tinnitus of vascular origin. **Methods *** Rotenone (1mg/kg/ i.p.) was used to induced PD in mice. Chronic rotenone administration for 21 days produced significant impairment in the behaviour pattern (learning, memory, motor coordination), decrease oxidative function (superoxide dismutase, catalase and reduced glutathione level) and mitochondrial function (Complex-I, Complex-II, Complex-III) as compared to normal control group of mice. **Results *** Simultaneous treatment with Cur and EGB combination at different dose level (50, 100 and 200 mg/kg, p.o) for 21 days significantly improved behaviour parameters ($P < 0.001$), oxidative damage ($P < 0.001$) and mitochondrial enzyme complex activities (< 0.05, $P < 0.01$, $P < 0.001$) as compared to negative control (rotenone-treated) group. The results of present study showed that the Cur and EGB combination restored the motor deficit function and

enhance oxidative and mitochondrial functions. **Conclusions *** The outcome of present investigation confirms that the treatment of mice with combination of Cur and EGB produced significant neuroprotection probably mediated through its antioxidant activity and provides a strong justification for the therapeutic potential of these compounds in management of PD. **References:** 1. **Abstract:** The motor symptoms observed in Parkinson's disease (PD) result from the loss of dopamine producing neurons in the Substantia Nigra pars compacta (SNc). The loss of these neurons has been repeatedly linked to neuroinflammatory processes. In particular, microglial are found in a highly activated state in human PD brains, as well as in animal models of the disease. Animal models of PD have often utilized toxicants, such as the herbicide paraquat, to induce microglial activation and the release of reactive oxygen species that are toxic to dopamine neurons of the SNc. While the short-term effects of paraquat exposure are well reported the long-term effects have yet to be explored in detail. To this end, we sought to examine the long-term effects of paraquat exposure in parallel with increasing animal age. It was found that the loss of SNc dopamine neurons remained stable over the six month course of the study. Interestingly, paraquat had long-term stressor-like effects, such that corticosterone was elevated for over a month following termination of the toxicant treatment. Finally, time-dependent changes in antioxidant and inflammatory mediators were also noted and might contribute to pathology. Most importantly, many of these changes only emerged months following termination of paraquat exposure. These data suggest that paraquat might have protracted stressor effects and

highlight the importance of age and time in the manifestation of the consequences of toxicant exposure.

**Title:** Antidepressant-like effect of curcumin in a 6-OHDA rat model of Parkinson’s disease

**Authors: *M. A. VITAL**, M. M. F. MACHADO, J. C. F. VIEIRA, T. B. BASSANI
Univ. Federal Do Paraná, Curitiba, Brazil

**Abstract: Introduction:** Depression is a frequent non-motor symptom of Parkinson’s disease (PD) which impairs the patients’ quality of life. The causes of depression in PD patients may involve neurodegeneration and dysfunction of neurogenesis. Curcumin is a polyphenolic compound from *Curcuma longa* with anti-inflammatory, antioxidant and neuroprotective properties. Curcumin presents antidepressant-like effects in animal models of depression, which would be associated with an improvement in hippocampal neurogenesis. The aim of this study was to test the hypothesis that curcumin would exert an antidepressant-like effect in the 6-hydroxydopamine (6-OHDA) model of PD in Wistar rats by enhancing hippocampal neurogenesis and/or protecting substantia nigra pars compacta (SNpc) dopaminergic neurons. **Methods:** Adult male Wistar rats ($n$ = 8/group) received a bilateral intranigral injection of 6-OHDA (6 μg per injection site) or vehicle, and the curcumin treatment (60 mg/kg, gavage) was performed for 21 days, starting 1 day after surgery. The sucrose preference test (SPT) was performed before the surgery to measure basal levels, and weekly on days 7, 14 and 21 after surgery. After the behavioral tests, the animals underwent transcardial perfusion for immunohistochemical analysis of tyrosine hydroxylase immunoreactive neurons (TH-IR) in the SNpc and doublecortin (DCX)-positive cells in the dentate gyrus (DG) of the hippocampus. Group differences were analyzed using two-way analysis of variance (ANOVA) with Tukey’s multiple comparisons for the SPT and one-way ANOVA for the other tests. Significance was set at $p < 0.05$. All procedures were approved by the Ethical Committee of Animal Experiment of Federal University of Paraná (protocol 590).

**Results:** 6-OHDA-lesioned animals exhibited anhedonia-like behavior, reflected by a decrease in sucrose preference, on days 7 ($p<0.05$) and 21 ($p<0.01$) after surgery, and a marked reduction in TH-IR neurons in the SNpc, 21 days after surgery ($p<0.01$). However, there were no alterations in the number of immature neurons (DCX-positive cells) in the DG of the hippocampus. Treatment with curcumin for 21 days reversed the anhedonia-like behavior in 6-OHDA-lesioned rats, but there was no increase in TH-IR neurons within the SNpc, and no significant alterations in the number of immature neurons in the hippocampus.
**Conclusions:** These results suggest that curcumin exerted antidepressant-like effects in the 6-OHDA intranigral model of PD, which was neither associated with dopaminergic neuroprotection nor an improvement in hippocampal neurogenesis.

**Title:** Myricetin derivatives ameliorate deficits in 6-OHDA animal model of Parkinson's disease

**Authors: D. THOMPSON**[1], S. TRUESDELL[1], M. KOPANITSA[2,6], D. MISZCZUK[2], *R. O. PUSSINEN[2], W. DURHAM[3], P. MILIANI DE MARVAL[3], T. JENSEN[3], G. FLIK[4], E. SEWARD[5], P. CRACKETT[5], P. BURY[5], D. SMALL[7], A. J. NURMI[2]
[1]GRDG Sci., Winter Haven, FL; [2]Charles River Discovery, Kuopio, Finland; [3]Charles River Discovery, Morrisville, NC; [4]Charles River Discovery, Groningen, Netherlands; [5]Charles River Discovery, Harlow, United Kingdom; [6]UK Dementia Res. Institute, Imperial Col., London, United Kingdom; [7]Charles River Labs., Wilmington, MA

**Abstract:** Flavonoids are natural polyphenols widely distributed in plants and herbs. Flavonoids, including myricetin possess anti-oxidative, anti-inflammatory, and neuroprotective properties and may therefore reduce the risk of neurodegenerative diseases. Data suggest a protective mechanism of myricetin in animal models of Parkinson Disease (PD).
An Integrated Drug Discovery program at Charles River was designed to synthesize, characterize and examine the efficacy of two novel myricetin derivatives, TA1 and TA2, in a range of therapeutic indications. Here, we present data on their pharmacokinetic (PK) properties, maximum tolerated dose (MTD), and efficacy in a rat model of Parkinson’s disease (PD). The MTD was assessed in CD1 mice over 25 days. Each compound was tested at three doses (150, 300, 600 mg/kg) QD or BID. Animals were weighed and observed for any adverse treatment

effects and clinical signs. For PK analysis, brain and plasma concentrations of TA1, TA2 and unmodified myricetin given p.o. at 100 mg/kg were assessed at 1-24 h post dose. Tissues underwent enzymatic hydrolysis to convert the conjugated metabolites into the free forms prior to bioanalysis. Finally, protective action of myricetin derivatives in prophylactic intervention against functional consequences of the degeneration of dopaminergic neurons in the substantia nigra were tested in rats that received unilateral intrastriatal infusions of 6-OHDA. In particular, effects of myricetin derivatives administered for 1 week before and 2 weeks after 6-OHDA (QD, 100 mg/kg, p.o.) on amphetamine-evoked rotations and tyrosine hydroxylase-positive cell counts (TH+) in substantia nigra were examined and compared to the effects of mesencephalic astrocyte-derived neurotrophic factor (MANF) delivered intrastriatally 24 h post 6-OHDA infusion.
Maximum plasma levels of TA1 and TA2 were detected at 1 h post dose. Both derivatives but not the unmodified myricetin crossed the blood brain barrier and were detected in the brain at 6h post dose. The brain:blood ratio was 0.02 and 0.03 for TA1 and TA2, respectively. In the MTD study, mean body weight losses for all treatment groups were acceptable and did not exceed 8%. There were no deaths or clinical signs related to treatments. In the PD model study, amphetamine-induced asymmetric rotational activity at 2, 4, and 6 weeks post 6-OHDA infusion were lower in rats treated with MANF, TA1, or TA2 than in vehicle-treated group.
In conclusion, obtained data suggest that the novel myricetin derivatives TA1 and TA2 show better PK profile then unmodified myricetin, lack pronounced side effects at high doses, and ameliorate deficits similarly to MANF in the 6-OHDA rat model of PD.

**Abstract:** Oxidative damage to proteins and nucleic acids is thought to contribute to the progressive loss of dopaminergic neurons in PD. The myeloperoxidase gene (MPO) is an oxidant generating enzyme normally expressed in myeloid precursor cells, yet it can be aberrantly induced in neurons or astrocytes under stress such as that caused by accumulation of misfolded protein aggregates in PD. To investigate the potential role of MPO generated oxidants in PD, we crossed the Thy-1-A53T-a-synuclein mouse model (A53T-a-syn) to our humanized MPO mice that express a single copy of the native human -463G-MPO gene with introns and flanking regions. The human MPO promoter contains transcription factor binding sites in an upstream Alu element that can result in aberrant expression not found with the mouse MPO gene. Behavior assays were carried out to assess the effect of MPO expression in the A53T-a-syn model. As early as two months of age, the hMPO transgene resulted in significant impairment of motor abilities for the A53T-a-syn mice as shown by reduced ability to maintain balance on a rotating rod or balance beam, and reduced ability to maintain grip on an inverted wire. Survival curves further showed the huMPO-A53T-asyn mice reached end stage paralysis earlier than A53T-a-syn mice. MPO protein and mRNA was detected in subsets of neurons in cortex, hippocampus, midbrain, thalamus, and spinal base of hMPO-A53T-a-syn but not in A53T-asyn mice. MPO was similarly detected in subsets of human neurons in the human PD substantia nigra. Notably, some neurons contained multiple MPO-positive granules surrounding large aggregates of nitrated a-synuclein. Synaptosomal extracts from MPO-A53T-a-syn brain showed increased levels of a-synuclein dimers by western analysis, along with increased levels of insoluble a-synuclein aggregates detected by cellulose acetate filter trap. In summary, these findings provide evidence that the human MPO gene can be induced in neurons in human Parkinson’s disease substantia nigra and in the hMPO-A53T-a-syn mouse model. In conclusion, the hMPO transgenic mouse when crossed to the A53T-a-syn model results in exacerbation of motor impairment accompanied by increased nitration and aggregation of a-synuclein. **Title:** Physical activity optimizes circuit-specific cellular metabolism in neuroplasticity: A role for hypoxia-inducible factor-1 and its downstream targets

**Authors: *M. W. JAKOWEC**, M. R. HALLIDAY, D. ABEYDEERA, G. M. PETZINGER
Neurol., USC, Los Angeles, CA

**Abstract:** Physical activity is emerging as an effective and economical approach to treat and prevent a wide range of neurological disorders, including Parkinson's disease. Studies by our research group have shown that exercise, in the form of treadmill running, mediates a type of experience-dependent neuroplasticity through the modulation of dopaminergic and glutamatergic neurotransmission, synaptogenesis, and cerebral blood flow. However, a clear understanding of the underlying molecular mechanisms driving exercise-induced physiological brain adaptation represents a major gap in our knowledge. Recently, hypoxia-inducible factor-1 (HIF-1), a member of the HIF family of proteins and master transcription factor, has attracted interest due to its ability to act as a metabolic "sensor" and relay changes in brain metabolic state to changes in homeostatic gene expression. Furthermore, the role of HIF-1 in neural tissues is not restricted to the regulation of energy metabolism and has been shown to play a critical role in regulating complex molecular events including neurogenesis, angiogenesis, and mitochondrial function (biogenesis), which are important for exercise-induced neuroplasticity and synaptogenesis. Here, we investigated the effects of aerobic exercise on the activation of the hypoxia-inducible factor-1 (HIF-1) gene program, as well as the functional transcription and translation of several candidate target genes involved in transport of energy substrates (GLUT1 and MCTs), anaerobic glycolysis (LDH), angiogenesis (VEGF). Transcript and protein levels were analyzed after one, three, five, and 10 days of exercise in the prefrontal cortex (PFC), caudate putamen (CPu), and ectorhinal cortex (ERC) using quantitative RT-PCR (qRT-PCR), Western immunoblot (WIB), and immunofluorescence (IF). Using qRT-PCR and WIB, we show evidence for an exercise dose-dependent effect on the activation of the HIF-1 gene program and downstream target genes. Additionally, our findings suggest that exercise regulates gene expression in a circuit-specific manner that primarily targets brain circuits involved in complex motor and cognitive behaviors (i.e. frontostriatal and corticostriatal circuits). Further elucidation of molecular mechanisms involving metabolic pathways will allow us to better apply exercise as a therapy for brain disorders and will aid in the search for novel therapeutic targets with the potential to enhance the benefits of exercise-induced circuit-specific neuroplasticity.

**Abstract:** While Parkinson's Disease (PD) is characterized by motor symptoms, a number of different non-motor symptoms (NMS) are also observed. Amongst the NMS, respiratory abnormalities have been noted in PD patients since the first description in 1817, and multiple causes have been proposed, including impaired central respiratory control. While the loss of dopaminergic neurons is the primary pathology of PD, it is also becoming better appreciated that serotonergic (5-HT) dysfunction may also play a role in the development of motor and NMS and complications in PD. To this end, recent studies addressing the role of 5-HT in PD symptoms have revealed that activation or antagonism of specific 5-HT receptor subtypes may have therapeutic benefit. 5-HT neurotransmission is also known to play a critical role in control of breathing; thus, respiratory abnormalities in PD may be further complicated by the progressive 5-HT dysfunction in PD. Ongoing work in our laboratory has focused on characterizing the respiratory phenotype of PD in 6-hydroxydopamine (6-OHDA) neurotoxin-induced unilateral substantia nigra (SN)- and medial forebrain bundle (MFB)-lesioned rat PD models. The goal of the current study was to assess the effects of acute administration of the $5\text{-}HT_{1A}$ receptor agonist 8-OH DPAT on inspiratory motor (diaphragm EMG) activity in spontaneously breathing urethane-anesthetized adult female rats at 2-weeks after SN (n=7) or MFB (n=12) 6-OHDA injections; control rats received vehicle injections (SN, n=4; MFB, n=6). We found that in both control and SN- and MFB-lesioned rats, administration of 8-OH DPAT produced an ~50% increase in burst frequency (above baseline (BL) frequency) within ~30 s, but by 5 min post injection, this increase was attenuated to an ~18% increase in MFB-lesioned rats while SN-lesioned and control rats still exhibited an ~27-40% increase. Administration of 8-OH DPAT also produced an increase in burst amplitude albeit the magnitude of this increase was somewhat varied. Regardless of the magnitude differences, both SN- and MFB-lesioned rats exhibited a progressive increase in amplitude over BL levels while control rats showed a sustained or slightly decreased magnitude elevation compared to BL levels. While these preliminary observations suggest that (compared to control rats), SN- and MFB-lesioned rats exhibit some differences in $5\text{-}HT_{1A}$ induced amplitude alterations, differences between the 6-OHDA PD models are also noted in $5\text{-}HT_{1A}$ induced frequency effects. Additional experiments will be needed to identify specific mechanisms underlying these differences.

Hlth. Ctr., Montreal, QC, Canada

**Abstract:** Dyskinesia causes significant morbidity to many of patients with advanced Parkinson's disease. Serotonin 2A (5-$HT_{2A}$) receptor blockade is a validated approach to alleviate dyskinesia, but its effectiveness appears to be of limited magnitude. Recently, we have demonstrated that activation of metabotropic glutamate 2 ($mGlu_2$) receptors with the positive allosteric modulator (PAM) LY-487,379 reduces L-3,4-dihydroxyphenylalanine (L-DOPA) induced dyskinesia in the 6-hydroxydopamine (6-OHDA)-lesioned rat. Because 5-$HT_{2A}$ and $mGlu_2$ receptors form a functional hetero-complex, we hypothesised that combining EMD-281,014, the most selective 5-$HT_{2A}$ antagonist commercially-available with LY-487,379, the most selective $mGlu_2$ PAM commercially-available, would be more effective at alleviating dyskinesia than modulating 5-$HT_{2A}$ and $mGlu_2$ receptors separately.
Female Sprague-Dawley rats were rendered hemi-parkinsonian by stereotaxic injection of 6-OHDA into the medial forebrain bundle. Following a recovery period, degree of parkinsonism was assessed through the cylinder test. Severely parkinsonian rats were then primed with chronic L-DOPA administration to induce stable axial, limbs and oro-lingual (ALO) abnormal involuntary movements (AIMs). On experimental days, rats were administered L-DOPA in combination with previously determined effective doses of each of EMD-281,014 (vehicle, 0.03 and 0.1 mg/kg s.c) and LY-487,379 (vehicle and 0.1 mg/kg s.c.). After a 3-day washout period, an acute low-dose L-DOPA challenge was administered with the combination EMD-281,014/LY-487,379, and the effect on L-DOPA anti-parkinsonian action was determined by the cylinder test.
Contrary to our hypothesis, we found that the combination EMD-281,014/LY-487,379 did not provide further anti-dyskinetic benefit compared to administration of each compound separately.

The combination of EMD-281,014 and LY-487,379 did not have any effect on L-DOPA anti-parkinsonian action.
Our results suggest that there may not be further anti-dyskinetic benefit achieved when combining 5-$HT_{2A}$ blockade and $mGlu_2$ activation in the 6-OHDA-lesioned rat model of PD. Whereas these results require confirmation in other animal models of PD, notably the parkinsonian primate, the results presented in this Abstract, coupled with these presented in the companion Abstract on EMD-281,014 and LY-354,740, suggest that there may be a maximal anti-dyskinetic benefit beyond which it may be impossible to go when modulating both halves of the 5-$HT_{2A}$/$mGlu_2$ receptor hetero-complex.

**Abstract:** Serotonin 2A (5-$HT_{2A}$) receptor blockade represents a promising approach to alleviate symptoms of a breadth of neuro-psychiatric disorders, from schizophrenia to Parkinson’s disease. EMD-281,014 is the most selective 5-$HT_{2A}$ antagonist currently available and therefore represents the ideal compound to assess the behavioural effects of antagonising 5-$HT_{2A}$ receptors. Moreover, it has already entered clinical testing, has a documented pharmacokinetic (PK) profile in human, and well-tolerated plasma levels in clinic are known. Here, we have determined the PK profile of EMD-281,014 in the rat and the common marmoset.

In rats, blood samples were collected at more than 10 different time points, at baseline and following sub-cutaneous (sc) administration of EMD-281,014 0.01, 0.03 and 0.1 mg/kg. In marmosets, we have used a sparse sampling technique, where minimal blood volume was collected at 10 different time points, from a limited number of animals, at baseline and following sc administration of EMD-281,014 0.1 mg/kg, Additional samplings were conducted at maximal plasma concentration ($C_{max}$) time ($T_{max}$) with EMD-281,014 0.01 and 0.03 mg/kg; mathematical modelisation was employed to predict the PK profile of these two additional doses. Plasma levels of EMD-281,014 were determined by liquid chromatography and tandem mass spectrometry (LC-MS/MS). Compartmental analysis was used to determine PK parameters such as $T_{max}$, $C_{max}$ and half-life ($T_{1/2}$).
In rats, $T_{max}$ occurred 10 min after injection, regardless of the dose administered, while $T_{1/2}$ was 117, 103 and 73 min, for EMD-281,014 0.01, 0.03 and 0.1 mg/kg, respectively. In marmosets, EMD-281,014 showed a slower absorbtion and metabolism with $T_{max}$ occurring 30 min after injection, while $T_{1/2}$ was 168, 144 and 120 min, for the doses 0.01, 0.03 and 0.1 mg/kg, respectively.
To the best of our knowledge, despite that it had been tested in the clinic, the PK profile of EMD-281,014 was undisclosed in both rat and marmoset. We hope that our results will help to refine experiments where this extremely-selective compound is used in pre-clinical research, so that doses leading to plasma levels shown to be well tolerated by humans will be employed.

Montréal, Montreal, QC, Canada; [6]Div. of Neurol., McGill Univ. Hlth. Ctr., Montreal, QC, Canada

**Abstract:** L-3,4-dihydroxyphenylalanine (L-DOPA) is the most effective treatment for Parkinson's disease (PD) but, with long-term treatment, patients develop complications such as L-DOPA induced dyskinesia and, though other factors might also be at play, psychotic behaviours. Pre-clinical and clinical studies have demonstrated that antagonising serotonin 2A (5-$HT_{2A}$) receptors is effective at alleviating both dyskinesia psychosis in PD. Recently, we have demonstrated that EMD-281,014, an extremely selective 5-$HT_{2A}$ antagonist, significantly reduce dyskinesia and psychosis-like behaviours (PLBs), at doses leading to clinically-relevant plasma levels, in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-lesioned marmoset model of PD. However, whether higher doses of EMD-281,014 would lead to greater anti-dyskinetic and anti-psychotic benefit remains unknown; in other words, given its extreme selectivity, EMD-281,014 is the ideal compound to determine whether there is, or not, a ceiling to the benefit that can be achieved by blocking 5-$HT_{2A}$ receptors. Here, we sought to answer this question.
Six marmosets were rendered parkinsonian by MPTP administration. Following repeated administration of L-DOPA to elicit stable dyskinesia and PLBs, animals were administered acute challenges of EMD-281,014 (0.1, 1, 10 mg/kg) or vehicle, in combination with L-DOPA, after which the severity of dyskinesia, PLBs and parkinsonian disability was rated.
EMD-281,014 (0.1, 1 and 10 mg/kg) significantly reduced the severity of peak dose dyskinesia, by ≈ 41%, ≈ 43% and ≈ 37% (each $P < 0.05$), respectively when compared to L-DOPA/vehicle. Peak dose PLBs were also reduced by ≈ 41% and ≈ 43% (both $P < 0.05$), respectively, when EMD-281,014 (0.1 and 1 mg/kg) was added to L-DOPA, compared to L-DOPA/vehicle, while EMD-281,014 10 mg/kg reduced severity of PLBs 2-4h after treatment administration, by ≈ 50% ($P < 0.05$), when compared to L-DOPA/vehicle. The anti-dyskinetic and anti-psychotic effects of EMD-281,014 were achieved without interfering with L-DOPA anti-parkinsonian action.
Our results confirm the findings that we made in a previous experiment, *i.e*. that highly-selective blockade of 5-$HT_{2A}$ receptors is effective at alleviating psychosis and dyskinesia in PD, without interfering with L-DOPA anti-parkinsonian action. However, our results also suggest that there may be a ceiling to the potential anti-dyskinetic and anti-psychotic benefits conferred by selective 5-$HT_{2A}$ blockade.

**Abstract:** L-3,4-dihydroxyphenylalanine (L-DOPA)-induced dyskinesia undermines the quality of life of patients with advanced Parkinson's disease (PD). There are numerous studies that showed that antagonising serotonin 2A (5-$HT_{2A}$) receptors may reduce L-DOPA-induced dyskinesia, but the evidence gathered to date suggests that there might be a ceiling to the effectiveness of this approach. Based on the fact that 5-$HT_{2A}$ receptors form a hetero-complex with metabotropic glutamate 2 ($mGlu_2$) receptors, we hypothesised that a synergistic effect may ensue upon simultaneous 5-$HT_{2A}$ blockade and $mGlu_2$ activation. Here, we have assessed the effect on dyskinesia of EMD-281,014, the most-selective 5-$HT_{2A}$ antagonist available, and of LY-354,740, a selective $mGlu_2$ orthosteric agonist, in the 6-hydroxydopamine (6-OHDA)-lesioned rat. Parkinsonism was induced in female rats by stereotaxic injection of 6-OHDA into the medial forebrain bundle. Following a recovery period, degree of parkinsonism was assessed using the cylinder test. Rats were primed with daily administration of L-DOPA to develop axial, limbs and oro-lingual (ALO) abnormal involuntary movements (AIMs). On experimental days, rats were administered L-DOPA in combination with previously determined effective doses of each of EMD-281,014 (vehicle, 0.03 and 0.1 mg/kg s.c) and LY-354,740 (vehicle and 0.1 mg/kg s.c.). After a 3-day washout period, an acute low-dose L-DOPA challenge was administered with the combination EMD-281,014/LY-354,740, and the effect on L-DOPA anti-parkinsonian action was determined by the cylinder test. Unlike what we had hypothesised, no synergistic effect was achieved by simultaneously administering EMD-281,014 and LY-354,740. The combination of EMD-281,014 and LY-354,740 did not have any effect on L-DOPA anti-parkinsonian action. Our results suggest that, at least in the 6-OHDA-lesioned rat model of PD, there does not seem to have any added anti-dyskinetic benefit resulting from combining 5-$HT_{2A}$ blockade and $mGlu_2$ activation. Further studies, perhaps with different compounds, or in different animal models, are required to shed light on this intriguing finding.

**Abstract:** The most effective symptomatic treatment for Parkinson's disease (PD) is dopamine replacement therapy with L-3,4-dihydroxyphenylalanine (L-DOPA). However, long-term use of L-DOPA leads to the emergence of complications such as L-DOPA-induced dyskinesia in the vast majority of patients. Previous studies have demonstrated that antagonising serotonin type 3 receptor (5-$HT_3$R) reduces dopamine levels within the basal ganglia, which could therefore regulate the erratic dopamine release that occurs in dyskinesia and, consequently, alleviate L-DOPA-induced dyskinesia. We hypothesised that selective 5-$HT_3$R blockade with the clinically available and highly-selective antagonists ondansetron and granisetron would reduce the severity of dyskinesia in the 6-hydroxydopamine (6-OHDA)-lesioned rat. Female Sprague-Dawley rats were injected 6-OHDA into the medial forebrain bundle and evaluated for the degree of parkinsonism by the cylinder test. Two sets of experiments were then conducted. In the first series, rats were primed with L-DOPA to induce the expression of stable axial, limbs and oro-lingual (ALO) abnormal involuntary movements (AIMs). On experimental days, animals were administered different doses of ondansetron, granisetron or vehicle, in combination with L-DOPA, and the severity of ALO AIMs was rated. The effect of ondansetron and granisetron on L-DOPA anti-parkinsonian action was also determined by the cylinder test. In the second set, following 6-OHDA lesion, animals were administered the effective dose of ondansetron (determined in the first set) or vehicle, started concurrently with L-DOPA, once daily for 22 days, during which the severity of ALO AIMs was monitored weekly. After a 3-day washout, an acute L-DOPA challenge was administered and ALO AIMs severity was assessed. When compared to vehicle, acute challenges of ondansetron 0.0001 mg/kg significantly reduced the duration and amplitude of ALO AIMs, by 53% and 51%, respectively (both $P < 0.01$), while acute challenges of granisetron 0.01 mg/kg significantly decreased the duration and amplitude of

ALO AIMs, by 46% and 50%, respectively ($P < 0.05$ and $P < 0.01$). Ondansetron, when started concurrently with L-DOPA, attenuated the development of ALO AIMs, by 51% ($P < 0.05$), when compared to vehicle. The anti-dyskinetic efficacy of ondansetron and granisetron did not interfere with L-DOPA anti-parkinsonian action. Our results suggest that selective 5-$HT_3$R blockade with ondansetron and granisetron is a novel and effective therapeutic approach to reduce the severity and attenuate the development of L-DOPA-induced dyskinesia that is likely to be well-tolerated by PD patients.

Kyung Hee Univ., Seoul, Korea, Republic of

**Abstract:** Growing evidences on the pathological roles of gut microbiota have been steadily reported, but whether a specific gut pathobiont may cause Parkinson’s disease (PD) remains unexplored. In this study, we describe for the first time that a specific gut pathobiont may involve in the pathogenesis of PD. We found the remarkable increase of *Enterobacteriaceae* bacterial colonies in PD animal models and that was identified as PB-1, a specific gut pathobiont. Oral administration of PB-1 significantly induced motor deficits in parallel with dopaminergic neuronal damage and neuroinflammation in normal mice. We reveal that this phenomenon is originated from gut leakage and inflammatory responses by lipopolysaccharides produced from PB-1. In addition, we found that MHE173, a Korean herbal medicine extract, could modulate PB-1-induced behavioral and pathological abnormalities. These findings indicate the therapeutic potentials of MHE173 on PD-like pathological conditions induced by a specific pathobiont. This work was also supported by Medical Research Center Program through the National Research Foundation of Korea funded by the Ministry of Science and ICT (NRF-2017R1A5A2014768).

**Abstract:** Alzheimer’s disease (AD), an irreversible and progressive degenerative disorder of the brain, is characterized by memory impairment, loss of neuron and synapse. Although the cause of AD has not been clearly elucidated, accumulation of amyloid beta (Aβ) is considered the major pathological feature in AD. Aβ can promote neuronal cell degeneration by the increases of intracellular reactive oxygen species, which reduce anti-oxidative enzymes such as heme oxygenase-1 (HO-1) and NAD(P)H quinine dehydrogenase 1 (NQO1). Thus, the aim of this study was to explore the neuroprotective effects of Korea herbal medicine extract (MHE100) in $A\beta_{25-35}$ plaque-induced Alzheimer’s disease models. MHE100 significantly ameliorated memory impairment, neuronal cell death and synaptotoxicity via elevated expression of phosphorylated-cyclic AMP response element-binding protein (pCREB) in $A\beta_{25-35}$ plaque-injected mice. Furthermore, MHE100 inhibited intracellular ROS generation induced by $A\beta_{25-35}$ plaque via elevated expression levels of pCREB, HO-1 and NQO1, resulting in the protection of hippocampal cells. These results suggest that MHE100 may be a potential candidate to regulate the progression of AD.

**Abstract:** The current leading treatment for the motor symptoms in Parkinson's disease (PD) is levodopa (L-DOPA). Unfortunately, the majority of patients treated with L-DOPA inevitably develop debilitating and disruptive motor side-effects called L-DOPA-induced dyskinesias (LID). While the mechanisms underlying LID are multifaceted, a wealth of research suggests that the dysregulation of dopamine (DA) synthesis and release as a false neurotransmitter by striatal serotonin (5-HT) projections originating from dorsal raphe nucleus (DRN) neurons plays a pivotal role in dyskinesogenesis. While DRN 5-HT neurons can convert L-DOPA to DA, they lack the regulatory mechanisms needed for modulation of DA signaling. This is hypothesized to lead to an unregulated release of DA into the DA-depleted, hypersensitive striatum, promoting dyskinesogenesis. Preclinical studies have shown that 5-HT lesions of the DRN and 5-HT1 receptor agonists can ameliorate LID. Unfortunately, promising preclinical results have been not translated clinically. While there is an abundance of circumstantial support for the 5-HT hypothesis of LID, there is no direct evidence that dysregulated DA release from 5-HT neurons causes LID formation. In the present study, we aimed to determine if LID could be prevented by ectopically expressing DA regulatory elements—specifically the D2 autoreceptor (D2R)—in DRN neurons. Adult male rats were rendered parkinsonian with 6-hydroxydopamine, followed by delivery of rAAV2/9 expressing either D2R or GFP to the DRN. When chronically treated with L-DOPA (2-12mg/kg), animals overexpressing D2R showed a complete resistance to LID development, whereas GFP controls showed robust LID expression. *In vivo* microdialysis showed that D2R expression in raphe neurons reduced DA efflux in the striatum with no effect on 5-HT release. This study definitively confirms that abnormal DA release from 5-HT neurons in a parkinsonian model is dyskinesiogenic, and more importantly show that D2R expression in DRN neurons is sufficient to achieve and maintain proper regulation of DA release. rAAV-D2R treatment did not change anti-parkinsonian efficacy of L-DOPA shown with cylinder and stepping tests. This direct evidence of false neurotransmission and its prevention with rAAV-D2Rs gene therapy confirms the 5-HT hypothesis in LID and a modulation of 5-HT neurons as a potential therapeutic approach for patients. Ongoing work is utilizing in vivo electrophysiology to measure the impact of D2Rs expression on serotonergic neuronal activity.

**Abstract:** Cell therapy for various degenerative diseases of the brain such as Parkinson's disease is an important and growing area in the therapeutic armamentarium, but surgical transplantation techniques for cellular grafts have been neither systematically investigated nor standardized. Accordingly, traumatic damage to the host tissue during transplantation and suboptimal survival and function of grafted cells are major unresolved issues for cell therapy. Here, we describe a system which we term "columnar injection technique", for precise control of injection volume and rate that makes use of the surgical entry track itself as the deposition site for the graft. This is designed to reduce pressure damage to the host tissue and results in a column of graft material with a greater surface area to volume ratio than traditional bolus injection techniques, allowing better graft uniformity and survival.

**Abstract:** Degeneration of the dopaminergic neurons in the nigrostriatal pathway is the major cause of the motor features associated with the neurodegenerative disorder Parkinson's disease (PD), which is characterized by rigidity, tremor and bradykinesia. Apart from dopamine (DA) itself, numerous neurotransmitter systems are involved in the finetuning of DA release in the striatum, including the nicotinic cholinergic system. Indeed, there is an extensive anatomical overlap between dopaminergic and cholinergic neurons, and activation of striatal nAChRs has been shown to modulate DA release both *in vitro* and *in vivo*.
Extensive studies in parkinsonian animal models show that nicotine has a protective effect against nigrostriatal damage - findings that may explain the well-established decline in PD incidence with tobacco use. In addition, several studies have shown that nicotine reduces L-dopa-induced dyskinesias (LIDs), a debilitating complication of DA replacement therapy for PD. These combined observations suggest that nAChR stimulation may be of therapeutic benefit in relation to neuroprotection in PD and treatment of LIDs. In this respect, drugs targeting α6-containing nAChRs (α6* nAChRs) have attracted immense interest since these receptors are highly and specifically expressed in midbrain dopaminergic neurons, making this receptor subtype an attractive drug target.
Here, we present preclinical data on AN317, which is a potent agonist of α6* nAChRs with functional selectivity over other nicotinic receptor subtypes. *In vitro* studies using rat primary neurons and midbrain slices indicated that striatal DA transmission was stimulated by AN317, since both the firing rate of putative dopaminergic neurons and DA release was significantly increased by AN317. In a dopaminergic neuronal survival assay using rat primary mesencephalic cultures, AN317 afforded a significant and concentration-dependent neuroprotective effect upon treatment with the neurotoxin MPP+. Furthermore, in a LIDs model applying 6-OHDA lesioned rats, AN317 induced a significant and dose-related decrease in L-DOPA induced abnormal involuntary movements (AIMs). Altogether, these data suggest that AN317 represents an interesting drug candidate in relation to the treatment of various aspects of PD.

Neurosci., Univ. of Kentucky, Lexington, KY

**Abstract:** Currently two clinical trials (NCT01833364 and NCT02369003) are underway which feature the implantation of autologous peripheral nerve grafts to the brain (targeted to the Substantia Nigra, Nucleus Basalis of Meynert, or Putamen) in combination with Deep Brain Stimulation (DBS) for the treatment of patients with Parkinson’s disease. This nerve tissue is harvested from the sural nerve, a cutaneous sensory nerve located in the lateral ankle, of patients undergoing DBS surgery. The nerve receives a conditioning injury 14 days before grafting, and samples are collected from the pre-conditioned and post-conditioned nerve. As of 5/1/18, 55 patients have received DBS plus the graft procedure.
RNA sequencing of these nerve samples shows transcriptome changes consistent with the expected pro-regenerative changes of transdifferentiated repair phenotype Schwann cells. However, the neurobiology of the graft within the brain, the regenerative activity of the pre vs post-lesioned nerve, and the survival of grafted tissue have not been examined.
In order to address these questions, this study aimed to develop an animal model of the grafting procedure using the same human tissue grafted into patients with Parkinson’s disease. Athymic nude (Hsd:RH-Foxn1$^{rnu}$) rats were stereotaxically implanted with segments of human peripheral nerve (pre-conditioned or post-conditioned) into the dorsal striatum. Each animal received a unilateral graft with a contralateral sham insertion. Two weeks or six months post-implant the brains of these animals were processed for histopathological analyses. Assessment of graft cell survival, graft morphology, and host tissue response will be reported. In summary, this study

completes the translational science cycle by using clinical trial findings and samples to answer basic science questions that will in turn guide future clinical trial design.

**Abstract:** Parkinson's disease (PD) is a devastating clinical disorders that is characterized by progressive and selective neuronal injury and cell death. Recent studies have provided accumulating evidence for a significant role of the immune system and neuroinflammation in PD pathogenesis. In particular, neuroinflammation associated to PD is the prerequisite for the maturation of dendritic cells (DC) and their migration to the respective sites in the brain. It has become clear that Toll-like receptors (TLRs), a major family of pattern recognition receptors could mediate innate and adaptive immune response, providing an important mechanism by which microglia are able to sense both pathogen- and host derived ligands within the CNS.
The aim of our study was to evaluate the role of TLR 7,8 and 9 in DC maturation that trigger to adaptive autoimmune response related to PD.
We performed an *in vivo* model of PD, by MPTP, in single KO mice for TLR7$^{-}$, TLR8$^{-}$ and TLR9$^{-}$; and in double KO mice for TLR 7/8$^{-/-}$ and TLR7/9$^{-/-}$. All animals was compared with WT animals used as a control group.
Animals were sacrificed after 8 days and their midbrains were harvested, sectioned and processed in order to evaluate: the principal markers of PD with particular attention to TH, DAT and α-synuclein aggregate; astrocytes and microglia activation through GFAP and IBA-1; pro-inflammatory cytokine’s expression such as INF-γ and TNF-α like major product of activated microglia and astrocytes. Moreover to evaluate the formation of neuromelanin pigments in the midbrain we made the Masson-Fontana staining.
The result obtained demonstrated that the genetic absence of TLR 7,8 and 9 modified PD pathway increasing significantly the immunoreactivity for TH and DAT compared to PD groups where we found an evident reduction of these markers.

Therefore, TLRs could be considered as a possible target to develop new therapies for neurodegenerative disorders.

**Title:** The effects of stem cell therapy on adult mouse neurogenesis in Parkinson's disease

**Authors: A. NELKE**, S. GARCIA-LOPEZ, A. MARTINEZ-SERRANO, *M. P. PEREIRA
Ctr. De Biologia Mol. Severo Ochoa, Madrid, Spain

**Abstract:** Introduction: Parkinson´s disease (PD) is the second most common neurodegenerative disease in the world and the most common motor movement disorder. PD is characterized by the impairment and death of dopaminergic neurons (DAn) in the Substantia Nigra pars compacta (SNpc). Current pharmaceutical treatments do not improve the patient´s life long-term; thus, a goal of PD therapy research becomes cell replacement. Here we have tested a stem cell therapy in a PD rodent model. Methods: Adult (5 month-old) and middle-age (12 month-old) male C57BL/6 mice received a transplant of human ventral mesencephalic hVM1 clone 32 human neural stem cells, or buffer, in the left striatum after receiving 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) injections. One and four months after transplantation, mice were sacrificed. Results: DAn loss in the SNpc and tyrosine hydroxylase (TH) fiber loss in the striatum of adult mice was lessened in stem cell-transplanted compared to buffer-transplanted mice. The stem cell transplant had an effect on neuroinflammation, namely the response of astrocytes and microglia, and in addition, behavioral changes were observed via open field and paw print tests. These aforementioned changes were not observed in middle-age mice. Neurogenesis in the subventricular and subgranular zones, as shown via doublecortin (Dcx) and nestin immunostaining, was decreased in all MPTP-treated mice one and four months post-transplant; this diminution was rescued in adult mice in the subgranular zone one month post-transplant, but not in the subventricular zone.
Conclusions: Transplantation of hVM1 clone 32 human neural stem cells, which have been shown to differentiate into dopaminergic neurons in vitro, triggers behavioral amelioration and reduced dopaminergic cell loss in adult mice. However, this is not observed in middle-age mice, thus emphasizing the importance of the age of recipient and the stage of PD progression when

receiving a transplant, and stressing the fact that some preclinical studies need to be done in animals older than middle-age, more similar to the age of onset of PD.

**Abstract:** Mutations in Leucine-rich repeat kinase 2 (LRRK2) are responsible for a large number of familial Parkinson's disease (PD) cases and variation in the LRRK2 genetic locus is a risk factor for sporadic PD. The most common mutation, G2019S, results in increased kinase activity. Consequently, LRRK2 kinase inhibitors are being aggressively developed as a potential treatment strategy, but much remains to be learned about the role of LRRK2 in neuronal function and the mechanism by which LRRK2 overactivity impacts neuronal survival. However, mounting evidence supports a role for LRRK2 in vesicle cycling and dopamine homeostasis. We are using fast scan cyclic voltammetry (FSCV) in a human G2019S LRRK2 BAC transgenic rat to probe the influence of the mutation on dopamine (DA) dynamics prior to degeneration of DA cells or terminals. FSCV coupled with carbon fiber microelectrodes implanted in the dorsal striatum of anesthetized rats revealed augmented DA responses evoked by electrical stimulation of the medial forebrain bundle, preferentially during 6-pulse ultrashort stimulations. Kinetic analysis of the DA responses showed that the G2019S mutation did not change the apparent $V_{max}$ or $K_M$ of DA uptake but rather increased DA release at the beginning of the stimulation. Pharmacological manipulation of the DA transporter (DAT) with nomifensine confirmed that impairment of DAT is not likely to account for the elevation in evoked DA signals. However, normalization of responses in the present of the D2 autoreceptor antagonist and agonist, raclopride and quinpirole, suggests an impairment in D2-mediated autoinhibition in the mutant. The enhanced DA responses in the G2019S rats are reversed by 5-day oral administration of LRRK2 inhibitor PF-360.

**Title:** Evaluating the effects of sub-anesthetic ketamine on microglia morphology in a pre-clinical model of L-DOPA induced dyskinesia

**Authors: *A. E. POTTENGER**[1], M. J. BARTLETT[2], T. FALK[3], H. W. MORRISON[4]
[1]Univ. of Arizona, Tucson, AZ; [3]Dept. Of Neurol., [2]Univ. of Arizona Col. of Med., Tucson, AZ; [4]Univ. of Arizona Col. of Nursing, Tucson, AZ

**Abstract:** Parkinson's disease (PD) is a neurodegenerative disease caused by the death of dopaminergic (DA) neurons in the substantia nigra pars compacta (SNpc), characterized by motor dysfunction. While PD symptoms are treated with levodopa (L-DOPA), continuous L-DOPA use can cause L-DOPA-induced dyskinesia (LID). We have previously demonstrated that sub-anesthetic ketamine reduced LID, measured by abnormal involuntary movements (AIMs). The literature suggests that ketamine treatment can lead to changes in dendritic spines. Microglia may play a role by phagocytosing an abundance of neuronal spines. In this exploratory study, we hypothesized that ketamine would prevent AIMs and increase microglia ramified morphology - an indicator of a microglia response. We studied the behavioral and histological outcomes with evaluators blinded to conditions. Male Sprague-Dawley rats (250 g, n = 4/group) were unilaterally lesioned with 6-hydroxydopamine (6-OHDA) to create a PD model. PD rats were then primed with daily injections of L-DOPA (6 mg/kg, *i.p.*). On days 0 and 7, rats were treated with ketamine (5x *i.p.* injections of 20 mg/kg, 2-hours apart; 5$^{th}$ injection was paired with L-DOPA) or vehicle. AIMs were scored every 3-4 days to assess changes in LID; all data were tested using ANOVA. On day 14, ketamine-treated rats showed a nearly 60% reduction in their total number of limb, axial, and oral AIMs as compared to controls ($p < 0.005$). A sub-analysis of AIMs scores in ketamine-treated animals revealed two distinct groups: those that responded to the ketamine treatment (KR) and ketamine non-responders (KNR), which showed no difference in AIMs as compared to controls. Brain tissue was collected for immunohistochemical staining in the SNpc. Microglia and DA neurons were visualized using antibodies against ionized calcium-binding adapter molecule and tyrosine hydroxylase, respectively. The SNpc on both the injured and uninjured side were imaged using confocal microscopy to obtain photomicrographs

for image analysis. All data collected from microglia analyses were normalized to the matching non-lesioned hemisphere. In the KR group, we observed a decrease in the number of microglia ($p < 0.001$ vs vehicle) and an increase in cell ramification (endpoints/cell $p < 0.0001$ and process length/cell $p < 0.001$ vs vehicle). These data are suggestive of a lingering microglia response to 6-OHDA injury in the SNpc among vehicle and KNR groups that was not present in the KR group. Future directions include microglia analysis in the motor cortex and striatum, evaluating if morphometrics and behavioral analysis correlate, and testing ketamine's effects on microglia morphologies in acute brain slices.

**Abstract:** As the second most common neurodegenerative disease, Parkinson's disease (PD) presents an immense burden for the aging population. PD is a progressive neurodegenerative disease characterized by the loss of dopamine neurons in the substantia nigra subsequent to the loss of striatal dopaminergic tone. The current gold standard treatment for PD is limited to oral levodopa which eventually can lead to the development of motor fluctuation and dyskinesias. Early work with fetal and embryonic tissues suggests that a cell replacement therapy may offer relief for motor deficits associated with PD. However, these tissue sources are associated with ethical and logistical concerns.
Previously, we have shown that cryopreserved human induced pluripotent stem cells (hiPSC) reprogrammed to post-mitotic midbrain dopamine (mDA) neurons survive engraftment in the rat striatum with low levels of proliferation. Further, when striatally transplanted following a 6-hydroxydopamine lesion to the medial forebrain bundle, hiPSC-mDA neurons reverse motor asymmetry as measured by amphetamine-induced rotations (Wakeman *et al.*, 2017).

In the present study we tested the in vivo efficacy of hiPSC-mDA neurons and progenitor cells after transitioning the differentiation protocol to a cell therapy-compatible manufacturing process. $4.5x10^5$ cells were unilaterally transplanted to the 6-hydroxydopamine-lesioned striatum of athymic nude rats. Here we show that hiPSC-mDA neurons progenitors cryopreserved at day 17 (D17), D24, and D37 of the differentiation process and iCell DopaNeurons survive and project tyrosine hydroxylase-immunoreactive processes into the host parenchyma. Animals that received grafts of D17 and D24 progenitor cells showed fully reversed amphetamine-induced rotations by 6 months post-transplant, with complete reversal seen by 4 months post-grafting in animals treated with D17 progenitors. In addition, the D17 progenitors exhibited superior mDA neuron and innervation of the striatum. We found low levels of proliferating cells and no evidence of teratoma formation within the grafts as indicated by human specific Ki-67 staining and did not observe cell migration or aberrant outgrowth, demonstrating a safety profile amenable to translation to the clinic. Ongoing studies will seek to determine optimal dosing to inform future human trials.

**Abstract:** We propose that the striatal transplantation of 3D-neural organoids of controlled cell size and cell content, named "Controlled Neural Organoids" (CNOs), could circumvent the limitations of current cell therapy and allow functional recovery in Parkinson's disease (PD). A major impetus for research in PD is centered on cell therapy strategies that aim at replacing the dysfunctional or dying neuronal cell populations. In the past decade, pluripotent stem cells have provided unprecedented access to various human cell types, especially to central nervous system neurons. The availability of patient-specific cell lines associated with the development of highly efficient protocols to in vitro generate specific neuronal cells is an important step in overcoming the ethical and logistical challenges associated with the use of embryonic stem cells. However, mature neuronal transplantation leads to poor survival due to their detachment sensitivity and the fragility of neuritic extensions. Similarly, the transplantation of neuronal precursors does not allow in situ tight control of the neuronal identity and carries a tumor risk. CNOs were generated through cell capsules technology developed in the lab associated with differentiation protocol of dopaminergic neurons (DN) from human pluripotent stem cells. Following the neuronal transplantation in immunocompromised hemiparkinsonian rats (6-OHDA), motor functions were evaluated by stepping test, cylinder test and amphetamine-induced rotations. CNOs characterization was carried out by immunostaining. In this study, we compared the therapeutic efficacy of 3D-neural organoids versus individual neurons transplantation. From eight weeks onwards after the transplantation, CNOs allowed functional recovery associated with tyrosine hydroxylase positive neurons into the graft whereas the transplantation of dopaminergic individual neurons did not induce any effect. Our CNOs constitute more efficient and safer cell therapy products than individual neurons. Pending further validation, this innovative cell therapy approach for the treatment of PD could become a real alternative to drug-based symptomatologic treatments.

**Abstract:** Although L-3,4-dihydroxyphenylalanine (L-DOPA) is currently the most effective medication for treating Parkinson's disease (PD) motor symptoms, its prolonged administration causes several adverse effects, including dyskinesia. To identify the mechanisms underlying the effects of acupuncture on L-DOPA-induced dyskinesia (LID), antidyskinetic effects of acupuncture were investigated in two mouse models of PD. Acupuncture stimulation at GB34 alleviated abnormal involuntary movements (AIMs) in *Pitx3*-deficient *aphakia* mice (*ak/ak*) following L-DOPA administration and these effects were reproduced in 6-hydroxydopamine (6-OHDA)-lesioned mice with LID. A transcriptome analysis of the hypothalamus revealed pro-melanin-concentrating hormone (*Pmch*) gene was highly expressed in acupuncture-treated mouse from *ak/ak* model of LID as well as 6-OHDA model of LID. Acupuncture combined with the administration of MCH receptor antagonist did not have any beneficial effects on dyskinesia in L-DOPA-injected *ak/ak* mice, but the intranasal administration of MCH attenuated LID to the same degree as acupuncture in both *ak/ak* and 6-OHDA mice with LID. A gene expression profile with a hierarchical clustering analysis of the dyskinesia-induced *ak/ak* mouse brain revealed an association between the mechanisms underlying acupuncture and MCH. Additionally, altered striatal responses to L-DOPA injection were observed after prolonged acupuncture and MCH treatments, which suggests that these treatment modalities influenced the compensatory mechanisms of LID. In summary, present study demonstrated that acupuncture decreased LID via hypothalamic MCH using L-DOPA-administered *ak/ak* and 6-OHDA mouse models and that MCH administration resulted in novel antidyskinetic effects in these models. Thus, acupuncture and MCH might be valuable therapeutic candidates for PD patients suffering from LID.

**Title:** Comparison between brain size and shape in two rat strains commonly used in xenograft studies for more precise targeting in pre-clinical validation of stem cell derived neurons

**Authors: *B. MATTSSON**, D. HOBAN, T. CARDOSO, S. GREALISH, A. ADLER, M. P. PARMAR

**Abstract:** Stem cell derived neurons are rapidly moving towards clinical trials. An important part of their pre-clinical validation is to test their safety, functional maturation and potency in xenograft models. The most common method to circumvent the problem of graft rejection when transplanting human cells into rodents are daily administration of immune-suppressive drugs (i.e. Ciclosporine A). However, human stem cell (hESC)-derived neurons mature slowly and therefore there is often a need to study the cells for longer timepoints than is possible in immune-suppressed animals. Therefore, the use of immune-incompetent hosts such as athymic “nude” rats, that allow for at least 12 month graft survival, is increasingly used for experimental studies and pre-clinical validation. In our studies of stem cell derived dopamine neurons transplanted to rat models of PD, we have noticed that the brain size and shape is markedly different between Sprague Dawley (SD) rats and nude rats. This poses a problem when calculating co-ordinates to target specific structures for toxin, virus or cell delivery using stereotaxic surgery. To overcome this, we have collected brains from nude and SD rats of same age and weight and processed them in parallel. Brains from each strain were cut into 30 µm sections and each fourth section stained with cresyl violet were scanned and placed in 3D using Cinema 4D using “flat” skull Bregma and Lambda as anatomical landmarks for correct placement in the 3D environment. Each brain structure was illustrated as a volume making it easy to comparable the two rat strains. We found that the brain of the SD rat matches closely the commonly used Paxinos atlas, while we detected major differences in cortical volume and shape in the nude rats. This in turn illustrates that the coordinates to precisely target deep structures as Substantia Nigra and MFB are markedly different in the SD rat compared to what can be calculated using the Paxinos atlas. We have therefore started to create a 2D vector-based atlas for nude rats. This has allowed us to precisely target the dorsal and ventral midbrain, enabling us to show that hESC-derived DA neurons receive host synaptic input from different regions of the striatum depending on their placement.

**Abstract:** Currently, there are no disease-modifying therapeutics for the treatment of Parkinson's disease (PD). Inhibition of the kinase activity of leucine-rich repeat kinase 2 (LRRK2) is one of the most promising targets for the treatment of PD and there is an abundance of ongoing studies to assess the potential efficacy of LRRK2 inhibitors in both clinical and pre-clinical studies. In addition to the efforts to understand the therapeutic potential of LRRK2 kinase inhibitors, efforts to understand the potential off target effects continue in parallel, the most studied of which in the lung. Recent data has demonstrated that pharmacological inhibition of the LRRK2 kinase increases lamellar bodies in type II pneumocytes. Here, we administered the selective LRRK2 inhibitor, PFE-360, chronically in diet to C57Bl6 and G2019S mice (1, 3, 10, 30 and 60 mg/kg/day; 42 days) and CD rats (1, 3, 10 and 30 mg/kg/day; 7 days). Following treatment, the lungs were harvested, inflated with 10% formalin, sectioned in toto and stained with H&E. For qualitative assessment, sections were evaluated by light microscopy; for quantitative assessment slides were scanned using an Aperio slide scanner and ten x40 objective field photomicrographs of parenchyma were randomly selected from each section (4 from the left lobe, 2 from each of the right cranial, right caudal, accessory and middle lung lobes). Alveolar parenchyma was assessed and type II pneumocytes were identified by their location in the alveolar walls. The numbers of vacuolated and enlarged type II pneumocytes per x40 field were counted using ImageJ software. In C57 mice, doses of 1 and 3 mg/kg/day of PF-360 were associated with minimal increases in vacuolated/enlarged type II pneumocytes in low numbers of treated animals (2/5). Similarly, low numbers of vacuolated/enlarged cells were observed in vehicle treated animals and those receiving 1 and 3 mg/kg/day of PF-360. At doses of PF-360 ≥ 10 mg/kg/day, a mild to moderate increase in the numbers of vacuolated/enlarged type II pneumocytes was observed qualitatively compared to vehicle treated animals and correlated with several fold (4.1 ± 0.9) increases in the numbers of these cells on image analysis. These findings

are more pronounced than those previously reported with LRRK2 overexpressing mice receiving the same treatment and suggest that the strain used is important in this research. Unlike the mice, rats demonstrated no meaningful change in lung endpoints. Collectively, the data reported here in mice and rats, when put into the context of previously reported data, demonstrate the importance of considering strain and species when evaluating the effect of LRRK2 inhibition on the lung.

**Abstract:** The LRRK2 kinase is one of the most studied potential disease modifying targets for the treatment of Parkinson’s disease (PD). Previous work has demonstrated that chronic administration of a LRRK2 inhibitor, PFE-475, has beneficial effects on the AAV alpha synuclein (aSyn) treated rats, which provides support for the hypothesis that LRRK2 kinase inhibitors will be effective in the treatment of PD (Daher et al., 2015). In mice, chronic in diet administration of the LRRK2 inhibitor MLI2 produces a mild lung phenotype (Fell et al., 2016). The purpose of the current work was to follow up on these findings and to create an in vivo model system to be used to assess the effect of chronically inhibiting LRRK2 pharmacologically. In addition to creating animal model platforms that can be used to assess the efficacy of novel LRRK2 kinase inhibitors, we are also working to establish the therapeutic index between efficacious doses and doses that produce measurable effects in the lung. In this study, we have assessed efficacy of another, structurally distinct LRRK2 kinase inhibitor, PF-360 in an AAV-A53T aSyn mouse model of PD. C57Bl6J and G2019S transgenic mice were unilaterally infused with either AAV-A53T or empty vector control into the substantia nigra (SNc). The treatment with a diet containing PF-360 was started 7 days prior to SNc injections, and four weeks after the

injection, the motor functions of the mice were evaluated using the fine motor kinematic analysis system. Five weeks after the infusions, the brains were processed for stereology and HPLC measurements, and the lungs were collected for histopathological evaluation. Chronic in diet treatment with PF-360 improved A53T aSyn induced motor deficits of the mice, and the motor readouts correlated with striatal dopamine concentrations (Pearson's correlation, $p < 0.001$, corr. coeff. $r = 0.80$), even though striatal dopamine levels were not significantly affected. The efficacy of PF-360 in this model was further supported by the finding that dopamine neuron loss (by TH-ir cell counting stereology) in the SNpc/VTA was spared by 41% compared to controls. Finally, drug treated animals had a significant reduction (by 81% compared to vehicle treated controls) in pS935-LRRK2 protein levels in cortex and lung indicating strong target engagement in both compartments. Taken together, these findings demonstrate the utility of the mouse AAV-A53T model as a useful tool for investigating disease-modifying strategies and that chronic in-diet administration of a LRRK2 inhibitor is effective in reducing dopaminergic related deficits mediated by AAV-A53T aSyn.

**Abstract:** To date, there have been no disease-modifying therapies developed for the treatment of Parkinson's disease (PD). We have previously identified two small molecule compounds PR001 and PR002, which exhibited putative neuroprotective efficacy in *Drosophila melanogaster* with PD-relevant mutations. Here, we evaluated their efficacy in rats that received a unilateral injection into the substantia nigra of recombinant human A53T-alpha-synuclein incorporated within a recombinant AAV vector . The effects of the compounds on general

behavior, locomotor performance, as well as on tyrosine hydroxylase (TH) positive cell counts and α-synuclein staining in substantia nigra pars compacta (SNpc) were assessed. This rat PD model has been previously shown to be sensitive to neuroprotective effects of LRRK2 inhibitors, the prominent class of putative therapeutics currently tested in clinical trials as potential disease-modifying treatment for PD. AAV-A53T-alpha-synuclein treatment produced a pronounced loss of TH-positive cells in ipsilateral SNpc compared to those in rats infused with AAV-Null empty virus. Additionally, rats treated with AAV-A53T-alpha-synuclein had a fine motor skills phenotype, which was significantly attenuated by daily administrations of PR001 for 4 weeks, Treatment with PR002 also led to moderate reversal of the motor phenotype caused by the infusion of AAV-A53T-alpha-synuclein, as the value of the Fine Motor Phenotype Score in this group was intermediate between values in AAV-A53T-alpha-synuclein and AAV-Null groups and statistically different from both of them. Interestingly, administration of neither test article affected the decrease in TH-positive cells in SNpc, as TH-positive cell counts in both groups were similar to that in vehicle-treated AAV-A53T-alpha-synuclein group. This suggests that the disease-modifying effect may be occurring through a different mechanism. Additionally, neither treatment affected the number of alpha-synuclein-positive cells in SNc, which suggests that the disease-modifying benefit was not a result of lowering the levels of alpha-synuclein. Collectively, these results provide confirmation of the benefits of PR001 and PR002 as disease-modifying agents in a mammalian species. Coupled with the findings previously reported in Drosophila, they represent potential novel mechanisms that deserve further exploration. Further work to better understand the mechanism of the disease-modifying benefit is ongoing.

**Abstract:** Parkinson's disease (PD) is a major neurodegenerative disease, economic burden and threat to an ever-ageing population. However, the discovery of a cure through disease-modifying therapeutics has been a challenge. It is therefore imperative that more effective discovery methods are developed.
Our laboratories have used transgenic *Drosophila melanogaster* as a model for phenotypic PD drug discovery for PD. In this report, we present recent findings on how these models can have impactful applications in drug repurposing, an approach that has been hailed as very promising for PD.
We used transgenic *Drosophila* lines, expressing forms of human alpha-synuclein under the control of pan-neuronal driver eval-Gal4, to screen a library of 1280 off-patent drugs, selecting the best hits and using a mammalian model of PD to pre-clinically validate them.
The library was initially screened using flies expressing wild type (wt) alpha-synuclein. We looked for compounds that reverse the well-documented climbing phenotype observed, 2 or 4 weeks post-eclosion. Of the 1280 compounds, 9 rescued the phenotype (p-value < 0.05 difference between treated and untreated groups of N = 60 flies), at both time points.
We then tested these 9 compounds in two streams, using in flies expressing either wt or A30P alpha-synuclein, looking for compounds that significantly reverse both the climbing phenotype as above but at a higher replicate number (N = 180 flies), but also the associated dopaminergic neuron death phenotypes, as quantified by measuring Tyrosine Hydroxylase immunoreactivity differences between treated and untreated whole brain samples (N = 10-15 brains, p-value < 0.05). We found 4 compounds that significantly rescued both phenotypes in both models. Of these we selected 2, PR001 and PR002, for further studies based on their assay results, combined with an analysis of their chemistry, pharmacological features and known targets.
The results of this work, in combination with the pre-clinical validation of PR001 and PR002 that followed, highlight the impact potential of *Drosophila* models in the discovery of new candidate drugs. To further strengthen this argument, it is worth noting that we followed up this work using a chemoinformatics search, which revealed
compounds free from intellectual property limitations. After compiling a library of these compounds we now have the first positive indications in preliminary experiments.

**Title:** Optical Ca2+ imaging of astrocyte activity during STN DBS

**Authors: *J. TREVATHAN**[1], A. J. ASP[3], E. N. NICOLAI[2], K. LUDWIG[4], J. LUJAN[5]
[1]Biomed. Engin. & Physiol., [2]Mayo Clin. Grad. Sch., Rochester, MN; [3]Biomed. Engin., Mayo Grad. Sch., Rochester, MN; [4]Neurologic Surgery, [5]Neurologic Surgery, Physiol. and Biomed. Engin., Mayo Clin., Rochester, MN

**Abstract:** The study of glia-neuron interactions is important for understanding the underlying therapeutic mechanisms of deep brain stimulation (DBS) therapies. Multiple studies using cell culture, slice, or cortical experiments have shown that activation of astrocytes by high-frequency stimulation can lead to a variety of effects including, but not limited to 1) release of gliotransmitters, 2) modulation of synaptic activity of nearby neurons, 3) modulation of neuronal activity away from the site of stimulation via propagation of calcium waves, and 4) modulation of synaptic plasticity (Fenoy 2014). However, in vivo characterization of the effects of DBS on astrocytes in intact deep brain neural circuits of awake animals remains a challenge. To address this critical need, we are using calcium imaging to directly visualize downstream effects of subthalamic nucleus (STN) DBS on astrocytes in the striatum, a brain region involved in the initiation and execution of volitional movement (Barbera, 2016, Klaus, 2017), in a Parkinsonian mice cohort.
We performed calcium imaging of striatal astrocytes in a 6-hydroxydopamine (6-OHDA) mouse model of Parkinson's disease using a miniature fluorescent microscope (Inscopix, Palo Alto, CA). To accomplish this, we transfected astrocytes within the dorsal striatum using AAV5.GfaABC1D.cytoGCaMP6f.SV40 to express GCaMP6f. Two weeks after injection, we implanted a bipolar stimulation electrode (PlasticsOne, Roanoke, VA) in the STN and a 1mm gradient index (GRIN) lens directly above the dorsal striatum. We will record changes in striatal astrocyte Ca2+ activity evoked by STN DBS under isoflurane anesthesia beginning two weeks after lens implantation, and weekly thereafter in awake freely-moving animals. Although these experiments are ongoing, we anticipate that optical imaging of astrocytic Ca2+ signaling in deep

regions of the brain in awake freely-moving animals during DBS will provide a major step toward confirming and understanding the role of glia in the therapeutic effects of DBS.

**Title:** Movement-based classification of striatal ensembles during DBS

**Authors: *A. J. ASP**[1], J. TREVATHAN[2], E. N. NICOLAI[3], K. LUDWIG[4], J. LUJAN[4]
[1]Biomed. Engin., Mayo Grad. Sch., Rochester, MN; [2]Biomed. Engin. & Physiol., [3]Mayo Clin. Grad. Sch., Rochester, MN; [4]Neurologic Surgery, Mayo Clin., Rochester, MN

**Abstract: Introduction**:
The motor symptoms of disease (PD) are thought to result from maladaptive neural ensemble activity in the dorsal striatum (Jones-Parker, 2018), a brain region involved in the initiation and execution of volitional movement (Barbera, 2016, Klaus, 2017). Deep brain stimulation (DBS) is regularly used to treat the motor symptoms of PD, but its exact mechanisms of action remain elusive. Thus, there is a critical need for understanding how DBS affects striatal ensemble activity responsible for movement. The motor symptoms of PD have a non-episodic nature that is difficult to analyze, particularly in animal models that are used to study the effects of DBS. In this work, we characterized the effects of STN DBS on striatal ensemble activity during biased turning, pathological rearing, darting behavior, and at rest using a k-means clustering approach in a mouse 6-hydroxydopamine (6-OHDA) lesion model of PD. .
**Methods:**
We used the nVoke (Inscopix, Palo Alto, CA) system to collect and analyze dorsal striatal calcium imaging data in 6-OHDA hemiparkinsonian animals implanted with a DBS lead in the subthalamic nucleus. We evaluated specific behavioral traits during open field, cylinder, and parallel rod tests with or without DBS. Simultaneously, we identified movement-associated neural activity via calcium imaging. We used video tracking software (Anymaze, Stoelting, IL) to determine animal position. Similarly, we used Matlab to perform PCA dimensionality reduction and k-means clustering of the position data to classify movements.
**Results:**

We identified cCalcium activity signatures were identified for different behavioral clusters. The rate at which specific behaviors were exhibited varied with and without DBS in healthy and parkinsonian animals.

**Conclusion:**

This work sets the foundation for future studies investigating how DBS influences neural activity and its associated behaviors .

**Abstract: Background**: Cognitive, mood, and movement disorders such as dementia, depression, and Parkinson’s disease (PD) are associated with degeneration of dopaminergic neurons. In an effort to understand the pathophysiology of the disease and develop new therapeutic interventions, previous studies have used fast scan cyclic voltammetry (FSCV) to measure neurotransmission in small animal models (Clark et al. 2010). Our own preliminary work has characterized the non-linear and time-varying dopamine (DA) dynamics using mathematical models of release evoked by burst stimulation of the medial forebrain bundle (MFB) in healthy anesthetized animals. However, this complex relationship has yet to be characterized in an animal model of DA degeneration. Here, we aim to characterize the nonlinear transfer function between electrical stimulation and evoked DA changes in a 6-hydroxydopamine (6-OHDA) lesioned rodent model. **Materials and Methods**: We lesioned the dopaminergic nigrostriatal pathway of male Sprague-Dawley rats with a unilateral intra-cranial injection of 6-OHDA into the dorsal MFB. After a fourteen days of toxin-exposure period, we electrically

stimulated the MFB to evoke striatal DA release under urethane anesthesia. We measured the evoked DA release using fast scan cyclic voltammetry with carbon fiber microelectrodes. Finally, we characterized the evoked DA responses using a multi-compartment parametric model. **Results**: The kinetics of MFB stimulation-evoked DA release following 6-OHDA lesioning vary with dopaminergic lesion level but the mathematical models successfully described the stimulation-evoked DA release. **Conclusions**: Characterization of burst stimulation-evoked DA release in a model of dopaminergic degeneration is an important step towards understanding neurotransmitter dynamics in the context of neurologic disease. Preliminary results demonstrate that kinetics of evoked DA release change as the DA lesion severity increases, thus suggesting that we may be able to predict the severity of DA lesion level based on the dynamics of DA responses. In the near future, we will use these kinetic responses to train machine learining strategies to predict stimulation-evoked neurochemical effects. Ultimately, this work will aid in understanding the neurochemical effects of neurodegenerative disorders and further the development of novel personalized therapeutic strategies.

**Title:** Predictive encoding of motor behavior in the SMA is disrupted in parkinsonism

**Authors: *H. E. BAKER**[1], C. M. HENDRIX[1], D. L. BAUER[1], Y. YU[1], M. D. JOHNSON[2], G. F. MOLNAR[1], J. L. VITEK[1]

**Abstract:** While the pathogenesis of parkinsonism and the role of the pre-supplementary motor area (preSMA) and SMA proper (SMAp) in normal movement initiation are well documented, the relationship between the pre-planning processes preceding movement occurring in the preSMa/SMAp and the onset of parkinsonism is not well understood. In the present study, two non-human primates (NHP) performed a visually-cued reaching task in both the naïve and

parkinsonian state, during which preSMA/SMAp local field potential (LFP) activity was recorded. This LFP activity was assessed to determine whether such activity encodes for changes in reaction time (RT) performance observed with the onset of parkinsonism. In the naïve animal, high and low-beta frequency band modulation prior to the onset of a visual go-cue were predictive of RT performance. The magnitude of high and low beta-band desynchronization and synchronization, respectively, also correlated linearly with the magnitude of RT on a trial-to-trial basis. Predictive encoding of RT in the naïve animal was also anatomically dependent and most prominent in the preSMA. In parkinsonism, predictive encoding of RT performance in the beta-band modulation of preSMA/SMAp areas was diminished, most notably in the high-beta frequency band. Additionally, the previously observed anatomical specificity of predictive encoding in the preSMA was not present in the parkinsonian state. The finding that encoding of RT was preferentially lost in high beta while remaining largely present in low beta in parkinsonism provides evidence in support of independently modulated beta rhythms, as well as beta rhythms with differing functional significance. Our findings in these areas are consistent with previous research suggesting a role for preSMA in executive functioning, and could suggest that the disruption of preSMA/SMAp predictive encoding may reflect a causal cortical mechanism underlying prolonged RT and executive function errors observed in PD.

**Title:** Modulating neural oscillations associated with parkinsonism using phase feedback and deep brain stimulation in-vivo

**Authors: *D. ESCOBAR SANABRIA**[1], L. A. JOHNSON[1], Y. YU[1], J. ZHANG[1], S. NEBECK[1], M. D. JOHNSON[2], G. F. MOLNAR[1], J. L. VITEK[1]

**Abstract:** Low-frequency synchronized oscillations in the subthalamic nucleus (STN) and globus pallidus internus (GPi) are hypothesized to be involved in the development of motor signs in Parkinson's disease (PD). Approaches capable of robustly modulating these oscillations using deep brain stimulation (DBS) could help us better understand their relationship with motor signs and develop more effective DBS therapies. Based on our observations that stimulation in the GPi can evoke large potentials in the STN, we tested the hypothesis that stimulation in the GPi timed to specific phases of neural oscillations in the STN can modulate these oscillations via destructive and constructive interference. A nonhuman primate was implanted with a DBS lead in both STN and GPi and rendered parkinsonian by injections of the neurotoxin MPTP. GPi contacts selected for therapeutic isochronal DBS were chosen to deliver stimulation. STN contacts where neural oscillations at ~12 Hz exhibited elevated amplitude in the parkinsonian compared to the normal state were selected for sensing. The phase of oscillations in the 10-14 Hz band was computed in real-time and a train of 3 stimulation pulses was delivered at phases 0, 10, ⋯, 350 deg. Stimulation artifacts were removed using dynamical models of the artifacts and a blanking procedure. Mathematical models of stimulation-evoked responses and neural data were used to characterize observed modulations. We observed significant suppression and amplification of oscillations at ~12 Hz in the STN when stimulation was delivered in the GPi at two specific phases. Numerical simulations support the hypothesis that the observed modulation was due to interference between the underlying neural oscillations and potentials in STN evoked by GPi stimulation. This modulation approach will enable us to quantify in controlled experiments the relationship between measured oscillatory activity in the STN and parkinsonian motor signs and provide a rationale for the development of closed-loop DBS systems that are specific to each subject's oscillatory activity.

**Abstract:** The paradoxical effect of external cues, particularly visual cues, is a hallmark of Parkinson Disease. Specifically, visual cues can both inhibit or disinhibit motor behavior, notably in upper limb freezing (ULF) and freezing of gait (FOG). While this influence of visual cues is prevalent on motor behavior, little is understood about the underlying pathophysiology contributing to these behavioral responses.
Visually-evoked responses in cortical local field potential (LFP) oscillations are driven by central theta rhythms originating within the medial frontal cortex (MFC). These structures are also implicated in the pathogenesis of motor disturbances found in parkinsonism. The current study examines pathophysiological changes in, and behavioral correlates of, visually-evoked LFP activity in bilateral somatic motor area (SMA) within naïve then parkinsonian non-human primates (NHPs). NHPs were trained in a controlled, visually cued center out behavioral task. Importantly, within-subject controls allow for analysis of intra-individual changes for reaction time (RT) variability, altered magnitude in visually evoked responses (ER), and inter-trial phase coherence (ITPC). Unique to this study is trial-based inference testing linking pathophysiological changes to behavioral responses on a trial-by-trial basis.
The relative change in the magnitude of the ER was greatly diminished in parkinsonism across all frequency bands (<40Hz) and animals as was the number of LFP recordings (% LFP with significant modulation). In the naïve condition, ITPC peak magnitude was centered within the theta band (5 +/- 2 Hz) and within 0.2 +/- 0.05 sec of the go-cue. In parkinsonism, peak coherence values varied considerably across frequency bands and onset relative to the go cue. Bilateral SMA frequency modulations during the reaction time were greatly diminished relative to baseline activity across 1-40 Hz frequency bands in PD and may provide a robust biomarker for PD. Disease severity and/or asymmetry may be reflected in the relative change across hemispheres. Altered theta ITPC observed in the SMA, both ipsilateral and contralateral to the working arm, likely contributes to a disruption in higher level processing related to motor behavior in PD i.e. ULF, start hesitation, etc. These findings are consistent with previous reports of structural, functional, and neurochemical declines in the frontal lobes associated with higher within-person behavior variability.

**Title:** Bayesian adaptive dual control of deep brain stimulation in a computational model of Parkinson's disease

**Authors: *L. GRADO**[1], M. D. JOHNSON[2], T. I. NETOFF[2]
[2]Biomed. Engin., [1]Univ. of Minnesota, Minneapolis, MN

**Abstract:** Deep brain stimulation (DBS) is an effective therapy for motor symptoms of PD. However, programming these devices is difficult and time consuming, and DBS therapy is limited by side effects and partial efficacy. Furthermore, traditional continuous DBS (cDBS) does not account for fluctuations in motor symptoms caused by factors such as sleep, attention, stress, cognitive and motor load, and current drug therapy, and as the patient's state changes, so does the need for stimulation. Current cDBS strategies are incapable of adapting to the needs of patients: once the clinician sets the parameters, they do not change until the next programming visit. In this study, we have created a Bayesian adaptive dual controller (ADC) that can respond to changes and autonomously learn to reduce pathological beta oscillations in silico.

We developed and tested the Bayesian ADC in a biophysically realistic mean-field model (MFM) of the basal ganglia-thalamocortical system, which simulates parkinsonian neural activity and responds to DBS. The Bayesian ADC is composed of two loops: an inner feedback control loop, and an outer parameter optimization loop. The inner loop is a closed-loop feedback stimulator. It delivers a stimulus to the MFM, triggered off of the phase and amplitude of the beta oscillation, thereby only delivering stimulus when the amplitude is high, and in the correct phase. The inner loop has three parameters: (a) oscillation phase threshold, (b) oscillation amplitude threshold, and (c) stimulus amplitude.

The outer loop of the ADC employs Bayesian optimization (BO) to intelligently sample the parameter space and select the optimal set of parameters in the fewest evaluations. BO is a powerful strategy for optimizing objective functions that are expensive, difficult, or time-consuming to evaluate. BO's efficiency stems from the incorporation of prior belief about the problem to balance exploration and exploitation: BO builds a model of the objective function from prior observations, and then uses the model to intelligently direct sampling. The outer loop operates on a timescale of 20s; after selecting a new parameter set, the outer loop waits 10s, and then measures the amplitude of the beta oscillation over the next 10s. It then augments the set of prior observations with the new, updates the internal model, and selects the next parameter combination.

The Bayesian ADC was able to efficiently learn the best parameters to reduce the power of a pathological oscillation in a computational model of PD. The algorithm has the potential to deliver individualized, adaptive DBS therapy that can improve the quality of life for PD patients.

**Title:** Network-level differences in fMRI BOLD signaling for orientation-selective deep brain stimulation

**Authors: *J. SLOPSEMA**[1], L. J. LEHTO[2], Y. ERYAMAN[2], N. KOBAYASHI[3], H.-K. MIN[4], K. H. LEE[5], S. MANGIA[2], S. MICHAELI[2], M. D. JOHNSON[1]
[1]Biomed. Engin., [2]Ctr. for Magnetic Resonance Res., [3]Univ. of Minnesota, Minneapolis, MN; [4]Radiology, [5]Mayo Clin., Rochester, MN

**Abstract:** Functional MRI (fMRI), which measures blood oxygen level dependent (BOLD) signaling, has become an important tool to probe the mechanisms of deep brain stimulation (DBS). Previous studies have shown that DBS of the ventrolateral (VL) thalamus results in notable fMRI BOLD activity changes in the sensorimotor cortex, basal ganglia, and cerebellum in a frequency and amplitude dependent manner (Paek et al., *Neuroimage*, 2015; Gibson et al., *Brain*, 2016). Here, we extend this original study by investigating the relative degree to which these brain regions can be modulated when using multi-contact, orientation-selective DBS patterns tuned to more selectively activate one or more pathways within the VL thalamus. The VL thalamus consists of a convergence of several axonal pathways, including cerebello-thalamic projections and corticothalamic / thalamocortical projections, whose main branches are oriented approximately tangential to each other. These two axonal pathways were specifically targeted with orientation-selective DBS (Lehto et al., *JNE*, 2017) in a domestic swine model . Swine underwent preoperative MRI followed by implantation of a directional DBS lead in the motor thalamus. A within-subject design was used to compare fMRI BOLD activation for each orientation-selective stimulus configuration to compare stimulation patterns predicted to modulate the cerebello-thalamic versus the corticothalamic / thalamocortical pathways more selectively. Stimulation was applied using a block design of 6 s of stimulation followed by 60 s of rest repeated 5 times for each stimulation parameter. Stimulation was preceded by 15 seconds

of blanking and an initial 60 seconds of baseline resting state. fMRI BOLD activation was measured in the motor cortex as well as the cerebellum. Preliminary results suggest that activation in the cerebellum and motor cortex was modulated when the electric field orientation was controlled using orientation-selective stimulation patterns. For example, maximal BOLD contrast in the motor cortex was found when stimulating with pulse patterns targeting fibers parallel to the DBS lead compared to pulse patterns targeting fibers perpendicular to the DBS lead, which showed reduced activation in the motor cortex. This work provides preliminary experimental evaluation of orientation-selective stimulation and motivates the need for further development of fMRI-based network analysis of orientation-selective DBS.

**Title:** Features of evoked compound action potentials in non-human primate thalamic deep brain stimulation

**Authors: *J. ROSING**[1,2], E. M. BELLO[2], L. WILMERDING[3], J. KRIEG[3], A. DOYLE[3], M. JOHNSON[3]
[2]Biomed. Engin., [3]Neurosci., [1]Univ. of Minnesota Twin Cities, Minneapolis, MN

**Abstract:** Deep brain stimulation (DBS) is known to modulate neuronal spiking patterns and rates as well as the spectral power of local field potential activity. Additionally, DBS is known to evoke compound action potentials (ECAPs) that immediately follow each stimulus pulse with feature intensities and delays that depend on the local anatomy and physiology of the stimulation and recording targets. Previous studies have investigated ECAPs in the thalamus of cats (Kent and Grill, 2013) and in the subthalamic nucleus of human patients with Parkinson’s disease (Gmel, et al. 2015). In this study, we sought to characterize ECAPs in non-human primates through chronically implanted DBS leads in motor thalamus and subthalamic nucleus. Specifically, we investigated the changes in ECAP responses over (1) time, (2) stimulation amplitudes, and (3) spatial positioning of the recording and stimulating electrodes. Stimulation

was delivered with trains of biphasic, charge-balanced pulses that alternated in polarity such that each cathodic-anodic pulse would be followed by an anodic-cathodic pulse. The different between these two pulses resulted in a nearly instantaneous ECAP measure. The effects of stimulation amplitude were investigated using a randomized sweep of current levels to apply to the stimulus pulse train. The ECAP in motor thalamus was characterized by multiple peaks and troughs. The first two peaks (P1, P2) and troughs (N1, N2) remained stable over time, while the third peak (P3) reduced in amplitude and sharpened in time over the first 4-10 seconds of stimulation. The average P3 maximum then continued to decrease over the next 30-60 seconds without a temporal shift. As stimulus current increased, the ECAP responses increase in magnitude following a sigmoidal curve, while the artifact magnitudes increase rapidly at a perfectly linear rate. Additionally, the N1, P2, and N2 responses were observed in the average ECAP response to a cathodic pulse, but not to an anodic pulse. The unique temporal change in P3 suggests that it may reflect a different source or process than other ECAP features, and that it appears to habituate over time. Additionally, the sigmoidal curve ECAP responses to increased stimulation amplitude suggest that there is a threshold of activation that must be reached before an ECAP response can be reliably evoked, and that there is a maximum response that can be achieved. The observation that certain ECAP features appeared solely after a cathodic pulse, or at least far more visibly than after an anodic pulse, further suggests that cathodic stimulation may be more effective than anodic stimulation in evoking neural responses local to the stimulation target.

**Title:** Exercise as a treatment for Parkinson's disease: The role of astrocytes in circuit-specific, exercise-induced neuroplasticity

**Authors: *A. LUNDQUIST**, M. R. HALLIDAY, G. M. PETZINGER, M. W. JAKOWEC
Neurol., USC, Los Angeles, CA

**Abstract:** Aerobic exercise, in the form of motorized treadmill running, is a type of experience-dependent neuroplasticity that has been shown to be beneficial in improving motor behavior and

modifying disease progression in Parkinson's disease. Studies in our lab have shown that exercise mediates circuit-specific neuroplasticity through modulation of dendritic spine density, glutamatergic and dopaminergic neurotransmission, and regional blood flow. Astrocytes are essential for normal neuronal function and synaptic plasticity. Recently, astrocytes have begun to attract interest in exercise and neuroplasticity due to their ability to modify synapses and transport energetic substrates (including glucose and lactate) to neurons from blood vessels or through intercellular metabolic coupling, including the astrocyte-neuron lactate shuttle. While the effects of exercise on neurons are well-established, the astrocytic response to exercise is less well-known. Here, we investigated the longitudinal and regional astrocytic response to intensive treadmill training in healthy, C57BL/6 mice. Astrocyte reactivity were measured after one, two or four weeks of exercise in the prefrontal cortex (PFC), caudate putamen (CPu) and ectorhinal cortex (ERC) using immunofluorescence (IF), quantitative RT-PCR (qRT-PCR), and Western blot (WB). Astrocyte morphology was measured across regions and time points using IF, including changes in distal-proximal length, number of primary processes, length of processes, and total density of astrocytes. Using qRT-PCR and WB, relative changes in expression of GFAP (glial fibrillary acidic protein), a marker of astrocyte reactivity, were found at both the transcriptional and protein levels. Taken together, these data demonstrate that astrocytes react in a regional- and exercise-dependent fashion, further helping to explain exercise as a form of experience-dependent neuroplasticity. Such findings provide evidence that targeting specific forms of exercise to circuits within the brain may provide a means to modify motor behaviors compromised in brain disorders such as Parkinson's disease.

Minnesota Dept. of Neurol., Minneapolis, MN; [4]Neurol., [6]Biomed. Engin., [5]Univ. of Minnesota, Minneapolis, MN

**Abstract:** Deep brain stimulation (DBS) of the globus pallidus internus (GPi) improves motor function in patients with Parkinson's disease (PD). Although the primary motor cortex (M1) is a key component of the basal ganglia-thalamocortical (BGTC) network and likely plays a key role in the pathogenesis of PD motor signs, little is known about the effect of GPi DBS on neuronal activity in M1. The objective of this study was to assess the impact GPi DBS has on M1 neuronal activity prior to and during movement. A rhesus monkey was chronically implanted with a DBS lead in the GPi and a microelectrode array in M1 and made parkinsonian using the neurotoxin MPTP. M1 single unit activity was recorded as the monkey performed a reach and retrieval task during DBS-OFF and DBS-ON conditions. We characterized baseline spontaneous firing rates and movement-related modulation of neuronal activity by aligning spike times to each behavioral epoch (i.e. cue, reach initiation, target touch, return initiation, reach end). Neurons were considered to have a significant modulation when a nonparametric statistical test detected a significant positive or negative change in mean discharge rate relative to spontaneous firing rates based on an alpha of 0.01 for at least 150 ms, reflecting excitatory or inhibitory effects on neuronal activity. GPi DBS significantly improved task performance, increasing the reach and return speed from 105.8 to 283.2 mm/sec and 63.4 to 180.6 mm/sec, respectively. DBS altered baseline firing rates (prior to the cue) in a subset of neurons (31%), with both significant increases (18%) and decreases (13%) observed, and was associated with more neurons showing significant changes in relation to the task in all behavioral epochs. DBS increased the number of neurons modulated in the reach epoch from 43% (6% suppressive and 37% excitatory) in the DBS-OFF to 71% (14% suppressive and 57% excitatory) in the DBS-ON condition. Of the neurons modulated, the depth of excitatory or inhibitory) modulation, defined as the magnitude of change from spontaneous firing rate to subsequent firing rate maxima or minima, was found to be greater in the DBS-ON condition. In sum, we observed that GPi DBS increased both the number of cells that were modulated during movement as well as their magnitude of modulation. These data suggest that one potential mechanism underlying the therapeutic effects of GPi DBS is via the augmentation of excitatory and inhibitory drive to selective M1 neurons leading to improved signal transmission in the BGTC network.

**Title:** Intensity and cycle rate impact the effectiveness of subthalamic coordinated reset deep brain stimulation

**Authors: *J. WANG**[1], S. P. FERGUS[1], S. D. NEBECK[1], L. A. JOHNSON[1], D. E. SANABRIA[1], J. ZHANG[1], S. KULKARNI[3], H. BOKIL[3], M. D. JOHNSON[2], G. F. MOLNAR[1], J. L. VITEK[1]
[1]Neurol., [2]Biomed. engineering, Univ. of Minnesota, Minneapolis, MN; [3]Boston Scientific Neuromodulation, Valencia, CA

**Abstract:** Coordinated reset deep brain stimulation (CR DBS) is a novel approach for the treatment of patients with Parkinson's disease (PD). Rather than using high frequency isochronal pulses, CR DBS delivers low intensity pulse trains randomized through multiple electrodes. Modelling studies have suggested that variations in the parameter space can produce different effect on synchronized neuronal activity. The relative effect of these changes in parameter space, however, has not been explored systematically in vivo. In this study, we examined the impact of intensity and cycle rate on the motor signs in the MPTP non-human primate (NHP) model of PD undergoing subthalamic nucleus (STN) CR DBS.
A NHP was rendered parkinsonian through IM injections of MPTP and implanted with an 8-electrode DBS lead (NuMed) in the STN for stimulation and recording of local field potential (LFP). Both the intensity and cycle rate of STN CR DBS were varied while other parameters remained constant. Four intensities (0.05, 0.1, 0.16 and 0.24mA) and cycle rates (5, 6.95, 8 and 8.88Hz) were used. CR DBS was delivered for 4 hours daily over 5 consecutive days. Parkinsonian motor signs were assessed using a clinical rating scale and a reach/retrieval task pre, during and post stimulation. Following discontinuation of CR, motor signs were assessed each morning until the animal returned to baseline.
The effect of CR DBS was specific to intensity and cycle rate. Results demonstrated that CR at 0.16mA, 2/3 of the traditional DBS (tDBS) intensity, induced the greatest degree of acute improvement in motor signs with prolonged carryover effects following discontinuation of stimulation. Thereafter, 0.16mA was used in cycle rate tests. Cycle rate of 8.88Hz induced the most improvement in motor signs acutely with the longest carryover benefit. We observed up to 50% of improvement in the mUPDRS and an average reduction of 30% in reach, retrieval and reaction times. A high beta peak at 27Hz was seen in the power spectral density of STN LFP signals, and was close to the inter-burst rate (3 times of 8.88Hz) of the optimal cycle rate.
In summary, the therapeutic effect of STN CR DBS is dependent upon both stimulation intensity and cycle rate. Exploration of the parameter space will be critical to optimize stimulation parameters for CR DBS. Further studies will be necessary to define the relationship between the optimal cycle rate and the high beta peak frequency which could serve to facilitate optimization of cycle rate and contribute to future exploration of closed loop CR approach.

**Title:** The effects of deep brain stimulation and L-dopa on single unit activity in primary motor cortex of an MPTP treated Rhesus macaque during a reach and retrieval task

**Authors: *S. NEBECK**[1], L. A. JOHNSON[2], J. ZHANG[2], M. D. JOHNSON[4], G. F. MOLNAR[5], J. L. VITEK[3]
[1]Neurol., Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Neurol., [3]Dept. of Neurol., Univ. of Minnesota Dept. of Neurol., Minneapolis, MN; [4]Biomed. Engin., [5]Neurol., Univ. of Minnesota, Minneapolis, MN

**Abstract:** Parkinson's disease (PD) is a chronic neurodegenerative disease that affects dopaminergic cells in the basal ganglia thalamocortical (BGTC) network and is characterized by cognitive and motor symptoms. L-dopa is a commonly prescribed treatment for PD patients, but over time higher doses are required and are often associated with motor fluctuations and drug induced dyskinesia. Deep brain stimulation (DBS) is increasingly being used to treat PD motor symptoms and reduce the dependence on high doses of L-dopa. Although DBS is used in combination with L-dopa, the effect of each therapy alone or in combination on the BGTC network is not well understood.
In this study a female MPTP (1-methyl-4-phenyl 1,2,3,6- tetrahydropyridine) treated Rhesus macaque was trained to perform a reach and retrieval task. While performing the task single units were recorded from the arm area of primary motor cortex during: no treatment, DBS, L-dopa and combined treatment conditions. A 96 channel Utah array was used to record single units in the primary motor cortex and an 8 channel DBS lead was implanted into the STN to deliver therapeutic DBS. Both primary motor cortex and STN were implanted contralateral to the arm used during the task. L-dopa was given orally in a dosage that alleviated motor symptoms without causing dyskinesia.
All treatment conditions (STN DBS, L-dopa only, combined STN DBS and L-dopa) improved

performance on the reach and retrieval task most notably with a reduction in reaction and return times. mUPDRS was improved between 30% and 45% with the greatest improvement occurring with combining DBS and L-dopa.
Eighty percent of M1 neurons were modulated during the task and a significant number of these were differentially affected by DBS vs L-dopa and in some cases demonstrated a combined effect that was different from either alone. By characterizing the relative effect of DBS to L-dopa on changes in primary motor cortex and motor behavior in the parkinsonian state we can gain a better understanding of the neurophysiological mechanisms underlying these therapies and how to optimally combine them.

**Abstract: Introduction:** Deep brain stimulation (DBS) therapy relies on precise targeting of neural pathways that are often embedded within complex networks within the brain. The thalamus, for example, has been the target of DBS for several clinical indications including essential tremor, epilepsy, minimally conscious state, and schizophrenia, among others. However, the thalamus has heterogeneous axonal tractographies that are difficult to characterize with traditional imaging techniques such as diffusion tensor imaging (DTI), limiting efforts to build predictive models of DBS therapy. In this study, we used polarization-sensitive optical coherence tomography (PS-OCT) imaging to visualize axonal pathways within non-human

primate (NHP) thalamus with 10-micron lateral resolution. **Methods:** Perfused and paraformaldehyde-fixed brain tissue was blocked about the right thalamus. PS-OCT was then used to image the thalamic tissue from the lateral sagittal face of the section. The size of the sample was such that it required imaging in tiles, each measuring 7.8 x 7.9 $mm^2$ with 5% overlap. After imaging four tiles to cover the lateral plane, a 100-micron thick slice was removed from the surface to access the deeper regions. The imaging and slicing procedure was repeated 95 times until the whole block was imaged. The reflectance, retardance, and cross polarization images were obtained from each of these tiles and then recombined based upon the designated overlap during the imaging process and correlative value assessed. The stitched images (enface images) were then aligned and stacked into a three-dimensional block to render thalamus axonal tracts. **Results:** PS-OCT enabled visualization of both afferent and efferent pathways that differed in orientation amongst thalamic nuclei are visualized. Well know tracts such as the mammillothalamic tract and stria medullaris of the thalamus were easily identified. Additionally, distinct bodies of the thalamus such as the anteriomedial and centromedian thalamic nuclei were identified. The resolution with which the myelinated fibers are seen sheds light on the intricacies of orientation. **Conclusions:** Improved understanding of axonal tractography within thalamus will be important to optimize DBS therapy for a range of existing and emerging clinical indications. This imaging approach is poised to enable rendering of axonal tracts in three dimensions and help guide future DBS lead designs and programming algorithms.

**Abstract:** Beta range synchronized oscillation has been hypothesized to be a biomarker of Parkinson’s disease (PD). Recently, it has been argued that the critical feature is not merely that

beta activity is increased, but rather that the duration of beta activity is prolonged. It is unclear, however, whether prolonged beta burst activity occurs across the basal ganglia-thalamocortical (BGTC) motor network. To address this, we studied beta burst dynamics across the subthalamic nucleus (STN), globus pallidus (GP), and primary motor cortex (M1) in non-human primates (NHPs) in the naïve and progressive PD states.
Local field potentials (LFPs) from the STN, GP and M1 were recorded with implanted deep brain stimulation leads and a 96 channel Utah array in the M1 arm areas at rest. Progressive parkinsonian states of NHPs were induced by sequential injections of the neurotoxin 1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine (MPTP). The modified Unified Parkinson's Disease Rating Scale (mUPDRS) was performed in each state to assess severity of the animal. Beta band envelope of LFPs, filtered around the peak frequency in the beta band (6 Hz bandwidth), was computed, after which beta bursts were detected using the threshold of 75 percentiles of its amplitude for naïve and PD states. The duration, average amplitude and co-occurrence of beta bursts across each structure was measured.
Results of mUPDRS scores indicated that NHP K&J reached a moderate PD state with MPTP injections. In both NHPs, more beta bursts with longer duration and higher amplitude were present in the STN and GP, and in M1 in only NHP J. The amplitude of detected beta bursts was positively correlated with the duration. Moreover, there was greater overlap in beta burst activity across M1, STN and GP in PD in both NHPs. Overlap of low beta band activity (8-20 Hz) across structures was present in the mild state and increased with severity of motor signs.
The presence and overlap of low beta band activity across multiple nodal points of the BGTC circuit that increased with severity supports the proposed role of low beta band activity in the pathogenesis of PD. We further hypothesize that this activity interferes with spatial-temporal processing of information flow and connectivity that leads to the impairment of motor function in PD.

**Title:** Relative effects of therapeutic subthalamic and pallidal deep brain stimulation on antidromic activation of the primary motor cortex

**Authors: *L. A. JOHNSON**[1], J. WANG[1], S. NEBECK[1], D. ESCOBAR SANABRIA[1], J. ZHANG[1], M. D. JOHNSON[2], G. F. MOLNAR[1], J. L. VITEK[1]

**Abstract:** Deep brain stimulation (DBS) of the subthalamic nucleus (STN) or internal segment of the globus pallidus (GPi) is an effective surgical treatment for advanced Parkinson's disease (PD), though its therapeutic mechanisms remain unclear. Several studies have suggested that direct activation of the motor cortex during DBS, via antidromic activation of axonal projections from cortical neurons, may underlie its therapeutic effects on parkinsonian motor symptoms. These studies have primarily investigated motor cortical responses during STN DBS, but it has been speculated that similar effects may be elicited during GPi DBS as well. In this study we tested the hypothesis that antidromic activation of primary motor cortex neurons is a prominent feature of therapeutic STN and GPi DBS by evaluating single unit activity from high density microelectrode arrays chronically implanted in the primary motor cortex (M1) of two non-human primates made parkinsonian using the neurotoxin MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). Each animal was implanted with two scaled-down versions of human DBS leads targeting the STN and GPi, respectively, enabling within animal comparisons of M1 activity to stimulation of both nuclei. We found that STN and GPi stimulation had similar therapeutic effects based on clinical ratings of parkinsonian motor signs, however antidromic firing in M1 was only observed during STN DBS. Although the percent improvement in clinical ratings during STN and GPi DBS was similar, the proportion of cells classified as having antidromic firing differed between animals (30% vs 7%). Firing patterns of cells with antidromic firing was highly regular, with the highest interspike interval probability equaling the interstimulus interval of the DBS pulse train. Notably, over the course of four hours of continuous STN DBS, antidromic classified cells fired less robustly, whereas therapeutic benefits were maintained. These findings do not discount a potential role of antidromic M1 activation in mediating the improvement in motor signs during STN DBS, however the difference in antidromic activation between animals, the reduction of antidromic activity over time, and absence of antidromic M1 activity during GPi DBS challenge the hypothesis that antidromic activation of the motor cortex is the primary mechanism underlying therapeutic benefits during DBS.

**Title:** Electrical power delivery predicts therapeutic efficacy in a mouse model of subthalamic nucleus deep brain stimulation for Parkinson's disease

**Authors: *J. SCHOR**, A. NELSON
Univ. of California San Francisco, San Francisco, CA

**Abstract:** Since the first demonstration of subthalamic nucleus deep brain stimulation (STN DBS) by Alim-Louis Benabid and Pierre Pollak, STN DBS has provided effective management of the motor symptoms of Parkinson's Disease (PD). Stimulation is traditionally delivered as rectangular pulses, which are defined by their width (pulse width), amplitude (current), and frequency. Largely due to technical limitations of early stimulators, neurosurgeons primarily varied frequency, observing greater therapeutic benefit at high frequencies compared to low frequencies. While modern stimulation devices are capable of greater ranges of stimulation, this initial observation has fueled the widely held hypothesis that frequency is the single-largest driver of effective DBS, with pulse width and current playing secondary roles. Indeed, the bulk of STN DBS research rests upon this supposition, leading to the theory that high frequency stimulation uniquely disrupts the abnormal neuronal activity seen in PD. However, due to the logistical difficulties inherent to systematically studying DBS parameter space in patients, this hypothesis has yet to be rigorously tested. Here, we developed a novel mouse model of STN DBS and used it to assess the parameter space. Contrary to the predominant theory, we find that the composite measure of average electrical power, rather than stimulation frequency, most strongly predicts therapeutic efficacy, and that this effect is borne out through retrospective analysis of human data.

**Abstract:** Epidural electrical stimulation of the spinal cord has shown positive outcomes addressing motor symptoms of Parkinson Disease (PD), increasing its potential as a new clinical treatment. However, spinal cord stimulation (SCS) requires a surgical procedure and therefore is not exempt from the complications associated to chronic implants. In this study we explored, for the first time, the effects of a less invasive method for neuromodulation of the spinal cord. Using adult Sprague Dawley male rats with unilateral nigrostriatal dopaminergic lesions induced by 6-hydroxydopamine (6-OHDA), we evaluated the effectiveness of Non-Invasive Spinal Cord Stimulation (NISCS) by measuring the neural activity in the cortico-basal ganglia circuit and the motor function. For the first outcome, we compared the local field potential (before, during and after stimulation) from 5 different areas of the motor circuit, using the uninjured hemisphere as a control. For the second outcome, we evaluated the motor performance during 11 days of stimulation, using the cylinder test and the amphetamine-induced rotation test. We compared the motor performance between the treated and non-treated (control group) parkinsonian rats. NISCS was able to modulate the pathological neural activity and also motor function. Since this strategy is less expensive, safer, and easier to administer than other neuromodulation techniques, our findings might be relevant to the clinical practice.

**Title:** Characterization of spontaneous and evoked neural activity in the substantia nigra pars reticulata for the accurate placement of deep brain stimulation electrodes

**Authors: *H. LI**, G. C. MCCONNELL
Biomed. Engin., Stevens Inst. of Technol., Hoboken, NJ

**Abstract:** The Substantia Nigra pars reticulata (SNr) is a promising target for deep brain stimulation (DBS) to treat the gait and postural disturbances in Parkinson's Disease (PD). The effects of DBS in subregions of the SNr on the treatment of gait and postural disturbances in PD is not clear. We recorded spontaneous and evoked neural activity of subregions of the SNr and the ventral tegmental area (VTA) using single tungsten microwire electrodes in anesthetized rats (n=17) as an approach to predict the placement of the electrodes. The location of each recording site was confirmed by immunohistochemistry. Analysis of neural recordings included action potentials and local field potentials (LFPs) during spontaneous and evoked responses to 0.5 Hz stimulation at 25 μA and 50 μA. Action potentials were analyzed based on temporal features (firing rate, amplitude, interspike interval (ISI) correlation, ISI variance, firing regularity) and waveform shape (amplitude, signal-to-noise ratio, half width at peak, half width at valley, latency). Spectral analysis was performed on action potentials and LFPs in the delta, theta, beta and gamma bands. For spontaneous activity, ISIs were positively correlated in VTA and lateral SNr (lSNr) but negatively correlated in medial SNr (mSNr); amplitudes of spikes in VTA were significantly higher than mSNr, and amplitudes in mSNr were significantly higher than lSNr; signal-to-noise ratio of spikes in VTA were significantly higher than mSNr; power of spikes in VTA were significantly higher than lSNr in the high beta (20-30 Hz) and low gamma (30-40 Hz) bands, whereas it was higher than mSNr in the high beta (20-30 Hz) band; power of LFPs in VTA was significantly lower than lSNr in low gamma (30-50 Hz), whereas it was significantly lower than mSNr in theta (4-10 Hz), low beta (10-20 Hz), high beta (20-30 Hz), and low gamma (30-50 Hz); the power of LFPs in mSNr was significantly lower than lSNr in the high gamma (70-80 Hz) band. For evoked activity, during 25 μA stimulation the waveform of spikes changed to a thinner and less asymmetric shape in mSNr but not in lSNr, and the power of spikes in high beta (20-30 Hz) decreased in mSNr but not lSNr. During 50 μA stimulation, ISIs changed from negatively correlated to positively correlated in both mSNr and lSNr, but the power of spikes

under mid gamma (50-60 Hz) increased in lSNr but not mSNr. Our findings suggest that action potentials and LFPs provide complementary information that correlate with the location of microelectrodes within the SNr. The results shed light on a rich set of features to aid in the accurate placement of microelectrodes within the SNr for future studies of SNr DBS.

**Abstract:** Movement disorders (MD) represent a wide range of neurological syndromes with different origins. The best-known disorders, such as Parkinson’s and Huntington’s diseases, are neurodegenerative but MD can also be caused by infection, inflammation, trauma or even medication. Despite recent advances in the development of new drugs, MD symptoms are not entirely alleviated by pharmacological treatments. The development of more advanced analysis methods opened up new potential for both clinical and preclinical electroencephalography (EEG) applications. An EEG approach can provide reliable biomarkers and quantifiable measures to assess the efficacy of a compound. These new findings can help developing new compounds in the field of movement disorders treatment. In particular, Parkinson's disease (PD) is a target of choice for such an approach. In both, parkinsonian patients and animal models, an increased power of beta frequencies has been observed. This abnormal beta oscillation was suppressed by dopaminergic treatments, along with motor symptoms. In addition, chronic L-DOPA treatment induced prominent gamma resonant oscillations, associated with abnormal involuntary movements (AIMs), in the motor cortex of both hemiparkinsonian rats (Halje et al. 2012) and patients (Oswal et al. 2013). More recently, an exacerbated phase-amplitude coupling (PAC) between beta-phase (13-30 Hz) and gamma-amplitude (50-200 Hz) has been characterized in the motor cortex of PD patients (de Hemptinne et al., 2013). The aim of this project was to evaluate the PAC in an animal model of PD, the unilaterally 6-OHDA-lesioned rat. We identified a strong coupling between the phase of theta (4-6Hz) and the amplitude of high gamma (90-160Hz) in the ipsilateral motor cortex of lesioned rats. This EEG signature is correlated with the locomotor activity of the animal: a high theta-gamma PAC is associated to an elevated locomotor activity. In addition, anti-parkinsonian drugs like L-Dopa, apomorphine or SKF-38393-2, significantly

suppressed this theta-gamma PAC. This theta-gamma PAC signature in an animal model of PD can be used as a new preclinical biomarker, thus providing a stable, quantifiable, reliable and objective endpoint for the development of new therapies against PD.

**Title:** L-DOPA-induced striatal gamma oscillations split into low- and high-frequency components following ketamine exposure in an animal model of L-DOPA-induced dyskinesia

**Authors: *T. YE**[1], M. J. BARTLETT[2], T. FALK[2], S. L. COWEN[3]
[2]Neurology, Pharmacol., [3]Evelyn F. McKnight Brain Inst., [1]Univ. of Arizona, Tucson, AZ

**Abstract:** Preclinical evidence from our group indicates that a single extended 10 hour exposure to sub-anesthetic ketamine leads to a weeks-to-month long reduction in L-DOPA-induced dyskinesias (LID) associated with the treatment of Parkinson’s disease (PD) (Bartlett et al., 2016). Considerable evidence also indicates that ketamine exposure provides lasting relief of treatment-resistant depression and chronic pain. Despite advances in its therapeutic application, the systems-level mechanisms underlying ketamine’s effectiveness are not understood. A common component of disorders treated with ketamine is the presence of hypersynchronous oscillatory activity. Our general hypothesis is that ketamine disrupts oscillatory activity associated with these disorders. In the present study, we investigated whether ketamine reduces hypersynchrony associated with LID. To answer this question, local-field recordings were acquired from rodent models of PD and LID (unilateral 6-OHDA-lesioned male rats; for the LID model PD animals were primed for 21 days daily with L-DOPA; 7 mg/kg, *i.p.*). Dyskinetic rats with abnormal involuntary movements (AIMs) scores of 33.6 ± 6.6 (mean ± SD) were implanted with electrode arrays in motor cortex (M1), dorsolateral striatum (DLS), dorsomedial striatum (DMS), and the nucleus accumbens (NAc). Neural recordings were acquired over 11 hours during which LID ($n$=7) and PD rats ($n$=7) were administered five ketamine (20 mg/kg *i.p.*) or saline injections every 2 hrs. As previously reported, we determined that L-DOPA administration (7 mg/kg, *i.p.*) was associated with wideband gamma oscillations (40-90 Hz) in M1 and DLS,

and that, contrary to our hypothesis, the power of these oscillations was not affected by ketamine administration. In the present investigation, we performed a more detailed analysis of the effects of ketamine on frequencies within the wideband gamma range (40-90 Hz). Analysis of this signal during LID revealed that ketamine administration resulted in this wideband signal splitting into a clearly discernable low-gamma (30-50 Hz) and high-gamma (70-90 Hz) component ($p$=0.005). This effect was not observed when ketamine or L-DOPA were administered separately. These observations suggest that an influx of dopamine produced by L-DOPA paired with NMDA receptor blockade by ketamine engages distinct gamma-generating networks in the striatum. This also suggests ketamine's therapeutic could be due to ketamine engaging distinct striatal networks.

**Title:** The relationship between local field potential activity in the basal ganglia and sleep-wake behavior in parkinsonism

**Authors: *E. MARSHALL**, S. DEYO, D. ESCOBAR, A. AMUNDSON, J. ZHANG, M. D. JOHNSON, G. MOLNAR, L. JOHNSON, J. VITEK
Univ. of Minnesota, Minneapolis, MN

**Abstract:** More than 75% of people with Parkinson's disease (PD) have significant sleep disturbances. In some cases, sleep-wake disorders can be more disabling and resistant to treatment than the motor symptoms of PD and there is a critical need for therapies to improve sleep quality in these individuals. Basal ganglia dysfunction is a hallmark of PD and likely contributes to disordered sleep in PD patients, yet relatively little is known how basal ganglia activity changes during different stages of the sleep-wake cycle in the parkinsonian brain. In this study we examined neural activity from the basal ganglia during the sleep-wake cycle of a non-human primate (NHP) made parkinsonian using the neurotoxin MPTP. We acquired and

analyzed muscle (EMGs), eye (EOGs), and cortical (EEG) activity (polysomnographic signals typically used for evaluating sleep stages), along with local field potentials from deep brain stimulation (DBS) leads targeting the subthalamic nucleus (STN) and internal segment of the globus pallidus (GPi), basal ganglia nuclei typically used as targets for treating the motor symptoms of PD. To record activity during the animal's standard sleep-wake cycle (6pm-6am), the NHP was fitted with an Avatar EEG, a device mounted on the head of the animal that enabled free moving wireless data collection (1kHz sampling rate). Using the standards for scoring sleep adapted from the American Academy of Sleep Medicine, sleep was manually scored using the polysomnography signals in 30 second epochs to get an accurate representation of the sleep staging throughout the 12-hr sleep-wake cycle. Sleep architecture was highly fragmented with minimal REM sleep epochs, similar to that previously reported in MPTP-treated NHPs. Power spectral analysis of local field potentials from the STN and GPi revealed that each structure had unique identifiable features during each sleep stage. These findings increase our understanding of how basal ganglia activity changes during different stages of the sleep-wake cycle and also suggest that a sleep classification scheme based on DBS field potentials is feasible. The ability to identify sleep stages based on neural recordings from DBS leads could contribute to the development of next generation of neurostimulation devices that monitor sleep architecture and tailor DBS parameters to improve disordered sleep in PD patients.

**Abstract:** Huntington’s disease (HD) is a hereditary neurodegenerative disorder caused by an expansion of a CAG repeat in the huntingtin (htt) gene, resulting in an aberrant form of the protein. HD patients and mouse models present hippocampal and corticostriatal alterations, but the molecular mechanisms causing selective neuronal dysfunction are not clear yet. Our group has previously showed increased lamin B1 levels in several brain regions of the R6/1 mouse model and HD patients. Lamin B1 is part of lamins family, the major structural proteins inside the nuclear lamina. Lamins functions are crucial for the structure and functionality of cellular nucleus; indeed, alterations in their genes are linked to some diseases, called laminopathies. Through imaging flow cytometry (FACS), we aimed to identify the specific neuronal populations affected by alterations in lamin B1 in each brain region. We found that lamin B1 protein is specifically increased in striatal medium-sized spiny neurons (MSN) and neurons from the CA1 hippocampal region, together with an alteration in nuclear morphology. These data suggest that altered lamin B1 levels may lead to alterations in nuclear structure that could play a role in HD symptoms. Moreover, we show that chronic treatment with betulinic acid improved cognitive function in R6/1 mice, in good correlation with a normalization of lamin B1 protein levels in the hippocampus. Altogether, our results show that alterations in lamin B1 may participate in the pathophysiology of HD, and the modulation of its levels may have a therapeutic benefit in this neurodegenerative disease.

**Abstract:** Huntington Disease (HD) is an inherited neurodegenerative disorder characterized by motor, cognitive, and psychiatric symptoms. Subtle cognitive deficits can be detected in HD mutation carriers upwards of 15 years prior to diagnosis, and many HD patients report cognitive

symptoms to be the most debilitating aspect of the disease. Very little is known regarding the cellular mechanisms underlying HD-associated cognitive symptoms. Rapid clearance of synaptically-released glutamate by membrane-bound transporters, particularly glutamate transporter-1 (GLT-1), is necessary to promote robust synaptic plasticity and healthy cognitive function. GLT-1 impairments have been observed in various HD mouse models, leading us to hypothesize that poor glutamate clearance may contribute to weak synaptic plasticity and the cognitive symptoms associated with HD. Ceftriaxone, a FDA-approved beta-lactam antibiotic that increases GLT-1 expression, improves motor symptoms in the R6/2 HD mouse model; whether increasing glutamate clearance can improve HD-associated cognitive symptoms remains to be seen. Here, we used a combination of electrophysiology and high-speed imaging of iGluSnFR, a fluorescent sensor of extracellular glutamate, to assess the effect of Ceftriaxone on long-term potentiation (LTP) and glutamate dynamics in the hippocampus of 6-month Q175FDN HD mice and age-matched wild-type (WT) littermates. To our surprise, we found that at this age, Ceftriaxone significantly decreased GLT-1 expression in the hippocampus and had no effect on glutamate clearance rates at CA3-CA1 synapses, regardless of genotype. While the magnitude of CA3-CA1 LTP was reduced in Q175FDN mice compared to WT, Ceftriaxone was unable to restore Q175FDN LTP to WT levels. In fact, Ceftriaxone significantly reduced LTP magnitude in WT mice. Overall our results demonstrate clear detrimental effects of a FDA-approved drug on synaptic plasticity in the healthy brain, and suggest that Ceftriaxone is unlikely to be a suitable agent for the effective management of HD symptoms.

**Abstract:** Huntington's disease (HD) is caused by an expansion mutation of the CAG trinucleotide repeat encoding polyglutamine (polyQ) near the N-terminus of Huntingtin (HTT). Identification of the pathogenic mutant HTT (mHTT) species and their correlation to disease progression remains to be the central question to study HD pathogenesis. However, the present methods are restricted to detecting soluble and likely monomeric or at most oligomeric HTT species. And it is unclear if there are certain mHTT species that could seed mHTT aggregation and be detected by a sensitive and automated assay. In the current report, we developed a stable cell line expressing a modified form of HTT N-terminal fragment tagged with GFP (HTT-GFP), which does not form aggregates by itself at the baseline. In contrast, HTT-GFP was induced to aggregate extensively by extracellular application of preformed mHTT aggregates, brain tissues from old but not young Q175 mice, or postmortem brain tissues and CSF from HD patients but not healthy controls. Importantly, the induced aggregation is specific with mHTT species, since it could not be elicited with fibrillar Aβ, phosphorylated tau, or CSF and brain lysates from control AD and PD patients. We further studied the correlation of the seedability of CSF with the disease progression using the CSF samples from the PREDICT-HD collection. The results demonstrated that the seedability of CSF significantly increases as the individuals are near the onset or diagnosed for HD. Importantly, the seedability of CSF increases as the disease progress, which is measured by various clinical assessments. In conclusion, we demonstrated that modified mutant HTT N-terminal fragments can sensitively detect HTT species in the HD patient biosamples. Importantly, our new assay is optimized for high-throughput automation. Our results suggest that the ability of CSF to induce mHTT aggregation could be a potential biomarker for measuring disease progression, and support future studies of their potential roles in the dsiease.

**Abstract:** Integrative systems biology has been a powerful approach to elucidate novel molecular networks in Huntington's disease (HD). We previously reported a large-scale RNA-seq and proteomics study to examine an allelic series of murine Huntingtin (Htt) knock-in mice, and defined Htt CAG-length dependent co-expression gene modules that involve multiple pathways in HD pathogenesis (Langfelder et al., 2016, PMID: 26900923). In this study, we applied systems biology to examine a possible interaction between mutant Htt (mHtt) CAG repeat expansion and aging in HD neuropathogenesis. From a clinical perspective, the products of mutant Huntingtin CAG repeat length and age (i.e. CAP score) is one of the best predictors of HD progression (Ross et al., 2014, PMID: 24614516). Moreover, our previous study using a DNA methylation biomarker of age (called epigenetic clock) showed that postmortem HD patient brains exhibit evidence for accelerated aging (Horvath et al., 2016, PMID: 27479945). Here we analyzed transcriptomes of wildtype mice across multiple adult ages from 2 to 10m and build age-dependent co-expression networks for multiple brain regions (striatum, cortex, hippocampus and cerebellum) and one peripheral tissue (liver). These age-dependent gene modules are enriched with known biological changes associated with aging (e.g. inflammation). Interestingly, when we compared the aging network and Htt-CAG-repeat dependent network in multiple brain regions, there is only a strong positive correlation found in the striatum, consistent with the concept of mHtt possibly accelerating aspects of striatal molecular aging. Importantly, we now begin to utilize both environmental and genetic perturbations that are known to affect the aging process in the HD mouse models to test the idea that targeting the aging process could modify HD pathogenesis in vivo.

**Abstract:** Huntington’s disease (HD) is caused by expansion of the Poly Q domain in Exon 1 of the gene for Huntingtin, leading to production of the mutant Huntingtin protein (mHTT). We demonstrated previously that TRiC, a molecular chaperonin, afforded neuroprotection against mHTT in neurons of the BACHD model of HD. Significantly, using microfluidic cultures in which we recreated the cortico-striatal circuit, we showed that overexpressing individual subunit(s) of TRiC acted to induce neuroprotective effects through increased delivery of BDNF from cortical neurons to striatal neurons. To further define the pattern of degeneration and cellular mechanism(s) responsible for defects in BACHD circuits, and the times at which TRiC reagents would act to protect these circuits, we established long-term microfluidic cortical-striatal cultures. We found that such cultures could be studied for up to 21 days in vitro (DIV). BACHD neurons in microfluidic cultures demonstrated significant, persistent deficits in synapse formation between cortical and striatal neurons; remarkably, while BACHD cortical neurons were deficient in supporting the trophic status of striatal neurons, there was little impact of mHTT on cortical neuron size or cortical axon growth. As in earlier studies, we examined the impact of adding the apical domain of TRIC 1 subunit, ApiCCT1, to cortical neurons in BACHD cultures. When added at DIV1, ApiCCT1 prevented both striatal atrophy and defects in retrograde axonal transport of BDNF. Our study further supports the utility of cortico-striatal cultures for exploring the biology of HD and a potentially important role for using TRiC derived reagents to intercept HD pathogenesis. Our current studies are focused on expanding our findings to other TRiC-based reagents and in the newly generated deltaN17BACHD mouse model.

**Abstract:** Huntington's disease (HD) is a neurodegenerative disease characterized by severe motor alterations. The neuropathological occurrences underlying behavioral changes are extensive and include significant loss of striatal and cortical parenchyma. Direct communication between cortex and striatum is ensured by glutamatergic corticostriatal (CTX-STR) fibers which play a pivotal role in shaping motor behavior. Not surprisingly, a growing body of evidence is revealing significant alterations of these fibers in several mouse models of HD. CTX-STR axons are mainly originating from two distinct classes of cortical neurons: intratelencephalic (IT) and pyramidal tract (PT) neurons. IT neurons project within the telencephalon ipsi- and contralaterally to cortex and striatum forming the main component of the callosal commissure. Conversely, PTs project only ipsilaterally to extratelencephalic regions such as thalamus or brainstem forming also *en passant*synapses in striatum. The severe and progressive reduction of corpus callosum fibers seen in HD clearly suggest that CTX-STR IT and PT projections are altered in HD. However, alterations of corticostriatal fibers originating from specific cortical neuronal subpopulations and specific cortical regions has not been studied in the context of HD. Using the Q175 mice and IT and PT - Cre expressing mouse lines, together with optogenetics and electrophysiology techniques, we found that *M1-originating* IT CTX-STR glutamatergic transmission onto both direct and indirect pathway SPNs is surprisingly increased in 8 - month-old Q175 symptomatic mice. Studies performed using a CRACM approach and confirmed by mGRASP reveal an increase in IT-SPNs synapses specifically in the dorsolateral quadrant of striatum. Conversely, in Q175 PT axons originating from M1 are not altered at this age.

**Title:** Cell type-specific transcriptome profiling of Huntington's disease mouse models

**Authors: *M. THERRIEN**[1], M. HEIMAN[2]
[1]Broad Inst., Cambridge, MA; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

**Abstract:** Huntington's disease (HD) is a fatal neurodegenerative disorder caused by CAG repeat expansions in the first exon of the *Huntingtin* gene (*HTT*). Disease severity is highly correlated with the size of the repeat expansion, wherein higher CAG repeat numbers correspond to an earlier age of disease onset. Changes to gene expression are a major hallmark of HD pathogenesis, and one of the earliest phenotypes observed in patients and in disease models. However, the causes and consequences of these changes are poorly understood with regard to disease progression and severity. In this project, we hypothesized that the identification of early changes in transcription in a cell type-specific manner could highlight important pathways of disease pathogenesis. We therefore characterized the transcriptome of different striatal cells and of corticostriatal neurons, the most affected cells in the HD brain. To do so, we have used the cell type-specific translating ribosome affinity purification (TRAP) methodology to carry out TRAP-Seq in *Drd1*- and *Drd2*- expressing striatal medium spiny neurons, striatal astrocytes, striatal interneurons, and corticostriatal projection neurons. Also, we have used five different allelic HD model knock-in mice (Q20, Q50, Q111, Q170 and zQ175) at 6 months of age, to capture early or pre- symptomatic stages of disease progression. Our study will identify early, cell type-specific changes in gene expression that are dependent on the *HTT* CAG expansion length in a cell type-specific manner. This project will lead to the identification of the cell types and pathways that are the most and earliest affected in HD and open new therapeutic avenues

**Abstract:** We have developed a phenotypic screen in HD-patient derived, polyQ48 embryonic stem cells (ESC) to identify compounds that reduce mHTT levels. This homogeneous time resolved fluorescence (HTRF) multiplex 384-well high throughput screen (HTS) was developed and optimized to measure both mutant HTT (mHTT) and total HTT (tHTT) protein levels. In order to efficiently process the output from a 150,000 compound screen, performed to identify novel modulators of mHTT, we have developed a series of hit deconvolution assays designed to characterize hits in relation to their on and off-target activities.Using an In Cell Western assay, we have developed assays enabling orthogonal detection of HTT, as well as measures of protein selectivity, by determination of TBP and actin levels after compound treatment. As additional measures of protein selectivity, we have also used the HTRF platform to determine changes in the key cellular proteins, AKT and CREB after compound treatment. Compounds which show the required levels of selectivity are then progressed into a branched DNA assay which determines whether the compounds act through repression of translation, either at a general level or more specifically to Htt. Assays are under development to determine compounds which block HTT translation or enhance its clearance. We aim to use these assays in profiling hits from the CHDI collection whilst expanding our search for novel molecules which lower HTT by additional screening of diverse chemical matter.

**Abstract:** Enhanced expression of ROCK, as well as dysregulation of its downstream elements, has been reported in Huntington's disease (HD) and other neurodegenerative disorders. More importantly, ROCK inhibition is reported to promote neuronal survival, decrease mHtt aggregation and improve synaptic function in HD cell and animal models, suggesting that ROCK inhibitors may have therapeutic potential in HD. A number of ROCK inhibitors exist, including marketed drugs such as fasudil and ripasudil (for glaucoma and ocular hypertension), although no known ROCK inhibitor combines a suitable kinase selectivity profile with good oral bioavailability and CNS exposure properties necessary for chronic efficacy studies in HD mouse models. Using literature-based information on known ROCK inhibitors and structure-based drug discovery methods we have conducted lead optimization activities to identify potential PoC tool compounds from two distinct chemical series with different selectivity profiles. Through implementation of a screening cascade, we have optimized compounds for ROCK biochemical and cellular potency, to achieve a CNS applicable pharmacokinetic profile and to maximize selectivity over key related kinases. We have applied an *ex vivo* target engagement approach (KiNativ™) and biomarker readouts to help guide dose selection for planned chronic efficacy studies in HD mice. Resulting lead compounds demonstrate good *in vivo* potency and selectivity and sustained brain exposure above levels predicted to result in inhibition of the target. We have utilized KiNativ™ technology to confirm dose-dependent target engagement and kinase selectivity *in vivo*. Lead molecules from both series offer promising potential to assess the therapeutic benefit of inhibiting ROCK in HD mouse models as orally bioavailable, brain penetrant and selective tool compounds.

**Abstract:** Mutation of huntingtin (HTT) leads to Huntington disease (HD), a neurodegenerative disorder characterized by the preferential dysfunction of cortical and striatal neurons. Whereas death of striatal neurons starts to be elucidated, the mechanism leading to the degeneration of cortical neurons remain unclear. One potential mechanism could involve the retrograde axonal transport of endosomes in cortical neurons that is known to induce survival of projecting neurons in various paradigms. We used state-of-the-art microfluidics to analyze distal-axonal TrkB trafficking in response to synaptic BDNF infusion. We observed that BDNF leads to a massive but transient retrograde flow of TrkB vesicles in cortical neurons, which requires receptor activation, the subsequent induction of the PLCγ pathway and Calcineurin (CaN) activation. Interestingly, we previously reported that vesicular HTT regulates transport directionality via its dephosphorylation of S421 by CaN promoting retrograde transport. Moreover, we found by mass spectrometry that CaN is present on vesicles. We observed via high-resolution microscopy that CaN localize on TrkB vesicles, suggesting that calcium released upon TrkB activation would be sufficient to drive the endosomal retrograde flow. Finally, we showed that TrkB re-routing requires HTT dephosphorylation using neurons derived from mice carrying point mutations on HTT at the S421 (S421D). Together these findings suggest that vesicles are able to sense calcium rich environments and modify the activity of their molecular motors via a CaN-HTT dependent mechanism on-board of vesicles. Furthermore, vesicles purified from mouse brains were perfused on *in vitro* polymerized microtubules and their movement was recorded by TIRF

microscopy after calcium uncaging. Preliminary data show that vesicles are able to sense the increase of calcium, which in turns would activate CaN leading to HTT dephosphorylation and to the reversion of trafficking directionality.In conclusion, we used microfluidic devices reproducing the corticostriatal connection in order to identify the BDNF-TrkB-PLCγ-CaN-HTT as a major pathway involved in the retrograde routing of TrkB signaling endosomes in cortical axons. Strikingly, we found that CaN localizes with HTT on board of TrkB vesicles and is able to direct the retrograde transport of vesicles. Together this study reveals HTT dephosphorylation as a crucial molecular event to induce axonal retrograde transport of neurotrophin signalling in neurons.

**Title:** Mutant Huntingtin proteotoxicty suppression by NAD salvage pathway proteins

**Authors: *A. RUETENIK**[1], A. BARRIENTOS[2]
[1]Neurosci. Program, Univ. of Miami Sch. of Med., Miami, FL; [2]Univ. of Miami, Miami, FL

**Abstract:** Huntington’s disease is caused by a single genetic abnormality in which the number of trinucleotide repeats encoding polyglutamine in exon 1 of the huntingtin gene expands past a threshold number of repeats to cause disease. This abnormally high number of glutamine repeats causes dysfunction and misfolding of the resulting huntingtin protein, neurodegeneration, and early death of patients with the disease. As no current treatments exist to prolong lifespan, we are interested in better understanding pathways and proteins that can protect against the toxic effects of mutant huntingtin. Previously, our laboratory discovered that several proteins that form a crucial salvage pathway in yeast protected against the toxic effects of a mutant huntingtin fragment in a yeast model of Huntington’s disease and degraded mutant huntingtin aggregates in the cell. Our continuing studies into these proteins demonstrate that their ability to protect against mutant huntingtin is independent of their catalytic function, and that they confer protection both during exponential growth and during experiments that parallel neuronal aging. Our data supports our hypothesis that these NAD salvage pathway proteins may confer protection through a previously undiscovered secondary role in the cell as molecular chaperones.

**Abstract:** Huntington disease (HD) is a neurodegenerative disorder characterized by motor, cognitive and psychiatric disturbances. HD is caused by a CAG trinucleotide expansion in the *HTT* gene coding the huntingtin (HTT) protein. HTT is a scaffold protein subjected to multiple posttranslational modifications (PTMs) such as phosphorylation, proteolytic cleavage and fatty acylation (palmitoylation) that regulate its function. In the presence of the HD mutation, some PTMs of HTT are significantly altered. Several PTMs have therapeutic relevance, as they modulate the toxicity of mutant HTT (muHTT). Mouse models expressing muHTT harbouring mutations that block or mimic specific PTMs exhibit drastic changes in the disease phenotype: blocking caspase cleavage at Asp586 (Asp to Glu mutation) suppresses muHTT toxicity; blocking phosphorylation at Ser421 (Ser to Ala) exacerbates HD phenotypes while mimicking phosphorylation (Ser to Asp) ameliorates muHTT-induced neurodegeneration. Palmitoylation involves the formation of a labile thioester bond between a cysteine thiol side chain and a saturated palmitic acid. This type of lipidation promotes protein-membrane association as well as protein-protein interaction, and therefore plays a vital role for many neuronal and scaffold proteins. We previously demonstrated HTT palmitoylation at Cys214 catalyzed by the acyltransferase huntingtin interacting protein 14 (HIP14). We showed that muHTT is less palmitoylated in vitro and in YAC128 HD mouse model leading to increased formation of inclusions and neuronal toxicity. The objective of this study is to characterize the interactions between HTT palmitoylation and specific HTT PTMs that are protective against muHTT toxicity, and therefore evaluate the therapeutic interest of normalizing palmitoylation of muHTT.
**Results - Methods** We show that palmitoylation level is dysregulated in various HD mouse models (6-month BACHD and humanized HD mice). We investigate the interactions between palmitoylation and key PTMs of HTT (phosphorylation at Ser421, caspase cleavage) using cell

lines and HD mouse models expressing the muHTT protein carrying various mutations blocking/mimicking PTMs. We demonstrate that protective phosphorylation of HTT at Ser421 and palmitoylation regulate each other. Additionally, we show that HTT palmitoylation promotes HTT clearance. **Conclusion** This work demonstrates that HTT palmitoylation regulates neuroprotective PTMs of HTT and promotes muHTT degradation. These results support the hypothesis that normalizing muHTT palmitoylation level would constitute a therapeutic strategy to reduce muHTT toxicity.

**Abstract:** Huntington's Disease (HD) is an autosomal dominant neurodegenerative disorder characterized by progressive impairment of motor function and cognition, and an invariably fatal outcome. HD is caused by a polyglutamine expansion at the N' terminal of huntingtin (HTT) protein, the accumulation of which causes striatal neuronal degeneration; but it is also associated with myelin loss, suggesting a mutant-HTT-dependent dysfunction of myelin-producing oligodendrocytes. In order to test this hypothesis, we have generated glial progenitor cells (GPCs) from human embryonic stem cells, derived from either mutant huntingtin (mHTT) embryos or controls, to assess the mHTT-dependent changes in gene expression by RNA sequence analysis (RNAseq). We found consistent downregulation of genes associated with astroglial and oligodendroglial differentiation in mHTT-expressing GPCs. Specifically, the expression of several myelin biosynthesis genes was significantly down-regulated, most notably,

MYRF and SOX10, transcription factors that tightly control the expression of a number of genes necessary for myelin formation, including MBP, MAG, OMG, PLP1 and MOG. All of these genes were significantly down-regulated in HD-derived GPCs but were restored upon over-expression of MYRF/SOX10. As predicted by the RNAseq data, when engrafted into neonatal myelin-deficient mice (Shiverer mice), mHTT-GPCs displayed a significant delay in myelination, resulting in hypomyelinated white matter and poor axonal ensheathment compared to control mice which had been engrafted with healthy GPCs. In addition, the incidence and density of HD-derived human astrocytes was lower in engrafted shiverer mouse brain than in age-matched controls. Furthermore, the HD-derived astrocytes had fewer, longer and less regularly distributed processes with gaps in radial coverage. These data suggest that glial differentiation in human HD exhibits a cell-autonomous defect in the terminal glial differentiation of mHTT-expressing GPCs, the pathology of which, rather than being secondary to neuronal loss, may be a major contributor to the etiology of HD.

**Title:** Intranasal delivery of mutant huntingtin-silencing antisense oligonucleotide nanoparticles for Huntington's disease therapy

**Authors: *A. E.-E. ALY**, N. S. CARON, H. FINDLAY-BLACK, M. R. HAYDEN
Ctr. for Mol. Med. and Therapeut., Univ. of British Columbia, Vancouver, BC, Canada

**Abstract:** Huntington disease (HD) is an autosomal dominant, progressive neurodegenerative disorder caused by a CAG trinucleotide repeat expansion in the huntingtin gene (HTT). Silencing mutant HTT using antisense oligonucleotides (ASOs) is a promising approach that has shown great therapeutic potential in pre-clinical studies and is currently being evaluated in clinical trials for HD. However, the therapeutic potential of ASOs in HD patients is limited by their inability to cross the blood-brain barrier (BBB) after systemic administration. In non-human primates, intrathecal infusion of ASOs results in limited brain distribution, with higher ASO

concentrations in superficial regions and lower concentrations in deeper regions. Thus, there is a strong need for a non-invasive means of administrating ASOs to the brain that results in a more widespread distribution and greater target engagement in the brain regions most affected in HD, the deeper layers of the cortex and striatum.
Here, we are evaluating the therapeutic potential of in-house nanoparticle (NP) formulations as novel delivery vehicles for mutant huntingtin-lowering ASOs to the CNS after intranasal administration. The intranasal route of administration offers a non-invasive approach for direct delivery to the brain of therapeutic macromolecules and results in widespread brain distribution. We have optimized NP formulations composed of a scaffolding (or reporter) protein and phospholipids that achieve ASO loading efficiencies between 60-70% while maintaining low polydispersity and particle sizes ranging from 15-20 nm. The first goal of this study was to demonstrate the ability of these NPs to bypass the BBB after intranasal delivery in an HD mouse model. Following intranasal administration of NPs, reporter protein levels were elevated along the rostral-caudal brain axis, with highest levels in the most rostral brain regions including the olfactory bulb and frontal cortex. Our second goal was to determine the cellular pattern of distribution of the reporter protein in brain after intranasal delivery of these NPs. Double-label IHC indicates that the reporter protein primarily colocalizes with CD31+ capillary endothelial cells throughout the brain, but was also found in neuronal, astrocytic, and microglial cells. Ongoing studies will examine mHTT-lowering efficacy of ASOs delivered to the brain using NPs in HD mice.
This approach could represent a novel non-invasive means for improving delivery and brain distribution of oligonucleotide therapies and enhance likelihood of efficacy. Improved oligonucleotide delivery to the brain has widespread application for treatment of many other CNS disorders.

**Title:** Elucidating the role of DNA repair dynamics in a human neuron model of Huntington's disease

**Authors: *L. BARBÉ**, S. FINKBEINER, J. KAYE
Gladstone Inst., San Francisco, CA

**Abstract:** Huntington's disease is a neurodegenerative disorder caused by the expansion of a 'CAG' repeat in the Huntingtin gene. This repeat is shown to be larger in more severe cases of the disease and DNA repair proteins were identified as the mainmolecules to create repeat enlargements. Patients with genetic variants in DNA repair genes have a later age of disease onset. However, the mechanism behind this protective effect of these genetic modifiers is unknown. Therefore, we wish to understand the contribution of DNA damage repair in Huntington's disease. We use live cell robotic microscopy to image reporters for the DNA repair proteins MSH3, MSH6, PCNA, MLH1 and FAN1 in medium spiny neuron-like cells differentiated from human pluripotent stem cells with or without a CAG expansion. We image these tagged DNA repair proteins after and before DNA damage at multiple time points on our robotic microscopy platform, which is an innovative and exquisitely sensitive method for quantifying neurological disease patterns in single cells over time in a high-throughput manner. We analyze the distribution of the DNA repair proteins using an in-house bioinformatics pipeline for segmentation, reference encoding and calculation of the number of puncta of DNA repair proteins per cell. We compare the distribution of DNA repair proteins and the response to DNA damage in CAG-expanded and control cell lines to determine the role of DNA repair in Huntington's disease.We hypothesize that the dynamics of DNA repair are altered in Huntington's disease and uncovering the activity of the DNA repair proteins may elucidate novel disease mechanism. We will report the results of our findings during this meeting.

**Abstract:** Huntington's disease (HD) is a progressive, neurodegenerative disorder caused by a genetic expansion of a CAG repeat encoding glutamine within the Huntingtin protein. Individuals with 40 or more glutamines will eventually develop HD. HD is devastating, causing atrophy of the brain, uncontrollable movements, psychiatric disturbances, and behavioral changes. The extracellular matrix (ECM) is a highly plastic component of the cellular environment, continuously being remodeled by architectural modifications that guide cell attachment, cell motility, and cell survival. In the brain, the ECM can provide neuroprotection and loss of certain ECM components leads to phenotypes commonly observed in neurodegenerative diseases. Additionally, perturbations of the ECM can alter synaptic plasticity in the adult brain. And while there is clear evidence regarding the importance of ECM participation in critical CNS functions and neuronal dynamics, little is known about the role of the ECM in neurodegenerative diseases, including HD. Additionally, ECM molecules have shown great promise as highly druggable targets for diseases associated with traumatic neuronal loss. Therefore, taking advantage of the malleability of the ECM and the influence it has on neural plasticity through exogenous introduction of ECM molecules or agonists may allow for the prevention or reversal of disease-associated changes in the HD brain. Identification of ECM disease regulators provides molecular targets that can then be perturbed within cellular systems to elicit disease-modifying effects. To understand these processes in human cells across a range of human subjects, we are using induced pluripotent stem cells (iPSCs) to study HD by providing a source of patient-derived cells of varying polyglutamine lengths. Here, we explore HD-related ECM dysregulation in two iPSC-derived cell types: 1) medium spiny neurons (MSNs) and 2) brain microvascular endothelial cells (BMECs). In MSNs, RNAseq data implicates a dysregulation of ECM-related genes and current work is focused on defining an MSN-specific cell adhesion phenotype and optimizing mass spectrometry analysis of the MSN secretome and proteome. We recently published data indicating that iPSC-derived BMECs demonstrate an HD-related increased in angiogenesis and reduced barrier properties, implicating blood-brain barrier (BBB) deficits in HD. In BMECs, RNAseq data also demonstrates ECM dysregulation. Current data explores the relationship between the ECM, the cytoskeleton, and angiogenesis for identification of specific ECM-related molecules that can be modulated to ameliorate HD phenotypes and restore BBB dysfunction.

**Abstract:** Huntington's disease (HD) is a dominantly inherited neurodegenerative disorder caused by a CAG repeat expansion mutation in the *HTT* gene, and characterized by loss of neurons in the caudate and putamen at earlier ages of onset with increasing number of CAG repeats. Altered cellular metabolism is believed to be an important contributor to pathogenesis of HD, demonstrated even before the discovery of the HD CAG repeat expansion mutation. Most research has focused on mitochondrial toxicity, which can cause death of the vulnerable striatal neurons, but other aspects of metabolism may also contribute. Most previous studies have used post-mortem human brain or non-human cells. Here we studied bioenergetics in an induced pluripotent stem cell (iPSC) based model of the disease. We found decreased ATP levels in HD cells compared to controls, across differentiation stages and protocols. Proteomics data and multi-omics network analysis revealed normal or increased levels of mitochondrial messages and proteins, but lowered expression of glycolytic enzymes. Metabolic experiments showed decreased spare glycolytic capacity in HD neurons, while maximal and spare respiratory capacities driven by oxidative phosphorylation were largely unchanged. ATP levels in HD neurons could be rescued with addition of pyruvate or late glycolytic metabolites, suggesting a role for glycolytic deficits as part of the metabolic disturbance in HD neurons. Pyruvate or other related metabolic supplements could have therapeutic benefit in HD.

**Abstract:** Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder that affects motor coordination and leads to cognitive decline. HD is caused by a trinucleotide repeat mutation in the *Huntingtin* gene (*HTT*) leading to a polyglutamine expansion in the huntingtin (htt) protein, which results in toxic aggregation that disrupts several neuronal pathways. HD neuropathology is characterized by substantial loss of medium spiny neurons in the striatum. Brain derived neurotrophic factor (BDNF) plays fundamental roles in the survival and activity of neurons, including striatal cells that die in HD. Previous reports shown substantial alterations in BDNF levels in the brains of HD cases; however, limited studies have explored the changes in BDNF across clinical stages of HD and levels present in peripheral fluids. We hypothesized that BDNF is increasingly deregulated during HD progression, and could be detected in plasma and saliva. Moreover, we propose that changes in BDNF expression may result from altered methylation on the BDNF promoter, as previously reported for other neurodegenerative disorders. Here, we examined the potential use of BDNF as a peripheral biomarker. We optimized an enzyme-linked immunosorbent assay to measure BDNF levels in plasma and saliva of patients in different HD clinical stages and control patients. We tested samples from n=14 pre-manifest patients, n=12 patients with full onset HD, and n=15 normal controls. We found significantly lower levels of BDNF in saliva samples from subjects that tested positive for the *HTT* gene mutation, regardless of HD clinical disease status in comparison to non-carriers. No significant changes in BDNF were found in plasma, although there was a trend towards lower levels in male patients. In addition, our results corroborate previous findings suggesting gender-

and age-based differences in BDNF. Further analysis of BDNF levels with clinical data showed no correlations of protein abundance with mental and physical states of subjects. Altogether, our findings suggest that the *HTT* gene mutation, gender, and age may give rise to fluctuations in BDNF, which may be detected in saliva. A larger sample and further studies will be needed to determine whether changes in BDNF levels may predict the onset of clinical symptoms in mutation carriers.

**Authors: K. HECKLAU**, *F. YILDIRIM
Dept. of Neuropsychiatry, Dept. of Psychiatry and Psychotherapy & Neur, Charite Med. Sch., Berlin, Germany

**Abstract:** Progressive transcriptional dysregulation in brain is an early and central feature of Huntington's disease (HD) pathogenesis. Using cell and mouse models, we and others have previously demonstrated genome-wide changes in transcription, DNA methylation and histone modification patterns that may underlie transcriptional dysregulation in HD. Thus, targeting epigenetic mechanisms for rescue of aberrant gene expression is a promising therapeutic strategy for HD. Here, we investigate potential therapeutic effects of a histone deacetylase inhibitor (HDACi) targeting selectively HDAC1 and HDAC3 in cell and mouse models. In primary striatal neurons transduced with lentiviruses carrying a mutant *HTT* fragment, HDAC1/3 inhibition resulted in beneficial effects against mutant *HTT*-induced toxicity and significantly restored mRNA levels of key genes commonly dysregulated in HD (e.g. *Drd2, Egr1, Darpp32, Arc*). In vivo, HDACi treatment of R6/1 transgenic mice improved motor learning skills in the accelerated Rotarod test. By volumetric MRI measurements, we detected that HDACi-treated R6/1 mice show reduced atrophy in various brain regions (e.g. Pallidum and Hypothalamus)

compared to vehicle-treated R6/1s. Analyses of several key HD-associated genes indicate improvement of their expression in R6/1 brain by HDAC1/3 inhibition. Overall, our findings suggest a beneficial effect of HDAC1/3 inhibition in HD. Further assays, including immunohistochemistry and RNA sequencing, to fully assess the therapeutic potentials of this specific HDACi in HD are currently ongoing.

**Abstract:** Huntington’s disease (HD) is an inherited neurodegenerative disorder caused by a polyglutamine (CAG) expansion in the huntingtin gene. Resultant striatal and cortical dysfunction are the hallmark neuropathological features underlying dyskinesia (e.g., chorea) and akinesia at later stages. However, motivational and cognitive deficits commonly manifest during a prodromal stage that precedes motor dysfunction. Recent studies report an early loss of striatal cannabinoid receptors (CB1) as well as endocannabinoid (eCB) degradation enzymes in HD patients and rodent models. Here, we show in the Q175 mouse model of HD that impaired motivation for reward was associated with maladaptive gamma oscillations and patterned spiking activity at the NAc. Yet, precise temporal, spatial, and cell type-specific measures of neuronal network dynamics at localized brain regions affected by HD onset in a longitudinal fashion, such as the pre-frontal cortex (PFC), remain elusive. By implementing miniature, fluorescence microscopes with an implantable endoscopic gradient-refractive-index (GRIN) lens, we recorded spatial and temporal neuronal activity at the PFC in wild-type (WT) and Q175 knock-in mice performing a task for motivation (progressive-ratio schedule). Following treatment with MAGL inhibitor JZL-184, which raises tissue levels of the eCB 2-arachidonoylglycerol in HD mice, rescued motivation and attenuated maladaptive accumbal gamma oscillations along with neural ensemble activity at the PFC. Our multi-modal analyses of cortical and striatal networks in HD

progression suggest that eCB-based pharmacological interventions are promising pharmacological tools to attenuate biomarkers associated with prodromal psychiatric deficits in HD.

**Abstract:** Huntington's disease (HD) is a neurodegenerative disorder characterized by the loss of the medium spiny neurons in the striatum and extends to other brain regions as the disease progresses. HD is caused by a CAG expansion in the gene encoding for the protein huntingtin. Huntingtin is widely expressed in neuronal and non-neuronal cell types. Understanding the toxic effects of mutant huntingtin (mHTT) in the various cell types in the brain is critical for identifying disease modifying therapies which target those cells specifically. Astrocytes are the most numerous and diverse set of neuroglial cells in the central nervous system (CNS). They perform a variety of tasks including synaptic support, axon guidance, ion homeostasis, transmitter synthesis, transmitter release, and transmitter removal. Previous studies showed that expression of the glutamate transporter (EAAT-2), is reduced in HD patient striatum. Impaired glutamate uptake could lead to excessive activation of glutamate receptors causing excitotoxicity. Although astrocyte involvement in HD has been suggested by recent studies, the pathogenic mechanisms have not been fully elucidated.
Preliminary data from our group showed that cortical astrocytes cultured from BACHD mice had increased SNARE-dependent vesicular glutamate release. We observed an amelioration of behavioral and neuropathological phenotypes in BACHD mice when full-length mHTT (fl-mHTT) expression was decreased only in astrocytes. Based on these findings, we **hypothesize that fl-mHTT expressing astrocytes play an important role in the progression of HD and may affect HD pathogenesis through increased gliotransmitter release.** To test our

hypothesis, we have used dominant negative (dn)SNARE mice to investigate decreased gliotransmitter release from astrocytes. The dnSNARE mice were bred to BACHD mice that contain a conditional human full length mutant huntingtin gene and display behavioral and neuropathological phenotypes reminiscent of HD patient disease. We report behavioral and neuropathological analyses of the BACHD/dnSNARE mice.

**Abstract:** Huntington’s disease (HD) is a severe neurodegenerative disorder characterized by motor, cognitive and psychiatric effects. HD is an autosomal dominant, inherited disease that is caused by an unstable trinucleotide repeat expansion (CAG repeats) in the *huntingtin (HTT)* gene. To better understand HD pathogenesis in a relevant cellular context, we developed a primary neuronal culture of cortical neurons on an astrocyte feeder layer (co-culture) derived from one of the well-characterized knock-in models, zQ175, further engineered to remove a neomycin cassette for genomic integrity. In particular, a robust HTT quantification assay was established in the co-cultures to study the effect of candidate therapeutics on endogenous soluble mutant HTT levels. First, Homogeneous Time Resolved Fluorescence (HTRF) genotyping was performed, allowing for rapid and reliable identification of the knock-in mice in mixed genotype litters. Cortical neurons were dissected and seeded on top of a rat astrocytic feeder layer. Soluble mutant HTT levels were quantified using a Meso Scale Discovery (MSD) platform and cell survival and toxicity was quantified using nuclear condensation and DRAQ7 as high content assays as well as several biochemical assays. Previously characterized reference compounds were tested for the assessment of a robust positive control. Our results demonstrate that primary cortical neurons co-cultured with astrocytes derived from the zQ175 knock-in mice can be

utilized as a robust model system, in particular, for the study of different candidate therapeutics for HTT lowering. In addition, genetic perturbation strategies were explored for validation of targets involved in the regulation of mutant HTT levels. In order to further develop phenotypic relevant primary neuron/ astrocyte co-cultures, current efforts are focused on exploring additional models.

**Abstract:** Our laboratory has shown that AAV1-mediated expression of mHTT in the caudate and putamen of adult rhesus macaques induces motor impairments, reduced spatial working memory capabilities and disease-related striatal pathology, replicating several key hallmarks of human HD. We recently refined our model using a new vector with significantly enhanced retrograde transport (AAV2.retro). Upon injection of AAV2.retro expressing eGFP into the caudate and putamen, we saw robust eGFP expression in the striatum, and profound transduction in several cortical and sub-cortical regions. We are now in the process of creating a 2nd generation NHP model of HD using AAV2.retro to deliver mHTT into the caudate and putamen and anticipate that we will generate mHTT-related neuropathology in the striatum and in structures that project to the striatum, including frontal and motor cortices, the thalamus, amygdala and other regions in the basal ganglia. To assess this, we will query the temporal disruption of cortico-basal ganglia circuitry using advanced imaging methods and link changes in brain connectivity to cognitive, motor, and affective phenotypes in this new model. We developed touchscreen tasks to assess working memory and impulsivity and we will assess motor skills with the Lifesaver Retrieval Task and an NHP-specific neurological rating scale.

Emotional reactivity and anhedonia will be characterized using the Human Intruder test and a sucrose preference assay, respectively. Alongside these behavioral assays, we plan to collect MRI data to measure volumetric alterations of cortical and basal ganglia structures, detect changes in white and grey matter microstructure (DTI), and identify areas of decreased functional connectivity (rsfMRI). In addition, we will collect longitudinal serum and CSF samples for further HD biomarker development. These data will enhance our understanding of the mechanisms impacted by the HD mutation, validate neuroimaging measurements used to stage HD pathology in human subjects, generate new therapeutic biomarkers of disease progression and provide a second viral-vector based monkey model of HD available to the research community for evaluation of promising therapeutics. This work is supported by grants from NIH/NINDS (R01 NS099136).

**Abstract:** Huntington’s disease (HD) is a genetic, progressive neurodegenerative disease that is caused by an expansion of polyQ at the N-terminus of huntingtin protein. R6/2 that expresses exon-1 fragment of mutant huntingtin (mHTT) protein has been widely used as a disease model for HD. In this study, we show that R6/2 mice manifest robust, progressive decline in rotarod, open field, and grip strength performance over 6-12 weeks. We ran a comprehensive volumetric MRI in the entire brain and MRS in striatum at 6 and 12 weeks. The MRI analysis shows significant changes in volume in cortex, caudate putamen, hippocampus, thalamus, olfactory bulbs, and ventricles in R6/2 compared to those in wild type (WT) mice. In the MRS analysis, the level of Gln, Glu, Glx, Cho, tNAA, tCr, and Tau was also significantly altered in R6/2 striatum compared to those in WT striatum. To better understand the correlation between and expression of mHTT and MRI/MRS changes, we then examined the distribution of mHTT in the

regions where we observe more robust changes in imaging studies by using various histological methods including CLARITY 3D imaging.

**Abstract:** Huntington's disease (HD) is a fatal autosomal dominant neurodegenerative disease caused by a CAG expansion translating into an elongated polyglutamine (polyQ) repeat near the amino-terminus of the huntingtin (HTT) protein. This results in production of a toxic mutant huntingtin (mHTT) protein that leads to neuronal dysfunction and subsequent neuronal death. Currently, no disease modifying treatments are available however numerous therapeutic strategies aimed at lowering HTT levels in the brain are under development. For all of these strategies, cell-type specific targeting is still an outstanding question. While it is clear that mHTT accumulation in medium spiny neurons play a role in their atrophy and ultimate death, there is mounting evidence that glial cells, and astrocytes in particular, play a key role in the disease process. Reducing levels of the disease causative mHTT protein in the brain has proven efficacious at ameliorating disease symptoms in a number of HD mouse models. To date these studies have not closely examined the contribution of mHTT reduction in neurons vs astrocytes and therefore a complete understanding of cell type specific targeting is outstanding. We sought to evaluate this question in the YAC128 mouse model of HD using AAV-mediated RNA interference (RNAi) to selectively lower HTT levels in neurons alone versus neurons and astrocytes. Previously we demonstrated that AAV-RNAi mediated HTT reduction using the AAV1 capsid (which transduces both neurons and astrocytes) is capable of ameliorating HD phenotypes in the YAC128 mouse model of HD. In the current preclinical study, a modified AAV2 capsid (AAV2-HBKO) with a similar distribution profile as AAV1 but strictly neuronal tropism showed comparable suppression of Htt mRNA and protein following injections into the striatum, however, it was not associated with correction of motor deficits in YAC128 mice. YAC128 mice show a significant rota rod deficit that was not ameliorated when mHTT levels were reduced only in neurons. As previously demonstrated, mice that received AAV1- miRNA

HTT, transducing both cells types, showed significant improvement on behavioral deficits suggesting that AAV-mediated HTT reduction in neurons alone was not sufficient to support full therapeutic benefit in the YAC128 mouse. This work indicates that astrocyte dysfunction may play a critical role in HD pathogenesis and represent an important therapeutic target. Additionally, therapeutics that target only neurons may be inadequate at restoring normal function and ameliorating all disease symptoms.

**Title:** Excitatory and inhibitory synaptic signaling is differentially affected in D1 and D2 MSNs in the Q175+/- mouse model of Huntington’s disease

**Authors: *J. GOODLIFFE**[1], A. RUBAKOVIC[2], M. SUMIOKA[3], J. I. LUEBKE[1]
[1]Anat. & Neurobio., [2]Boston Univ. Sch. of Med., Boston, MA; [3]Boston Univ., Boston, MA

**Abstract:** Huntington’s Disease (HD) is an autosomal dominant neurodegenerative disorder caused by the replication of CAG repeats in the *Huntingtin* gene and the expression of mutant *Huntingtin* (mHtt). HD neuropathology manifests as a loss of cortical and striatal volume, and striatal medium spiny neurons (MSNs) of the direct (D1) and indirect (D2) pathways are particularly vulnerable. These neurons receive excitatory inputs from thalamo-striatal and cortico-striatal afferents and inhibitory inputs from other MSNs, from parvalbumin positive (PV+) fast-spiking interneurons (FSIs), and from other classes of local interneurons. Previous studies have shown significantly reduced excitatory and increased inhibitory postsynaptic current frequencies in unidentified MSNs from R6/2 and BACHD mouse models of HD (Cepeda et al., 2003), and a reduction in excitatory synaptic current frequency in D1 but not D2 MSNs in one year old BACHD and YAC128 mice (Andre et al., 2011). However, the anatomical underpinnings of these functional synaptic changes are not known. To address this question as well as the specificity of any changes to D1 vs. D2 MSN subtypes, we used whole-cell patch clamp recordings to characterize spontaneous excitatory and inhibitory synaptic currents in identified D1 and D2 MSNs in one year old Q175+/- x D2eGFP vs. wild-type (WT) x D2eGFP

mice. Subsequently we assessed both excitatory and inhibitory appositions on these neurons using immunohistochemistry for Vglut1, Vglut2, PV and Vgat and high resolution confocal imaging. We observed a significant decrease in excitatory synaptic current frequency in D1 but not D2 MSNs and a significant increase in inhibitory synaptic current frequency in D2 but not D1 MSNs in Q175+/- relative to WT. The number and distribution of Vglut1+ and Vglut2+ appositions on D1 and D2 MSNs did not differ between Q175+/- and WT. The number and distribution of inhibitory FSI (PV+/VGAT+) and nonspecific inhibitory appositions (PV-/VGAT+) to D1 and D2 MSNs are currently being assessed. We also assessed the morphological features of D1 and D2 MSNs, as well as of PV+ FSIs using confocal imaging and Neurolucida software-guided reconstruction. Interestingly, D1 MSNs in Q175+/- mice showed significant proliferative increases in dendritic length together with significant spine loss while the morphological features of D2 MSNs did not differ between Q175+/- and WT mice. Finally, the dendritic arbors of PV+ FSIs were significantly reduced in total length and volume in Q175+/- compared to WT mice. Taken together, these data reveal complex and nuanced changes to excitatory and inhibitory synaptic signaling in MSNs.

**Abstract:** Huntington disease (HD) is an autosomal dominant neuropathology associated with severe degeneration of basal ganglia neurons. It characterized by progressive motors symptoms, cognitive deficits and dementia. The gene HTT (Huntingtin) is located at the chromosome 4p163. The genetic mutation induces CAG trinucleotide repeat expansion. The CAG repeat is translated into a polyQ stretch. In this study we inoculated quinolinic acid (QA) intra cerebrally (Atlas of Paxinos and Watson, 1986: AP = +1.2 ahead of Bregma, L = +2.8 and DV = -5.5). Incisor bar location to 2 mm below the interaural line), to wistar rats in an experimental model of
